When separation reaches critical values, the traction is equal to the corresponding cohesive strength (σ_{max}, τ_{max}). Nine input parameters, including normal fracture energy (ϕ_n), tangential fracture energy (ϕ_t), normal cohesive strength (σ_{max}), tangential cohesive strength (τ_{max}), normal shape parameter (α), tangential shape parameter (β), normal initial slope indicator (λ_n), and tangential initial slope indicator (λ_t) are needed to be identified to model the behavior of each interface. For more details about the formulation and applications see [2,23].

The ability of the model to capture the mixed mode fracture makes it very suitable to three-dimensional framework of this study.

Numerical Implementation

Material parameters of ferrite phase are identified through a generated pure ferrite polycrystalline RVE. Cubic elastic parameters are taken from [24] as C_{11}=231.4 GPa, C_{12}=134.7 GPa, C_{44}=116.4 GPa and experimental data presented in [6] is utilized to fit the flow curves obtained from RVE simulations (see [12] for more details). Obtained hardening parameters are tabulated in Table 1. Reference slip rate $\dot{\gamma}_0$ is taken to be 0.001 s^{-1} while rate sensitivity exponent n is determined as 25 and the ratio of latent to self-hardening assumed to be 1.

Table 1. Crystal plasticity parameters for ferrite phase.

Slip Systems	g_s [MPa]	h_0 [MPa]	g_0 [MPa]
{112}⟨111⟩	252	475	98

Eq. 1-6 with the provided material parameters are implemented as a user material subroutine (UMAT) in ABAQUS software based on the framework of Huang (see [25]).

Bao-Wierzbicki uncoupled damage model (see Eq. 3) is applied amongst martensite grains to observe the damage behavior of martensite phase in polycrystal RVEs. The parameter identification of the model is performed by the simulation of a tensile specimen to match the

experimental data of the martensite phase given in [6] (see e.g. [15]). Obtained model parameters are α=1.54, C_1=0.04 and C_2=0.04. This damage model with the provided model parameters is then implemented in ABAQUS by means of a user-defined field subroutine (USDFLD).

Identification of PPR cohesive zone model parameters is a rather comprehensive problem. Since ferrite/ferrite grain boundary decohesion is also considered on top of ferrite/martensite grain boundary decohesion in this study, PPR model parameters of both interfaces must be fitted all together to the experiments. For that, first results provided in [2] are utilized for ferrite/martensite interface. Then, in order to find the critical stress and failure energy of the ferrite/ferrite interface a CT-specimen study is performed as exemplified in [13]. Lastly, ferrite/martensite inclusion problem that includes both ferrite/ferrite and ferrite/martensite interfaces is analyzed for the final parameter calibration of each constituent interface simultaneously. For compactness, details of the parameter identification study for PPR cohesive zone model are not shown here. See Table 2 for the identified model parameters for the ferrite/ferrite and ferrite/martensite interfaces.

Table 2. Calibrated PPR CZM parametes for ferrite/ferrite and ferrite/martensite interfaces.

Interface	σ_{max} [MPa]	τ_{max} [MPa]	ϕ_n [N/mm]	ϕ_t[N/mm]	α	β	λ_n	λ_t
F/F	650	227.5	230	230	4.46	2.74	0.001	0.002
F/M	1500	525	0.4	0.4	4.46	2.74	0.01	0.02

In the FE calculations, 10-node second-order tetrahedral elements (C3D10) are used to simulate bulk elements, while 12-node compatible triangular cohesive elements are used between the interfaces. The Voronoi-based tessellation generator software Neper [26] was used to create 3D microstructures. Input files are modified by an in-house MATLAB code that identifies the ferrite/ferrite and ferrite/martensite interfaces and inserts cohesive elements to those interfaces by considering element connectivity in the original mesh. Updated input files are then run through ABAQUS along with the user material subroutines (UMAT) for both crystal and J2 plasticity, user element subroutine (UEL) for the PPR CZM and user-defined field (USDFLD) for the Bao-Wierzbicki damage model. The next section presents and discusses the findings.

Numerical Examples

This section presents numerical findings in three-dimensional RVEs, and briefly discusses the impact of microstructural parameters on the plastic deformation and failure behavior of dual-phase steels. This is accomplished by producing a number of cubic polycrystalline RVEs, which are non-periodic, with 250 and 280 randomly oriented and distributed grains. There are two main morphologies with different martensite distributions but same volumetric fraction of 15%. The input files for ABAQUS are generated via an in-house MATLAB script as mentioned previously. While the martensite phase is assigned to the classical J_2 plasticity theory with isotropic hardening as given in Eq. 7, the rate-dependent crystal plasticity model that has been presented through Eq. 1–6 with the hardening parameters in Table 1 is assigned to the ferrite phase. Boundary conditions are defined such that RVE analysis can follow the mechanical response of the material under various stress states that have different overall triaxiality values (see [12] for more details). For all simulations, applied strain rate is assumed to be 0.001 s^{-1}. Volumetric averaging method is then used to obtain the true stress-strain curves.

First, six RVEs, each of three having the same martensite distribution, are analyzed. Crystal orientations of ferrite grains are randomly changed for each RVE to study the effect of grain orientation and microstructure on the material response and damage initiation. Fig. 1 shows the homogenized stress-strain curves of the simulations plotted on top of the experimental results [6].

The results from the first morphology show a slight anisotropy due to the relatively lower number of ferrite grains with respect to the second morphology. When Fig. 1a is compared to Fig. 1b, it is very obvious that variation in the martensite distribution and morphology changes the overall response of the material to a great extent. Looking at this figure, the effect of crystal orientation may not be clear enough to distinguish. In order to have a better understanding of how grain orientation affects the stress and damage evolution on the microstructure, von Mises Stress and damage contours are plotted for each morphology at the same cross section and instant in Fig. 2 and Fig. 3. Here, by examining the significant difference between decohesion, deformation and damage accumulation patterns, one can easily deduce that microstructural parameters of DP-steels have a considerable influence on the crack initiation, growth, and propagation. Here, it should be noted that ferrite grains are colored gray in all damage distribution contours as no damage model is employed for the ferrite phase.

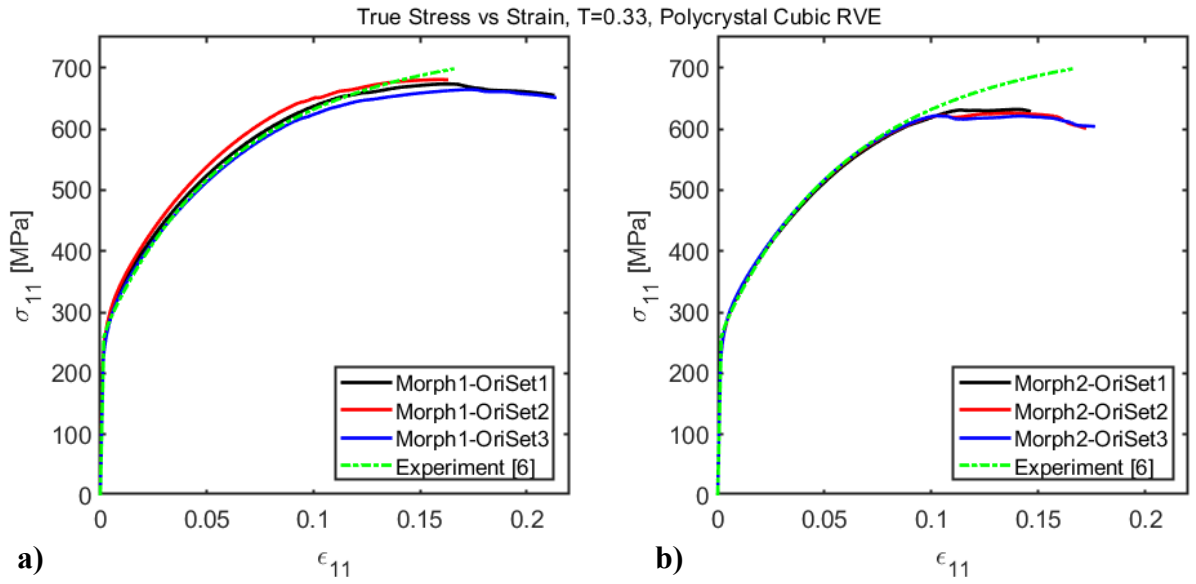

Fig. 1. True stress versus true strain curves of a) the first morphology b) the second morphology with three different orientation sets.

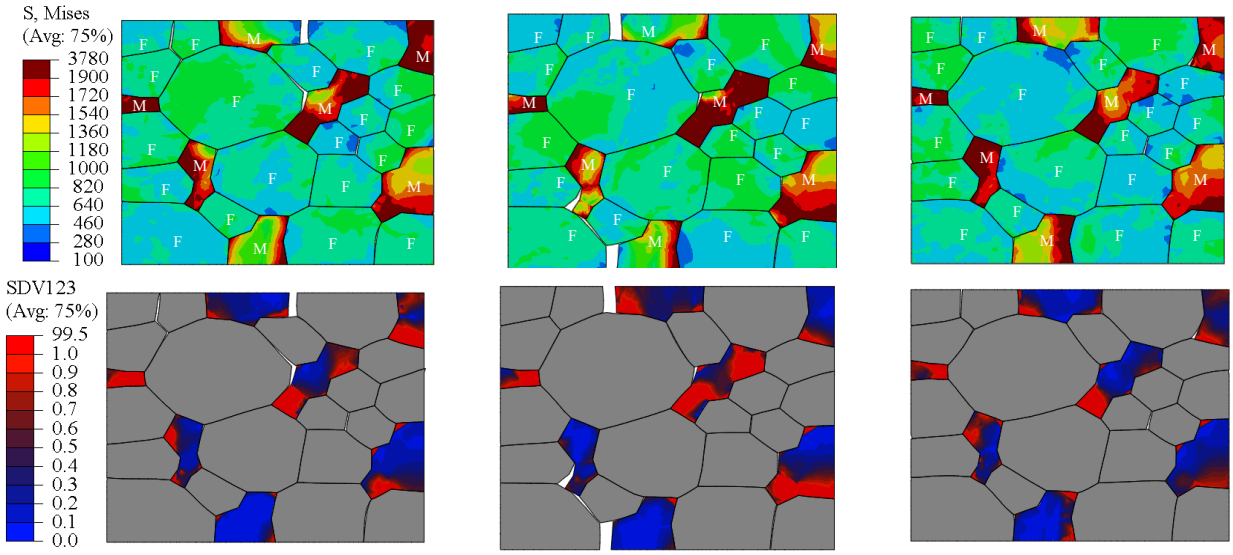

Fig. 2. Von Mises Stress (Top) and Damage (Bottom) distributions of Morph1-Oriset1 (Left), Morph1-Oriset2 (Middle), Morph1-Oriset3 (Right). F: Ferrite, M: Martensite.

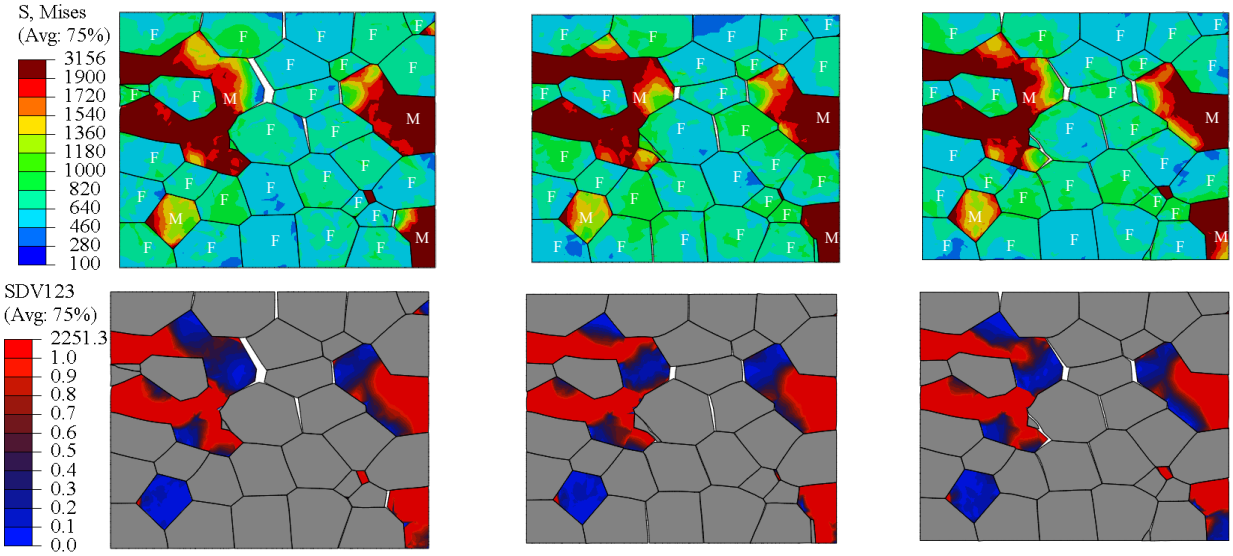

Fig. 3. Von Mises Stress (Top) and Damage (Bottom) distributions of Morph2-Oriset1 (Left), Morph2-Oriset2 (Middle), Morph2-Oriset3 (Right). F: Ferrite, M: Martensite.

Then, the analyses are carried out for three RVEs having the same crystal orientation and martensite distribution with three different stress triaxialities. Martensite distribution selected here is the same as the first morphology to be able to capture the sole effect of stress state on the failure mechanisms and stress distribution. Obtained flow curves are shown in Fig. 4. As per expectations, higher stress triaxiality translates to lower failure strains. From Fig. 5, it can be inferred that when triaxiality is held at 1.5, intergranular decohesion leads to complete failure with the martensite grains remaining below critical damage, in contrast with the other examples.

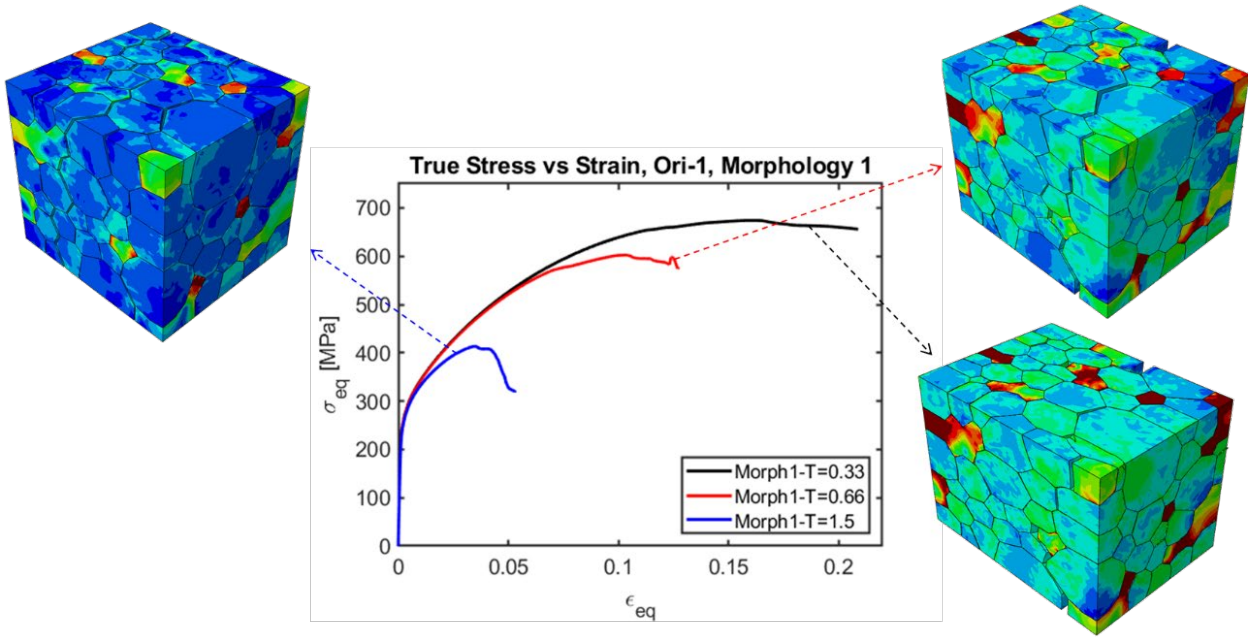

Fig. 4. True stress versus true strain curves of the first morphology with three different stress triaxialities.

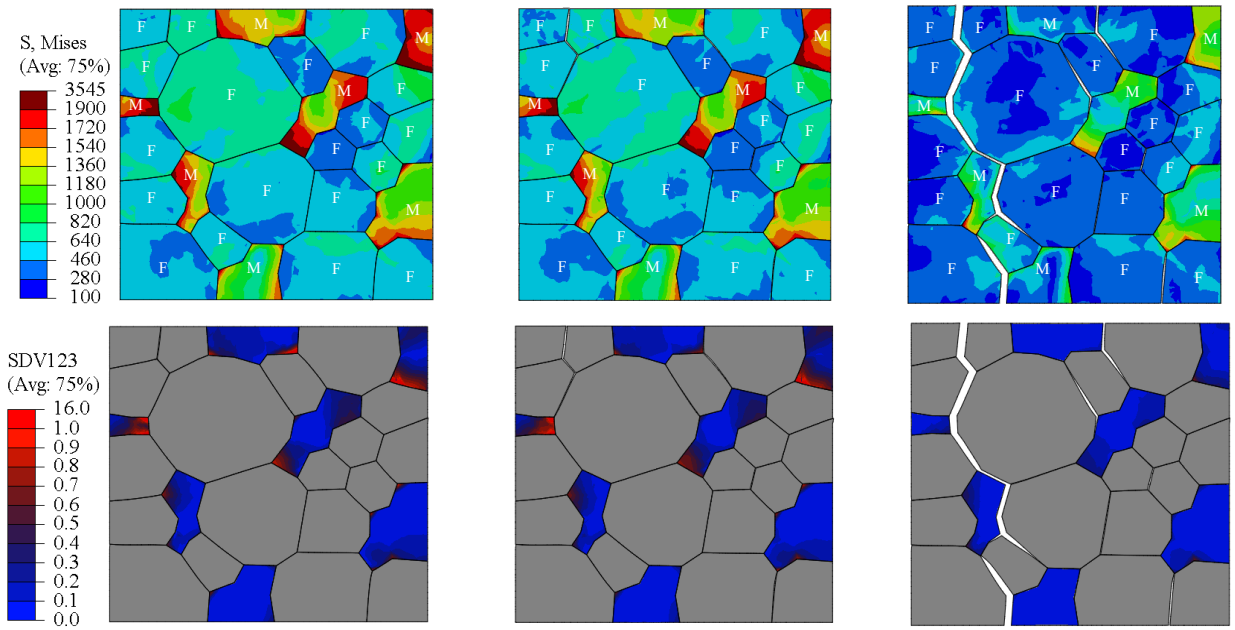

Fig. 5. Von Mises Stress (Top) and Damage (Bottom) distributions of Morph1-T=0.33 (Left), Morph1-T=0.66 (Middle), Morph1-T=1.5 (Right). F: Ferrite, M: Martensite.

Summary

This study makes an attempt to address the microstructure evolution, constitutive response, and failure in three-dimensional dual phase steel microstructures through polycrystalline RVEs employing J_2 and crystal plasticity frameworks in addition to cohesive zone and damage models. Analyses are performed for different orientation sets and morphologies under various stress triaxialities. The study clearly demonstrates how damage and fracture behavior of DP steels at the microstructure scale depend on the orientation set, morphology, and triaxiality. Obtained results prove that for the numerical analysis of failure in DP-steels, an extensive study in microscale is

necessary that includes modeling of inter/intra-granular failure mechanisms, and microstructural evolution.

Keywords: Strain Gradient Plasticity, CMSG Theory, Size Effect, Finite Element Method

Abstract. Micro scale manufacturing technologies have been a productive area of research due to the increase in miniaturization in various industries. However, most of the know-how in conventional metal forming processes cannot be readily transferred into micro/meso forming processes due to the size effect. By incorporating the length scale into the formulation, strain gradient theories offer a viable solution to the issues arising from size-dependent complications. This paper aims at implementing a lower-order strain gradient plasticity (SGP) theory developed from the Taylor dislocation model to numerically analyze the impact of the plastic size effect on the forming of metallic materials. The material model together with local and nonlocal approaches for the strain gradient calculations is implemented in a commercial finite element (FE) code through user subroutines. The flat punch indentation problem is examined using the implemented code.

Introduction

Modeling plastic deformation on small scales has seen a significant increase of interest in recent years. Experimental observations show that many metal manufacturing processes are affected by noticeable sensitivity toward non-conventional deformation measures, resulting from size effects. A notable example being flat punch indentation. Having become a popular microforming process, metallic microscale devices fabricated from flat punches have been shown to outperform silicon-based devices [1]. Since the manufacturing processes for these metal-based HARMS (High-aspect-ratio microscale structures) are expensive and time-consuming, it is crucial to understand the mechanical interactions that take place when metals are micromolded. A better understanding of the interactions between the flat punch and the material might contribute to improving the strength and hardness of the final material [2]. Other examples of size dependent plasticity include MEMS, biosensors, and thin film applications which demonstrate significant size effects for sufficiently small specimens [3-5]. As the notion of smaller is stronger prevails, it has become vital to include gradient-dependent effects in the modeling of elastic-plastic materials.

Since there is no internal length scale parameter, the classical continuum models of plasticity can only remain limited at the micron scale [6]. It is a widely known fact that dislocations are created, moved, and stored when a material is deformed, and the storing of dislocations causes the material to harden. Dislocations could be stored in two distinct mechanisms: they can either accumulate by randomly trapping one another or they can be stored as they are necessary for compatible deformation of the material. The former is termed statistically stored dislocations (SSDs) [7] while the latter is known as geometrically necessary dislocations (GNDs) [7-8]. The gradients of plastic shear in a material are related to geometrically necessary dislocations. Consequently, plastic strain gradients can be identified as the result of the response of the material to inhomogeneous deformation.

A number of strain gradient (SG) frameworks have been proposed to bridge the gap between micromechanics and classical continuum-based plasticity theories [9-10]. In literature, strain

gradient theories have been separated into two classes [11]. The first class of SG theories referred to as higher-order theories, initially proposed by [12], uses higher-order stress terms as the work conjugate to the strain gradient. Due to this, the equilibrium equations need to be adapted and additional boundary conditions and tractions must be considered. The second class known as lower-order SG theories, initially proposed by [13], involves the conventional stress description, retains all of the features of classical J_2 theory and requires no additional boundary conditions. These models incorporate the strain gradient effects in the calculation of the flow strength of the material. Therefore, they do not require any change in the equilibrium equations as only the hardening function of the material is modified. This feature essentially makes lower-order theories easy to implement in a commercial finite element code, however, the lack of higher-order stress terms and additional boundary conditions might cause inaccuracies, a notable example being the boundary layer phenomenon [6].

This study aims to use the widely popular Conventional Mechanism-Based Strain Gradient (CMSG) plasticity theory to model size-dependent behavior in small scale metal forming processes. CMSG, which is based on the Taylor dislocation model [14], is the lower-order counterpart of the more general higher-order Mechanism-Based Strain Gradient (MSG) theory. Further, two distinct approaches for calculating strain gradients are implemented. The first approach uses a local, intra-element level numerical differentiation scheme in which the plastic strain increments are interpolated through their values at the integration points and the strain gradient is evaluated as a common value at the centroid of each element. The second approach considers the calculation of strain gradients on an inter-element level by extrapolating the plastic strain from integration points to nodes and performs a nodal averaging scheme to nonlocalize the gradient. Both approaches are implemented in a three-dimensional setting via User Material Subroutines (UMAT) in the commercial finite element solver ABAQUS.

The paper is outlined as follows. The constitutive model together with the strain gradient calculation methods are explained in Section 2, a benchmark problem to verify the implementation is addressed in Section 3. The obtained results for flat punch indentation simulations are presented in Section 4, which is finally followed by summary and outlook in Section 5.

Conventional Mechanism-Based Strain Gradient (CMSG) Plasticity

Taylor Dislocation Model. The conventional mechanism-based strain gradient plasticity theory is based on the Taylor model of dislocation hardening [14]. The shear flow stress is related to the dislocation density by

$$\tau=\alpha\mu b\sqrt{\rho} \tag{1}$$

where μ is the shear modulus, b is the Burgers vector and α is an empirical coefficient, which takes values between 0.3 and 0.5. The dislocation density ρ is decomposed into ρ_S for statistically stored dislocations (SSDs) [7] and ρ_G for geometrically necessary dislocations (GNDs)

$$\rho=\rho_S+\rho_G. \tag{2}$$

Effective strain gradient can be related to the GND density, by

$$\rho_G=\bar{r}\frac{\eta^p}{b} \tag{3}$$

where $\bar{r}$, is a Nye-factor and is around 1.90 for the Face Centered-Cubic (FCC) polycrystals [15]. This parameter reflects the effect of crystallography on the distribution of GNDs. The tensile flow stress σ_{flow} is then related to the shear flow stress τ, by

$$\sigma_{flow}=M\alpha\mu b\sqrt{\rho_S+\bar{r}\frac{\eta^p}{b}} \tag{4}$$

where M is the Taylor factor ($M = 3.06$ for fcc metals), which serves as an isotropic interpretation of the crystalline anisotropy at the continuum level [16].

By using the formula $\sigma_{flow} = \sigma_{ref} f(\varepsilon^p)$, where σ_{ref} is a reference stress and f is a nondimensional function derived from the uniaxial stress-strain curve, it is also possible to link the flow stress for uniaxial tension to the plastic strain ε^p. Since the plastic strain gradient η^p vanishes for the uniaxial tension, the SSD density can be determined from Eq. 4, as

$$\rho_S=[\sigma_{ref} f(\varepsilon^p)/(M\alpha\mu b)]^2 \tag{5}$$

Then the flow stress in Eq. 4 becomes

$$\sigma_{flow}=\sqrt{[\sigma_{ref} f(\varepsilon^p)]^2+M^2\bar{r}\alpha^2\mu^2 b\eta^p}=\sigma_{ref}\sqrt{f^2(\varepsilon^p)+l\eta^p} \tag{6}$$

where l is the is the intrinsic material length scale in strain gradient plasticity and is given explicitly by

$$l=M^2\bar{r}\alpha^2\left(\frac{\mu}{\sigma_{ref}}\right)^2 b=18\alpha^2\left(\frac{\mu}{\sigma_{ref}}\right)^2 b \tag{7}$$

The intrinsic material length l for typical metallic materials is usually on the scale of microns. Note that from Eq. 6, as the material length scale parameter l vanishes, conventional J_2 plasticity relations are recovered.

Constitutive Relations. The governing equations of CMSG plasticity are nearly identical to those of conventional plasticity because higher order terms are not included. The volumetric and deviatoric strain rates are obtained as

$$\dot{\varepsilon}_{kk}=\frac{\dot{\sigma}_{kk}}{3K},\quad \dot{\varepsilon}'_{ij}=\frac{\dot{\sigma}'_{ij}}{2\mu}+\frac{3\dot{\varepsilon}^p}{2\sigma_e}\dot{\sigma}'_{ij} \tag{8}$$

From the Taylor dislocation model, the equivalent plastic strain rate $\dot{\varepsilon}^p$ includes the flow stress. In order to incorporate the gradient effects without higher-order stress terms, $\dot{\varepsilon}^p$ is replaced by a viscoplastic formulation to express plastic strain gradient in terms of effective stress σ_e rather than its rate $\dot{\sigma}_e$ (for more details see [17])

$$\dot{\varepsilon}^p=\dot{\varepsilon}\left(\frac{\sigma_e}{\sigma_{flow}}\right)^m=\dot{\varepsilon}\left[\frac{\sigma_e}{\sigma_{ref}\sqrt{f^2(\varepsilon^p)+l\eta^p}}\right]^m \tag{9}$$

The substitution of Eq. 9 into Eqs. 8 gives the strain rate which then can be inverted to get the stress-rate in terms of the stain-rate as follows

$$\dot{\sigma}_{ij}=K\dot{\varepsilon}_{kk}\delta_{ij}+2\mu\left[\dot{\varepsilon}'_{ij}-\frac{3\dot{\varepsilon}^p}{2\sigma_e}\left(\frac{\sigma_e}{\sigma_{ref}\sqrt{f^2(\varepsilon^p)+l\eta^p}}\right)^m\dot{\sigma}'_{ij}\right] \tag{10}$$

Materials Research Proceedings 28 (2023) 1453-1462 https://doi.org/10.21741/9781644902479-157

Above constitutive relations allow for gradient effects without the higher order stress terms. Since the effective plastic strain gradient reduces the plastic incremental moduli, it falls under the lower-order framework of strain gradient plasticity theories [13]. Effective strain gradient η^p definition is the same with Gao et. al [6]. The quadratic invariants of three models of geometrically necessary dislocations for bending, torsion, and void formation serves as the basis for calculating the effective strain gradient. The resulting expression reads

$$\eta^p=\varepsilon^p_{ik,j}+\varepsilon^p_{jk,i}-\varepsilon^p_{ij,k} \tag{11}$$

Finite Element Implementation. In this study, CMSG framework has been implemented in ABAQUS via user material subroutine (UMAT) in a three-dimensional setting. The only additional task beyond classical plasticity is the assessment of the plastic strain gradient within the UMAT as the equilibrium equations, boundary conditions, and kinematic relationships between the strain and displacement are identical to those in classical plasticity. For the calculation of the effective strain gradient η^p, two different approaches have been utilized, the first approach evaluates the strain gradient at the local element level. Plastic strains are interpolated in the isoparametric space through the shape functions as

$$\varepsilon^p_{ij}=\sum_{k=1}^{8} N_k(\xi,\eta,\zeta)\left(\varepsilon^p_{ij,IPT}\right)_k \tag{12}$$

such that, the plastic strains ε^p_{ij} represents the interpolated values within the element, obtained from the values at the integration points $\left(\varepsilon^p_{ij,IPT}\right)_k$. Where $N_k(\xi,\eta,\zeta)$ is the shape function vector, with three-dimensional linear shape functions adapted as

$$N_k=\frac{1}{8}\left(1+\xi\xi_i\right)\left(1+\eta\eta_i\right)\left(1+\zeta\zeta_i\right) \tag{13}$$

In this context, the implementations are considered on an 8-noded full integration C3D8 elements from ABAQUS Standard element library, with the node and integration points numbering given in Fig. 1.

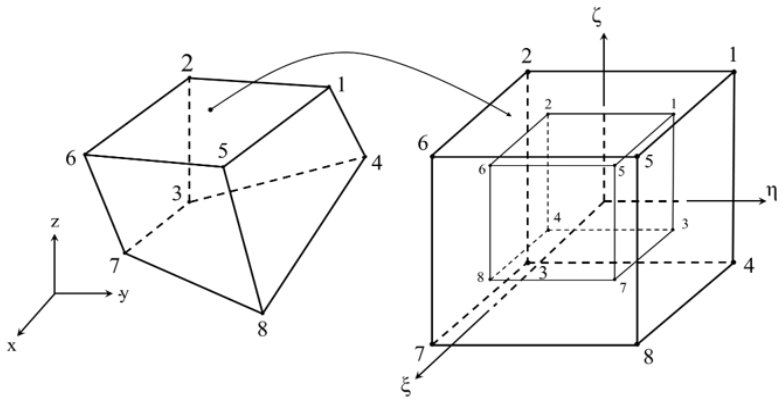

Fig. 1. Numbering scheme used in the Gauss point-based interpolation.

Materials Research Proceedings 28 (2023) 1453-1462 https://doi.org/10.21741/9781644902479-157

Derivatives of the shape functions with respect to global coordinates can be obtained by using the chain rule and the inverse of the Jacobian.

$$\begin{bmatrix} \frac{\partial N}{\partial x} & \frac{\partial N}{\partial y} & \frac{\partial N}{\partial z} \end{bmatrix}^T = J^{-1} \begin{bmatrix} \frac{\partial N}{\partial \xi} & \frac{\partial N}{\partial \eta} & \frac{\partial N}{\partial \zeta} \end{bmatrix}^T \tag{14}$$

where J is the element Jacobian matrix describing the derivatives of the global coordinates in relation to the natural coordinate system. With the plastic strain gradient definition from Eq. 11, components of η^p within the element can be computed as

$$\eta^p_{ijk} = \sum_{m=1}^{8} \frac{\partial N_m}{\partial x_j} \varepsilon^p_{ik,IPT} + \sum_{m=1}^{8} \frac{\partial N_m}{\partial x_i} \varepsilon^p_{jk,IPT} - \sum_{m=1}^{8} \frac{\partial N_m}{\partial x_k} \varepsilon^p_{ij,IPT} \tag{15}$$

where x_i for i=1,2,3 denote x, y, z coordinates respectively. In this method, since the values at the integration points are interpolated, the plastic strains obtained stay within the confines of the element, and effective plastic strain η^p, is a single value evaluated at the centroid. This is clearly a local approach as computations are done on a single element basis. For more details related to this approach the reader is referred to [18].

In the nonlocal approach, the plastic strain values are extrapolated to the nodes. This is done by inverting the shape function matrix used to interpolate nodal values to integration points,

$$\varepsilon^p_{ij,IPT} = \sum_{k=1}^{8} N_k(\xi,\eta,\zeta) \left(\varepsilon^p_{ij,N}\right)_k \tag{16}$$

$$\varepsilon^p_{ij,N} = \sum_{k=1}^{8} N_k^{-1}(\xi,\eta,\zeta) \left(\varepsilon^p_{ij,IPT}\right)_k \tag{17}$$

where $\varepsilon^p_{ij,N}$ denotes the extrapolated nodal values of the plastic strains and $\varepsilon^p_{ij,IPT}$ is again the plastic strains at the integration points. Hence, plastic strain values at the nodes can be obtained. However, because each node is tied to several elements, different plastic strain values will be assigned to the same node for each element to which it is attached. To overcome this and ensure continuity of an otherwise discontinuous field, a nodal averaging scheme is employed. Fig. 2 depicts the basic concept of this technique for a one-dimensional case. After nodal averaging is performed, using the shape function derivatives and the element Jacobian, the gradient of plastic strain can be calculated at the position of each integration point.

$$\nabla \varepsilon^p_{ij,IPT} = \frac{\partial \varepsilon^p_{ij,IPT}}{\partial \mathbf{x}} = \frac{\partial \varepsilon^p_{ij,IPT}}{\partial \boldsymbol{\psi}} \frac{\partial \boldsymbol{\psi}}{\partial \mathbf{x}} = \frac{\partial \left(\sum_{k=1}^{8} N_k \left(\varepsilon^p_{ij,N}\right)_k\right)}{\partial \boldsymbol{\psi}} \frac{\partial \boldsymbol{\psi}}{\partial \mathbf{x}} \tag{18}$$

Following this, the gradient of the plastic strains can be written concisely as

$$\nabla \varepsilon^p_{ij,IPT} = \nabla_{\boldsymbol{\psi}} \left(\sum_{k=1}^{8} N_k\right) \left(\varepsilon^p_{ij,N}\right)_k J^{-1} \tag{19}$$

$\nabla_{\boldsymbol{\psi}} \left(\sum_{k=1}^{8} N_k\right)$ describes the gradient of shape functions with respect to isoparametric coordinates. Therefore, Eq. 11 for the nonlocal approach can be written as

$$\eta^p_{ijk} = \sum_{m=1}^{8} \frac{\partial N_m}{\partial \psi_j} \varepsilon^p_{ik,N} J^{-1} + \sum_{m=1}^{8} \frac{\partial N_m}{\partial \psi_i} \varepsilon^p_{jk,N} J^{-1} - \sum_{m=1}^{8} \frac{\partial N_m}{\partial \psi_k} \varepsilon^p_{ij,N} J^{-1} \tag{20}$$

where ψ_i for i=1,2,3 denote ξ, η, ζ coordinates in isoparametric space respectively. With this approach, the strain gradients are assigned to each integration point separately. Because nodal averaging takes into account the effects of neighboring elements, the strain gradient is nonlocalized.

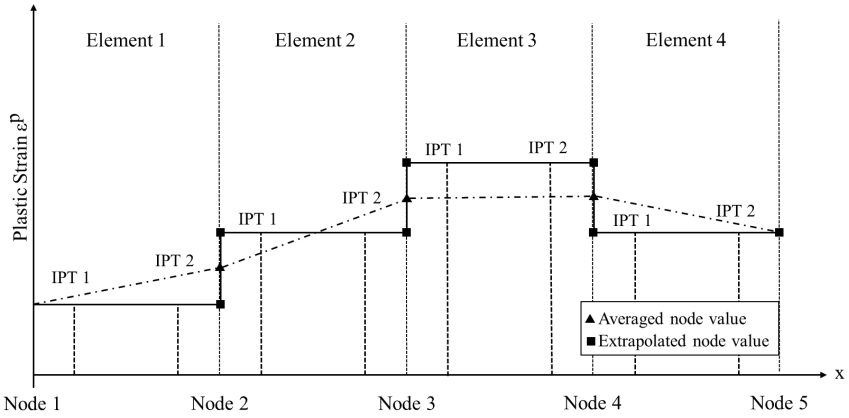

Fig. 2. Plastic strain field along four one-dimensional elements.

Numerical Example

Uniaxial tension subject to a constant body force. A bar subjected to a constant body force is analyzed to evaluate the mechanism-based strain gradient plasticity implementation and assess the capacity for depicting the size dependency. Simulations with local and nonlocal approaches are performed and compared. The model, inspired by the works of [17] is a basic example where gradient effects can be observed, consists of a uniform mesh of 10x10x100 C3D8 elements with 100 elements through the length of the bar.

The nodes at the top of the bar are constrained in all three directions, and the nodes at the bottom of the bar are constrained in z and y directions but not in x direction. A constant body force g is applied to the bar to induce a gradient along x direction. Also, a traction $\bar{\sigma}$ is applied at the far end. A sketch of the model, with the mesh is illustrated in Fig. 3.

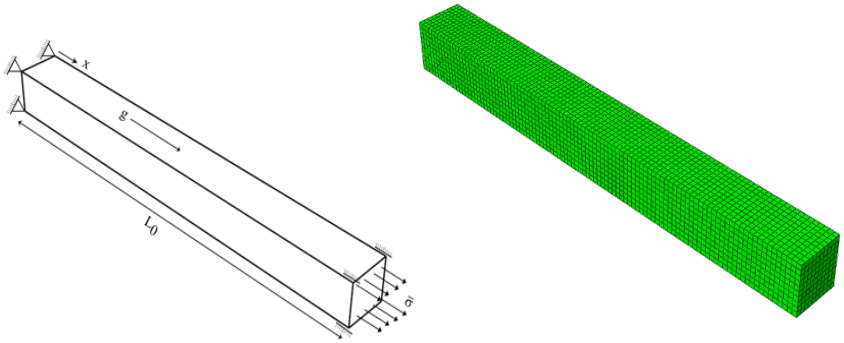

Fig. 3. Boundary conditions and mesh for the gravity loaded bar.

Loads are given in proportion to the yield strength σ_Y, such that for a material with $\nu = 0.3$ and $\sigma_Y/E = 0.002$, the traction boundary condition is $\bar{\sigma} = \sigma_Y$, and the body force, $g = \sigma_Y/L_0$. Further, for isotropic hardening, a classical power law hardening relation is adopted, with $\sigma_{ref} = \sigma_Y(E/\sigma_Y)^N$ and $f(\varepsilon^p) = (\varepsilon^p + \sigma_Y/E)^N$ in Eq. 10. Throughout the study, the strain hardening exponent and the yield strength have been taken as N=0.2 and σ_Y=400 [MPa], respectively.

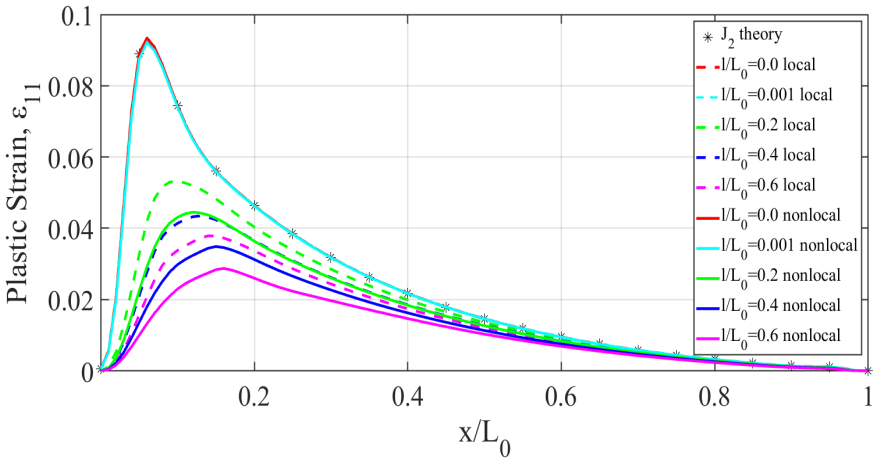

Fig. 4. Plastic strain distribution for bar loaded with

Size dependency for several different length scales is illustrated in Fig. 4. The curves show the plastic strain distribution over the length of the bar. The classical J_2 response is recovered if the length scale for either method is zero or a small value that is non comparable with the characteristic length of the material. Moreover, raising this value leads to a stronger material response. However, results from the two methods are different. Nonlocal approach consistently predicts lower plastic strain distributions. This could be attributed to the nodal averaging scheme, which averages out the high plastic strains onto the neighboring elements, consequently smoothing out the distribution.

Flat Punch Indentation

Flat punch indentation has found many applications with the advance of microforming applications. Experiments on metals such as aluminum showed that, besides the required punch

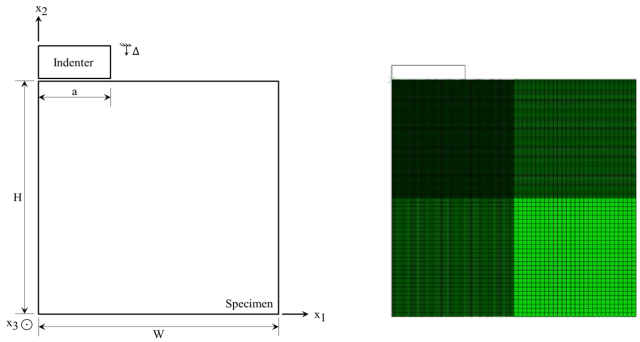

Fig. 5. Frontal view for the flat punch indentation with, W=H=50 μm, a=0.3W and $\Delta = 1.5$ μm.

load, both the size and shape of imprinted features are affected by the scale of the as substantial details are lost when the characteristic length is on the order of 10 μm [19]. Frontal view sketch and mesh of a three-dimensional flat punch indentation problem is highlighted in Fig. 5.

In the mesh, 42849 three-dimensional hex elements are used to model the process using a single layer through x_3. Only half of the sample is modeled by exploiting the symmetry boundary conditions on the left face through x_1 direction. A rigid flat indenter of half width a is given a downward displacement of Δ and the mesh is refined around the edges of the punch where highest stresses are obtained. The material parameters and the hardening function are the same with the earlier example. The downwards displacement is set to be Δ=1.5 μm and the friction between the contact surfaces is modeled with Coulomb friction with a friction coefficient of μ=0.2. The width and the height of the model are equal with, W=H=50 μm and the indenter width a=0.3W=15 μm.

Fig. 6 shows dimensionless displacement versus the dimensionless location for different length scale ratios, together with the classical plasticity solution. Indenter half width a is kept constant. Details of the imprint get lost as the length scale parameter increases. This effect is called indentation size effect (ISE) and agrees well with the experimental observation of [20] and numerical simulations of [19]. Again, the nonlocal approach, predicts higher resistance to deformation in contrast to the local approach though the difference is small.

Fig. 7 shows the equivalent stress contours for the local and nonlocal solution. Expectedly, as the length scale increases stresses also increase. Moreover, even though the patterns of deformations left by the imprint are quite similar, stress contours show a difference. For the nonlocal approach, the stresses are diffused owing to the nodal averaging.

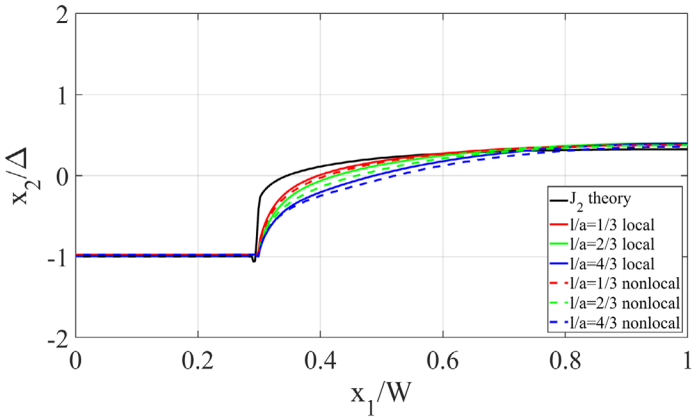

Fig. 6. Deformation patterns of imprints for different ratios of length scale l and constant indenter half width a.

Summary

In this paper, size dependency in plastic deformation is investigated. A lower order strain gradient theory is implemented and two different methods for strain gradient calculations are discussed. It has been observed that nonlocal approach consistently predicts stronger material response, however the difference between the two approaches is small. It is noted that, for the flat punch indentation problem the length scale has a notable effect on the deformation pattern, pile up characteristics, and the stress distributions, yet the simulations done in this paper unfortunately remain at the qualitative level.

Our ongoing focus is on performing more detailed simulations for flat punch indentation accounting for realistic materials with actual experimental data. Using this approach, it would be interesting to predict the behaviors of real materials response and study deeply the underlying mechanisms of plastic gradient effects on micro-sized materials.

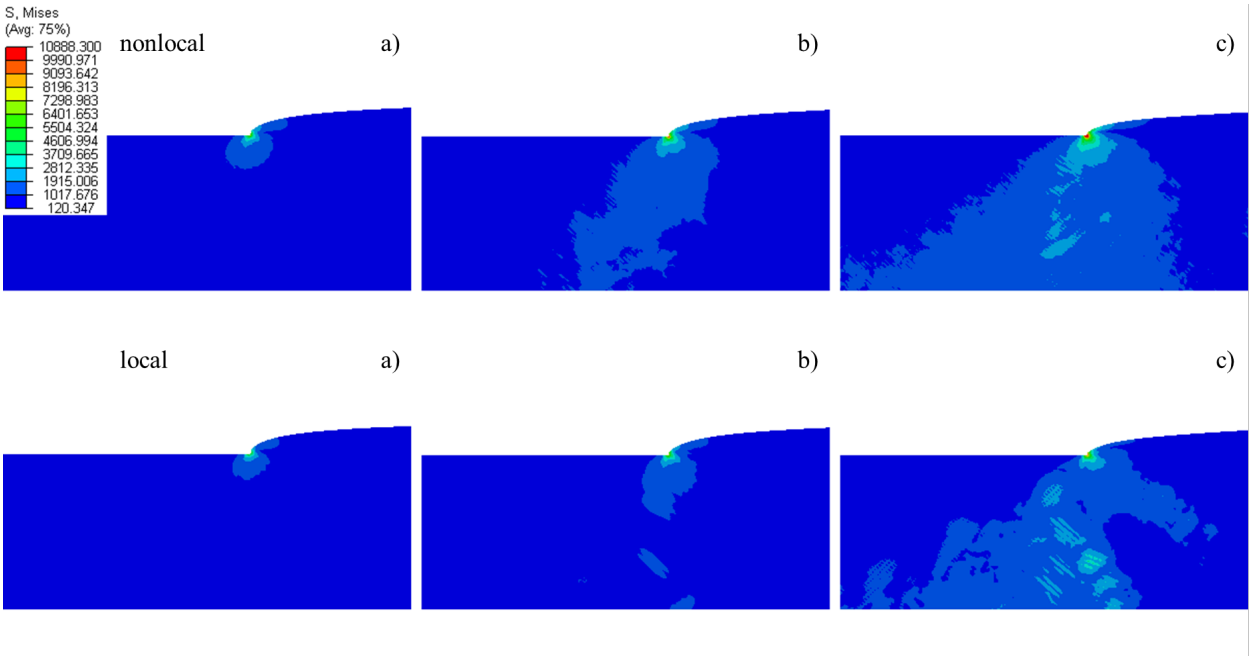

Fig. 3. Stress contours for the flat punch indentation for local and nonlocal approaches for different length scales a) l/a =1/3 b) l/a=2/3 c) l/a = 4/3.

Keywords: Cruciform Sample, Biaxial Tensile Test Simulation, Ductile Damage Criterion

Abstract. In this study, the Finite Element (FE) simulation of an initially pre-deformed DC-5 steel cruciform specimen has been carried out and compared to experimental results. A new geometry of the sample with local reinforcements and without thickness reduction allows distribution of plastic deformation and gets high strains in its gauge region. The simulation is divided into two steps. The first one introduces initial deformation to the sample arms. For the second step, the calculated strain field is introduced as an initial pre-strain field before the application of loading along the two perpendicular arms of the cruciform specimen during the in-plane biaxial tensile test. The described numerical study expands the knowledge of material plastic flow using a ductile damage criterion under different biaxial tensile strain paths. The numerical and experimental results are in good agreement for different strain paths, from uniaxial to equibiaxial strain states.

Introduction

Sheet metal forming is a very popular manufacturing process in many industrial sectors. Therefore, the knowledge of the mechanical behaviour of materials under large plastic strain is essential to build reliable numerical models for the prediction of the final shape and quality of formed parts. The characterization of mechanical behaviour needs dedicated tests, able to reproduce the forming conditions of the processes. Different tests have been proposed to characterize anisotropy, flow stress, or forming limits (at necking or at rupture). Some of them are very common and standardized, like the Nakazima [1] or Marciniak [2] tests for the determination of Forming Limit Curves (FLC). Non-conventional tests have been also proposed to improve the knowledge of the material under complex loadings, including multiaxiality or non-linear strain paths for high strains. The use of cruciform shapes [3] stretched along two perpendicular directions in the sheet plane is very promising. Unfortunately, the level of strain reached in the gauge region is generally low and not suitable for the forming applications. Many cruciform shapes have been proposed and optimized to achieve a localization of high strains at the centre of the samples, before necking and rupture onset in the arms.

In order to localize the strains at the centre of the samples, a reduction of sheet thickness is proposed in the gauge region. Besides, longitudinal slots are generally designed to decrease the transversal stiffness of the arms [4]. The number and the position of each slot can have a great influence on the strain and stress fields in the central zone of the samples. Recently, Zhang et al. [5] conducted an extensive review of the existing cruciform specimen designs. The authors

proposed three different geometries of samples which subsequently were evaluated numerically and by experiments.

The reduction of sheet thickness can affect the characterization of the mechanical behaviour. Some defects may occur when reducing the thickness (surface finish, precision for small thicknesses) and the behaviour of the material is not always homogeneous through the sheet thickness. In order to avoid this operation, a new cruciform shape with a constant thickness in the gauge region was proposed [6]. Out of plane deformations were applied around the gauge region to strengthen the connection zone between the arms and the central region.

The aim of this study is to evaluate the potential of this new specimen to achieve large strains in the gauge region for different strain paths. A Finite Element (FE) model of the pre-forming step followed by the in-plane biaxial stretching of the specimen is defined. A comparison is done between the predictive strain fields and the experimental ones from the Digital Image Correlation (DIC) method.

Cruciform Sample

Sample shape. The sample has been designed (arms' length and dimensions of the middle part) according to the capacity of the biaxial testing machine [7]. The geometry is in accordance with the international standard ISO 16842 [8] which recommends that the ratio between the sample thickness "a" and its arm width "B" should be smaller than 0.08 (Fig.1). The width of the arms is B = 30mm and the thickness of the sample is a = 0.5mm.

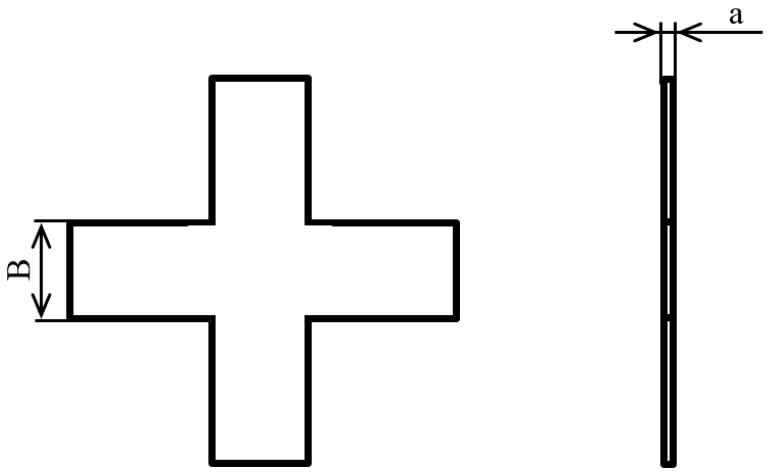

Fig. 1. Sheet thickness "a" and the arm width "B".

In order to achieve higher plastic deformation in the gauge region during biaxial stretching, the sample is preformed (Figs. 2 and 3). The aim of this preforming operation is to strengthen the sample material in the junction area between the arms and the gauge region. This solution has been already described in the previous work of Mitukiewicz and Głogowski [6].

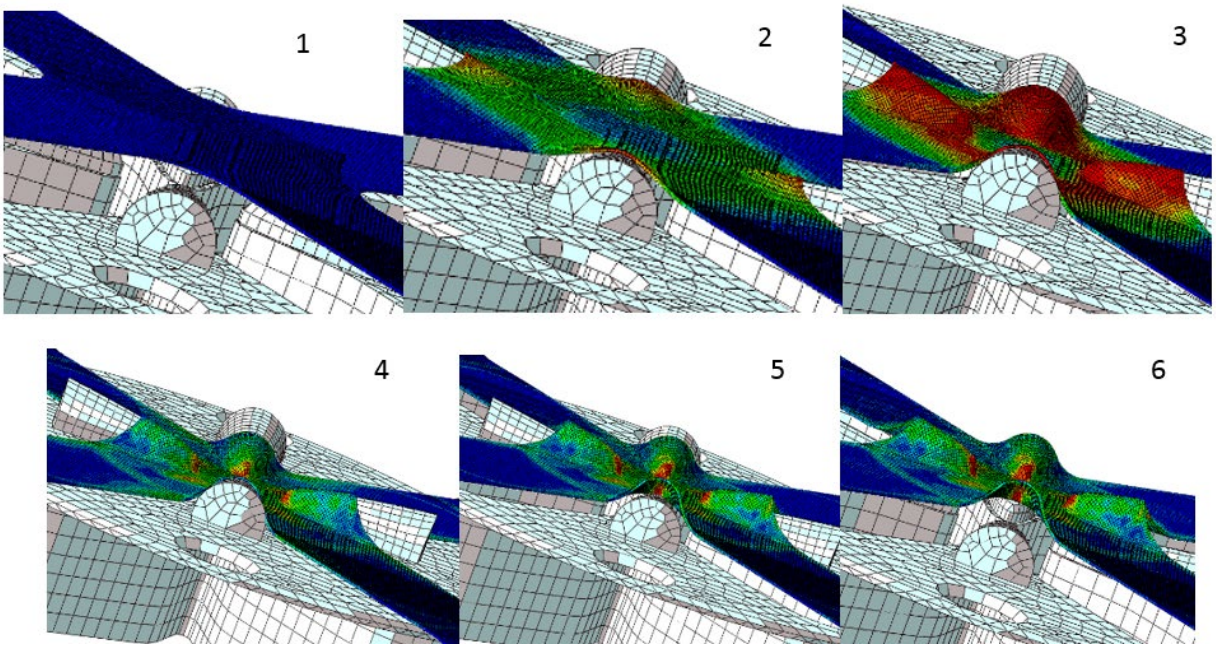

Fig. 2. Cruciform sample preforming (1 to 6 - successive steps).

Material. For this study, a DC-5 low-carbon steel specimen is used. The elastic mechanical properties of this material are as follows: Young's modulus of 210 GPa and Poisson's ratio of 0.3. Regarding the plastic behavior, an isotropic plastic criterion of von Mises is assumed with an initial yield stress of 225 MPa. The plastic strain hardening behavior is described by means of the true stress versus equivalent plastic strain curve from a uniaxial tensile test performed along the rolling direction (Fig. 3).

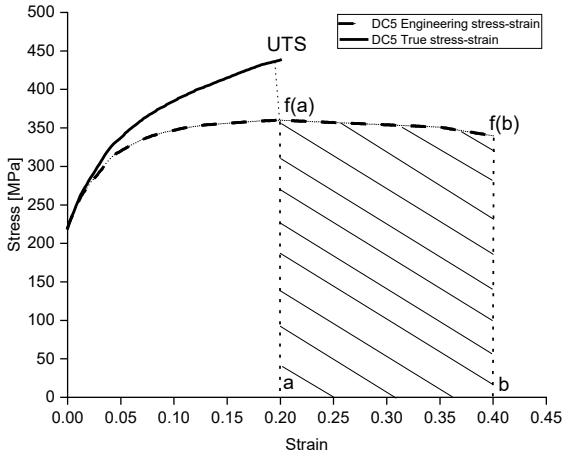

Fig. 3. True stress-plastic strain curve vs. engineering stress-plastic strain curve (UTS - ultimate tensile strength).

In-Plane Biaxial Test

Experimental setup. To test the samples, a servo-hydraulic testing machine provided with four independent dynamic actuators is used (Fig. 4). Thanks to an efficient servo-hydraulic control, the center point of the sample is always maintained stationary during the tests. The loading capacity

Materials Research Proceedings 28 (2023) 1463-1470 https://doi.org/10.21741/9781644902479-158

of the machine is 50KN for each actuator and a wide range of testing velocities can be applied (from quasi-static to 2m/s).

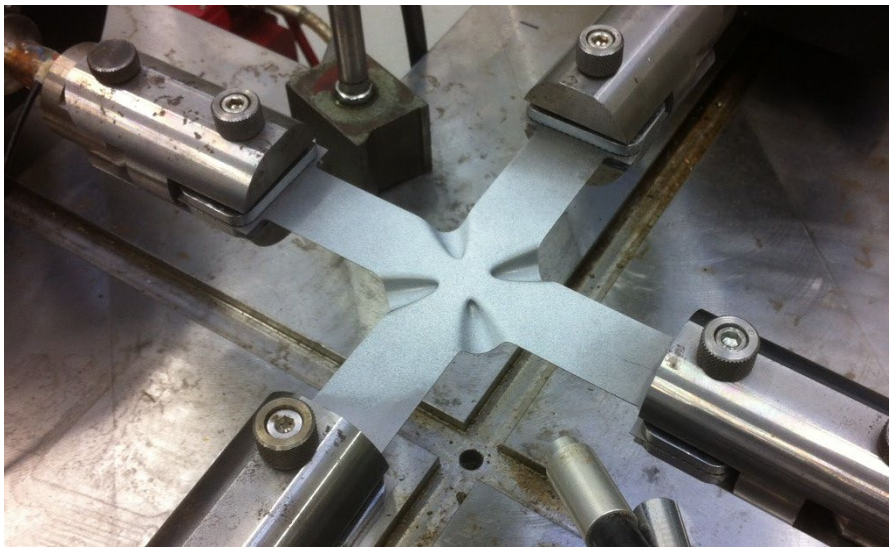

Fig. 4. Experimental setup with the pre-deformed cruciform sample.

During the test, the gauge region of the cruciform sample is filmed. The image resolution is 1024pixels×1024pixels and the acquisition rate is 250 frames/s. A random speckle pattern is applied on the surface of the specimen (Fig. 5). For the calculation of the strain field at the top surface of the specimen, the DIC method is used thanks to the CORRELATE software of the GOM Company.

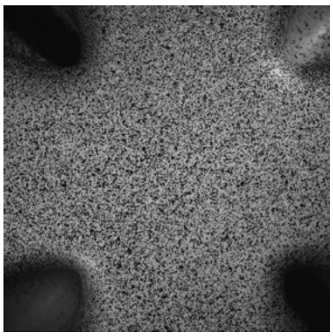

Fig. 5. Random speckle pattern applied on the top surface of the gauge region.

Loading conditions. The strain path measured at the center of the sample is directly linked to the ratio of actuator velocities applied along the two perpendicular directions of the biaxial test. By changing the velocity ratio, all the strain states between uniaxial and equibiaxial stretching can be reached.

Three loading conditions were studied:

- Biaxial stretching (**case 1**): the same velocity ($V=V_X=V_Y=1$mm/s) is applied along the two perpendicular directions
- Near plane strain (**case 2**): the velocity of $V_X=1$mm/s is applied along the rolling direction and a smaller velocity ($V_Y=0.02$mm/s) is applied along the perpendicular direction to compensate the Poisson effect.

- Uniaxial stretching (**case 3**): only the velocity (V_X =1mm/s) along the rolling direction is applied. No velocity is applied along the perpendicular direction, the sample remains free.

FE Model

The finite element modeling is performed using Abaqus software. To simulate the in-plane biaxial tensile test of this reinforced sample, two steps are defined in the FE model: the punching process (Step-I) and the tensile test process (Step-II). A view of the components of the punching die and the 3D model assembly are shown in Fig. 6. The model consists of three parts, the upper part, the cross holder, and the base part. A cruciform sample is placed between the bottom base and the cross holder to prevent any movement of the specimen during the forming process (Step 1).

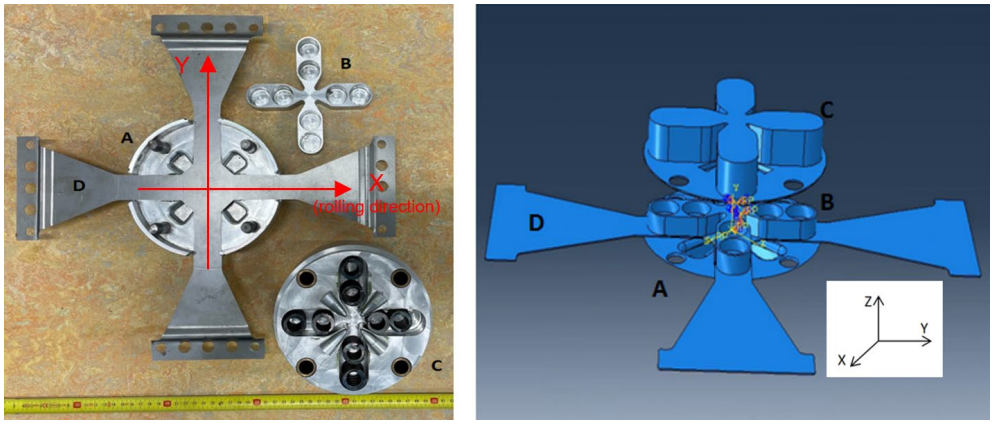

Fig. 6. Components of punching die and view of the 3D model assembly:

A - base part; B - cross holder; C - upper part; D - 0.5 mm cruciform sample.

In the FE model, the different tools are considered rigid. Only the cruciform specimen is considered deformable (C3D8R element type). Tangential contact behaviour is applied for all the contact areas during the punching process. The frictional coefficient is assumed to be 0.1. A refined mesh size of 0.5 mm is defined in the gauge area. Fig. 7 gives the distribution of the plastic equivalent strain at the surface of the specimen at the end of the first step. One can notice that the centre of the specimen does not deform during the punching process of Step 1. For Step 2, a damage evolution criterion [9], calibrated from the uniaxial test (Fig. 2), is introduced.

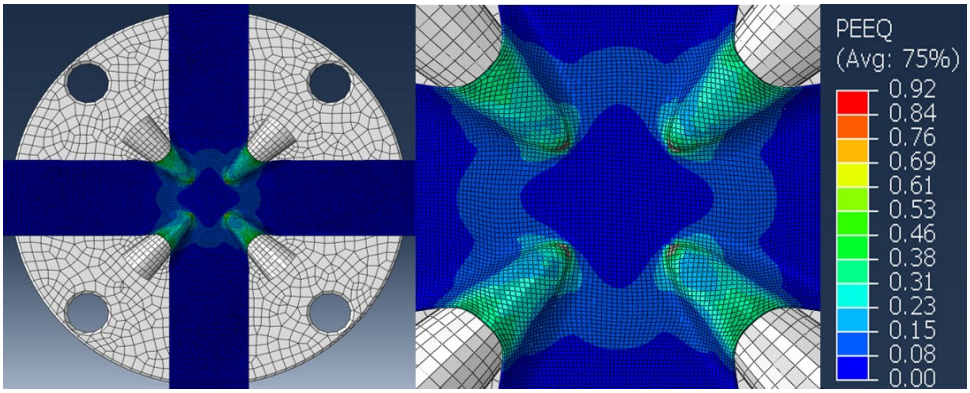

Fig. 7. Plastic equivalent strain distribution at the end of Step 1.

Materials Research Proceedings 28 (2023) 1463-1470 https://doi.org/10.21741/9781644902479-158

Results and Discussion

As mentioned before, three loading conditions (cases 1 to 3) are studied. The following figures (Figs. 8 to 10) show the comparison between experimental and predictive in-plane strain components ε_{11} and ε_{22} along the two perpendicular directions X and Y defined in Fig. 6 respectively. The time for the comparison corresponds to the onset of necking in one of the four arms.

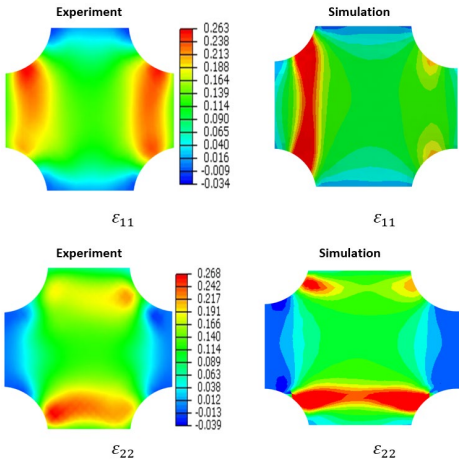

Fig. 8. Case 1 – Biaxial stretching.

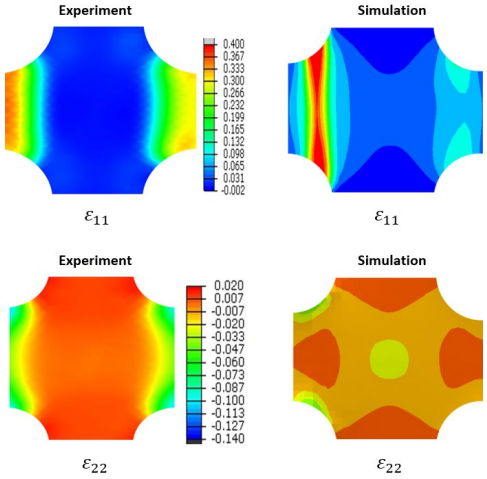

Fig. 9. Case 2 – Near plane strain condition.

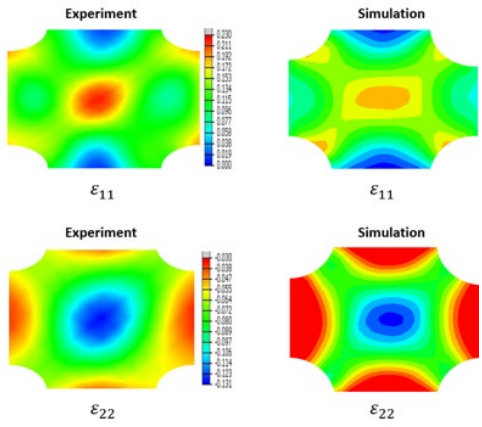

Fig 10. Case 3 – Uniaxial stretching.

Figs. 8 to 10 show a similarity in the strain distribution between the experimental and the predictive results. For cases 1 and 3, the level of strain measured at the centre of the sample is rather high. It leads to values of equivalent strain similar to or higher than the ones measured in the uniaxial test. This is an essential result for the use of this cruciform shape for mechanical characterization (hardening behaviour or anisotropy). The evolution of major and minor strains (in-plane principal strains) can be plotted for the three loading conditions. The comparison of the maximum equivalent strain (failure strain) values for three cases is shown in Table 1. The maximum equivalent strain values represent the starting of the structural failure. The quantitative comparison between simulated and experimental strains at the specimen center can reach up to 30% depending on the considered condition. Fig.11 compares the strain paths for three cases between experimental and numerical results. As expected, the three loading conditions lead to very different strain paths. For this cruciform shape, the strain path measured at the centre of the sample is directly linked to the ratio of actuator velocities. Moreover, as already observed for cruciform samples with reduced thickness [5], the strain paths for the three cases are quasi-linear.

Table 1. Comparison of maximal strain values between experimental and numerical study at the centre point of the specimen.

	Experiment		Simulation		Difference	
	$\varepsilon 11_{max}$	$\varepsilon 22_{max}$	$\varepsilon 11_{max}$	$\varepsilon 22_{max}$	$\Delta\varepsilon 11_{max}$[%]	$\Delta\varepsilon 22_{max}$[%]
Case1 [Biaxial stretching]	0.132	0.121	0.109	0.080	17.4	33.9
Case2 [Plane strain]	0.075	-0.019	0.052	-0.023	30.7	21.1

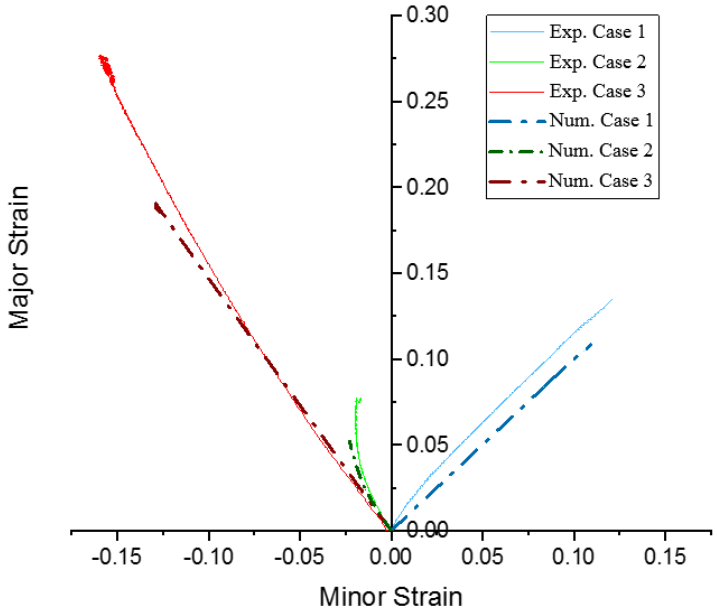

Fig. 11. Comparison of the strain paths for the three loading conditions.

Summary

A numerical model of the forming and testing of an original cruciform sample, without local thickness reduction, was proposed. This cruciform sample was subjected to three different loading conditions (biaxial stretching, near plane strain condition, and uniaxial stretching) in order to evaluate the potential of this sample to characterize advanced mechanical behaviour for different strain states. The predictive qualitative results from the FE model are in agreement with the strain fields measured during the tests for the same loading conditions however the quantitative

comparison between simulated and experimental strains at the specimen center can reach up to 30% of difference depending on the considered condition. Specimen geometry and the dimensions of the preforming die were obtained through FE analysis by a limited number of comparisons. Since the character of the deformations obtained from simulation and experiments is similar, the current numerical model can be used for further optimizations of the proposed geometry in order to emphasize the strain localization at the gauge region and use the sample for mechanical characterization at high strain level (hardening behaviour or forming limits).

Keywords: Crystal Plasticity, Size Effect, t/d Ratio Influence

Abstract. Manufacturing devices at the microscale requires a precise analysis for desirable mechanical behavior. As the products of microscale forming operations have a comparable thickness dimension with grain size, the ratio between thickness and grain size (t/d) becomes an important aspect of mechanical behavior. A number of experimental studies investigated this phenomenon and have shown the influence of the t/d ratio in micron-sized sheet specimens. On the other hand, the computational studies addressing this phenomenon employing micromechanics-based models are quite restricted. The current study aims to investigate the t/d ratio effect through finite element method (FEM) simulations with both local and nonlocal crystal plasticity frameworks. The numerical analyses with the local crystal plasticity framework are obtained by utilizing two different methodologies, where the initial slip resistance is taken as constant or modified using a subroutine based on grain size effects and slip system interactions (see [1]).

Introduction

Microelectromechanical systems are commonly used in different areas such as medicine, portable devices, and inertial measurement units. These systems are composed of micron-sized components that necessitate an investigation of their mechanical behavior. At such small scales, material behavior is heavily size dependent. The effect of grain boundaries and grain dimensions begin to dictate the material behavior (see [2]). However, when these specimens become so thin that there are very few grains in thickness direction, it is not enough to consider the grain size effects only (see [3]). Experiments in the literature have shown that the ratio of specimen thickness to average grain diameter is an important factor determining material response (see e.g. [4,5,6]). In these experiments, the t/d ratio is controlled by keeping one parameter (either specimen thickness or average grain diameter) constant while changing the other. The experiments show that the plasticity response from t/d parameter can be categorized in three main regions (see [5]). Very thin materials that lie in $t/d < 1$ region contain one or very few grains in the thickness direction. This results in a large majority of grains lying at the material surface and an independence of material response from the t/d ratio. Beyond this region, the number of grains in thickness direction begins to increase, yielding a multi-crystal behavior and rapid increase of stress response until the critical t/d ratio is achieved. The critical t/d ratio can be thought of as a material property. Upon reaching this value, the material begins to show proper polycrystalline behavior and acts as a bulk material. The influence of t/d ratio becomes insignificant since the surface grains are in very few numbers (see [7]).

In this paper, the behavior of such thin specimens is examined with three different approaches. First, a conventional local crystal plasticity is used. Local crystal plasticity frameworks do not have an intrinsic length scale parameter. Then, a lower order strain gradient crystal plasticity framework is implemented as an ABAQUS UMAT subroutine. Strain gradient methods have an intrinsic length scale parameter that allows them to predict size effects at the microscale (see e.g.

[8]). The higher order strain gradient formulations have higher order stresses which make them challenging to implement (see e.g. [9,10]). However, since the magnitude of the higher order stresses are often small, lower order approaches have also been used to obtain similar result except for boundary layers near interfaces or material surfaces as explained in [11]. The last method used is a subroutine that uses Hall-Petch theory to define initial slip resistance to crystals at each material point. This subroutine is implemented into the crystal plasticity framework. It is modified to work together with Voronoi tessellation geometries obtained from Neper program (see [12]). Grain misorientations and distance to grain boundaries at each point of the crystal structure is taken into account to provide a non-uniform distribution of initial slip resistance throughout the polycrystal specimens. Specimens with different thicknesses are simulated under uniaxial tension condition with all three methods and the results are discussed in detail.

The structure of this paper is as follows. First, the constitutive relations for both local and strain-gradient framework are described. Then, the material constants of aluminum alloy AA6016 in T4 temper condition, as well as the geometry parameters used in the finite element models are given. Additionally, the boundary conditions of the uniaxial tension are explained. Finally, the results are presented and compared with experimental findings in the literature.

Crystal Plasticity Frameworks

In the finite element analysis of the t/d effect, both a rate-dependent local, and a rate-dependent strain gradient crystal plasticity model is employed. This framework is based on a local crystal plasticity ABAQUS user material subroutine (UMAT) (see [13]). The UMAT subroutine is modified to include non-local strain-gradient effects using lower-order formulation following the theory of [10]. Since local crystal plasticity models do not inherently include size effects, it would not be possible to correctly predict the intrinsic size effect due to the change in grain size. The modification to include strain gradient effects in the constitutive formulations allows the size effects of crystal grains to be captured in simulations through geometrically necessary dislocations (GNDs).

The deformation gradient is decomposed into elastic and plastic components,

$$\mathbf{F}=\mathbf{F}^{e}\mathbf{F}^{p} \tag{1}$$

It is assumed that plastic deformation only occurs as a result of plastic slip. The elastic component of the deformation gradient only considers the stretching and rotation of the crystal lattice. The plastic component of the deformation gradient evolves according to the following flow rule

$$\dot{\mathbf{F}}^{p}=\mathbf{L}^{p}\mathbf{F}^{p} \tag{2}$$

where the plastic component of velocity gradient $\mathbf{L}^{p}$ is defined as the integration of plastic slip rate $\dot{\gamma}^{\alpha}$ on each slip system α that has slip direction and normal $\mathbf{m}^{\alpha}$ and $\mathbf{n}^{\alpha}$ respectively. The crystal plasticity framework consists of 12 active slip systems for a face-centered cubic material.

$$\mathbf{L}^{p}=\dot{\mathbf{F}}^{p}\mathbf{F}^{p-1}=\sum_{\alpha=1}^{N}\dot{\gamma}^{\alpha}\left(\mathbf{m}^{\alpha}\otimes\mathbf{n}^{\alpha}\right) \tag{3}$$

The slip rate is expressed in power law form, as,

$$\dot{\gamma}^{\alpha}=\dot{\gamma}_{0}\left|\frac{\tau^{\alpha}}{g_{T}^{\alpha}}\right|^{n}\operatorname{sign}(\tau^{\alpha}) \tag{4}$$

where $\dot{\gamma}_0$ is the reference slip rate, τ^α is the resolved shear stress, g_T^α is the total slip resistance, n is the rate sensitivity exponent, and $\mathrm{sign}(x)$ is the sign function. In this formulation, the total slip resistance is a combination of slip resistance caused by statistically stored dislocations (SSDs) and geometrically necessary dislocations (GNDs).

$$g_T^\alpha = \sqrt{{g_{ssd}^\alpha}^2 + {g_{gnd}^\alpha}^2} \tag{5}$$

The SSD slip resistance is described by the following relation,

$$\dot{g}_{ssd}^\alpha = \sum_{\beta=1}^{N} h^{\alpha\beta} \left|\dot{\gamma}^\beta\right| \tag{6}$$

From [14], the self and latent hardening law is expressed as,

$$h^{\alpha\alpha} = h_0 \, \mathrm{sech}^2 \left|\frac{h_0 \gamma}{g_s - g_0}\right| \tag{7}$$

$$h^{\alpha\beta} = q^{\alpha\beta} h^{\alpha\alpha} \tag{8}$$

where h_0 is the initial hardening modulus, g_s is the saturation slip resistance, g_0 is the initial slip resistance and $q^{\alpha\beta}$ is the latent hardening coefficient. The strain gradient framework assumes that there are no initial GNDs in the model, and GNDs only evolve because of strain gradient effects over time. Hence, the initial slip resistance is purely related to SSDs. The GND slip resistance is a formulation based on internal length scale parameter as well as the GND density of the crystals.

$$g_{gnd}^\alpha = g_0 \sqrt{l \eta_{gnd}^\alpha} \tag{9}$$

The length scale parameter l is defined as,

$$l = \frac{\alpha_T^2 \mu_s^2 b}{g_0^2} \tag{10}$$

Here, α_T is the Taylor coefficient that depends on the dislocation mechanisms of the crystal, μ_s is the shear modulus and b is the Burger's vector length. The GND density is described as,

$$\eta_{gnd}^\alpha = \left|\mathbf{n}^\alpha \times \sum_{\beta=1}^{N} \mathbf{m}^\alpha \mathbf{m}^\beta \nabla \gamma^\beta \times \mathbf{n}^\beta\right| \tag{11}$$

The calculation of strain gradient in a lower-order framework involves finite element operations. Using an 8-node 3D brick element with 8 Gauss integration points, the plastic slip values on each integration point is extrapolated to element nodes (see [15] for details). Then, a nodal averaging of the plastic slip is performed on nodes of neighboring elements. Finally, the gradient of strain is computed at the position of integration points.

Numerical Analysis

The numerical parameters of thickness/grain diameter ratio simulations are given in this section. A user material subroutine (UMAT) in the finite element software ABAQUS is used for crystal plasticity finite element method (CPFEM) simulations. The details of crystal plasticity parameters and the geometry-based initial slip resistance subroutine parameters are provided hereafter.

Using the material data of AA6016 in T4 temper condition from [16], the material parameters for the crystal plasticity framework are identified using a representative volume element (RVE) with 300 grains. This number of grains is sufficient to obtain an isotropic response from a polycrystal RVE in a reasonable computation time. The stress-strain response of the simulations is fitted to experimental material data under symmetric boundary conditions and tensile loading. Since the RVE is not morphologically periodic, symmetry boundary conditions are used to simulate the uniaxial tension at constant stress triaxiality of 0.33. Elastic stiffness coefficients for Al alloy are taken for cubic behavior from [17] as $C_{11} = 108.2$ GPa, $C_{12} = 61.3$ GPa, $C_{44} = 28.5$ GPa. Reference slip rate $\dot{\gamma}_0$ and the rate sensitivity exponent n are $10^{-3}\,s^{-1}$ and 20, respectively. The latent hardening parameter q is taken as 1.4. The hardening parameters are fitted using an RVE are initial hardening modulus h_0, saturation slip resistance g_s and initial slip resistance g_0, which are 190 MPa, 95 MPa and 47 MPa, respectively.

Table 1. Dimensions and total grains of the specimens used in simulations.

thickness [μm]	mean grain diameter [μm]	t/d ratio	Total number of grains	Number of finite elements	Avg. elements per grain

568	105	5.4	3805	280000	73.6

The lower-order strain gradient theory requires an intrinsic length scale parameter for the slip resistance contribution of GNDs to be determined and the size effects to be predicted. The relation for the length scale parameter that governs the gradient effects is given in Eq. 10 (see [10]). The details of Taylor alpha coefficient can be found in [18]. In this problem, it is taken as 0.5. The shear modulus of AA6016 T4 is taken as 26 GPa and the Burger's vector magnitude is taken as 0.286 nm from [19]. The length scale parameter is calculated as 23.86 μm. However, above a certain element size in the FEM mesh, the lower-order model is mesh dependent. The GNDs are high in density in regions with non-uniform strain states such as grain boundaries. New dislocations must be introduced to obtain a homogenous plastic deformation in these regions (see [20]). If these regions are not modeled with an adequately fine mesh, strain gradients cannot be realized correctly. In this work, since there are many grains in the polycrystal structure, the computation times would be very long if a finer mesh was used. Hence, the length scale parameter is set to 500 μm after an element size sensitivity analysis to perform a qualitative comparison with the experiments.

A subroutine that calculates initial slip resistance based on the distance to grain boundaries on each integration point is implemented and tested in this work. This subroutine is built into the crystal plasticity framework and is only used to determine g_0. The details can be found in (see [1]). The size effects are realized in the initial slip resistance by the following relation,

$$g_0^{\alpha}=\tau_0+\frac{k^{\alpha}}{\sqrt{L^{\alpha}}} \tag{12}$$

where τ_0 is the critical resolved shear stress of a theoretically infinite crystal, taken as 0.05 MPa. L^{α} is the distance at a material point from grain boundaries in the direction of slip for a slip system. k^{α} is the micro Hall-Petch coefficient calculated as,

$$k^{\alpha}=K\left(1-m^{\alpha'}\right)^{c} \tag{13}$$

K and c are empirical coefficients, taken as 0.414 and 0.134, respectively. These values are obtained by fitting the stress-strain response using a 300 grain RVE with uniform 47 MPa initial slip resistance. $m^{\alpha'}$ is the Luster-Morris parameter for each slip system based on grain misorientation,

$$m^{\alpha'}=\left(\frac{\mathbf{m}_A^{\alpha}.\mathbf{m}_B^{\alpha}}{|\mathbf{m}_A^{\alpha}||\mathbf{m}_B^{\alpha}|}\right)\left(\frac{\mathbf{n}_A^{\alpha}.\mathbf{n}_B^{\alpha}}{|\mathbf{n}_A^{\alpha}||\mathbf{n}_B^{\alpha}|}\right) \tag{14}$$

where $\mathbf{m}^{\alpha}$ and $\mathbf{n}^{\alpha}$ are slip directions and normals respectively of each slip system α for grains A and B.

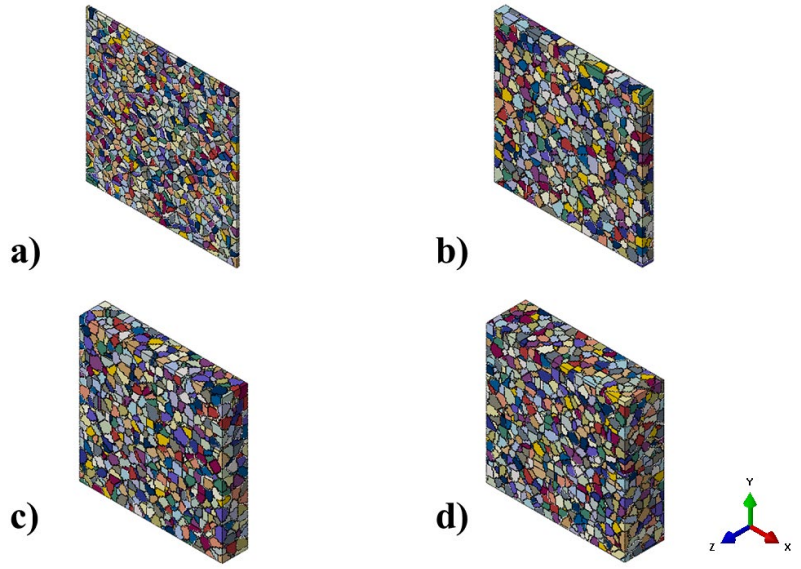

Fig. 1. Polycrystal microstructures of a) t/d = 0.48, b) t/d = 1.4, c) t/d =3, d) t/d = 5.4.

Tensile specimens of 2 mm x 2 mm x t mm thickness are generated through Neper software with dimensions given in Table 1. Examples of polycrystal structures at different t/d ratios are given in Fig. 1. Each grain is given a random crystal orientation. These orientations are random for each specimen with a different t/d ratio. However, they are kept constant while comparing local, strain-gradient, and geometry-based slip resistance simulations. 10% uniaxial tension is applied to each specimen in y-direction with a loading rate of $10^{-3}s^{-1}$ over 100 seconds.

Numerical Results

The numerical examples are presented in this section and a qualitative comparison with the experimental observations is conducted. Experimental results of true stress at 0.05 strain for a nickel polycrystal are represented in Fig. 2 from [5].

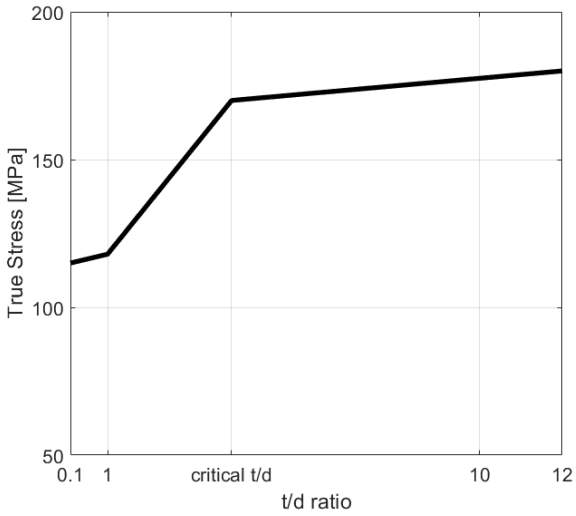

Fig. 2. Experimental values of true stress at 0.05 strain for different t/d ratios of Ni polycrystal (see [5]).

The FEM analysis results using the local crystal plasticity framework shows that, at low t/d ratio specimens (1 and below), the grains do not yield a stronger response despite their lower size compared to large t/d ratios. This is because the local crystal plasticity framework cannot predict intrinsic size effects. As a result, a monotonous increase in strength is observed in this region as seen in Fig. 3a. However, experimental results show that the stress response should not change significantly in t/d < 1 region. Without using a strain gradient framework or modifying the grains to have slip resistance based on their size and geometry, the increased strength of smaller grains cannot be reflected.

Finite element simulation results utilizing the strain gradient crystal plasticity framework are shown in Fig. 3b. The size-dependent solution shows that the strength of specimens in t/d < 1 range does not significantly change, similar to experimental findings. As specimen thickness decreases in this region, the average grain diameter also decreases. Hence, the material response gets stronger, and the significant stress increase in local solution due to surface grains and the presence of additional grains is no longer observed when the size effects are captured. Additionally, the critical t/d value is predicted as t/d = 3. In both Fig. 3a and 3b, a sharp, discontinuous increase can be seen between t/d = 1 and t/d = 1.4. This is a result of increased number of grains in the thickness direction. These grains allow for additional grain boundaries to be created, thus, a jump in stress response is observed.

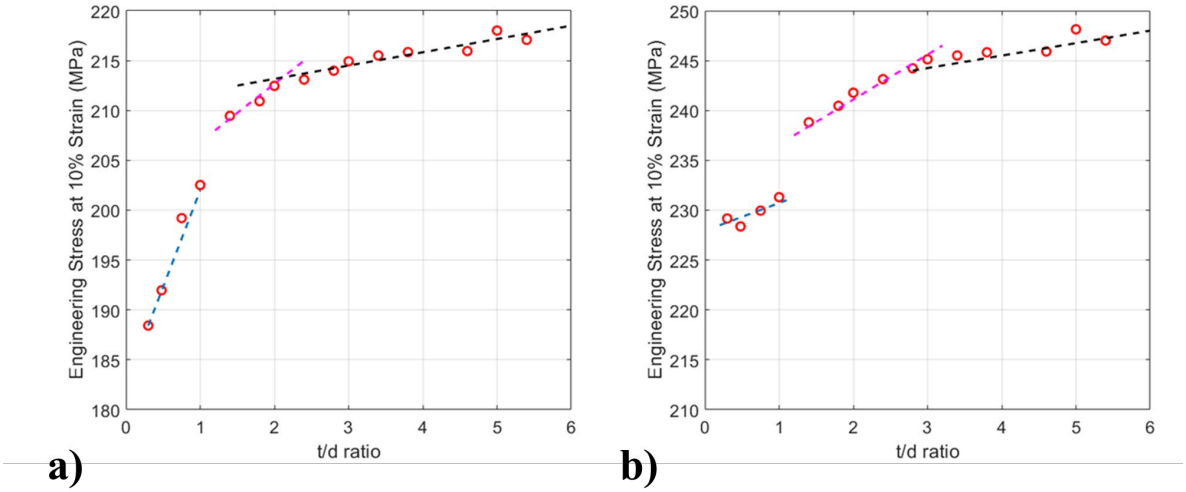

Fig. 3. Flow stress values of different t/d specimens at 10% strain with a) local crystal plasticity framework, b) strain gradient crystal plasticity framework.

After the critical t/d value is reached, the increase in stress response becomes less significant with increasing t/d values. This is in line with the experimental results. In the 1 < t/d < critical t/d region, there is a sharp increase in strength since additional grains in the thickness direction are now appearing and significantly increasing the material's strength. After the critical value, the thickness effect is no longer observed since the specimen approaches bulk size. There are enough grains in thickness direction so that newly formed grain boundaries do not impede dislocation motions significantly. The stress levels reached for every specimen is higher compared to results from local solution since GNDs impede deformation by increasing the slip resistance at locations where their densities are high.

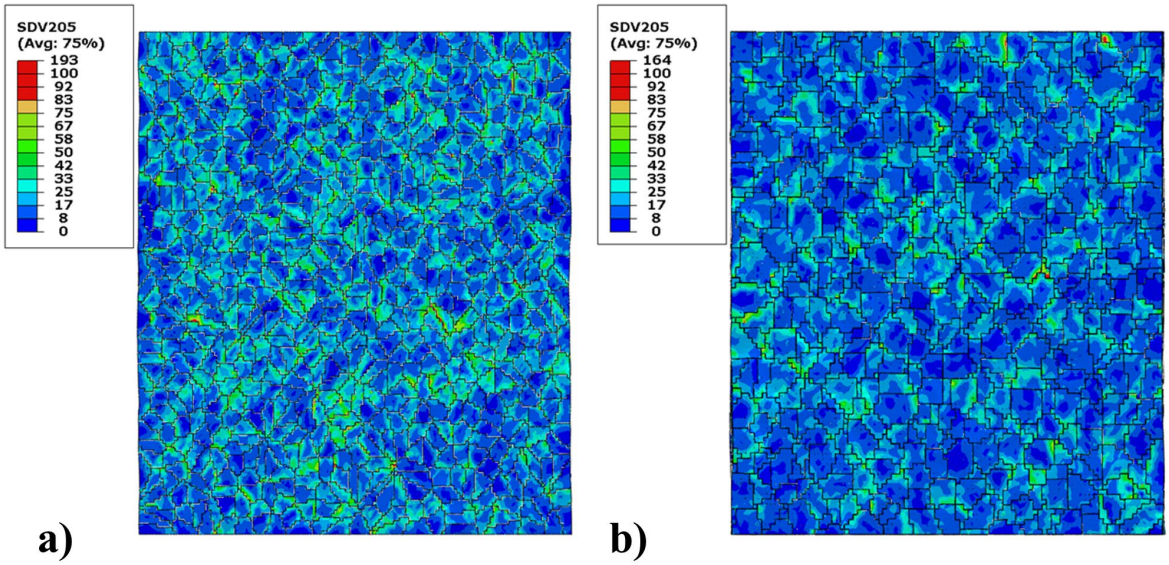

Fig. 4. GND densities [1/mm] of a) t/d = 0.48 and b) t/d = 5.4.

The GND densities of specimens having t/d ratios of 0.48 and 5.4 are presented in Fig. 4. Here, GND densities for each grain are highest at the grain boundaries. Neighboring grains with significant misorientation between each other can be spotted since GND densities would

concentrate at those locations. The density of GNDs is higher in the specimen with smaller t/d ratio, resulting in a higher slip resistance due to smaller grain sizes.

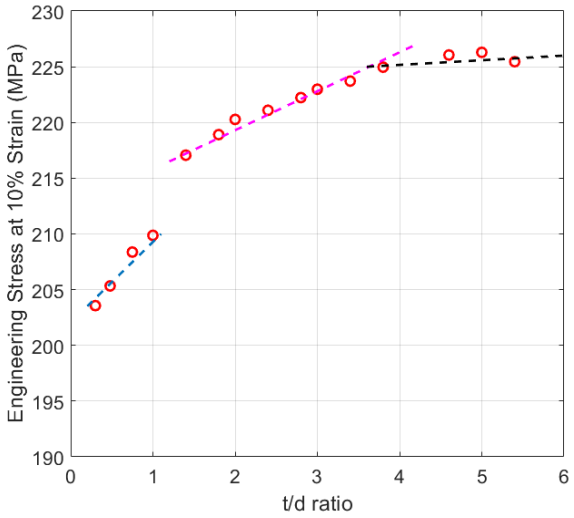

Fig. 5. Flow stress values of different t/d specimens at 10% strain with geometry-based initial slip resistance simulations.

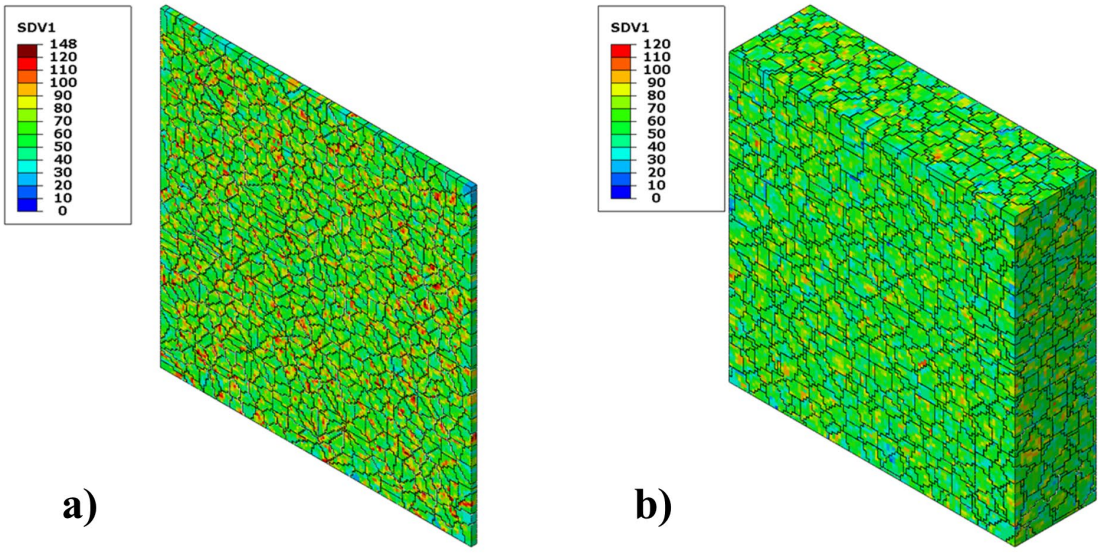

Fig 6. Comparison of initial slip resistance [MPa] at a) t/d = 0.48 and b) t/d = 5.4 for slip system (111)[0$\bar{1}$1].

Finally, the results of simulations where a geometry-based initial slip resistance is used are shown in Fig. 5. The critical t/d value is predicted higher with this method as approximately 4. Since the distance to grain boundaries is a parameter that determines the initial slip resistance at each material point, size effects are taken into account. At t/d < 1, an increase in strength can still be observed with increasing t/d, although at a much lower rate than the local solution. Moreover, after the critical t/d value, the strength increase slows down as expected from the experimental findings. Fig. 6 shows the comparison of initial slip resistance at t/d ratios 0.48 and 5.4 for one of the slip systems. There is a larger initial resistance assigned to elements in $t/d = 0.48$ on average since the grains are smaller and the integration points are closer to grain boundaries as a result.

Summary

In this work, a series of crystal plasticity finite element method simulations are conducted to examine the uniaxial tension loading responses of micron-sized specimens. Three different approaches have been used to obtain these results. Local crystal plasticity frameworks yield size-independent results since there is no information regarding grain or specimen size in their constitutive relations. A subroutine is utilized in a local framework to determine the initial slip resistance of crystals at every material point through a size-dependent approach. While this method does not influence constitutive relations, it is still able to capture the effects seen in experiments since smaller grains in low t/d ratios have their slip resistance increased compared to larger grains. The last method used is the lower-order strain-gradient framework. With this method, the density of GNDs is calculated and used in the constitutive relations directly based on a length scale parameter.

The results show that by using a strain-gradient framework or employing Hall-Petch theory to determine initial slip resistance of crystals, a similar trend to experimental findings in t/d<1 region can be found. As the thickness and t/d ratios of the specimens increase, an increase in their stress/strain response can be seen in every result case. This is attributed to the fact that new grain boundaries and more grains in the thickness direction are developing rapidly. Once the critical t/d value is reached, a different value is obtained with every method. The simulations using local crystal plasticity framework show that the critical t/d is obtained at 2. With the strain gradient framework, the critical value is found as 3. This indicates that there is still a considerable size dependence until this point. On the other hand, when Hall-Petch theory is utilized, the specimens reach this critical value and start showing bulk-material behavior at a t/d value of 4. This is consistent with the trends obtained from experiments as seen in Fig. 2. Additionally, the stress increase in the post-critical region is predicted slightly less in this case.

Keywords: Sheet Metal Forming, Ironing Stage, Deformable Tools, Numerical Analysis

Abstract. Ironing can occur in cylindrical cup drawing whenever the thickness of the drawn flange is larger than the gap between the punch and the die. This is particularly relevant for materials that present *r*-values lower than 1.0, such as the aluminium alloys, since they tend to present more thickening of the flange. The aim of this study is to evaluate numerically the impact of the elastic deformation of the forming tools on the final cup geometry, i.e., the earing profile and the evolution of thickness along the circumferential direction, at different heights. Different contact conditions are also analysed since they strongly affect both the thickness strain and the earing profile. The process conditions considered are the ones from EXACT, the ESAFORM Benchmark 2021, enabling the comparison with experimental results. Considering the deformation of the forming tools mainly impacts the ironing stage, enabling predicting wall thickness values larger than the gap between the punch and the die.

Introduction

Ironing processes are commonly adopted in deep drawing to produce cylindrical cups with uniform thickness in the wall. It is mainly a bulk forming process where the wall of the cup is submitted to compression in the radial direction and shear stress in the contact areas with the tools. These compression forces can result in the elastic deformation of the forming tools, changing the desired thickness reduction. Typically, finite element analysis of sheet metal forming processes assume that the forming tools are rigid. This allows a significant reduction of the computational cost of the simulations since only the outer surface of the tools is modelled. Indeed, in most cases this simplification generates accurate results.

The actual increasing accuracy of both the plasticity and the friction models in predicting the material flow raised questions regarding the influence of the elastic deformations of dies and press lines. In fact, nowadays, it is consensual that they are responsible for many of the differences between the forming simulation results and the manufactured geometries. The iterative spotting steps performed during the die try-out aim to homogenize the contact pressure within the die, to compensate for the fact that the elastic deformation is unknown [1]. Different methods for analysis and virtual rework of tool structures and surfaces, including the combination of structural behaviour with sheet metal forming simulations are described in [2]. The results show that the elastic deformation of the tools changes the blank draw-in significantly, leading to considerable changes in the product's quality measures [2]. Nevertheless, many of the methods suggested to combine the structural analysis and forming simulation into one FE-model lead to large models, which are time-consuming to solve when scaled to industrial dies. Therefore, work has been done

to develop methods to include die and press deformations in sheet metal forming simulations, where the die surfaces are still represented as 2D surfaces [3], including some to circumvent the fact that the press stiffness is commonly unknown [4]. The models that enable predicting the elastic deformations of dies can also be used to improve their structure using, for example, topology optimization [1]. Nevertheless, reliable results require accurate plasticity and the friction models, as pointed out in [2,3].

For small industrial or experimental dies, it is possible to combine structural analysis with sheet metal forming simulations, without resorting to model reduction strategies. This allows an improved understanding of the evolution of the contact conditions during the forming process and its impact in the final geometry. This can be particularly relevant for processes that involve high contact forces, such as the ones that occur in the ironing process. The Swift cup drawing test proposed under the benchmark EXACT [5] was adopted in the present study to assess the importance of the stiffness of the forming tools on the numerical predictions, in particular their accurate dimensions. Accordingly, the finite element model considers that the forming tools are modelled either as rigid or as deformable bodies [6]. Then, the numerical results are compared with the experimental ones, highlighting the impact of the tools deformation in the ironing stage.

Finite Element Model

The benchmark EXACT - Experiment and Analysis of Aluminium Cup Drawing Test [5], proposed at ESAFORM 2021, was selected to analyse the effect of the forming tools stiffness on the ironing conditions. The forming process involves a punch, a die and a blank-holder. Nevertheless, due to the thickening of the flange, the drawing operation is followed by an ironing one, promoted by the same forming tools. The blank presents a diameter 107.5 mm and a nominal thickness of 1.0 mm. The cylindrical punch presents 60 mm of diameter while the die opening diameter is 62.4 mm, i.e., the gap between the punch and the die is 1.2 mm. The cylindrical cup is fully drawn considering a constant blank-holder force of 40 kN. To avoid the pinching of the cup rim by the blank-holder, a stopper with the same thickness of the blank was used, guaranteeing a minimum gap between the blank-holder and the die (1.0 mm) [5].

The numerical simulations are performed with the in-house finite element code DD3IMP [7]. Due to geometrical and material symmetry, only a quarter of the geometry was modelled. The blank was discretized with linear hexahedral finite elements, combined with a selective reduced integration technique. Note that the use of solid elements seems to be the more accurate approach to predict the forming forces and strains (see also [5,8]). Two layers of elements were adopted through the thickness, which allows an accurate evaluation of the contact forces and of the through thickness stress gradients. The region corresponding to the bottom of the cup was defined with an unstructured coarse mesh while for the zone corresponding to the cup wall a refined structured mesh was used, yielding a total of 15,408 finite elements and 16,006 nodes.

Typically, the forming tools are modelled as rigid surfaces. Accordingly, Fig. 1 (a) presents the forming tools modelled by Nagata patches [9], which allows the use of a coarse finite element mesh to define the outer surface of the tools. In addition to the classical approach (rigid tools), the forming tools were also modelled as deformable elastic bodies (E=210 GPa and ν=0.3). The prediction of the elastic deformation of the forming tools requires a proper definition of the geometry (volume) of each one, particularly the punch and the die used in the ironing operation. Two different geometries for the die were studied and modelled by solid elements, which are illustrated in Fig. 1 (b) and (c). The main differences are in the outer diameter and height. The model (#1) presented in Fig. 1 (b) presents an outer diameter of 230 mm and 63 mm of height, while the model (#2) presented in Fig. 1 (c) contains an outer diameter of 180 mm and 25 mm of height. Considering the deformable tools, the total number of elements involved in the numerical simulation increased up to 24,704 elements in model #1 and 23,580 elements in model #2. To impose a constant force over the deformable blank-holder, a pliable (E=0.70 GPa) hollow cylinder

(61 mm of inner diameter and 100 mm of outer diameter) was used with a prescribed displacement on the upper face (1.07 mm). The friction conditions between the blank and the forming tools were described with the Coulomb's law. Two different values of the friction coefficient were adopted in the numerical study to best describe the drawing and the ironing force, respectively.

Constitutive Model

The mechanical behaviour of the AA 6016-T4 aluminium alloy is assumed to be isotropic in the elastic regime, being described by the Young's modulus, E, and the Poisson ratio, ν. Regarding the hardening behaviour, it was described with the Swift law:

$$Y = K(\varepsilon_0 + \bar{\varepsilon}^{\mathrm{p}})^n \tag{1}$$

where Y is the flow stress, $\bar{\varepsilon}^{\mathrm{p}}$ is the equivalent plastic strain and K, ε_0 and n are material parameters. The values considered for these parameters are the ones suggested by the benchmark committee, as shown in Table 1 [5]. The orthotropic behaviour was described by the yield criterion proposed by Cazacu and Barlat, usually referred as CB2001 [10]. The CB2001 is a generalization of the Drucker's isotropic criterion to orthotropy, such that:

$$\bar{\sigma} = \left\{27\left[\left(J_2^0\right)^3 - c\left(J_3^0\right)^2\right]\right\}^{\frac{1}{6}} \tag{2}$$

where J_2^0 and J_3^0 are the second and third generalized invariants of the deviatoric Cauchy stress tensor, defined as:

$$J_2^0 = \frac{a_1}{6}(\sigma_{11} - \sigma_{22})^2 + \frac{a_2}{6}(\sigma_{11} - \sigma_{33})^2 + \frac{a_3}{6}(\sigma_{11} - \sigma_{33})^2 + a_4\sigma_{12}^2 + a_5\sigma_{13}^2 + a_6\sigma_{23}^2 \tag{3}$$

$$
\begin{aligned}
J_3^0 = {} & (1/27)(b_1+b_2)\sigma_{11}^3 + (1/27)(b_3+b_4)\sigma_{22}^3 + (1/27)[2(b_1+b_4)-b_2-b_3]\sigma_{33}^3 \\
& -(1/9)(b_1\sigma_{22}+b_2\sigma_{33})\sigma_{11}^2 - (1/9)(b_3\sigma_{33}+b_4\sigma_{11})\sigma_{22}^2 \\
& -(1/9)[(b_1-b_2+b_4)\sigma_{11}+(b_1-b_3+b_4)\sigma_{22}]\sigma_{33}^2 \\
& +(2/9)(b_1+b_4)\sigma_{11}\sigma_{22}\sigma_{33} - (\sigma_{13}^2/3)[2b_9\sigma_{22}-b_8\sigma_{33}-(2b_9-b_8)\sigma_{11}] \\
& -(\sigma_{12}^2/3)[2b_{10}\sigma_{33}-b_5\sigma_{22}-(2b_{10}-b_5)\sigma_{11}] - (\sigma_{23}^2/3)[(b_6-b_7)\sigma_{11}-b_6\sigma_{22}-b_7\sigma_{33}] \\
& +2b_{11}\sigma_{12}\sigma_{23}\sigma_{13}
\end{aligned}
\tag{4}
$$

where $a_1,...,a_6$ and $b_1,...,b_{11}$ are the anisotropy parameters and c is a weighting parameter. The procedure adopted for the identification of the anisotropy parameters is detailed in [5] and the corresponding values are listed in Table 2. Note that the a_5, a_6 and b_k $(k = 6, 7, 8, 9, 11)$ are the anisotropy parameters corresponding to the off-plane properties, for which the isotropic values, i.e., 1.0 are assumed. Fig. 2 compares the uniaxial tensile tests experimental results (obtained by the Tokyo University of Agriculture and Technology (TUAT) and by the University of Aveiro (UA)) with the ones predicted by CB2001 yield criterion. Note that the in-plane evolution of the *r*-values is well captured but the same is not valid for the yield stress distribution. Although not shown here, the direction of the plastic strain-rate is also well captured by this yield criterion (see [5]).

Results and Discussion

The comparison between predicted and experimental punch force evolution is presented in Fig. 3, using both rigid and deformable tools in the numerical simulation. Besides, as previously mentioned, two different values of friction coefficient were used in the numerical analysis, namely μ=0.1 (Fig. 3 (a)) and μ=0.05 (Fig. 3 (b)). The drawing force is accurately described using μ=0.1 while the ironing force is clearly overestimated. Reducing the friction coefficient to μ=0.05 leads to a global reduction of the punch force during the drawing stage but, the ironing force is still overestimated. The increase of the punch force at approximately 35 mm of punch displacement results from the thickening of the blank during the drawing operation, leading to a thickness larger than the gap between the punch and the die (1.2 mm), i.e., results from the ironing. For both values of friction coefficient, the effect of the elastic deformation of the forming tools on the predicted drawing force is negligible. Nevertheless, the ironing force is reduced when the elastic deformation of the forming tools is considered in the numerical simulation. This is a consequence of the slight increase of the die opening diameter and, consequently, of the gap, due to the high values of contact pressure arising during the ironing stage of the cylindrical cup. Although the die in model #1 is stiffer than the one of model #2 (see Fig. 1), the bigger differences in the punch force only arise after 45 mm of punch displacement, i.e., when the cup wall is sliding over the vertical surface of the tools.

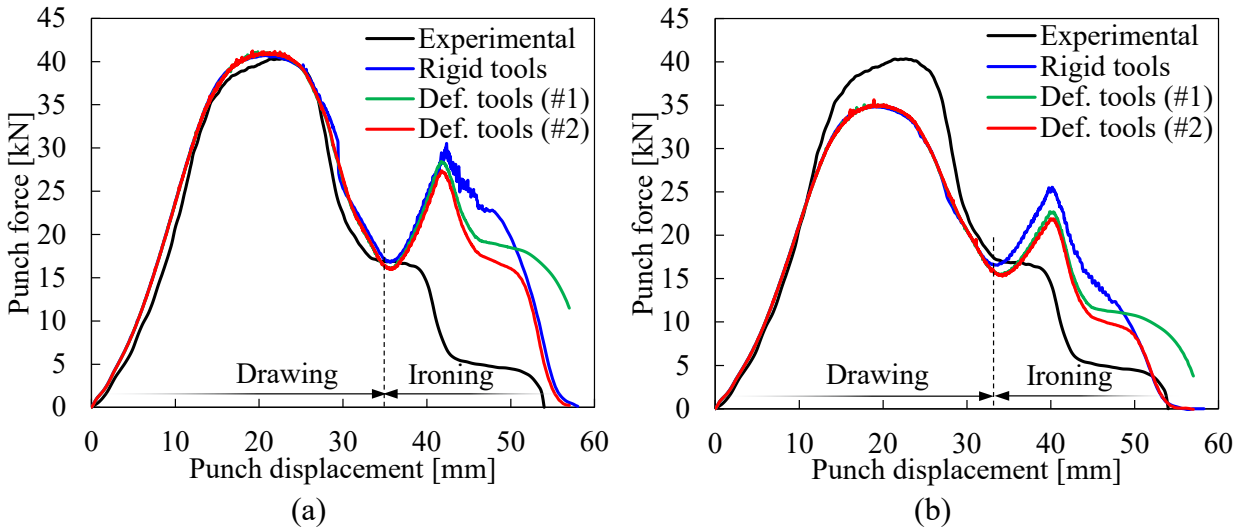

Fig. 3. Comparison between experimental [5] and numerical punch force evolution using different values of friction coefficient in the numerical analysis: (a) μ=0.1; (b) μ=0.05.

The numerical prediction of the blank-holder force evolution is presented in Fig. 4, for the different values of friction coefficient used in the numerical analysis. Regarding the rigid tools, the blank-holder force is kept constant (magnitude of 40±4 kN) by adjusting the position of the blank-holder. On the other hand, when the deformable tools are considered in the numerical model, the blank-holder force is proportional to the axial compression of the hollow cylinder. Thus, the blank-holder force increases slightly until about 25 mm of punch displacement (thickening of the flange) and then decreases quickly. At about 30 mm of punch displacement the stopper is activated, i.e., the gap between the blank-holder and the die decreases to 1.0 mm. The models with a lower friction coefficient predict the loss of contact between the blank and the blank-holder earlier (punch displacement lower than 30 mm) due to the reduction of the restraining forces. This effect is also visible in the punch force evolution, with a sudden drop, as shown in Fig. 3. This also means that

the models that use a lower value for friction coefficient predict lower strain values in the radial direction of the blank during this stage of the forming process.

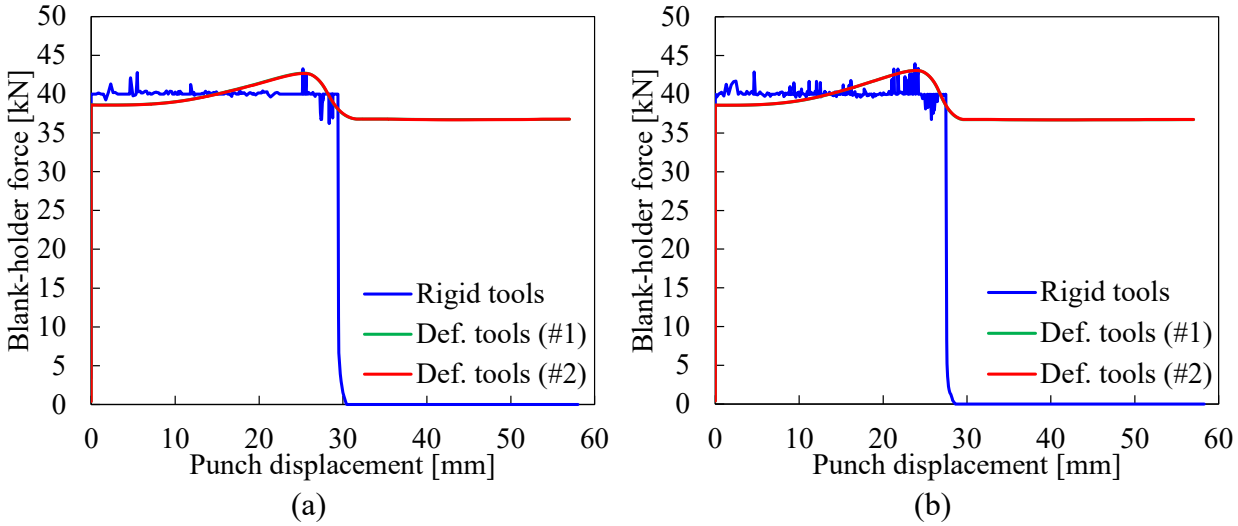

Fig. 4. Numerical prediction of the blank-holder force evolution using different values of friction coefficient in the numerical analysis: (a) μ=0.1; (b) μ=0.05.

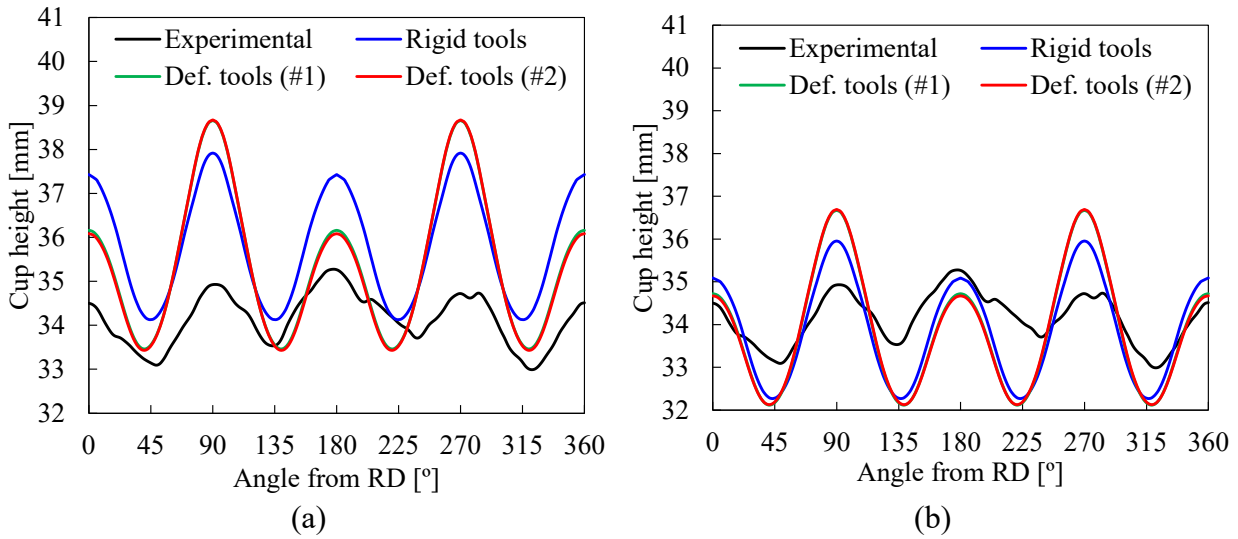

Fig. 5. Comparison between experimental [5] and numerical earing profile using different values of friction coefficient in the numerical analysis: (a) μ=0.1; (b) μ=0.05.

The comparison between the predicted and the experimental earing profile is presented in Fig. 5, using both rigid and deformable tools in the numerical simulation. The stiffness of the die has a negligible effect on this geometrical parameter. The decrease of the friction coefficient from μ=0.1 (Fig. 5 (a)) to μ=0.05 (Fig. 5 (a)) leads to a global decrease of the cup height. The amplitude of the ears experimentally measured is clearly overestimated by the numerical simulation, either using rigid or deformable tools. However, both the number of ears and the position of the valleys/peaks is accurately predicted. This can be related with the accurate description of the in-plane evolution of the *r*-values, while the overestimation of the amplitude of the ears can be associated with the less accurate prediction of the yield stress in-plane distribution, as shown in Fig. 1 and detailed in [5].

Whatever the friction coefficient adopted, the elastic deformation of the forming tools leads to the increase of the cup height in the transverse direction and a decrease in the rolling one. Nevertheless, the effect between the rolling direction and 45º is more evident for μ=0.1, corroborating the uneven distribution of the contact forces in the flange for anisotropic materials [11]. Considering the lower value of friction coefficient (μ=0.05), the elastic deformation of the forming tools leads to a slight increase (about 0.5 mm) of the amplitude of the ears. On the other hand, for μ=0.1 the amplitude of the ears increases about 1.7 mm in comparison with the results obtained using rigid tools. In both cases, the elastic deformation of the forming tools leads to a larger deviation from the experimental earing profile.

The distribution of the equivalent plastic strain is presented in Fig. 6, for the model that considers the deformation of the tools (#2), comparing the two different values of friction coefficient. The global increase of the cup height generated by the increase of the friction coefficient (see Fig. 5) results from a larger plastic strain at the cup bottom, as shown in Fig. 6. The ironing force when the cup wall is sliding between the punch and the die increases from 9.5 kN, when using μ=0.05, to 16.5 kN, for μ=0.1 (see Fig. 3). This increase of the punch force leads to a thinning of the cup bottom. Indeed, the predicted thickness in the middle of the cup bottom is reduced from 0.938 mm for μ=0.05 to 0.900 mm for μ=0.1.

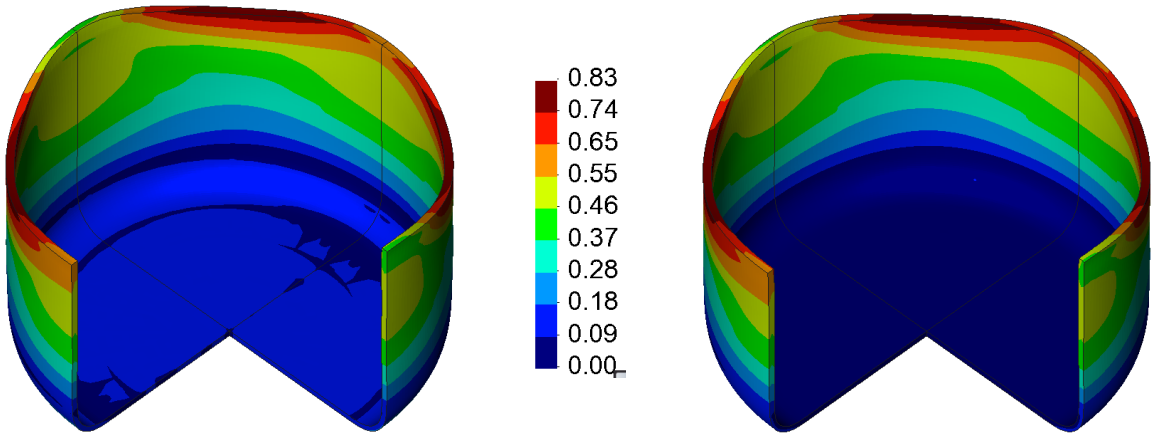

Fig. 6. Predicted equivalent plastic strain distribution considering the deformable tools (#2) described by solid elements using different values of friction coefficient: (a) μ=0.1; (b) μ=0.05.

Fig. 7 (a) compares the position of the outer radius of the blank along the circumferential direction, when using deformable tools (model #2) and the two values of friction coefficient, for two values of punch displacement. For a punch displacement of ~23 mm, there is still a flange (radius higher than 41.2 mm, which corresponds to the die opening radius plus the die shoulder radius). On the other hand, for a punch displacement of ~30 mm, the blank lost contact with the blank-holder (see Fig. 4). The results show a small effect of the friction coefficient on the draw-in, confirming that the increase of the friction coefficient constrains the radial movement of the flange. Fig. 7 (b) compares the thickness of the blank rim along the circumferential direction, for the same instants. The compression of the flange along the circumferential direction imposes an increase of the thickness. On the other hand, some locations present thinning (close to 90º) when the blank partially loses contact with the blank-holder, causing some pinching of the blank still in contact with the blank-holder (see Fig. 7 (a)). Globally, the lower value of the friction coefficient leads to slightly higher thickening, close to 45º. A higher thickness value should correspond to a higher contact pressure between the blank and the ironing tools (die and punch). Nevertheless, this seems to have a negligible impact in the ironing force evolution (see Fig. 3), because of the lower

friction coefficient. In fact, for both values of the friction coefficient in the simulations performed with deformable tools the ironing force presents an identical slope, between a punch displacement of ~ 36 mm and ~ 40 mm. Then, the force starts to drop in the numerical simulations performed with μ=0.05, while it keeps on increasing for μ=0.10, until a punch displacement of ~ 42 mm. This seems to be mainly dictated by the difference in the height of the cup, which is approximately 2 mm higher at the end of the forming, for the simulations performed with μ=0.10 (see Fig. 5). Note that, as previously mentioned, the increase of the friction coefficient constrains the radial movement of the flange, leading to a slightly lower draw-in (see Fig. 7 (a)) and a larger plastic strain at the cup bottom (see Fig. 6).

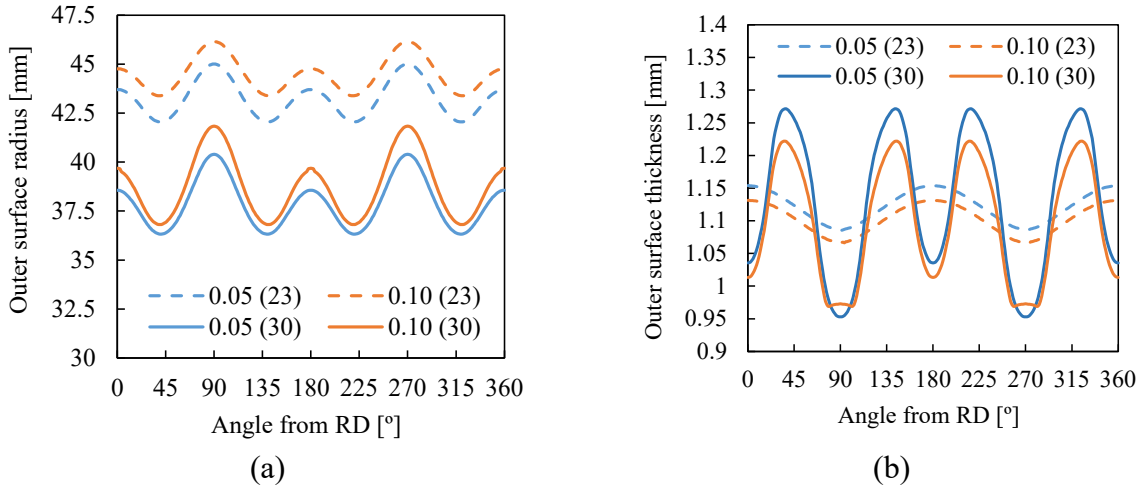

Fig. 7. Comparison between numerical distribution along the circumferential direction in the outer surface: (a) radius and (b) thickness, for a punch displacement of ~23 mm and 30 mm, using different values of friction coefficient (μ=0.1; μ=0.05) and deformable tools (model #2).

The comparison between predicted and experimental cup wall thickness distribution along the circumferential direction is presented in Fig. 8, which was evaluated at three different values of cup height (H), using both rigid and deformable tools in the numerical simulation. The decrease of the friction coefficient from μ=0.1 (Fig. 8 (a)) to μ=0.05 (Fig. 8 (b)) leads to a global increase of the final wall thickness, particularly at locations close to the cup bottom. In fact, using the largest value of friction coefficient (μ=0.1), the cup wall thickness is underestimated by the numerical models (rigid and deformable tools) at all locations, as shown in Fig. 8 (a). The largest difference between numerical and experimental data occurs for H=30 mm, where the numerical simulation considering rigid tools predicts a maximum value equal to the gap between the punch and the die. On the other hand, considering the elastic deformation of the forming tools, the final wall thickness is up to 0.03 mm larger than the nominal gap between the punch and the die. The comparison with the evolution presented in Fig. 7 (b) confirms that the ironing contributes to the uniformization of the thickness.

Due to the material anisotropy, the effect of the deformation of the tools is non-uniform along the circumferential direction. Thus, the thickness predicted using deformable tools is higher around the rolling direction and lower around the transverse direction (in comparison with the prediction obtained with rigid tools). The smaller difference between numerical and experimental thickness was obtained for the lower value of friction coefficient (μ=0.05), for which the predicted ironing force is closer to the experimental measurement (see Fig. 3). Nevertheless, the value is still higher than the experimental one, although the drawing force is clearly underestimated. This corroborates the difficulties in describing both process conditions using a constant value for the friction

coefficient. The results indicate that the friction coefficient between the blank and the die is very low during the ironing operation due to the high levels of contact pressure (see also [5]). The average thickness evaluated both at *H*=10 mm and *H*=20 mm is accurately predicted using the lower friction coefficient (see Fig. 8 (b)), although there is a larger variation of the cup wall thickness predicted by the numerical models along the circumferential direction (anisotropic behaviour). This variation is influenced by the yield criterion adopted, as discussed in [5].

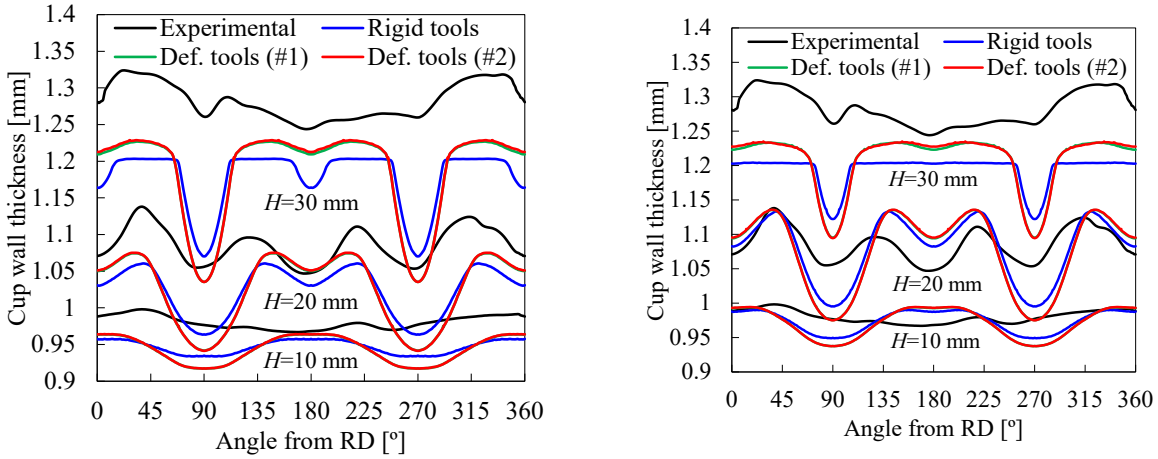

Fig. 8. Comparison between experimental [5] and numerical cup wall thickness distribution along the circumferential direction evaluated at three different cup height values using different values of friction coefficient in the numerical analysis: (a) μ=0.1; (b) μ=0.05.

Summary

The Swift cup drawing test proposed at the benchmark EXACT was used to study the importance of the stiffness of the forming tools on the numerical predictions. Accordingly, the numerical results are compared with the experimental ones. When considering a small value for the friction coefficient, the punch force is underestimated in the drawing stage and overestimated in the ironing stage. Besides, the decrease of the friction coefficient leads to a global decrease of the cup height. The smaller difference between numerical and experimental thickness was obtained for the lower value of friction coefficient. Considering the deformation of the forming tools in the numerical simulation, the main conclusions are:

- The predicted ironing force is significantly reduced, while the effect on the predicted drawing force is negligible;
- The amplitude of the ears is enlarged, particularly for the largest value of friction coefficient;
- The predicted wall thickness is larger than the gap between the punch and the die.

Abstract. The 1st ESAFORM Benchmark, called EXACT [1], enabled an in-depth study of the factors that contribute to the accuracy of predictions and efficiency of finite element (FE) simulations of deep drawing of a cup from AA 6016-T4 sheet through the joint work of 11 teams. FE analyses were conducted with elasto-plastic models or crystal plasticity approaches using commercial or academic FE codes. This paper reminds the content of EXACT benchmark and gives new results that highlight the importance of the tool stiffness and various contact conditions to predict the ironing forces and the thickness distribution along the cup wall. The use of the Benchmark experimental data and virtual tests performed with DAMASK crystal plasticity code to identify and validate a two-surface kinematic hardening model based on Yoshida and Uemori approach is also discussed.

Introduction

Hereafter, the work performed within ESAFORM 2021 benchmark is described and the structure and content of the quite extensive article (96 pages) [1] are reminded. Indeed, this detailed paper provides both theoretical equations and details on the identification methodologies, before the analysis of the FE results *versus* experiments. As pointed out in the next section, some discrepancies between measurements and predictions justify further investigations and the current article summarizes the ongoing activities around all the gathered data.

ESAFORM 2021 Benchmark consisted of a cup drawing process of a 1 mm thick AA 6016-T4 sheet with a strong cube component (52% volume fraction of grains). As shown in Fig. 1, the main goal is to accurately predict the punch force-displacement curve, the earing profile, the thickness distribution and the wall height. Another objective was to provide the dataset necessary to identify advanced models, both elasto-plastic macroscopic models or models accounting for the behavior of the constituent grains. Mechanical characterization tests and texture measurements post tests were also performed, including measurements of the texture of the fully-drawn cup (see Fig. 1)

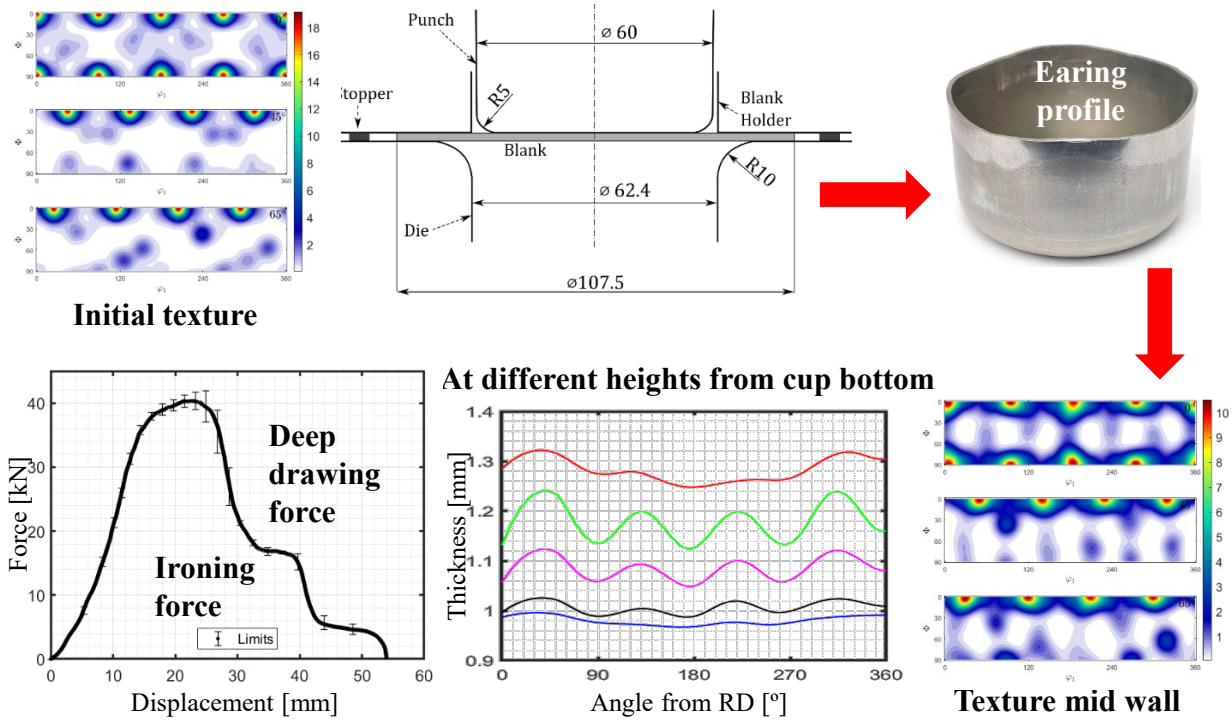

Fig. 1. Cup drawing of a circular blank (Φ =107.5mm) of AA 6016 sheet, adapted from [1].

Specifically, cup drawing tests done at University of Porto (UPorto) were complemented with extensive mechanical characterization by 2 independent teams: tensile tests in 7 orientations (true stress-strain curves and Lankford coefficients, obtained from several repeats of any given test, measured at Tokyo University of Agriculture and Technology (TUAT), and at the University of Aveiro (UA)), biaxial tests in TUAT, shear and reverse shear tests in UA and in the University of Liege (ULiege). For a detailed discussion of testing procedures and experimental errors see [1].

Finally, the initial texture and the one present after forming in the middle and at the top of the cup were measured at UA from coupons taken in the rolling direction (RD), 45° and 90° to the RD. The benchmark results (earing, wall height, thickness distribution, deep drawing, and ironing forces) were measured by UPorto (see [1]).

Eleven institutions participated using either commercial codes with built-in models or their implementation of other models in ABAQUS implicit or explicit, LS-DYNA, MSC.MARC, PAMSTAMP or academic FE Softwares (DD3IMP from Coimbra University (UCoimbra) or Lagamine from University of Liege (ULiege)). Some participants used various models.

The organization of the result presentation in article [1] is shown in Fig. 2. After describing the experimental tests, and a general discussion on friction effects, the choices made by the participants concerning material description, finite element models and FE type were described. Tables 10-12 in article [1] identify the hardening law, yield criterion and homogenization approaches. Fig. 2 summarizes where to find in [1]: the description of the numerous laws used (also reminded in Fig. 3), their identification and how results were presented. Finally, it points to some of the conclusions.

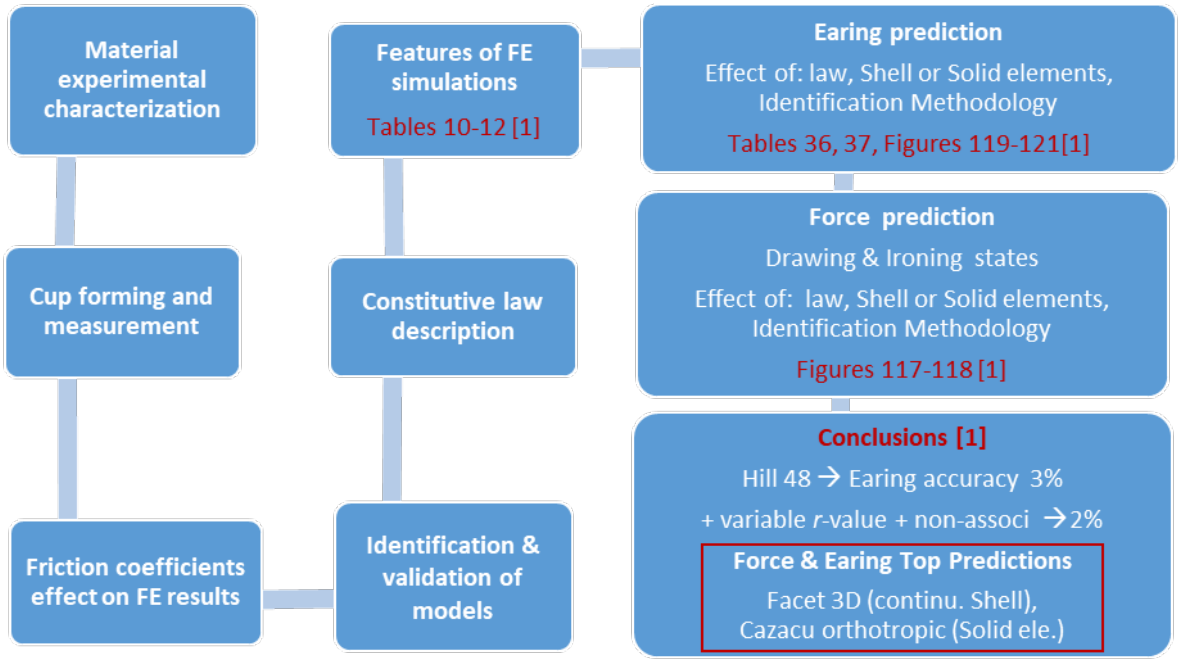

Fig. 2. Sections of article [1] describing the ESAFORM Benchmark 2021.

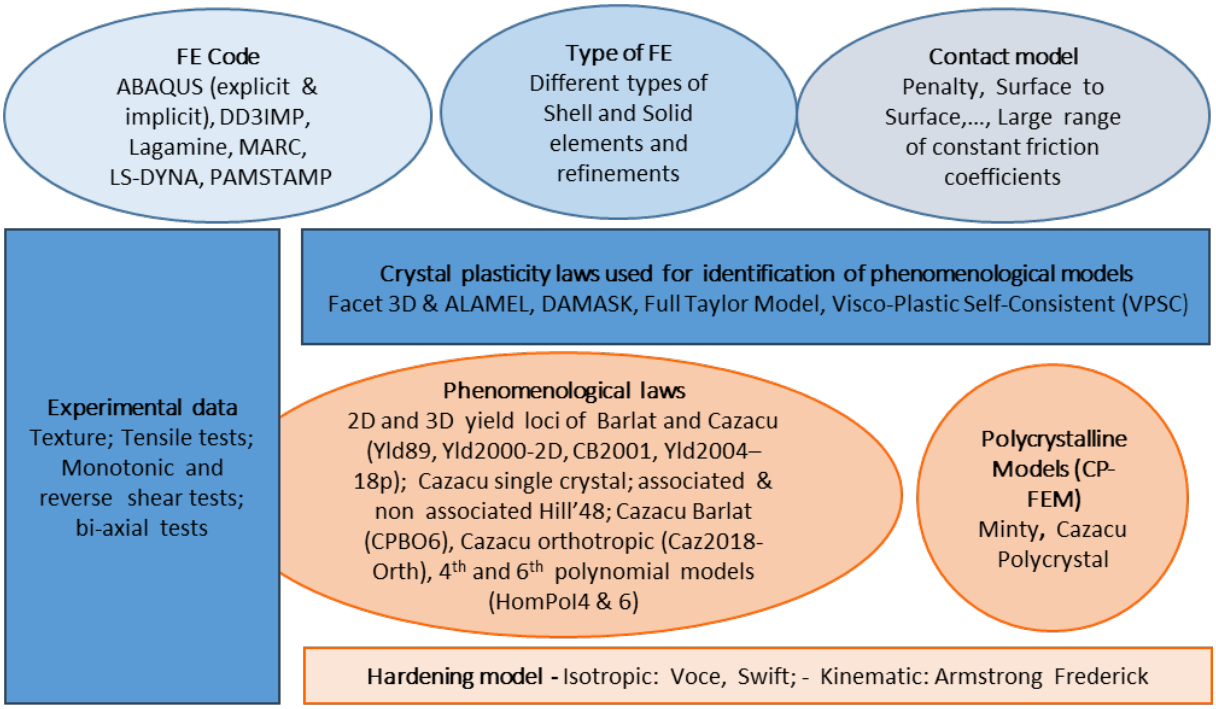

Fig. 3. Different model features involved in ESAFORM 2021 Benchmark: light blues define the FE codes, elements, contact models, while pink color points the constitutive laws used and dark blue rectangles explain how they are identified.

Fig. 3 summarizes all the material models used. An extensive discussion on model identification is provided in [1]. Here we just mention that for crystal plasticity models (CPM), it was detailed: i) the choice of the set of representative grains to model the texture; ii) the detailed methodology for identification of the parameters of the CPM; with tables for all parameter values, iii) predictions of Lankford coefficient variation and yield stress variation (see a summary in Fig. 4.). For both classical and recent anisotropic yield functions, the data set used for identification was either based on physical tests or on virtual tests computed with CPM, as synthesized in Fig. 5.

Fig. 5. List of mechanical physical or virtual (CPM) tests used for the identification of the anisotropic yield functions used by the participants (see [1] for more details).*

To check the validity of the parameter identification of the anisotropic yield functions and respective CPM models, the participants had to provide the predicted in-plane evolutions for the Lankford coefficients and the yield stresses, for tensile directions varying from 0° to 90° to the RD. Cup drawing simulation results were discussed in detail in several subsections. First the FE results (solid and shell FE simulations) obtained using anisotropic yield functions, identified either from physical or virtual tests, and then FE results of cup drawing obtained with polycrystalline model results. It can be concluded that Hill48 provides satisfactory earing results (within 3% of earing measurements, see Fig.2); small differences in results obtained with Hill48, between various teams, due to FE modelling features. An overestimation of the ironing force was observed when using shell elements. Various possible improvements using a non-associated flow rule or variable Lankford coefficients were also discussed. Two models provided very accurate results for both earing and force: Facet 3D constitutive law [2], with continuum shell elements and identification based on CPM; and Cazacu orthotropic law [3], with solid elements and an identification relying on the 7 available physical tensile tests. The reader is referred to [1] for more details.

Influence of the Tool Stiffness

A part of the EXACT benchmark reported data was the measurement of the thickness at the top of the cup. It was roughly 0.1 mm larger than the gap between the punch and the die. Explanations were sought and discussed, one being that the gap was slightly bigger than initially reported, i.e., enough to justify the measured values. However, the geometry for the EXACT benchmark was done very carefully (see [1]), which did not support this assumption.

Here, we discuss further investigations done to provide explanations for attaining a cup with a thickness higher than the gap between the punch and the die. This could be related with the elastic deformation of the tools during the process. Note that the modelling of the tool deformation can be performed using different approaches, namely by adjusting the stiffness of the surfaces that describe the tool or modelling them as deformable bodies. The latter approach was adopted and simulations were conducted with the academic code DD3IMP, considering the Swift law and the Hill48 yield criterion, with the parameters provided by the benchmark committee. A friction coefficient of 0.06 was assumed between the blank and the tools, to improve the description of the drawing force. More details concerning the constitutive model and the friction coefficient adopted are presented in Table 1 (column Def1). For reference, simulations were performed considering rigid tools (Rig1 results).

Materials Research Proceedings 28 (2023) 1491-1502 https://doi.org/10.21741/9781644902479-161

* Note that different meshes (blank and tools) and CPUs were used with different codes; ** 5 through thickness integration points; *** 11 through thickness integration points

A similar approach was adopted at University of Siegen (USiegen) and simulations were conducted using the commercial code PAMStamp considering also hexahedral solid elements and the same constitutive model. The results were compared with those obtained with rigid tools, which were presented in [1]. To be noted that with rigid tools, a slightly higher value for the friction coefficient was considered, to capture the maximum punch force in the drawing stage in [1]. The model with deformable tools uses the same value such as to allow for direct comparison, as shown in Table 1 (Rig 2 and Def2).

In ESAFORM 2021 benchmark, the use of Facet-3D yield function with Abaqus/Explicit led to an accurate cup height profile and punch force curves. However, the thickness measured at different height sections was underestimated. In the follow up research, Facet-3D was used in AutoForm R10, since it allows implementing a user material and enables a convenient adjustment of the tool stiffness. In this work, the value of 10 GPa/mm was used for the punch, while for the die and the blank holder a higher value of 60 GPa/mm was adopted. This combination was found by trial and error to somehow trade-off the ironing force and the thickness distribution. With lower tool stiffnesses, the maximum sheet thickness increases and the ironing force decreases. Other details about these models are presented in Table 1 (Rig3 and Def3).

Fig. 6 (a) presents the comparison of the punch force evolution with its displacement, obtained with the different models, as well as the experimental results. Globally, the adoption of rigid or deformable tools has a negligible impact on the drawing stage, where the maximum value attained is mainly dictated by the value of the friction coefficient. Nevertheless, the maximum value of the ironing force drops when adopting deformable tools and solid elements for the blank. When the blank is discretized with solid-shell elements, the model with deformable tools shows a slight increase of the ironing force, but these results are not directly comparable, because different codes were used. Regarding the earing profile, although models Rig1 and Rig2 present quite similar average height and trend (see Fig. 6 (b)), the effect of considering deformable tools leads to a lower cup height for Def1, while for Def2 it increases. On the other hand, for the models adopting solid-shell elements the impact of considering deformable tools is negligible (Rig3 and Def3). Note that in this case the earing profile is not symmetric, because the initial position of the blank was off set, to improve the comparison with the experimental results [1].

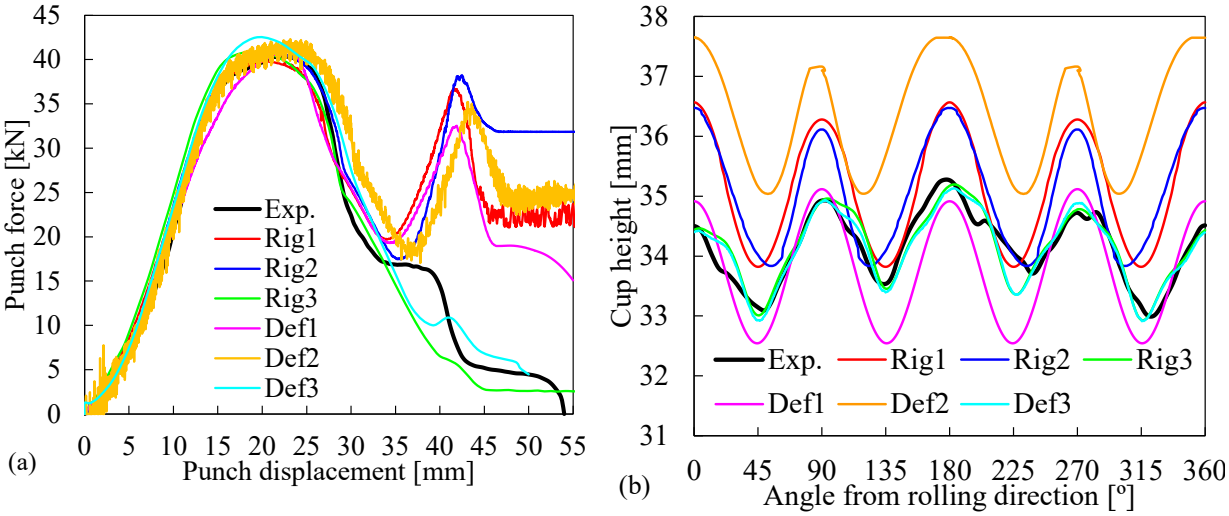

Fig. 6. Comparison between experimental and predicted results using rigid and deformable tools: (a) punch force-displacement and (b) earing profile.

The thickness distribution along the circumferential direction is presented in Fig. 7, for two values of cup height, 20 mm and 30 mm. The models that use rigid tools and solid elements (Rig 1 and Rig2) led to a trend like the experimental one for the lower height. For the higher height, the thickness is constant and equal to the value of the gap (1.2 mm) for Rig 1 while Rig2 predicts a slightly higher value, which indicates that the contact algorithm implemented in DD3IMP imposes the contact constraints more strictly. When adopting deformable tools, the models that use solid elements present different trends, with Def1 leading to higher thickness values for both heights, while Def2 underestimates the thickness value for both heights. These results seem to be coherent with the average cup height because lower thickness values result in a higher cup and *vice-versa* (see Fig. 6 (b)). Although the results are not directly comparable for solid-shell elements (Rig3 and Def3), one can see that the thickness estimation improves when considering deformable tools. In brief, deformable tools lead to thickness values on the top of the cup higher than the gap between the die and the punch, like in the experiment. In this context, it should be mentioned that the option of adjusting the stiffness of the surfaces has a negligible impact on the CPU time, when compared with the use of solid deformable tools (see Table 1).

The lower punch force value predicted for the ironing stage when adopting solid-shell elements had already been reported in [1]. The differences observed in the models obtained with solid elements and deformable tools seem to be related with distinction features in the treatment of the contact conditions. In fact, although not shown here, it was observed that the adoption of the penalty algorithm instead of the hard contact one, adopted in this work for PAMStamp, would lead to a clearly lower value for the force during the ironing stage. Thus, even when adopting deformable tools, an evolutional friction law is suggested to capture the drawing and the ironing forces in a more realistic way [4]. In this context, some of the authors are working on an improved analysis of the contact conditions, considering the experimental analysis of the contact conditions using flat strip drawing friction tests.

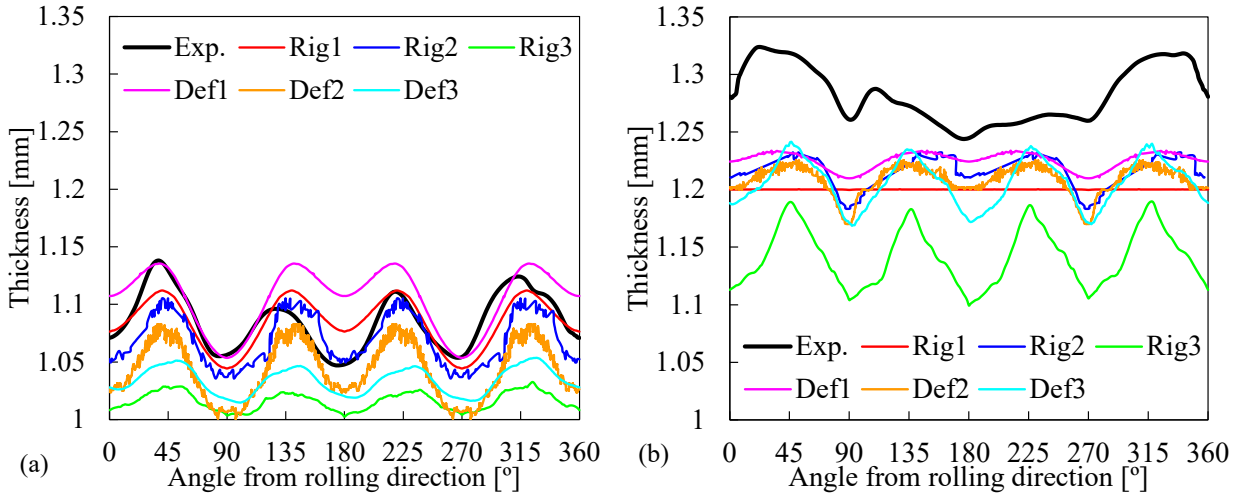

Fig. 7. Comparison between experimental and numerical wall thickness distribution along the circumferential direction evaluated at different cup height values: (a) H=20 mm; (b) H=30 mm.

CP-Based and Phenomenological Modelling of Kinematic Hardening Behavior

The experimental cyclic shear deformation behavior of AA 6016-T4 sheet, observed in Fig.12 of [1] and reported in Fig. 8 (b) hereafter, presents a kinematic hardening phenomenon. To capture this phenomenon, a two-surface model was proposed by Yoshida and Uemori (YU) and has been widely used in sheet metal forming analysis [5-6]. It consists of a yield surface and a bounding surface, in which the kinematic hardening is described by moving the yield surface within the bounding surface. Hereafter, an associated flow rule (AFR) based two-surface hardening model is proposed, which is modified from the non-AFR based two-surface model proposed by Ghaei et al. [7]. The YU hardening model was incorporated with an advanced yield function to describe the complex deformation behavior in sheet metal forming. In this model, the yield criterion f_y determines the boundary between the elastic and plastic zone using the yield stress y in the stress space and the function $\boldsymbol{F}$ determines the shape of the bounding surface, as given by:

$$f_y(\boldsymbol{\eta}) - y = 0 \tag{1}$$

$$F(\boldsymbol{\Sigma} - \boldsymbol{\alpha_2}) - b_0 - r(p) = 0$$

$$\boldsymbol{\eta} = \boldsymbol{\sigma} - \boldsymbol{\alpha}$$

where $\boldsymbol{\sigma}$ is the Cauchy stress tensor in current state, $\boldsymbol{\Sigma}$ is the stress tensor corresponding to the bounding surface, and $\boldsymbol{\alpha}$ is the backstress tensor controlling the movement of the yield surface. $\boldsymbol{\eta}$ is substituted into the yield criterion to calculate the effective stress. $\boldsymbol{\alpha_2}$ is the corresponding backstress tensor and b_0 is the initial size of the bounding surface. r controls the expansion of the bounding surface, which is governed by the equivalent plastic strain p:

$$r(p) = Q[1 - \exp(-bp)] \tag{2}$$

where the Q and b are the material constants that need to be calibrated. In this model, the kinematic hardening behaviour is governed by the state of the backstress $\boldsymbol{\alpha}$, which can be decomposed as $\dot{\boldsymbol{\alpha}} = \dot{\boldsymbol{\alpha}}_1 + \dot{\boldsymbol{\alpha}}_2$. $\dot{\boldsymbol{\alpha}}_1$ is dependent on the rate of equivalent plastic strain $\dot{p}$, and can be described by:

$$\dot{\boldsymbol{\alpha}}_1 = \gamma_1 \left(\frac{b_0 + r - y}{y} \boldsymbol{\eta} - \boldsymbol{\alpha_1} \right) \dot{p} \tag{3}$$

where γ_1 is the material constant. $\boldsymbol{\alpha_1}$ is the deviation between the central position of the yield surface and the bounding surface, whose motion is controlled through $\dot{\boldsymbol{\alpha}}_2$, as given by:

$$\dot{\boldsymbol{\alpha}}_2 = \gamma_2 \left(\frac{c_2}{y} \boldsymbol{\eta} - \boldsymbol{\alpha_2} \right) \dot{p} \tag{4}$$

where c_2 and γ_2 are the material parameters. $\boldsymbol{\alpha_2}$ is the central position of the bounding surface in the stress space. To obtain the equivalent plastic strain rate $\dot{p}$, the classical AFR is employed:

$$\dot{\boldsymbol{\epsilon}}^{\boldsymbol{p}} = \dot{\lambda} \frac{\partial f_y}{\partial \boldsymbol{\sigma}} = \dot{\lambda} \boldsymbol{m} \tag{5}$$

where $\dot{\boldsymbol{\epsilon}}^{\boldsymbol{p}}$ is the rate of the plastic strain tensor and $\dot{\lambda}$ is the plastic multiplier, which is equal to the equivalent plastic strain rate in AFR, i.e., $\dot{p} = \dot{\lambda} \boldsymbol{m}$ is the first order of the yield function, which makes the plastic potentials normal to the yield surface. A consistency condition in the yield surface and bounding surface is utilized to solve the equivalent plastic strain rate:

$$\frac{\partial f_y}{\partial \boldsymbol{\sigma}} : \dot{\boldsymbol{\sigma}} + \frac{\partial f_y}{\partial \boldsymbol{\alpha_1}} : \dot{\boldsymbol{\sigma}}_1 + \frac{\partial f_y}{\partial \boldsymbol{\alpha_2}} : \dot{\boldsymbol{\sigma}}_2 = \boldsymbol{m} : \dot{\boldsymbol{\eta}} = 0 \tag{6}$$

Here, the elastic stress tensor follows Hooke's law, and hence the rate of the stress tensor is obtained by:

$$\dot{\boldsymbol{\sigma}} = \boldsymbol{D} : \left(\dot{\boldsymbol{\epsilon}} - \dot{\boldsymbol{\epsilon}}^{\boldsymbol{p}} \right) = \boldsymbol{D} : \left(\dot{\boldsymbol{\epsilon}} - \dot{\lambda} \boldsymbol{m} \right) \tag{7}$$

where $\boldsymbol{D}$ is the elastic stiffness matrix, and $\dot{\boldsymbol{\epsilon}}$ is the rate of the total strain tensor. The plastic multiplier can thus be represented by:

$$\boldsymbol{m} : \boldsymbol{D} : \left(\dot{\boldsymbol{\epsilon}} - \dot{\lambda} \boldsymbol{m} \right) - \boldsymbol{m} : \dot{\boldsymbol{\alpha}}_1 - \boldsymbol{m} : \dot{\boldsymbol{\alpha}}_2 = 0 \tag{8}$$

Therefore, the plastic multiplier (equivalent plastic strain rate) can be obtained:

$$\dot{p} = \frac{\boldsymbol{m} : \boldsymbol{D} : \dot{\boldsymbol{\epsilon}}}{\boldsymbol{m} : \boldsymbol{D} : \boldsymbol{m} + \boldsymbol{m} : \frac{\dot{\boldsymbol{\alpha}}_1}{\dot{p}} + \boldsymbol{m} : \frac{\dot{\boldsymbol{\alpha}}_2}{\dot{p}}} \tag{9}$$

In addition, the tangent consistent modulus $\boldsymbol{D^{ep}}$ of the two-surface hardening model is determined:

$$\dot{\boldsymbol{\sigma}} = \boldsymbol{D^{ep}} : \dot{\boldsymbol{\epsilon}} = \left(\boldsymbol{D} - \frac{(\boldsymbol{D} : \boldsymbol{m}) \otimes (\boldsymbol{D} : \boldsymbol{m})}{\boldsymbol{m} : \boldsymbol{D} : \boldsymbol{m} + \boldsymbol{m} : \frac{\dot{\boldsymbol{\alpha}}_1}{\dot{p}} + \boldsymbol{m} : \frac{\dot{\boldsymbol{\alpha}}_2}{\dot{p}}} \right) \tag{10}$$

Besides the permanent softening, workhardening stagnation is observed at the early stage of reverse loading [5]. To describe this phenomenon, a stagnation surface is introduced to limit the expansion of the bounding surface. In this method, the expansion of the bounding surface is only

Materials Research Proceedings 28 (2023) 1491-1502 https://doi.org/10.21741/9781644902479-161

allowed when the central position of the bounding surface is within the range of the stagnation surface. This stagnation surface is given as follows:

$$f_s(\boldsymbol{\alpha_2} - \boldsymbol{\alpha_s}) - y_s = 0 \tag{11}$$

where y_s and $\boldsymbol{\alpha_s}$ are the initial size and the central location of the stagnation surface in stress space, respectively. A non-linear kinematic hardening law is utilized to describe the translation of the bounding surface:

$$\dot{\boldsymbol{\alpha}}_s = \dot{\mu}(\boldsymbol{\alpha_2} - \boldsymbol{\alpha_s}) = \dot{\mu}\boldsymbol{\xi} \tag{12}$$

where the tensor $\boldsymbol{\xi}$ and rate $\dot{\mu}$ are achieved using the following criterion:

$$\frac{\partial f_s}{\partial \boldsymbol{\alpha_2}} : \dot{\boldsymbol{\alpha}}_2 + \frac{\partial f_s}{\partial \boldsymbol{\alpha_s}} : \dot{\boldsymbol{\alpha}}_s - \dot{y}_s = 0 \tag{13}$$

where the $\dot{\mu}$ is obtained by,

$$\dot{\mu} = \frac{\boldsymbol{n} : \dot{\boldsymbol{\alpha}}_2 - \dot{y}_s}{\boldsymbol{n} : (\boldsymbol{\alpha_2} - \boldsymbol{\alpha_s})} \tag{14}$$

where $\boldsymbol{n} = \frac{\partial f_s}{\partial \boldsymbol{\alpha_2}}$. The rate of y_s is defined as:

$$\begin{cases} \dot{y}_s = h\boldsymbol{n} : \dot{\boldsymbol{\alpha}}_2, & when \quad \dot{r} > 0 \\ \dot{y}_s = 0, & when \quad \dot{r} = 0 \end{cases} \tag{15}$$

where h is the calibrated material constant, which controls the expansion level of the stagnation surface. The $\dot{r}$ determines that the stagnation surface is only allowed to expand associated with the expansion of the bounding surface.

Kinematic hardening model calibration and validation was based on the results of DAMASK solver, a CPM model (see [1] Norwegian University of Science and Technology (NTNU) participant approach) used to predict the stress response of AA6016-T4 during the cyclic deformation. The parameters of the modified YU kinematic hardening model are identified with a virtual uniaxial tension-compression test in RD (1.5 cycles), as given in Table 2. To evaluate the performance of the calibrated hardening model at various strain levels, a comparison between the stress-strain curves predicted by CPM simulation and YU model for five tension-compression cycles was illustrated in Fig. 8 (a). It was found that the calibrated YU hardening model can well capture the tension-compression full-CPM history stress-strain response. Fig. 8 (b) shows that the modified YU model identified by the virtual uniaxial tension-compression tests coupled with Yld2004-18p yield function is capable of accurately predicting the experimental mechanical response of AA6016-T4 in the shear-reverse shear deformation mode measured in [1].

Table 2. The parameters of the modified two-surface kinematic model for the AA6016-T4 sheet.

Summary

The ESAFORM Benchmark series is an ongoing adventure (https://esaform.org/grants/), do not hesitate to apply. It allows a whole community to exchange ideas about an issue that poses difficulties to realize reliable and efficient forming processes and, or simulations.

In 2021 cup drawing benchmark, the simulations pointed out that phenomenological laws identified using only physical experiments or completed by crystal plasticity results could reach accurate predictions of force evolution, final earing and thickness distribution. Additionally, an issue about the ironing force, the wall thickness distribution and the punch-die gap drew attention to the question of friction and tool elasticity. The current article demonstrates that both effects are important and it suggests that a variable friction parameter could be required to improve ironing force prediction. Nevertheless, even with a single tuned friction coefficient, the Facet 3D model, considering the tool deformation available in AutoForm R10 was able to improve its thickness prediction accuracy at the top of the cup compared to its results based on rigid tools. Models with rigid and deformable tools, built in DD3IMP and PAMStamp, led to physically consistent results, coherent with the experimental ones.

The extensive experimental results gathered in [1] allow the identification of advanced anisotropic elastoplastic models, as shown by the work of NTNU and Northwestern Polytechnical University (Taican, China), with their advanced two-surface model. Validated on experimental reverse shear tests, pointing the need of an accurate kinematic behaviour model, their work is still ongoing to present a cup deep drawing application.

The reader can consult the open access article [1] for a more detailed analysis of all the benchmark results and access to the data (https://zenodo.org/record/6874577#.Y4YhzHbMKyA).

Abstract. In order to increase the accuracy of cold forging simulations, flow curves obtained by experimental compression tests are used instead of the material models existing in the software library. The parameters of Ludwik material model were determined with respect to the constructed experimental flow curves at different temperatures and strain rates. Then, the flow curves were defined into the software by using these parameters. While Ludwik model can represent the material flow curve with high accuracy at low plastic strain values, the error rate between the experimental flow curve and the Ludwik model increases at high plastic strain values. Voce material models were known to predict the flow curve of materials with high strain hardening exponents more accurately, especially at high temperature and strain values. In this study, the performance of Ludwik material model was compared to four Voce material models given in the literature and a more accurate combined material model was defined for each flow curve at different temperature and strain rates for 42CrMoS4 material. All experimental flow curves were predicted with a minimum R^2 of 0.99 and the lowest mean absolute error value with the new combined material model.

Introduction

The accuracy of cold forming process simulations using finite element analysis (FEA) software depends on the true stress -plastic strain curves used. In cases where plastic deformation is high, the stress and strain distributions are not uniform, that is, they do not show a certain trend. For this reason, it is difficult to predict the flow curves of steel materials with a high strain hardening exponent, where high plastic strain values are observed in the flow curves, using a single material model. Defining the flow curves of such materials separately according to the deformation transitions increases the accuracy of the prediction models. Plastic deformation transitions in flow curves can be listed as follows: i) the part from the beginning of plastic deformation to the maximum compression stress value, ii) after the maximum compression stress value, the material exhibits strain softening part until the actual rupture of the material. In the literature, there are models such as Hollomon [1], Ludwigson [2], Ludwik [3], Swift [4] and Voce [5] that consider the work hardening rate for material flow curve prediction. However, these models are insufficient to represent the hardening and softening behavior of materials at high plastic strain values. Guo et al. [6] suggested a model that includes both the hardening and softening phases by combining the Voce Model for Hardening [5] and a linear softening model (Voce Model with Linear Softening). The developed model was able to predict the flow stress over a wide plastic strain range. Nguyen [7] has proposed a combination of Voce hardening and Voce softening models. On the other hand, Rotpai et al. [8] proposed a new piecewise model for flow curve prediction at room and elevated temperatures in order to minimize the deviation between the predicted flow curves and the experimental flow curves. A Swift-Voce model to describe the large deformation behavior of 7050-T7451 aluminum alloy under uniaxial stress, notched stress, and pure shear operations was developed by Cao et al [9]. The combination of Swift model and the 4th order polynomial was

also proposed in order to describe the large deformation behavior of the Ti-6Al-4V alloy in the same study. In addition to predicting material flow curves with mathematical models, there are also studies carried out to predict flow curves with machine learning or regression models [10,11]. An artificial neural network model was suggested by Kocatürk et al. [10] to estimate experimental flow curves of a medium carbon steel material at different temperatures and strain rate values, and the flow curve predictions with high accuracy were obtained with this method. In another study, Aydın et al. [11] proposed a model that can obtain true stress-strain curve from experimental compression test data. Moreover, machine learning models and various regression models were used to predict the flow curves for the intermediate temperature and strain rate values where experimental flow curves are not available and promising flow curves were estimated. In this study, flow curves at different temperatures and strain rates, which were constructed by using the compression test results of a medium carbon alloy steel material, were employed. The parameters of Ludwik Model, Voce Model for Hardening [7], Voce Model for Softening [5], Voce Model with Linear Softening [2] and Voce Model for Hardening and Softening [5] were determined using the "curve_fit" function in the Scipy library on the Python programming language for every temperature and strain rate values. Voce Model for Hardening and Softening best-predicted the flow curve up to maximum compression stress point while Voce model with linear softening and Ludwik Model best-predicted the part from maximum compression stress to the maximum loading point. A new combined material model based on plastic strain subintervals was proposed for the flow curves at different temperatures and strain rates.

Materials and Method

The flow curves were obtained from the experimental compression test results of 42CrMoS4 medium carbon alloy steel material. To obtain the flow curves from the experimental compression test data of the materials, the model suggested by Aydın et al. [11] was used. Compression tests were carried out at different temperatures and strain rates in accordance with ASTM E9 standard [12]. Compression tests were performed with a ZWICK universal tensile/compression testing machine for temperatures at 25, 100 and 200°C and strain rates of 0.001 and 0.275 s^{-1}. Before each compression test, MoS_2 based lubricant was used for test plates in order to minimize the friction effects. A model was developed in the Python programming language to compare the performance of the material models used to predict the experimental flow curves obtained. In this model, the material models are defined firstly, then the model coefficients that give the best prediction are determined with the curve fitting method according to the defined plastic strain intervals, and the performances of the models are reported according to the coefficients obtained. The determined coefficients, R^2 and mean absolute error (MAE) were used for the performance comparison of the obtained flow curves. Functions in the Numpy library were used to calculate the performance criteria. The "curve_fit" function in the Scipy library was used to find the model parameters according to the experimental flow curves. Finally, the Matplotlib library was used to plot the resulting flow curves. The material models used to predict flow curves are defined below. In these models, σ represents the true stress, ε the true plastic strain, n is the hardening exponent, and $\sigma_0, \beta, K, A, B, C, D, k$ represent the material coefficients, respectively.

Ludwik model [9]:

$$\sigma = \sigma_0 + K\varepsilon^n \tag{1}$$

Voce hardening model [12]:

$$\sigma = \sigma_0(1 - Ae^{-\beta\varepsilon}) \tag{2}$$

Voce softening model [12]:

$$\sigma = \sigma_0(1 - Ae^{\beta\varepsilon}) \tag{3}$$

Voce linear softening model [8]:

$$\sigma = \sigma_0\left(1 - Ae^{-\beta\varepsilon}\right) - k\varepsilon \tag{4}$$

Voce hardening and softening model [3]:

$$\sigma = \sigma_0 + A(1 - e^{-B\varepsilon}) + C(1 - e^{D\varepsilon}) \tag{5}$$

Comparison of Ludwik and Voce Models

In this section, the flow curve prediction performances of Ludwik and Voce material models in the true plastic strain range of [0, 1.8], which is the whole plastic strain range for 42CrMoS4 material, were compared for 3 different temperatures and 2 different strain rates. The results obtained are given in Table 1. In order to compare the models fairly, the "curve_fit" function in the Scipy library is used with initial parameter values for all models. The Voce Hardening and Softening model best predicted the flow curves at all temperatures and strain rate value of 0.001 s^{-1} with a minimum R^2 value of 0.97. For 25°C and 0.275 s^{-1} strain rate, the Voce Linear Softening model best predicted the flow curve with 0.97 R^2, while the Ludwik model best predicted the flow curves at 100 and 200°C, 0.275 s^{-1} strain rate with 0.65 and 0.78 R^2, respectively. Flow curve predictions obtained at 100 °C and strain rate values of 0.001 and 0.275 s^{-1} were shown in Fig. 1 for the plastic strain range of [0, 1.8].

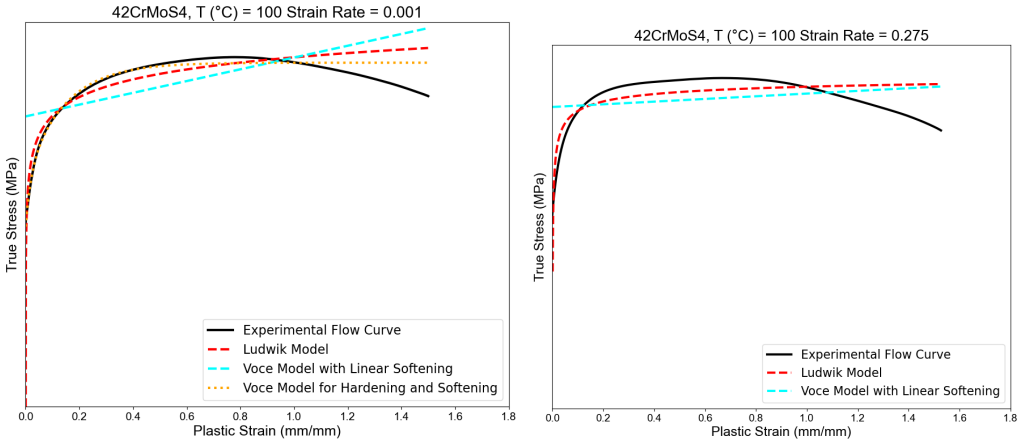

Fig. 1. Flow curve predictions in the plastic strain range of [0, 1.8] for 100°C, 0.001 and 0.275 s^{-1} strain rates.

In order to obtain closer results to the experimental flow curves for 42CrMoS4 material, and to identify models that predict the hardening and softening phases during plastic deformation more accurately, the model predictions for the lower plastic strain ranges were also compared. In order to determine the model that best predicts material behavior up to the maximum compression stress value, the flow curve prediction performances of Ludwik and Voce material models in the true plastic strain range [0, 0.6] were compared for 3 different temperatures and 2 different strain rates. Flow curve predictions obtained at 100 °C and strain rate values of 0.001 and 0.275 s^{-1} were shown in Fig. 2 for the plastic strain range of [0, 0.6]. The results obtained for the true plastic strain range of [0, 0.6] were tabulated in Table 2. The Voce Hardening and Softening model best predicted the flow curves at all temperatures and strain rate values with a minimum R^2 value of 0.999.

In order to determine the model that can predict the hardening and softening behavior of 42CrMoS4 material more accurately, model predictions were compared. For this purpose, the flow curve prediction performances of Ludwik and Voce material models in the plastic strain range of [0.6, 1.8] were compared for three different temperatures and 2 different strain rates. The results were given in Table 3. Flow curve predictions obtained at 100 °C and strain rate values of 0.001 and 0.275 s^{-1} were shown in Fig. 3 for the plastic strain range of [0.6, 1.8]. The Voce Linear Softening model with a minimum R^2 of 0.78 obtained the best prediction for the flow curves with strain rate of 0.001 s^{-1} and for all temperature values. The Voce Linear Softening model also obtained the best prediction with 0.92 R^2 for the flow curve at 200°C and 0.275 s^{-1} strain rate. The best predictions for both flow curves at 25 and 100°C and 0.275 s^{-1} strain rate were obtained with the Ludwik model with 0.999 R^2.

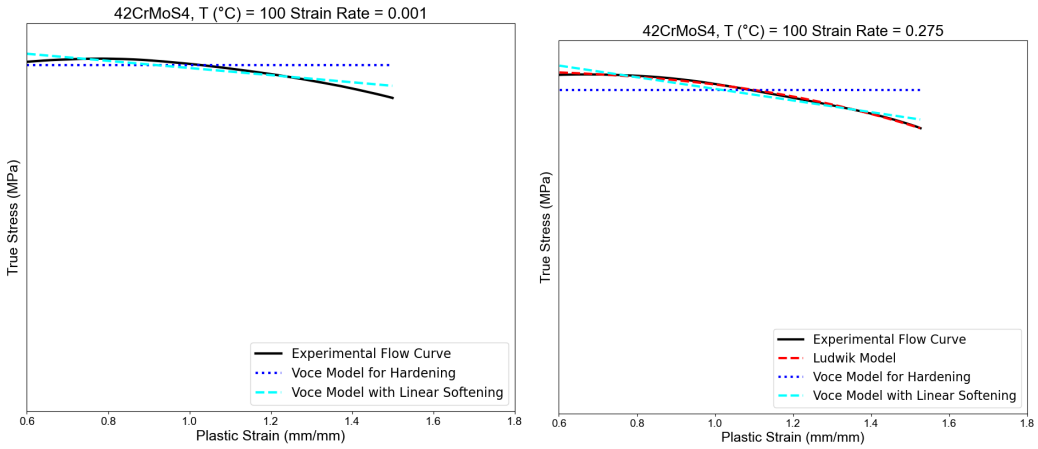

Fig. 3. Flow curve predictions in the plastic strain range of [0.6, 1.8] for 100°C, 0.001 and 0.275 s^{-1} strain rates.

200	0.275	**Voce with Linear Softening**	0.6-1.8	**0.920**	**734**

According to the flow curve prediction results, while the Voce Hardening and Softening model best predicted the material behavior up to the maximum stress point, the Voce Linear Softening and Ludwik models best predicted the hardening and softening behaviors observed after the maximum compression stress value. In order to determine the transition points for these stages, analyzes were carried out to find the model that gives the best estimate in each interval by dividing the whole plastic strain range into 9 equal parts with a true plastic strain range of 0.2. As a result, a new combined material model was determined for each flow curve, which predicts the flow

curves very close to the experimental data. The performances of the combined models that give the best predictions at each determined subinterval of true plastic strain range for the flow curves at each temperature and strain rate value were reported in Table 4. Flow curve predictions obtained with the combined model for strain rate values of 0.001 and 0.275 at 100°C were shown in Fig. 4.

Summary
Within the scope of the study, flow curves obtained from experimental compression test results of medium carbon alloyed 42CrMoS4 steel were used. The coefficients of both material models were determined for different temperature and strain rate values. In order to fit the curve with model equations, "curve_fit" function in the Scipy library has used on Python programming language. The performances of different material models were also examined by dividing the total plastic strain range into subintervals, and combined piecewise material models were proposed according to the true plastic strain values for each temperature and strain rate value. Flow curve prediction performances of Ludwik material model and four different Voce material models were compared. In the comparisons, the flow curve up to the maximum compression stress point was best predicted by the Voce Hardening and Softening model, while the Ludwik and Voce Linear Softening models best predicted the part after the maximum compression stress point to the breaking point. For the flow curves at different temperatures and strain rates, the new combined material model depending on plastic strain ranges were proposed by using Ludwik and four different Voce models. All experimental flow curves were predicted with a minimum R^2 of 0.99 and lower absolute error values with the new combined material model while Ludwik model predicted the flow curves with a maximum R^2 of 0.90.

Keywords: Yield Point Phenomenon, Lüders Bands, Strain Localization, Strain Gradient, Mesh Size Dependency

Abstract. In this study the yield point phenomenon in Bake-Hardening grade steel is predicted using a physically based thermo-mechanical model. A modified Taylor equation is proposed with a physically based dislocation density evolution approach. The softening that follows the higher yield point is incorporated with a Voce type decaying exponential function. The strain rate dependency of the plastic hardening is also incorporated in the model. The yield point in the decay function is also strain rate dependent but does not follow the same dependency of plastic hardening. This was solved by making the decay function strain rate dependent by adding a modified strain rate stress term to the exponential function. This parameter is calculated based on tensile experiments. Due to the softening behavior of the material, the numerical model is mesh size sensitive. Hence, a lower order strain gradient enhanced approach is implemented. The gradient is in a form of an additional hardening term assigned in the locally strained bands based on the plastic strain gradient. Hill48 yield criterion is used to assimilate the anisotropy in the steel grade. The numerical results show good correspondence with experimental tensile tests. The regularization significantly reduced the mesh size dependency of the numerical results.

Introduction

The yield point phenomenon creates an inhomogeneous plastic yielding in steels during forming, which results in unfavorable surface defects in form of stretcher marks on the formed steel products. Hence, modeling the yield point phenomenon has been a point of interest for many researchers in past few decades.

In a tensile test, the yield point phenomenon exhibits a distinct higher yield point followed by softening and a constant stress yield elongation, prior plastic hardening. Hahn [1] attributed the higher yield point to the extra stress required to unpin the locked dislocations by the Cottrell atmosphere. The unpinned dislocations are now mobile and multiply due to short range interaction with other dislocations resulting in a softening of the curve. A locally strained shear band(s) is(are) formed near the specimen shoulder at about 54° to the tensile axis and propagates along the tensile axis to the other shoulder of the specimen, termed as Lüders band. Hahn [1] was among the earlier researchers to propose an analytical model for the yield point phenomenon as an extended Orowan's equation based on dislocation density evolution and the dependency of the Lüders band velocity on the applied stress. Yoshida et al. [2] further proposed a constitutive model based on an extended Hahn model. They considered two modes the Lüders propagation and the subsequent plastic deformation with different sets of constitutive equations, the transition between the two was governed by a change in strain rates. Similarly, Estrin et al. [3, 4] and McCormick et al. [5] proposed a constitutive model for yield phenomena incorporating the dislocation dynamics based on diffusion of the dislocations to active slip systems on surrounding grains and their short-range interaction with immobile dislocations and solutes.

Contrary to Hahn's theory, Akama et.al [6] and Nes et al. [7] observed that the phenomenon is triggered not only by the release of dislocations locked by the Cottrell atmosphere but also by substitutional elements segregated at the grain boundaries. Nes et al. [7], therefore proposed a Taylor based dislocation density evolution equation [8] to incorporate grain size and dislocation cell size dependency, along with a thermally dependent parameter. Similarly, Ballarin et al. [9] developed a physically based model for bake-hardening steels to predict the macroscopic behavior based on carbon solute concentration, wherein the band propagation was modeled with a Voce type equation. Kyriakides et al. [10] modelled the Lüders phenomenon with a trilinear stress-strain curve with an intermediate softening response in bending of steel tubes. Span and van Liempt [11], proposed a physically based dislocation density evolution model for temper rolling that quantitatively described the Lüders band behavior in conjugation to temper rolling parameters and chemical composition of a particular steel grade. The softening in the model was attributed to the Lüders front velocity.

As stated earlier, in a tensile test, the yield point phenomenon is accompanied by a peak stress followed by a softening, which results in an inhomogeneous localized plastic shear band. In a finite element framework, this shear band is associated with the localization of strain along row(s) of elements. Simultaneously, the adjoining elements along this localized strain band undergo softening to compensate for the instability. Therefore, the band width, the strain gradient across the band and the resultant macroscopic flow stress (within Lüders strain elongation region) are mesh dependent [2,9,10,12]. Therefore, a regularization solution serves two objectives: firstly, to attain mesh–independent finite element results and secondly to account for the correlation of numerical Lüders band width to the actual observed in experiments. The regularization can be achieved by either introducing rate dependency to the model [10] or by introducing a higher order strain gradient to the model [12,13]. Kyriakides et al. introduced a mild rate dependency in the model via a strain rate power law, for the regularization of the solution. Mazière et al. [12] introduced the Aifantis strain gradient plasticity model, wherein a higher order modulus and a characteristic length scale is introduced, the latter being fitted with experiments. In this study, the mesh size dependency is reduced by using a lower-order gradient enhanced approach by the addition of a hardening term based on studies by Perdahcioglu et al. [14].

In the current study, a novel approach is modelled expanding on Taylors equation to incorporate thermal and strain rate dependency of the yield phenomena. The softening, or decay, function expands on the similar concept of dislocation density evolution and its short range interaction with immobile or mobile dislocations and solutes. This gives a better prediction of the Lüders phenomena in the model. Tensile tests to characterize Lüders phenomenon are elaborated in *Section Tensile Experiment*. The strain distribution and evolution over the specimen surface are captured with digital image correlation (DIC). A constitutive model detailed in section *Model* is proposed based on underlying physical dislocation density evolution. An extended Taylor model [8] is proposed, wherein the evolution of dislocation density is given by an extended Bergstrom model [15,16] for plastic hardening. For the softening an exponential equation is proposed. The model further incorporates strain rate dependency of the material based on Krabiell and Dahl [17] model. Based on experiments an anisotropic yield criteria Hill48 is used. The Lüders band width and strain distribution is observed to be mesh size sensitive. Hence a regularization method as proposed by Perdahcioglu et al. [14] is adopted to reduce the mesh size dependency of the numerical results; detailed in the section *Gradient Plasticity*. Finally the experimental and model results are discussed in the *Results and Discussion* as well as in the section *Conclusion*.

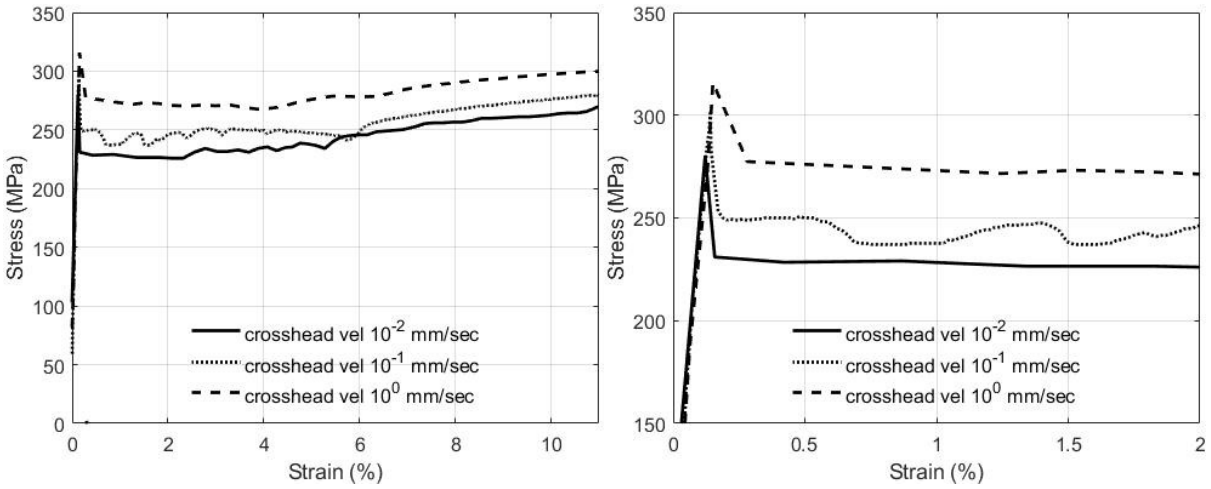

Fig. 1. Experimental tensile test of as-received Bake Hardened steel at three cross-head velocities.

Tensile Experiments

Bake hardening steel utilized in this study is in as-received state without undergoing temper rolling. Thus, the steel displays a distinctive yield point phenomenon with an elongated Lüders strain at a constant lower yield stress, see Fig. 1. The band is observed to nucleate just prior to higher yield point near the specimen shoulder and propagates across the specimen gauge length as the test progresses at a constant stress. The specimen is tested at three different cross-head velocities 10^0, 10^{-1}, 10^{-2} mm/s and at rolling, transverse and 45° direction. The local strain distribution and evolution across the specimen surface is measured with DIC during the tensile test. The surface of the specimen (gauge length) is therefore covered with a speckled pattern for the DIC (Aramis) measurement.

The higher yield point is observed to be linearly dependent to strain rate. Similarly, the Lüders stress and elongation are observed to be strain rate dependent. In each test, the band nu- cleated near the specimen shoulder at approximately 54° to the tensile loading axis and propagated along the loading axis across the gauge length. The band and its strain gradient could be seen in the DIC full field measurements Fig. 2 over the gauge length for the tensile test results at 10^{-1} cross head velocity. The band width is measured at half height with reference to the band (strain rate) peak height in this study. The mean peak width thus measured at half height was 5.6mm with a standard deviation of 0.79. The Lüders strain elongation is also observed to be directly proportional to the test cross-head velocity, and is in accordance with studies by Yoshida et al. It is also peculiar to see that the band does not limit to a single shear band, but forms a combination of two bands in a 'V' shape. A few tests also showed multiple bands being nucleated at both specimen shoulders during the test. It can be speculated that the band nucleation and propagation in a tensile test is a product of two factors: the dislocation density mechanics and the geometry of the test specimen. During band nucleation, the local shearing strain in a grain expands to neighboring grains, which deform in a preferred orientation resulting in a macroscopic shear band. Furthermore, the limitation imposed by the specimen width, causes the band to propagate during tensile loading.

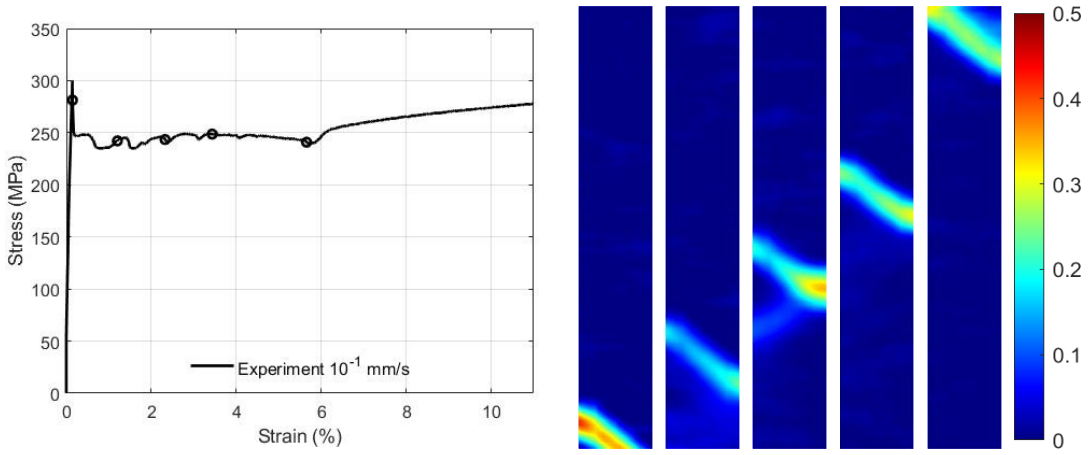

Fig. 2. Strain rate across the gauge length is plotted by DIC field measurements at stages highlighted in the flow stress.

Model

Work hardening.

A physically-based model, based on extended Taylor's equation is proposed in this study. The model therefore includes the dependency of flow stress in material on strain rate and temperature, and dislocation density evolution as a product of strain hardening.

$$\sigma(\epsilon) = \sigma_0 + \sigma_{thermal} + \sigma_{decay} + \alpha G b\sqrt{\rho(\epsilon)} \quad (1)$$

Where, σ_0 is the initial flow stress (MPa), $\sigma_{thermal}$ is the dynamic stress based on Krabiell and Dahl model [17], σ_{decay} is the softening function, α is constant parameter depending on immobile dislocations distribution, G is the shear modulus for steel, b is the Burgers vector, $\rho(\epsilon)$ is the dislocation density. Van Liempt [18] proposed an extended Bergstrom model [15] to show the dislocation density ρ development with strain. Eq. 2 describes the hardening as a development of the dislocation structure with strain.

$$\frac{d\rho}{d\epsilon} = M[B\rho^c\, g(\epsilon_t)] - \Omega\rho. \quad (2)$$

Where, ϵ gives total accumulated strain, B_u is the proportional constant for the increase of immobile dislocation in the cell walls, c is the exponent describing the influence of the dislocation density on the decrease of dislocation cell size, given by $d_{cell} = k\rho^{-c}$, M is the Taylor constant, parameter Ω is the strain rate and temperature dependent and represents the remobilization (dynamic recovery) of immobile dislocations. Here Ω is taken constant, β term provides for the linear hardening behavior at higher strains. The function $g(\epsilon)$ was introduced by van Liempt [18] to describe the change in dislocation mean free path due to change in dislocation cell geometry at higher strains. Vegter et al. [16,19] postulated that at high strains dislocation cell walls within the grains are deformed, and the small orientation difference between the cells influences the dislocation mean free path. This influence of the cell shape distortion on the mean free path is given with an exponential function $g(\epsilon) = \exp(\beta\epsilon)$. The first order term of Taylor series expansion of the function was used to avoid unexpected deflection at high strains in the flow stress giving the function: $g(\epsilon) = 1 + \beta\epsilon$. This gives a linear hardening at high strains, and by substituting the same in Eq. 2 the following is obtained:

$$\frac{d\rho}{d\epsilon} = M[B\rho^c\,(1 + \beta\epsilon_t)] - \Omega\rho. \quad (3)$$

Eq. 3 is integrated between the limits $\epsilon = 0$ and $\epsilon + \epsilon_0$, where ϵ_0 is the pre-deformation parameter accounting for the existing dislocation density prior to deformation, finally giving the dislocation density evolution as a function of equivalent strain as presented in Vegter et al. [19]:

$$\rho(\epsilon)^{\frac{1}{1-c}} = \frac{B_u}{\Omega}\left[\beta(\epsilon+\epsilon_0) + \left(1 - \frac{\beta}{M\Omega(1-c)}\right)\left[1 - \exp\left(-M\Omega(1-c)(\epsilon+\epsilon_0)\right)\right]\right] \quad (4)$$

This physically based density evolution is then substituted in Eq. 1 making the expression of the flow stress as a function of equivalent strain. The constants for the equation shown in Table 1 are referenced from [19].

Table 1. Parameters used for the hardening model.

σ_0	[MPa]	80
M	[-]	2.7
A	[-]	0.88
G	[MPa]	80.0E3
B	[-]	2.5E-7
Ω	[-]	2.1
B_u	[-]	8.3E8
B	[-]	0.38
ϵ_0	[-]	0.005
C	[-]	0.0

Dynamic stress.

The dynamic stress as postulated by Krabiell and Dahl [17], was incorporated into the model to account for the strain rate dependency of the material. The dynamic term describes the thermal activation of mobile dislocation past obstacles with regard to its dependency on strain rate and temperature.

$$\sigma_{thermal}(\dot{\epsilon}, T) = \begin{cases} 0 & \dot{\epsilon} < \dot{\epsilon}\exp\left(-\frac{\Delta G_0}{k_{boltz}T}\right) \\ \sigma_0^*\left(1 + \frac{k_{boltz}T}{\Delta G_0}\ln\frac{\dot{\epsilon}}{\dot{\epsilon_0}}\right)^p & \dot{\epsilon}\exp\left(-\frac{\Delta G_0}{k_{boltz}T}\right) < \dot{\epsilon} < \dot{\epsilon_0} \\ \sigma_0^* & \dot{\epsilon} > \dot{\epsilon_0} \end{cases} \quad (5)$$

Where, σ_0^* is the dynamic stress at zero thermal activation, ΔG_0 is the maximum activation enthalpy, p is the exponent for thermally activated contribution, $\dot{\epsilon_0}$ is a structure parameter pertaining to density of mobile dislocation and obstacle distribution; effectively the limiting strain rate for thermally activated movement, k_{boltz} is the Boltzmann constant and T is the temperature.

Decay stress.

The higher yield point can be attributed to either the additional stress required to unpin the locked dislocations in Cottrell atmosphere [1], or due to interaction of dislocation with grain boundaries [7] and the solutes segregated at grain boundaries [6]. Once the dislocations are 'free' from the obstacles, they become mobile. This can be considered as an instant drop in the number of immobile dislocations which causes a drop in the flow stress. An exponential Voce type equation is therefore proposed to represent the decay in the flow stress. It was also observed that the higher yield point is strain rate dependent and does not follow the work hardening strain rate

dependency. Thus, a modified Krabiell and Dahl [17] strain rate dependency model was implemented in σ_{decay} resulting in following equation:

$$\sigma_{decay} = \left(\Delta\sigma + \sigma_t^d\right) \exp(-n\epsilon) \tag{6}$$

Table 2. Thermal stress and Decay stress model parameters.

σ_0^*	[MPa]	1083
k_{boltz}	[mJ/K]	1.38E-20
T	[K]	300
ΔG_0	[mJ]	1.6E-16
$\dot{\epsilon}_0$	[-]	10.0E8
m	[-]	3.982
A	[-]	40
n	[-]	300

Where $\Delta\sigma$ corresponds to stress difference between higher yield point and yield point without the yielding phenomenon; the later estimated from Interstitial Free (IF) grade steel tests. This will correspond to the higher stress required to unpin the dislocations and set them to mobile phase. The exponential decay corresponds to the softening as a result of mobile dislocations multiplying by interaction with other dislocation networks and solutes. The constant n influences the softening rate due to dislocation multiplication. σ^d gives an additional stress term to the yield point, enabling strain rate dependency of the yield point. The parameters shown in Table 2 are fitted to experimental data by adjusting σ^* (from Eq. 5) keeping rest parameters constant.

Yield criterion.

The material exhibited anisotropy, with a variation in yield stress when tested under uniaxial and shear loading. Hill48 yield function was therefore used:

$$\phi = F\left(\sigma_y - \sigma_x\right)^2 + G(\sigma_z - \sigma_x)^2 + H\left(\sigma_x - \sigma_y\right)^2 + 2L\tau_{yz}^2 + 2M\tau_{zx}^2 + 2N\tau_{xy}^2 - \sigma_y^2 \tag{7}$$

The anisotropy coefficients, in terms of R values, were calculated from uniaxial and shear experiments. The model thereby showed a good fit with uniaxial tensile and shear test with same hardening parameters.

Gradient Plasticity.

The band size and strain gradient over the band showed mesh size dependency. Hence, the mesh size dependency is reduced using a lower-order gradient enhanced approach using an additional hardening term based on studies by Perdahcioglu et al. [14]. This non-local hardening term is calculated from the plastic strain gradients across the band. Perdahcioglu et al. [17] referred to this phenomenon as stress created by the evolution of geometrically necessary dislocations (GNDS) within a locally sheared zone and thus calculated them from incremental plastic strain and Burgers vector. The rate of change of the additional dislocations generated due to the strain gradient is therefore given by:

$$\dot{\rho}_{grad} = \frac{2\dot{\eta}^p}{b} \tag{8}$$

Where $\dot{\eta}^p$ is the rate of equivalent plastic strain gradient, b is the Burgers vector. The total change in dislocation density for a given strain increment ρ_{grad} is then placed in Eq. 1, resulting in an additional hardening stress across the band during its evolution and propagation.

$$\sigma(\epsilon) = \sigma_0 + \sigma_{thermal} + \sigma_{decay} + \alpha G b \sqrt{\rho(\epsilon) + \rho_{grad}} \quad (9)$$

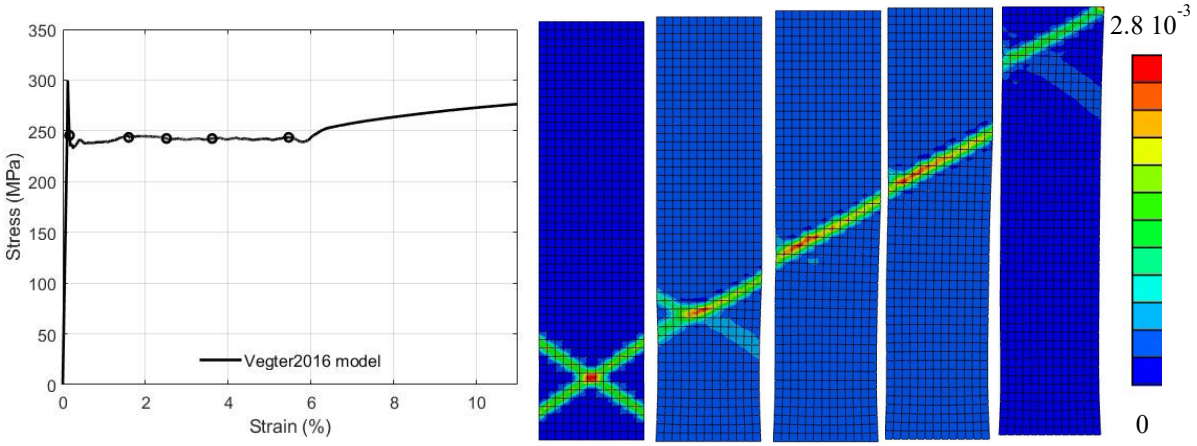

Fig. 3. Numerical tensile test strain-rate stages highlighted in flow stress.

Results and Discussions

The model was validated with a numerical tensile test. The gauge area 50x12.5x0.74 mm (length x width x thickness) was subjected to uniaxial loading. To replicate the material's inhomogeneity, numerical instability was incorporated by introducing fluctuating yield stress in a range 0 – 1 MPa randomly assigned to integration points. In Abaqus software, the arc-length method to solve for iterations during softening. The resultant flow stress and Lüders band are presented in Fig. 3. Fig. 4 shows the results of the simulations incorporating the hardening model combined with the anisotropic yield criterion tested at three cross-head velocities and shows a good fit with the experiments. The higher yield point is predicted well in the three velocities, attributed to the independent strain-rate model included in the decay function. The strain-rate dependency of the decay function also results in an increase in Lüders strain elongation with increasing test velocity. The thermal stress model's implementation shows a good fit with experimental tests at varying cross-head velocities. The band inclination is also observed between 52°-55° in accordance with the experiments.

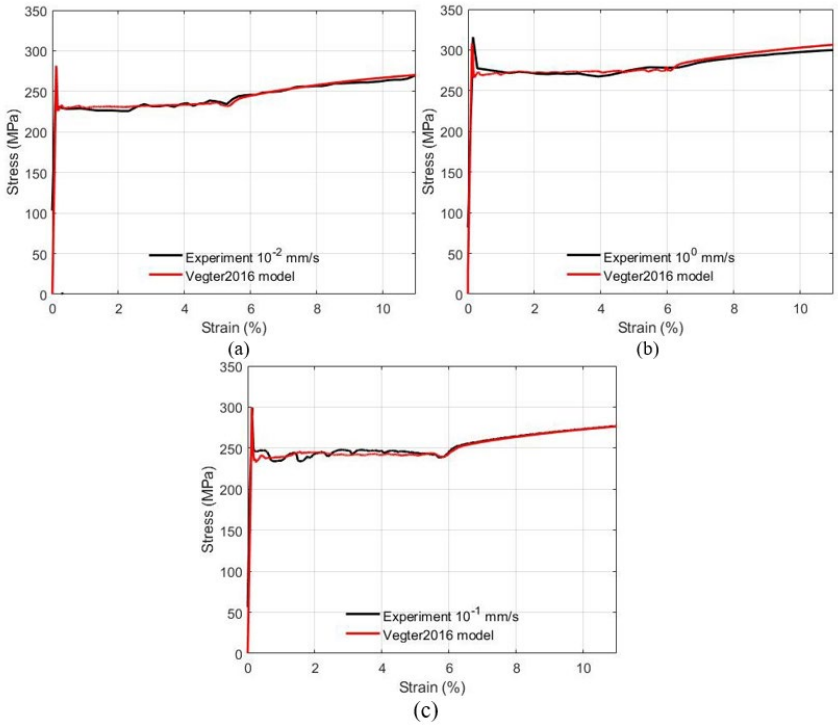

Fig. 4. Numerical tensile test compared with tensile experiments at three different cross-head velocities (a) 10^0 (b) 10^{-1} and (c) 10^{-2} mm/s.

Due to the softening and strain rate dependency in the model, the numerical test result is mesh dependent. Hence the first step was to test the mesh dependency of the model, by conducting the numerical tensile test by varying mesh sizes. Thus, numerical uniaxial tensile test was conducted with three-dimensional quadratic mesh with reduced integration at varying mesh sizes of 0.5, 0.75 and 1mm. The mean band peak width is calculated at every increment and plotted with reference to nodal displacement (Fig. 5 a). The mean peak width (calculated at half height of the peak) observed for mesh sizes 0.5, 0,75 and 1 mm are 1.30, 1.42 and 1.83mm. In either case the strain-rate peak is observed to be higher with a lower mesh size which further ascertains the mesh dependency of the Lüders band. The implementation of the gradient model results in an additional hardening term implemented only at the regions with localized strains, and is determined with a number of integration points within a prescribed radius. The integration points within the assigned radius experience an additional hardening term influencing the gradient width. This could be seen in the peak width determined from simulations with the gradient model, in Fig. 5b. Although a major difference could not be seen in the average peak widths for different mesh sizes, the variation of the peak width with different mesh sizes has more overlap with each other.

Summary

The modified dislocation density evolution model gives a good approximation of the experimental data. The dynamic stress factor implemented in the decay function enables predicting the higher yield point as well as Lüders elongation in coordination with applied strain rates. The decay function also facilitates understanding the underlying dislocation dynamics behavior: a higher yield stress term required to unpin the dislocations and an exponential decay to accommodate the softening by dislocation multiplication and short range interaction [1]. This includes its interaction with solutes at grain boundaries in accordance with [6]. It is also postulated that apart from dislocation dynamics, the specimen geometry in combination with its loading condition influences

formation of shear band and its propagation. The mesh size dependency of the strain bands was reduced by inclusion of the gradient model, however the simulated band size could not be achieved as observed in experiments. This could be further improved by modifying the decay function to control the rate of softening in the model.

Abstract. Near Solidus Forming (NSF) process, performed at semi-solid material state is gaining popularity due to its good physical properties, low manufacturing cost and material waste. Although the process possesses many advantages over traditional hot forging, the nature of the process itself is very complex and due to this the researcher struggles to identify the material behavior at NSF conditions. Especially the material model in this condition has not been stated clearly before and therefore it is important to develop a reliable digital twin (DT) strategy which can validate the material model efficiently. Therefore, the objective of this work is to investigate the influence of all DT parameters like billet material and dimensions, billet and dies temperature, heat transfer coefficient, emissivity, ambient temperature, and friction coefficient, in two industrial components such as H spindle and R spindle. The Taguchi Design of Experiments (DOE) approach combined with numerical simulation in FORGE NxT® is employed to develop the sensitivity analysis of the process. The impact of all parameters in the DT are evaluated in terms of die filling and forming forces, and its importance in the material model is studied. Results show that the newly developed approach proposed a novel optimum NSF-DT calibration strategy for material-model validation. Which can be used to develop an accurate model of the NSF process at the laboratory and industrial scale

Introduction

Forging is a widely used technology in the field of automotive, aerospace, and other engineering sectors around the world. The process is important due to its cost efficient and reliable spectrum of manufacturing for planes, cars, and ships components. Furthermore, the processed components possess superior mechanical properties which are best suited for critical applications. The process is done either at room or high temperature based on the material and the desired properties of the components. In particular, Near solidus Forming (NSF) process is referred to the one developed critically close to the solid temperature and it is gaining popularity due to its good physical properties, low manufacturing cost and material waste compared to traditional hot forging process [1,2]. Although gaining popularity, the process is not still fully developed, and it is not clear how the physics behind the NSF develops [1]. This is due to the complex behavior of the material at such a high temperature. Previous NSF-DT studies have shown an important gap on the prediction of forces and filling [2]. Researchers suggested that material is the key factor influencing the process and developing a correct model can be a key object to understanding how this process

works [3]. Others investigated that the boundary conditions play a significant role in the process and by controlling certain parameters the processes could be developed accurately [2].

Talking about the history of the process the main development was gained in the semi-solid forming processes initially from the investigation of low melting point alloys [4], even some trials were carried out with stainless steels [5]. However, the high costs associated with the production of globular aluminum alloys, compared with the die casting ones, made this process infeasible for industrial production. Despite this drawback, some electronic consumer goods and automotive parts were manufactured by taking advantage of this technology [6].

Nevertheless, in 1992 the first investigations about semi-solid forming of steels at high solid content were performed by P. Kapranos et al. [7]. Since then, many researchers have tried to manufacture sound components by gaining the advantage of this near-net-shape technique to bring it closer to industry without fortune[8, 9]. Gourlay et al. studied material behavior at a high solid fraction, typical in NSF processes [10]. For instance, at values from 0.9 to 1, granular behavior was reported. Another important aspect is the process temperature as maximum load and ductility were shown to decrease when the temperature is increased [11].

To learn the process deeply, the investigation of certain factors is necessary such as the values of the heat transfer coefficient (HTC) and friction factor during the process. This knowledge is necessary to achieve realistic simulations and generate reliable, and useful results about the process.. As friction is a universal phenomenon influencing the metal forming process and it is inevitable for friction to exist between dies and workpieces. In addition, friction gives rise to redundant energy usage by increasing the process load requirement. The forming load, the die wear and the surface finish of the product are significantly influenced by the friction. For this reason, an appropriate evaluation of this parameter is very essential in metal forming. To obtain precise friction characterization during the forming process, several experimental methods were presented. There are several friction tests, some of which has advantages over another and also shortcomings. Noticeable among them are the ones employed in metal forming: the ring test, double-cup extrusion test and the spike test [12,13]. Specifically for the case of NSF, a T-Shape spike test which is developed by Zhang et al. can be used to avoid the difference of friction conditions on the cylinder surface and end surface of a round billet [13,14]. Deformations, including both extrusion and compression, are involved in this test and only the cylindrical surface of the billet is in contact with the punch and die.

Furthermore, Dadras and Burte et al. investigated the interface HTC [15]. Later, Burte and Stone extended the work of Dadras and predicted HTC values and simulated forging operations [16]. To understand the heat transfer under lubricated condition, Azushima et al. conducted the compression and compression-sliding tests of aluminum-coated 22MnB5 under dry and lubricated conditions using the hot fat drawing test simulator [17]. Similarly, Y. Chang et al. also investigate factors that influencing the HTC and an actual hot-formed automotive B-pillar was obtained in experiment to validate its formability under various contact pressures [18, 19].

Bai et al. introduced an efficient closed-form technique for the determination of HTC at different forming and contact conditions based on finite element (FE) heat transfer analysis using FE software DEFORM [20]. Similarly, Chang and Bramley used FE tools to determine the HTC at the work-piece/die interface for forging process by conducting an upsetting test where the surface temperature of the die was recorded [19]. Then the measured and predicted temperatures were combined using an inverse algorithm to determine the HTC.

The nature of the NSF process is that the real-time experiments are time-consuming and costly [21]. To overcome this, the Finite Element Method (FEM) tools are widely used to model and simulate forming processes and results such as temperature changes, stress, strain, deformation and load history in the die, and in the workpiece can be studied [22]. However, advances in the numerical analysis of complex forming processes require the better understand of interface

characteristics for heat transfer and friction. For example, Petersen et al. proposed the FEM in conjunction with metal experiments to verify the general feasibility of the proposed test geometry and pointed out that the practical ring-compression test was more commonly used for the quantitative evaluation of the tribological conditions at the die/work-piece interface in metal forming [23].

Nevertheless, many authors compared the DT material models to their experiments and concluded that the material model plays a vital role in the forming processes and the actual models are not capable of correctly representing the NSF phenomenon[24]. However, NSF-DT are strongly depended on the process parameters noise and BC uncertainty, e.g., HTC, friction coefficient, billet tolerances. Therefore, without having all these dependencies under control one can does not assure that the differences shown between experimental, and NSF-DT are coming from the material model. This work has a double objective. On the one hand, by means of a DOE approach, the sensitivity to the main outputs (force and filling) to the material model and other influencing parameters is studied. In this way, the impact of each factor can be evaluated. On the other hand, once the influencing parameters and their impact are established, the optimum NSF-DT strategy is developed in order to be able to rely on the DT for material model validation purposes.

Material and Methods

The material used in this process is 42CrMo4 steel and its chemical composition is shown in the Table 1. The material is suited for high-temperature forming due to its fatigue strength and ductility properties. The industrial process used as a reference in this study consists of three major steps, shown in Fig.1. Initially, the billet is heated homogeneously in the furnace to the desired temperature by maintaining a uniform temperature throughout the furnace. Next, the billet is transferred from the furnace to a worktable through a mechanical arm as quickly as possible to minimize heat loss. The deformation die-set consists of top and bottom dies while a punch which deforms the billet. Finally, in the last step, the punch moves from the top dead center to the bottom dead center and the deformation takes place, this way the desired shape is achieved.

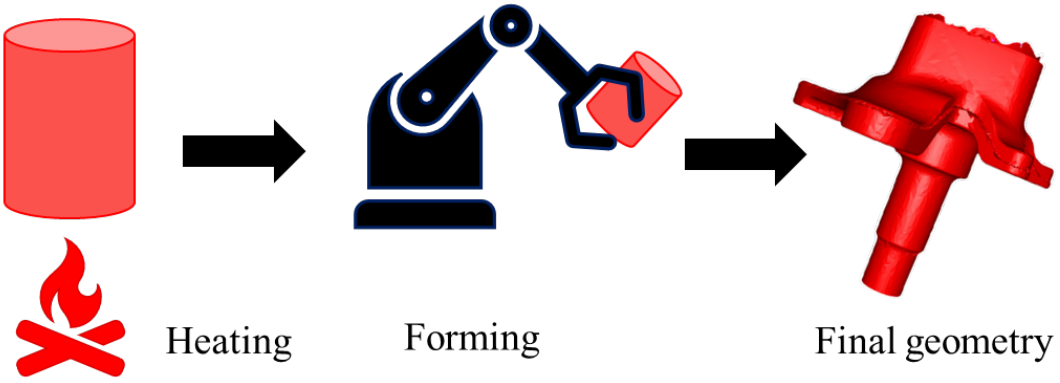

Fig. 1. NSF process flow detail.

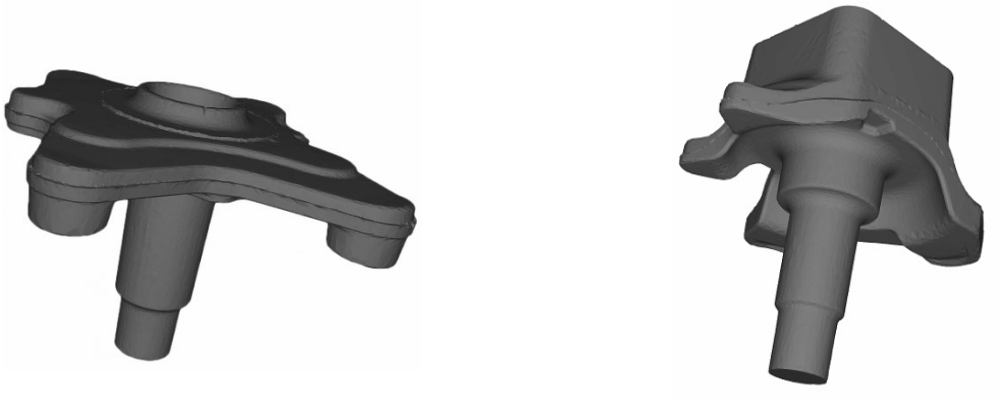
The two industrial components used in this study which were recently manufactured at Mondragon University are shown in Fig. 2. The weight of H spindle workpiece is a ~2.3 kg and the R Spindle a ~3 kg.

Materials Research Proceedings 28 (2023) 1521-1530 https://doi.org/10.21741/9781644902479-164

Table 1. Chemical composition of 42CrMo4 steel %wt.

Cr	Mn	C	Mo	Si	P	S
1.05	0.75	0.41	0.22	0.20	0.02	0.02

The numerical tool FORGE NxT® is used to reproduce the entire NSF process in order to analyze the effect of all parameters during forming. The simulation procedure includes all the steps such as heating of the billet in the furnace, transfer of the billet and lastly the deformation phase. A servomechanical press with a capacity of 400 tons was used and its specification of forces, ram speed and ram position during deformation can be seen in work from Lozares et al. [2].



(a) (b)

Fig. 2. NSF industrial components (a) H spindle and (b) R spindle.

In the study, the effect of 10 parameters such as material, billet dimensions and temperature, (HTC), friction coefficient (FC), ambient temperature and emissivity are investigated. To study the effect of material on the process the strength of the material is reduced by changing the constitutive parameters. The level of each individual parameter is presented with symbol letters from V1 to V10, shown in the table 2. Since a list of parameters are considered in this study and to fully investigate the effect of individual parameter a design of experiment Taguchi DOE approach is used where the effect on input parameters is studied in relation to the forming force and fillings. However, based on the available data, the L16 orthogonal array is selected. The experimental design table is generated by employing data into Minitab software. Overall, total of 32 simulation were run, 16 of which for the H spindle and 16 for the R spindle and their result has been presented in the results section.

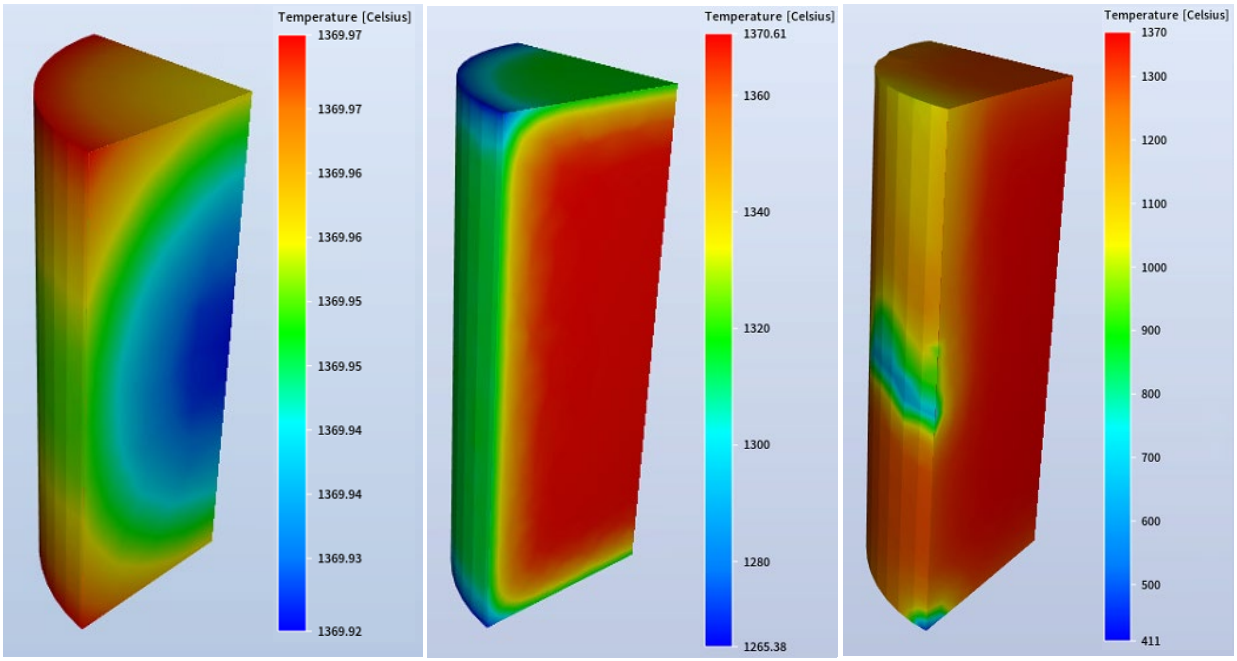
Billet Location (four points)	V1	1,2	3,4	1,2	3,4
Billet Diameter (mm)	V2	64.7	65.3	68.7	69.3
Billet Length (mm)	V3	89.5	90.5	92.5	93.5
Material Strength %	V4	50%	100%	50%	100%
Billet Temperature (°C)	V5	1360	1370	1360	1370
Dies Temperature (°C)	V6	200	270	200	270
Heat Transfer Coefficient (kW/m^2.K)	V7	2000	20000	2000	20000
Emissivity	V8	0.35	1	0.35	1
Ambient Temperature (°C)	V9	50	70	50	70
Friction Coefficient	V10	0.25	0.45	0.25	0.45

For filling calculation, horizontal and vertical filling has been selected and based on the components shapes five points have been selected for the R and H spindle. The filling has been calculated from these reference points at three different punch strokes in each case. Similarly, the forces were also calculated at three different strokes.

Results and Discussion

NSF process strongly depends on the temperature and a small variation can make a big difference in the output. Therefore, knowledge of the process cycle during heating and also in the transfer phase is mandatory. A typical example of the billet heating phases from heating to the deformation stage is shown in Fig. 3. Fig. 3(a) represents the temperature field of the billet inside the furnace when heated up to 1370°C. The temperature distribution seen in Fig. 3 (a) shows clearly that the outer surface of the billet has the highest temperature reading as it is directly in contact with the heat source. Overall, it can be seen that uniform temperature distribution is achieved at the end of the heating phase. Fig. 3(b) represents the temperature plots after the transfer phase, which indicates that the surface of the billet cold fairly fast even for the transfer time of ~3 seconds. The temperature field after the stand-by time of workpiece for ~2 seconds on the compression tool is given in Fig. 3(c), where the temperature range is between 411°C and 1370°C. This? shows how quickly the heat can be transferred from the billet to the contacting surfaces especially the ones with lower temperatures. That's why it is always preferred to deform the billet as soon as it is placed inside the forming tool.



(a) (b) (c)

Fig. 3. Temperature distribution (a) After heating the billet up to 1370 ºC (b) temperature field at 1370 ºC after transport to compression table (c) temperature field after waiting time.

The deformation phases of R spindle during simulation from start to end is shown in Fig. 4. The equivalent strain representation shows that the higher values of stresses are develop in the contacting area of the billet and the punch at the initial stages of the process. Once the process crosses through a certain threshold, the stress concentration shifts to the lower side of the billet where the deformation is intense as can be seen in the Fig. 4 right side geometries. Similar behavior is noticed in H spindle as well.

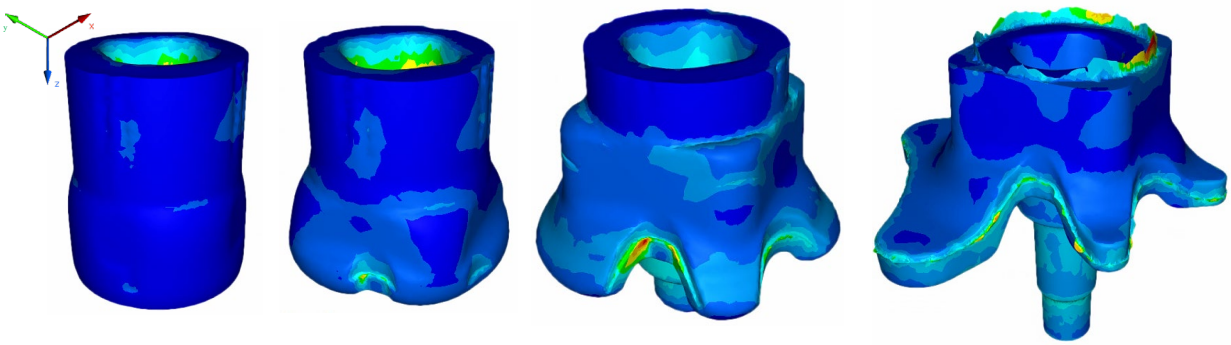


Fig. 4. Deformation phases of the R spindle from the start to the end of the process.

The results of the die filling and forces are indicated in Fig. 5. The x-axis of the plots shows the ten parameters while the y-axis represents the nominal value percentage of filling and forces values. As mentioned before that we have two types of filling, Fig. 5(e) represents the filling calculation in the punch direction which will be in the z-axis according to the Fig. 4, while Fig. 5(a-d) indicates the filling in the horizontal axis horizontal to the z plan. The forces are indicated in Fig. 5(f). The plots are calculated at three different strokes in each benchmark in order to have an overall view of the parameters effect by taking the average of the outputs values.

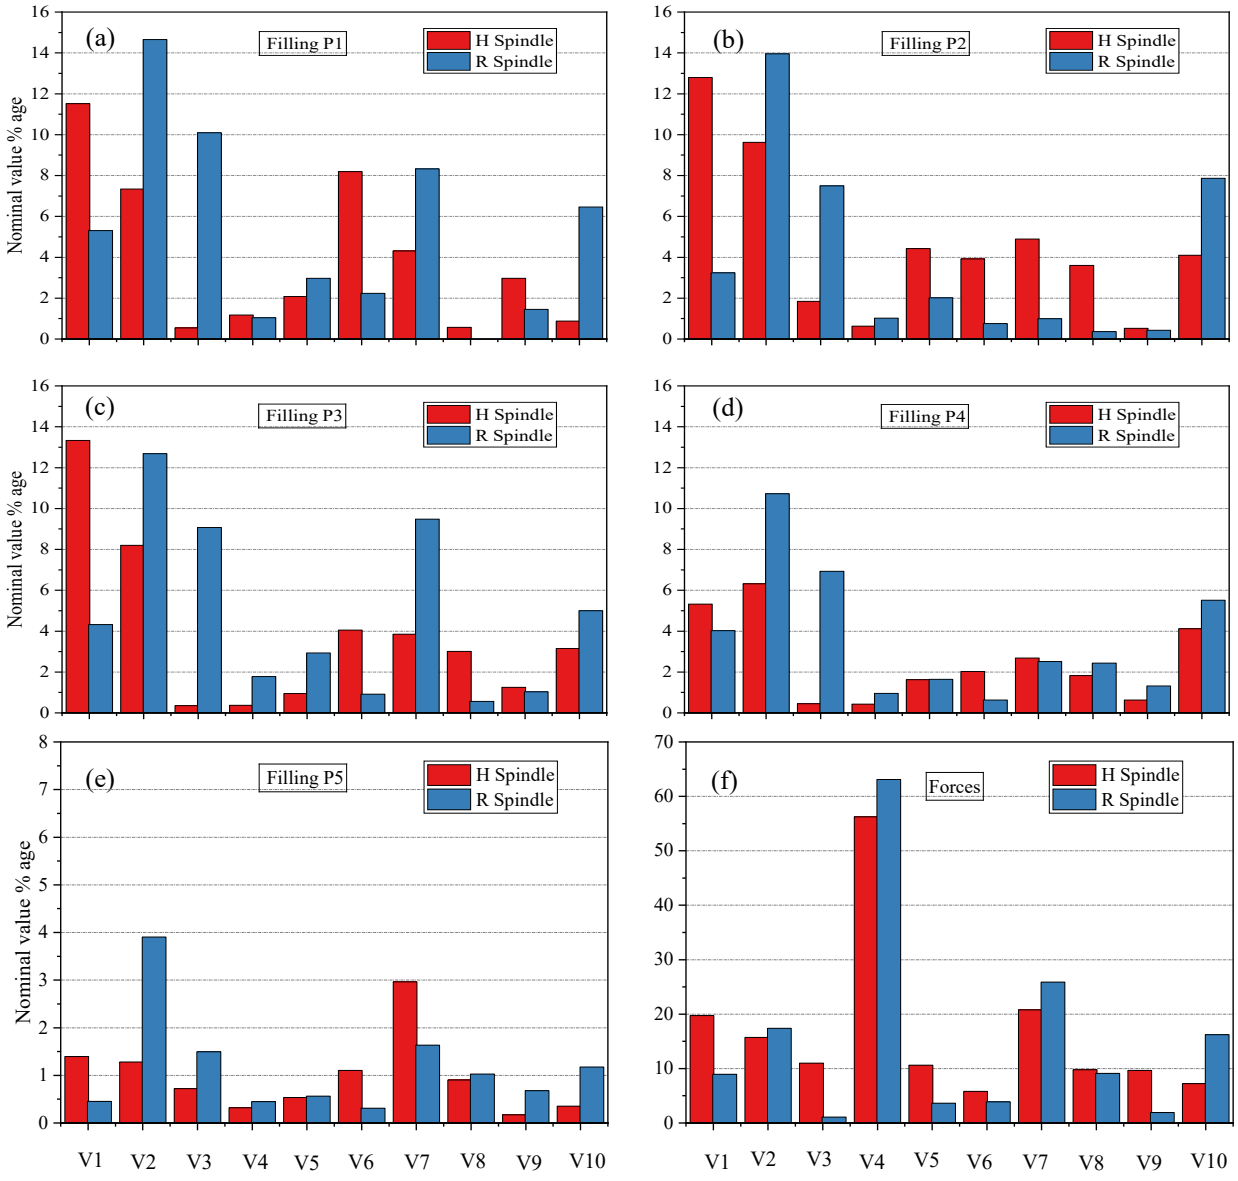

Fig. 5. Nominal value percentage of H and R spindle (a-e) die filling (f) punch forces.

Nevertheless, it is clear that the filling in the horizontal axis strongly depends on the location of the billet placement as shown in Fig. 5(a-d). Where in terms of forces the location plays a minor role in this process, see Fig. 5(f). The billet location can be optimized by trial and error, and it can be always different for every single component. Next when it comes to the dimension of the billet, its effect is always found to be high seen in Fig 5(a-e). For example, filling in any axis is strongly dependent on the diameter and length of the billet meaning the billet with a bigger size can achieve better and complete fillings whereas a smaller billet can cause pores or unfinished surfaces in the part.

In the boundary conditions parameters, which can be of the most interest for the NSF process. The major influencing factors are the heat transfer coefficient, friction coefficient (FC) and material strength which is having a nominal value percentage effect of up to 9 % on the process as shown in Fig. 5. The result suggested that by increasing the FC from 0.25 to 0.45 the material flow in the process was reduced and similar behavior was noticed for HTC and material strength. Other boundary condition parameters such as ambient temperature, billet and dies temperature are

negligible as they have on average of 2-3 % effect and changes in its values had a minor effect on the process.

Next, the punch forces are found to be strongly dependent on the material of the component as shown in Fig. 5(f), with a whopping value of 55-65 %. It is obvious, a material with high strength will require more force to deform compared to ductile material. The most interesting thing to notice here besides material is the effect of HTC and FC on the forces. The effect of HTC is found to be 24 % and FC at 15 %. From the calculation, the forces are found to be rising by making an increase in the values of these two individual factors. And the remaining parameters are found to be least influencing factors with the individual effect below 9 %.

Overall, we can conclude from the DT of the NSF process, to optimize the filling it is important to focus on the location, billet dimensions, HTC and FC. While to reduce the punch forces it is important to study and optimize the material properties, HTC and FC. And by characterizing these parameters and optimizing their values at the NSF condition, one can create a material model with good accuracy.

Summary

The effect of process parameters and boundary conditions in the NSF process is numerically investigated for 42CrMo4 steel. Taguchi design methodology combined with Minitab is employed and the data were simulated in the FORGE NxT®. The outcome of the process is stated in terms of forces and material filling in the dies. The following conclusions are drawn from the present work:

- Among all ten factors, the most significant factor which affects the filling is the location and dimensions of the billet, which are subjective factors and can be optimized by trial and error.
- The important parameters which can be of scientific interest for the development of the NSF process model are the material strength, HTC and FC, and their impact is also high on the filling.
- For the forces, the major influencing factor is the material, and this factor contributes 55-65 % of the total force values. Other factors such as HTC and FC are found to be up to 30 %.
- The remaining factors such as billet and dies temperature, emissivity and ambient temperature can be neglected and always remember that these parameters can have a different effect on the process if their ranges are different to the assumed ones. But since NSF is performed at high temperatures these ranges are considered based on the temperature requirements of the process.
- With all this knowledge in hand, it is concluded that to develop an accurate model of the process it is important to characterize first the most influencing factor both in filling and also for forces. These factors can be characterized by using experiment tests such as spike test for FC and compression test for HTC and so on.

Overall, the developed DT strategy provides useful information regarding NSF process at the industrial level and using this result one can develop an accurate material model by focusing on the major influencing factors in the process.

Acknowledgments

The authors would like to acknowledge Hybrid Semi-Solid Forming project funded by the "Research Fund for Coal and Steel" (RFCS) program of the European union, with the grant number 800763. Also, we sincerely thank CIE Automotive for their technical support.

Keywords: Bipolar Plates, Micro-Stamping, Thin Foil, Finite Element Method

Abstract. Bipolar plates are the essential components of a Proton Exchange Membrane Fuel Cell. Lightweight bipolar plates can be micro-stamped from an ultrathin metallic foil. A major concern is the manufacturability of the foil in the micro-stamping process. The typical stamped micro-channels have end cavities or corners where the deformation mode can be different from the two-dimensional plane strain conditions that occur at the straight sections of the micro-channels. The thin foil has a large ratio of length (or width) to thickness, and shell elements were often used for three-dimensional models. Currently, it is unknown if the shell elements available in commercial software packages are able to predict the ultrathin material behaviour correctly. In addition, the deformation behaviour and forming limits of titanium foil in the micro-stamping process are not well understood. The current study uses a micro-stamping tool to produce straight micro-channels from commercially pure titanium foil. The experimental data are used to validate a two-dimensional and a three-dimensional finite element model of the process. It is shown that there are deviations between the experimental and the numerical thinning results. Material thinning is different between the straight and the cavity end sections suggesting that three-dimensional process models are required to accurately analyze forming.

Introduction

Fuel cells are capable of producing clean energy and reducing greenhouse gas emissions and are considered a suitable alternative to internal combustion engines [1]. The bipolar plate is an essential component of the Proton Exchange Membrane Fuel Cells (PEMFC) to distribute gas (hydrogen, air) uniformly through micro-channels and to conduct current [2].

Bipolar plates can be made of various materials, and metal bipolar plates have been considered to reduce weight and enable high-volume manufacture at low cost [3]. Aluminium alloys [4], titanium [5], and stainless steel [6] have been applied for metal bipolar plates and formed with stamping [7], rubber pad forming [8], and hydroforming [9]. Liu and Hua [10] applied rubber pad forming to manufacture multi-row micro-channels from SS304. They investigated process control parameters (rubber hardness, internal and outer radii, draft angle) by two-dimensional (2D) finite element (FE) simulation. Kolahdooz et al. [11] studied the rubber pad forming of SS316L bipolar plates with 0.1 mm thickness and considered three-dimensional (3D) shell elements in their simulation. Osia et al. [12] used a 3D FE model to investigate two convex and concave hydroforming methods to form SS304 bipolar plates. Bong et al. [13] implemented a multi-stage micro stamping process and according to the major deformation mode of plane strain employed 2D plane strain elements in the numerical analysis. In contrast, Karacan et al. [14] applied 3D shell elements to study the forming of different channel depths in micro stamping. They found that the dominant stress state in micro-stamping was a combination of biaxial and plane strain. Modanloo

et al. [15] studied the micro stamping of titanium bipolar plates with parallel flow channels and predicted fracture using different ductile fracture criteria in combination with a 3D FE model.

Typical stamped micro-channels have end cavities or corners where the deformation mode can be distinctly different from the two-dimensional (2D) plane strain that occurs in the straight U-section profile of the micro-channels[16]. This requires 3D models to represent the different deformation conditions. The thin foil has a large ratio of length (or width) to thickness, and shell elements are often used for 3D models. However, limited research has been done to study the effect of the element type on the thinning or strain predictions in micro stamping. Currently, it is unknown if shell elements available in commercial software packages can predict the ultrathin material behaviour correctly. The situation becomes more complicated when analysing the forming of titanium foil. The current study uses a micro-stamping tool to produce straight micro-channels from commercially pure titanium foil. The experimental data are then used to validate a 3D FE model of the process. The findings of this study will help guide future FE analysis and will give insights into the micro-stamping of titanium foil.

Material Properties

A commercially-pure titanium (CP-Ti) foil with a thickness of 0.1 mm was used. To determine the tensile properties of the titanium sheet, samples were prepared at 0° to the rolling direction and tensile tests were performed based on the ASTM standard (E8M-04) [17]. "Orange peel" was obtained on the dogbone sample surfaces after the tensile tests, which indicates that the limited number of grains within the thickness may lead to local deformation before fracture [18]. The true stress-strain curve was determined, and the Swift law (Eq. 1) fitted to the plastic part of the curve, as shown in Fig. 1. In future work, a biaxial stretching experiment will be conducted for fitting the Swift law at a larger plastic range.

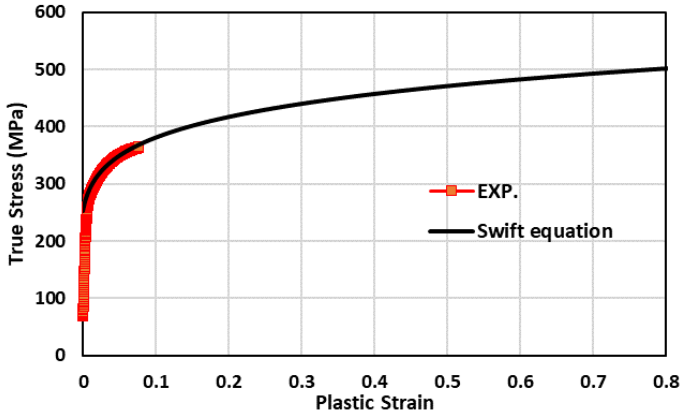

Fig. 1. True stress-strain curve and calibrated swift law results of Titanium foil

$$\sigma = K(\varepsilon + \varepsilon_0)^n \quad (1)$$

where σ and ε are the true stress and plastic strain obtained from the uniaxial tensile test. k, n and ε_0 are the constants of a particular material. The mechanical properties are listed in Table 1.

Table 1. Mechanical properties of the titanium sheet.

	E (GPa)	υ	K (MPa)	n	ε_0
titanium	120[15]	0.361[15]	517.2	0.135	0.005

Experimental Tests

The micro stamping tool was installed in an Instron 500 kN universal testing machine. A CP-Ti strip with dimensions of 195 mm × 97.5 mm was guillotined from the coil and the rolling direction

was aligned with the transverse direction of the channel. Fig. 2 presents the experimental setup [16]. Fig. 3 illustrates the dimensions of the designed micro-channels.

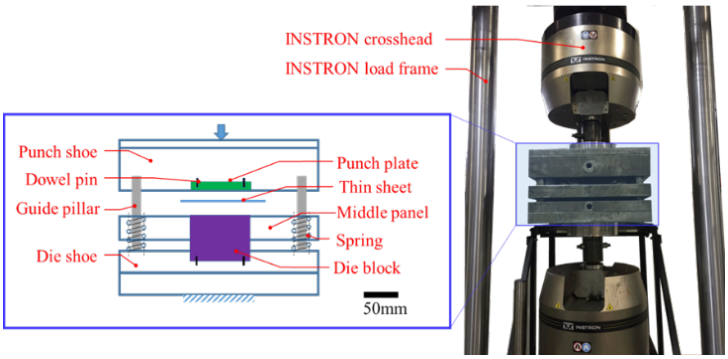

Fig. 2. The experimental equipment for the micro stamping trials [16].

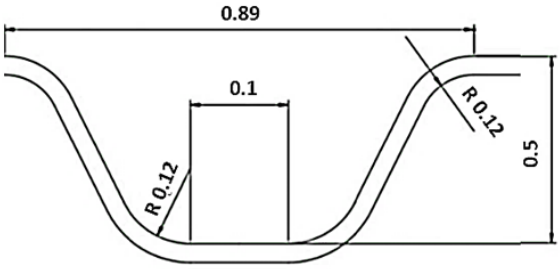

Fig. 3. Schematic of cross-section shape of one micro-channel, units in mm.

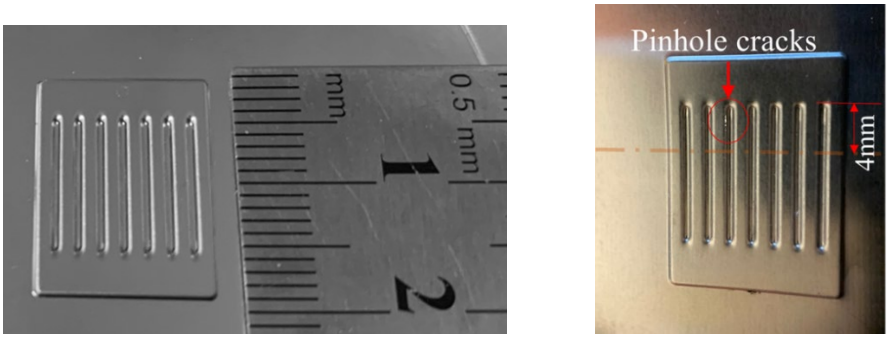
The top crosshead travelled at a load-controlled speed of 35 kN/min. The tests were stopped at a force of 90kN when cracks were found on all seven micro-channels and then repeated with more tests that stopped at sequentially reduced loads. After each test, the formed sheet was taken out for crack examination using the white-light method [16]. This identified a pinhole at a load of 78 kN (Fig. 4). The punch (male tooling) displacement at fracture initiation of the sheet was determined using an Alicona profilometer and determined to be approximately 0.32 mm when the pinhole initiated.



(a) (b)

Fig. 4. CP-Ti bipolar micro channel plate produced by micro-stamping. (a) Formed without cracks and (b) with pinhole cracks, the location of cross-section for microscope observation is 4mm from the end cavities.

For evaluating the thinning, a segment of the sample was cut from the formed sheet at the cutting location marked in Figure 4-b. Then the sample was mounted in resin, ground and polished to a flat surface. An Olympus DP71 microscope with a digital camera system was used to capture images at 5× magnification (Fig. 5). The thickness was measured based on the captured image. A

line perpendicular to both sides of the surfaces was constructed at each measurement location, and the line length was measured [19] with Digimizer Image Analysis software [20]. This measurement approach can achieve subpixel (~0.001mm) accuracy. The thinning values are measured from two different channels (No. 2 & 3 in Fig. 5) and the averaged value is presented in this paper

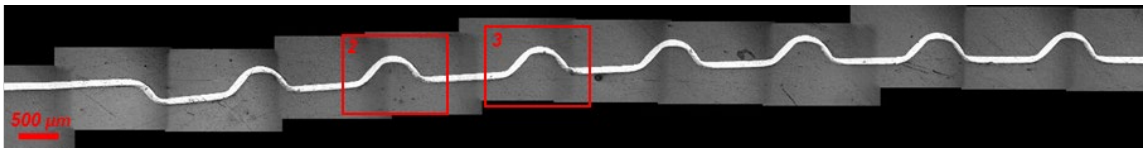


Fig. 5. Microscope image of a cross-section of the micro-stamped channel titanium

In this research, the thinning is used as the target parameter. Therefore, the thinning is defined as:

$$\%Thinning = \frac{t_0 - t_f}{t_0} \quad (2)$$

where $t_0$is the initial blank thickness, and t_f is the thickness of the final formed part.

The forming die (female tooling) surfaces were also scanned, and Fig. 6-a and b show the 3D image of the surface scan obtained with the Alicona for one single corrugation. The cross-section tool profiles in the transverse and the longitudinal direction were determined by performing a section cut on the scanned 3D surface, as illustrated in Fig. 6-c and d. In this study the point cloud of the tool surface scan of the top and bottom die was used to generate the tool surfaces in the FE model. For this, the tool radii were approximated with smooth arcs, and the radii of the punch and die represent the best fit from a group of 10 points distributed at the corner. The tool dimensions and geometric features of the experimental set up are shown in Fig. 6-d.

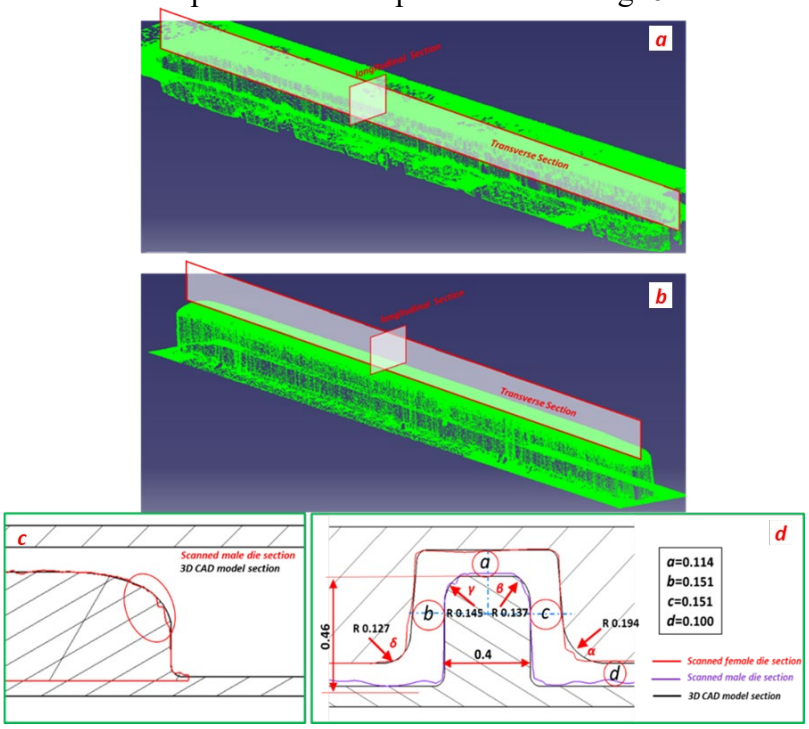

Fig. 6. a) Point cloud of female die. b) Point cloud of male die. c) Male die cross-section in longitudinal diection. d) Top and bottom die cross sections in transverse direction.

Finite Element Simulation

The commercial software package Abaqus explicit was used. Only one half of one channel was modelled in the 3D FE model. The model set up is shown in Fig. 7-a. In order to apply the force on the sheet, a displacement boundary condition is applied to the punch while the die is constrained in all directions. A symmetry boundary conditions was applied to the sheet on the symmetry axis as illustrated in Fig. 7-b (right end of the sheet). The left end was fixed to simulate the clamping of the sheet. According to the distance of the channels in transverse direction, the individual channel patterns do not influence each other during the forming process and therefore the two sides of the channel can be assumed to be fixed.

In this research, a 2D simulation was also considered to investigate the effect of different elements. Fig. 7-c demonstrates the 2D FE model. All the dimensions of FE models were considered based on the experimental set up.

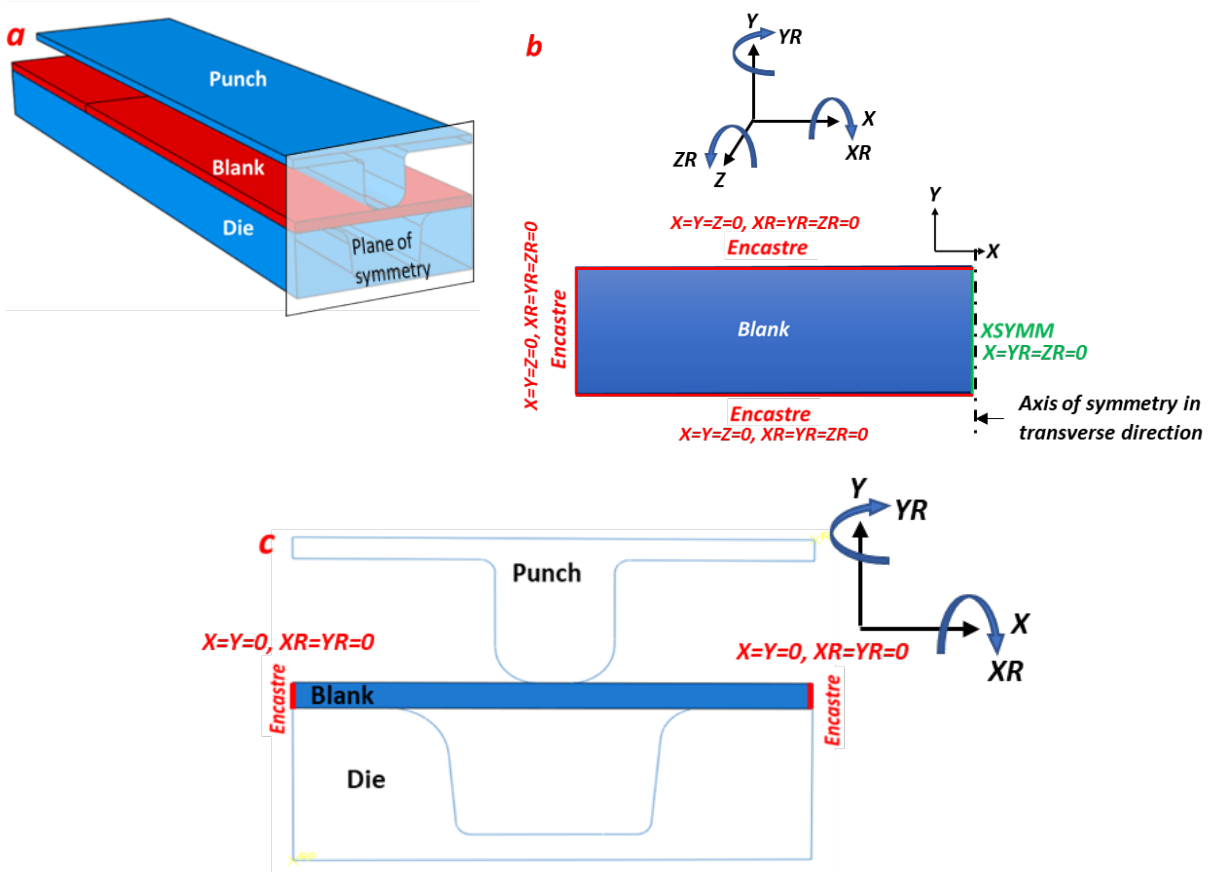

Fig. 7. a) 3D FE model for punch, die and blank. b) The boundary conditions of the blank in 3D FE model c) 2D FE model with blank boundary conditions.

The 3D geometry of the scanned punch and die surfaces profiles were converted to CAD and imported to the Abaqus explicit. The blank was modelled as a deformable part and was meshed with 3D stress, eight-node solid, reduced integration elements (C3D8R) with 10 elements through the material thickness. A mesh sensitivity study was performed to reach convergence. This gave an optimum mesh size of 0.01 mm (Fig. 8-a). For the 3D simulation with shell elements, a 4-node doubly curved thin shell (S4R) with 5 thickness integration points, reduced integration and hourglass control was used (Fig. 8-b).

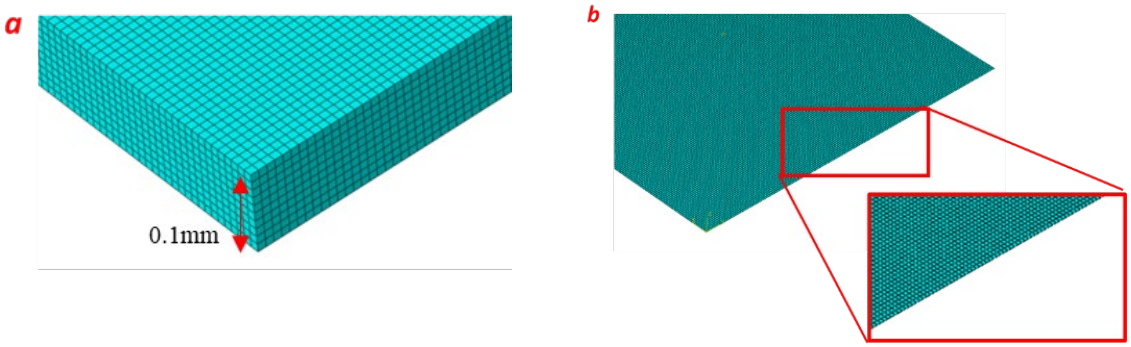

Fig. 8. FE model of the blank. a) Solid element (C3DR8) b) Shell element (S4R).

The die sets were meshed as discrete rigid bodies with four nodes of 3D bilinear rigid quadrilateral element (R3D4). The mesh size of the tools was considered in a way to discretise the geometry of the parts completely and with the desired accuracy. A refined mesh size of 0.01 mm was used in the critical contact locations of the die and the punch radius as shown in Fig. 9.

The 2D simulation was performed according to the geometry of Fig. 6, and the blank meshed with plane-strain, reduced integration CPE4R elements. The mesh size for 2D simulation was chosen the same as in previous research [16]. The Punch and die were meshed with 2-node 2-D linear discrete rigid element (R2D2). A surface-to-surface condition was implemented to define interaction between die setup and sheet.

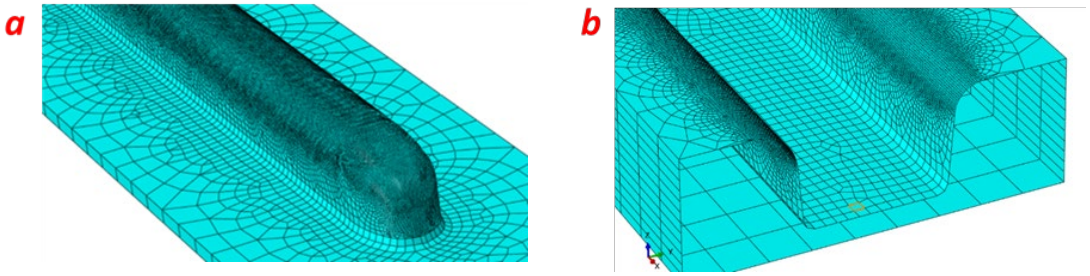

Fig. 9. FE model of the (a) punch and (b) die.

The friction coefficient between the tooling and sheet was assumed to be 0.4 in all simulations (2D and 3D) [16]. The mechanical properties of the sheets were applied in the simulation based on the material parameters given in Table 1 assuming isotropic material behaviour.

The explicit solution method used mass scaling to reduce the simulation time. The value of the mass scale coefficient (10^9) was determined in such a way that the ratio of kinetic energy to internal energy during the process was less than 1% to maintain the quasi-static nature of the problem.

Results and Discussion

The experimental thinning curves of the titanium blank are compared in the straight channel cross-section 4 mm away from the end cavities and at a punch stroke of 0.32 mm, which is when the pin hole originated. As shown in Fig. 10, the maximum thinning occurs in the die radius area. It should be noted that this is the smallest radius of the tool. Therefore, the critical forming regions are identified near the bending area of the die (δ region). The FE model represents the experimental thinning results but there is some error. This might be due to the presence of sharp points in the physical male and female tooling profile (Fig. 6-d) that were not considered in the FE model. This leads to severe deformation and, as a result, severe thinning in this area. In the FE model these

Materials Research Proceedings 28 (2023) 1531-1540 https://doi.org/10.21741/9781644902479-165

points are simplified as perfect arcs which could be why the FE model underpredicts deformation severity in this region.

There is only a minor difference in thinning prediction between the 2D and the 3D model. This may be due to material deformation being mostly plane strain tension in the investigated cross-section which is located in the straight channel and not in the end cavity. This allows for the simplification to 2D plane strain forming.

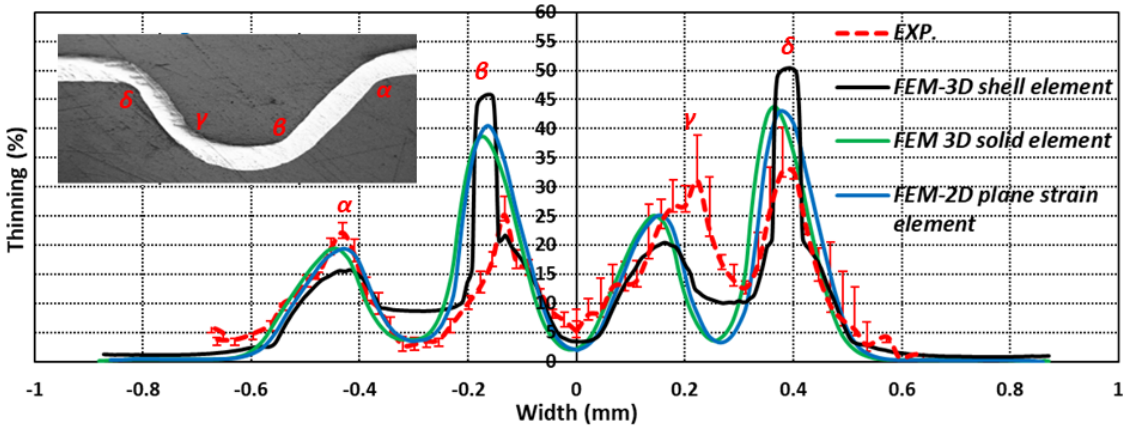

Fig. 10. Thinning prediction compared with the experimental (EXP.) results for titanium sheet.

The shell element is not able to accurately predict the distribution and level of material thinning (Fig. 10). In fact, when the punch displacement reaches to 0.26 mm, the shell element becomes extremely thin at the end of the cavity in the die area (δ region), and then thinning continues along the channel in longitudinal direction.

The thinning curves numerically predicted with the solid 3D element model for the straight channel region and the end cavity, sections 1 and 2, are shown in Fig. 11-a. There is a clear difference in the thinning behaviour between the two cross-sections (Fig. 11-b).

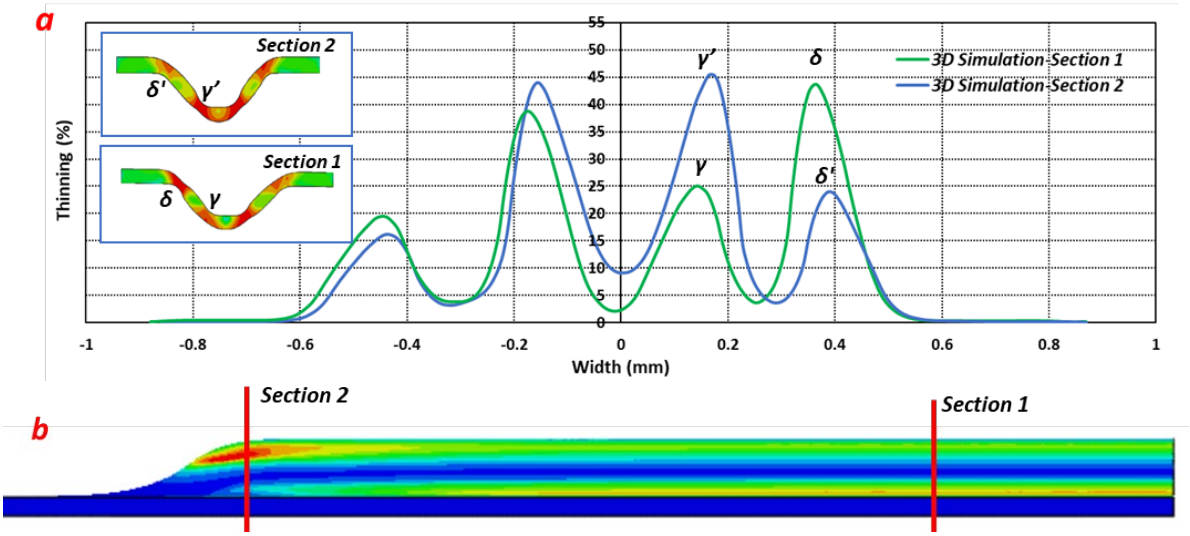

Fig. 11. a) Comparison of material thinning in sections 1 and 2. b) The location of section 1 and 2 in the simulation model.

The maximum thinning is transferred from the die radius in section 1 (region δ) to the punch radius area in section 2 (region γ'). The strain path of a node in the different radius areas was measured for both cross-sections during the process, and the result is shown in Fig. 12.

At the straight region, the strain path of the micro-channel corner regions that contact with the male and female tool radius are plane strain deformation (γ and δ Fig.12-b). The sheet at the cavity regions shows different strain path. The corner that was formed by the male tool radius region has a strain path starting with the biaxial stretching initially, but deviating to plane strain as the channel formed deeper (γ' in Fig.12-b). The female tool gives the bottom sheet corner negative minor strain (along the longitudinal of the channel direction), but the deformation mode shifts to plane strain towards the end of forming (δ' in Fig.12-b). In the cavity end area (section 2), the thinning is higher compared to the straight channel section and therefore closer to material failure. This, however, does not correlate well with the experimental pinhole location, which was in the straight channel section (Fig. 4b).

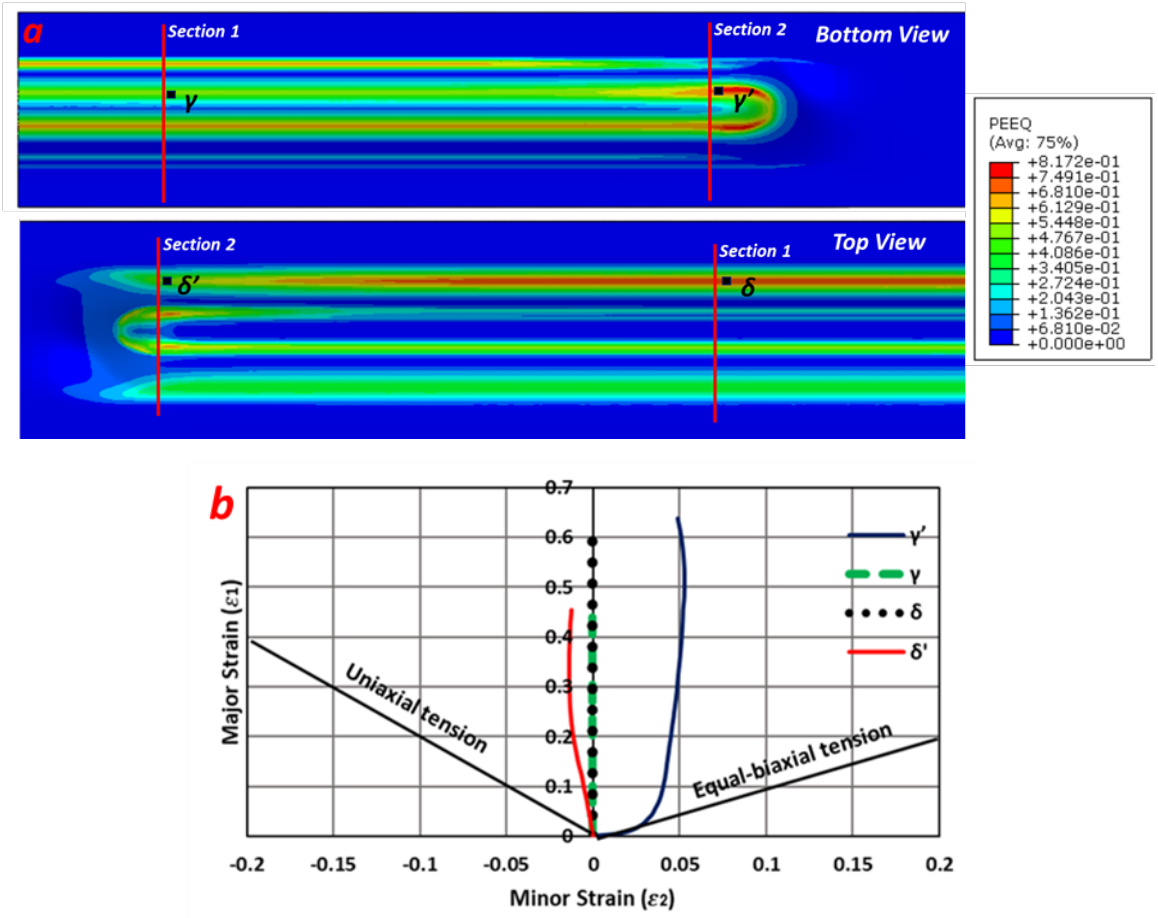

Fig. 12. a) The location of the considered nodes in the different sections, showing contours of equivalen plastic strain (PEEQ) on the bottom and top surfaces of the blank. b) The strain path of the bending area elements at both sections during the process.

Summary

- Titanium foil was micro-stamped, and the 3D FE model predictions did not match the experimental data in some of the channel regions. More research is required to accurately model the material behaviour and fracture limits of titanium foil in micro stamping.
- The analysis of solid and shell elements in the 3D model suggests that the shell elements cannot accurately represent material thinning.

- The stress state at the end cavity of the channels is different from that in the straight channel region. The assumption of 2D conditions for micro-channel deformation is therefore only valid in the straight section but does not represent the higher material deformation in the cavity that was observed in this study.
- As future work, implementing a comprehensive model that includes microstructural properties, and anisotropic properties, and performing accurate fracture criteria will be considered for the micro-stamping of the titanium foil.

Abstract. The continuous casting process is one of the initial operations in the entire metal forming chain used in the metallurgical industry. The phenomena of solidification and unification of properties that occur during slab casting are highly dependent on the steel composition and the purity of the metal. The high cleanliness of steel is the determinant of the good quality of the final products, without internal cracks or inhomogeneities in mechanical, thermal or electrical properties. Therefore, one of the production goals is to avoid the non-metallic inclusions in the molten steel by intensifying their removal processes. One of the most important metallurgy equipment responsible for cleaning the steel is the ladle furnace, where special mixing processes are executed to increase the removal process of unfavourable elements. Another critical piece of equipment is the tundish, located just before the slab casting, which can additionally improve the microstructure final composition and homogeneity. Therefore, the investigations presented in the paper are centred on the development of an advanced Computational Fluid Dynamic (CFD) model of the flow behaviour of the molten steel inside the tundish. The key element of the model is to include the effect of an additional electromagnetic stirring device which can improve the cleanliness and the composition of the steel and hence its final properties. The role of this device is often omitted during practical research, but its direct influence on the properties of the steel has a clear impact on the characteristics of the formed metallic parts under further processing operations. Therefore, optimization of the process inside the tundish is essential from an industrial point of view. The paper includes a detailed analysis of the flow and stirring energy distributions to predict and understand the active and dead zones inside the tundish to avoid the regions with stagnant velocity distribution. As an outcome of such a developed coupled electromagnetic/fluid dynamic model, optimizing the mixing processes to control the product's properties is possible.

Introduction

In the metallurgical industry, intensive investigations are conducted to obtain the best properties of the products and, at the same time, reduce production costs and environmental pollution. The steel composition and microstructure significantly influence material behaviour during further metal forming processes and need to be optimized early in the production stages. Thus, researchers have been working to improve the steel's cleanliness by, e.g., minimizing the amount of non-metallic inclusions leading further to, e.g., crack initiation. In reality, the proper classification and detection of inclusions is a crucial aspect of developing the production process. Zhang and Thomas in [1] reviewed the different sources of inclusions which occur during the whole continuous casting process. The phenomena leading to the generation of inclusions in molten steel are complex. Many

aspects influence their formation, e.g., the high oxidizing atmosphere in the electrical arc furnace (EAF), which is the first stage of the process, reoxidation or slag entrainment in the next steps of the production etc. Researchers also focus on the improvement of steel cleanliness, mainly in the ladle, tundish and directly, in the slab casting operation. The common practice is the absorption of inclusions to the slag layer [2], intensification of the removal process by the additional inert gas injection [3-5], introduction of special channels with induction heating [6] or finally, dedicated control devices can be added to improve the stirring of the melt like baffle walls or electromagnetic stirrers (EMS) [7,8]. Currently, the research in this area mainly focuses on mathematical or numerical modelling due to the difficulties with the measurements under real production conditions. The numerical approach of Computational Fluid Dynamics (CFD) enables the wide investigation of the flow and inclusions behaviour for each metallurgical equipment starting from the electrical arc furnace, ladle furnace, and tundish. It also enables the solidification phenomena predictions occurring during the casting.

Therefore, the main goal of this research is the development of a complex coupled electromagnetic/fluid dynamic model of the steel behaviour in the tundish equipped with electromagnetic stirrers. Material flow in the tundish is critical as it is the last production stage with fully liquid metal. The overall goal is to simulate the molten steel flow, the velocity and stirring energy distributions to understand the development of so-called active and dead zones inside the tundish. As a result, the mixing process could be appropriately designed to increase the homogeneity of the steel and avoid areas with the stagnant flow or inhomogeneous temperature distribution. Both phenomena lead to catastrophic problems related to the quality and clogging of outlets. These issues are dangerous from a safety point of view and can lead to production faults, exposing the company to unexpected costs.

Methodology

The numerical investigations of the flow behaviour inside the tundish were conducted in the commercial CFD software Ansys Fluent. The geometry of the tundish was prepared according to the industrial specification of the real device. Simulations focused on the different computational scenarios within the tundish with additional control devices namely baffle walls, electromagnetic stirrers and stoppers, to control the mass flow rate through outlets. The tundish geometry used during the research is presented in Fig. 1a, as a case with additional stoppers and in Fig. 1b, as a case with a baffle wall to control the flow distribution. In both cases, additional electromagnetic stirring is also considered.

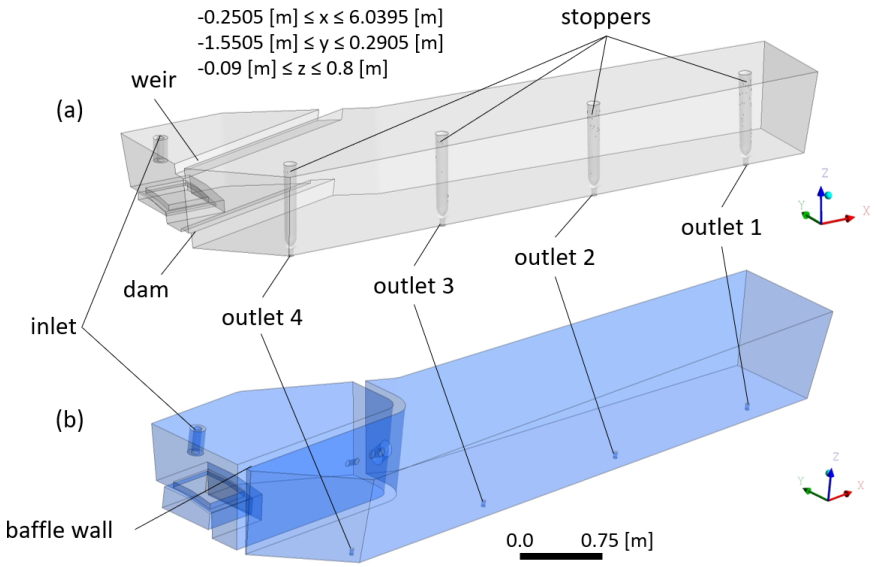

Fig. 1. The geometry of the tundish used in the numerical simulations (a) with stoppers and (b) with baffle wall.

The parametric study included comparing the different scenarios of the current applied during EMS operation to understand the influence of such additional stirring mechanism on the mixing process and optimize the power input to avoid energy losses. The list of cases which were conducted to compare the velocity and stirring energy distributions is presented in Table 1.

Table 1. List of cases to compare the flow behaviour.

Case no.	Description
1	without EMS, without baffle wall
2	with 100% of EMS, normal direction of stirring
3	with 100% of EMS, reversed direction of stirring
4	without EMS, with baffle wall
5	with 100% of EMS, without baffle wall, with stoppers
6	with 84% of EMS, without baffle wall, with stoppers
7	with 69% of EMS, without baffle wall, with stoppers
8	with 60% of EMS, without baffle wall, with stoppers
9	with 31% of EMS, without baffle wall, with stoppers

Electromagnetic stirring used to induce the steel flow is realized by the additional momentum source terms introduced into the momentum equation. Forces from the electromagnetic stirring are mapped into the fluid computational domain and depend on the velocity. The following equation describes this dependence:

$$\vec{F} = \overrightarrow{F_0}\left(1 - \frac{\overrightarrow{F_0} \bullet \vec{V}}{2\tau f \bullet \left|\overrightarrow{F_0}\right|}\right), \quad (1)$$

where $\overrightarrow{F_0}$ - stirring force calculated for stationary melt [N/m3], $\vec{F}$ - stirring force after compensation with moving melt [N/m3], τ - pole pitch [m], f - frequency [Hz], $\vec{V}$ - velocity of melt [m/s].

Materials Research Proceedings 28 (2023) 1543-1550 https://doi.org/10.21741/9781644902479-166

The exemplary force field mapping operation to include the effect of electromagnetic stirring in the tundish is presented as a force density in Fig. 2.

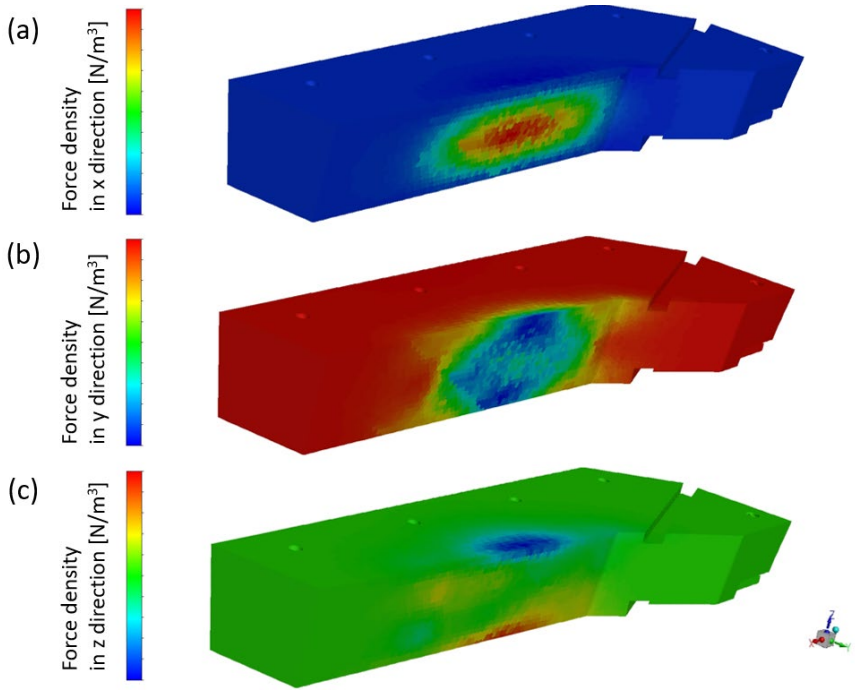

Fig. 2. Force densities in (a) x-direction, (b) y-direction and (c) z-direction, respectively.

During the investigations, the mixing process was also taken into consideration. Visualization of the mixing operation in the molten steel is realized by additional discrete phase particles available in the Discrete Phase Model (DPM), which interact with the continuous phase. To understand the flow behaviour, the massless particles were injected into the domain in accordance with the boundary conditions of the stream. The particles, as a tracers, travel with the continuous phase and enable observation of the liquid steel's movement.

Results and Discussion

CFD simulations help to understand the flow inside the tundish under the additional electromagnetic forces. Based on the evaluated turbulent dissipation rate that occurs in the molten steel, the stirring energy can be calculated. The simulations were performed for different cases to evaluate the influence of the applied current scenarios, which directly correspond to the force factor of the EMS, on the velocity distribution and stirring effectiveness. The first comparison between the velocity and stirring energy distribution for 100% , 84%, 69%, 60% and 31% of EMS stirring force and for the case with stoppers is presented in Fig. 3. It should also be pointed out that inside the tundish, the clogging of outlets is a rather common phenomenon and depends on the solidification of the molten steel, mainly in the areas of the dead zones and sedimentation process, where different remains detach from walls are clogged up the outlets. This issue is very often inside the tundish because of the relatively low stirring energy inside compared with the ladle furnace, where the mixing process is the most intensive. Based on that, the analysis of the stirring energy close to the outlets can improve the design process and optimization of the work of the device. The comparison between the stirring energy distribution in the area of each outlet for cases with stoppers for 100% and 31% of EMS is presented in Fig. 4.

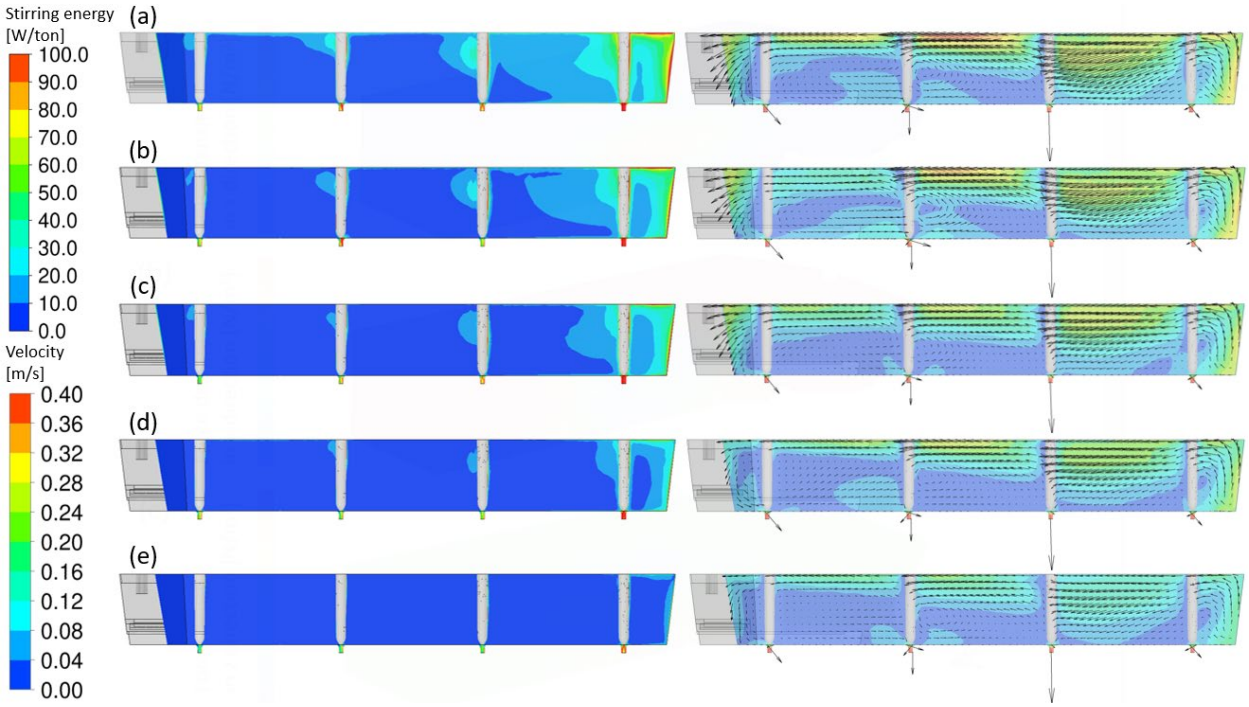

Fig. 3. Stirring energy (left) and velocity (right) distribution for different EMS force factors (a) 100% - case no. 5, (b) 84% - case no. 6, (c) 69% - case no. 7, (d) 60% - case no. 8, (f) 31% - case no. 9.

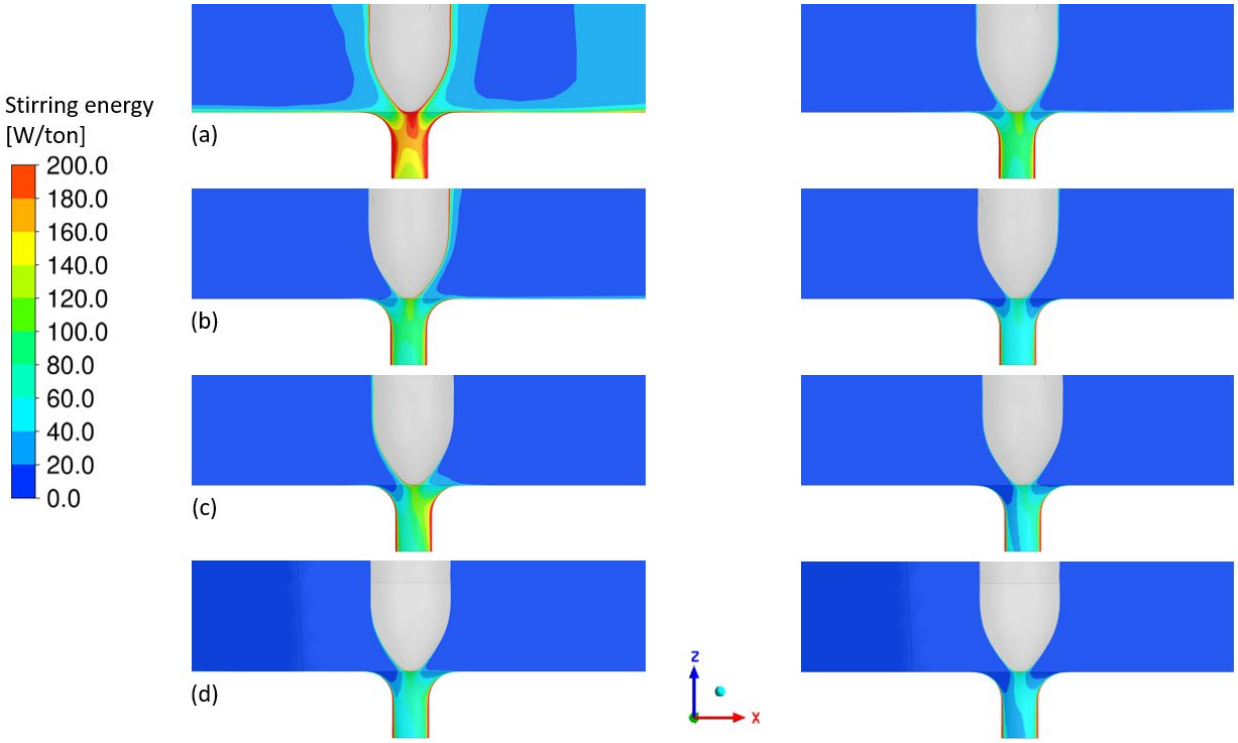

Fig. 4. Stirring energy distribution for case no. 5, 100% of EMS (left) and case no. 9, 31% of EMS (right) for different outlets: (a) outlet 1, (b) outlet 2, (c) outlet 3, (d) outlet 4.

Based on Fig. 4, stirring energy distribution close to outlet 3 has the most asymmetric character, and the gradients of the values are the highest.

Another important investigation is the evaluation of the molten steel mixing inside the tundish. This mixing can be easily visualized by the mentioned massless particles whose behaviour is dependent on the steel flow in the tundish. The observation of the tracers in the numerical model can be compared to the analysis of the dye injected into the water during the water model tests. The particles flow inside the device is presented in Fig. 5 and Fig. 6, where different types of cases were compared to each other. The simulation model without any additional control devices is presented as a reference case. Then, the results for the case with 100% of EMS are shown. The investigation also included the reversed direction of the stirring to compare the behaviour of particles and the results with a common control device like a baffle wall with openings used to improve the liquid steel mixing process. The comparison confirms that the best mixing is presented for the case with 100% EMS stirring. The results are much better than the baffle wall and indicate the high efficiency of homogenising velocities and temperatures. Obtained results also indicate an increase in the inclusions removal process, which is important to the steel's quality.

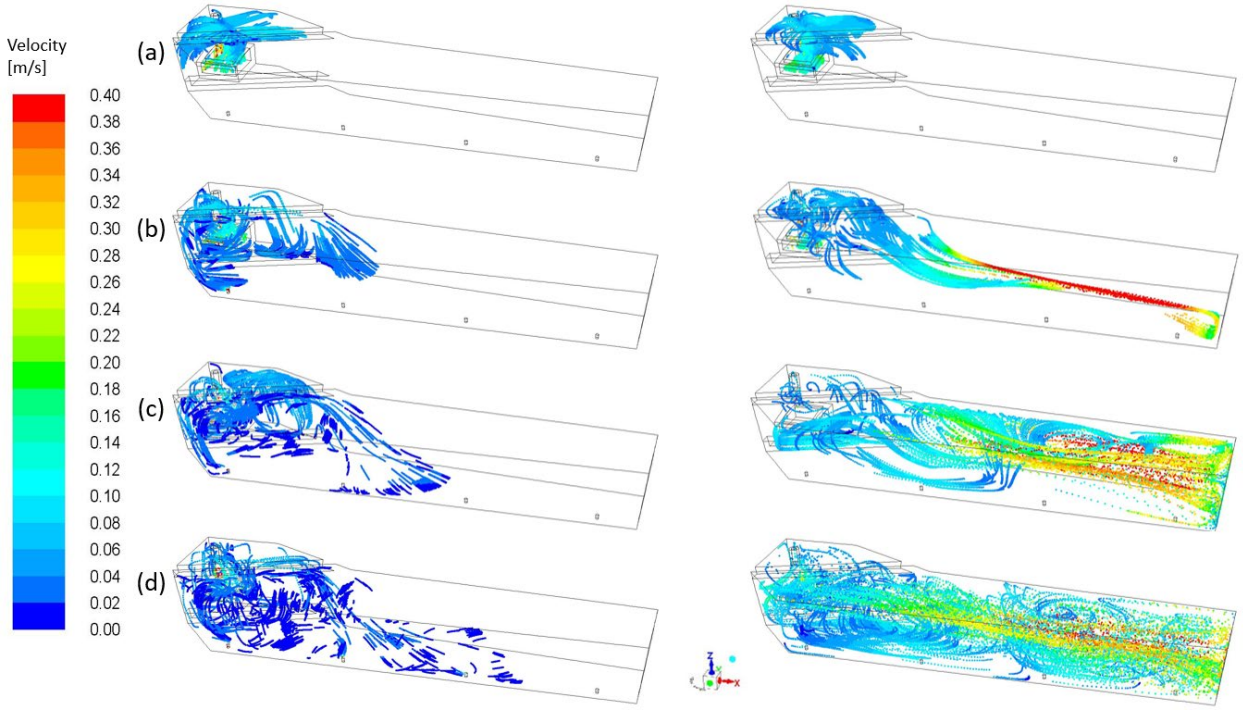

Fig. 5. Massless DPM tracers to visualize the mixing process for case no. 1 without EMS, without baffle wall (left) and for case no. 2 with 100% of EMS, the normal direction of stirring at (a) 20 [s], (b) 50 [s], (c) 100 [s], (d) 200 [s].

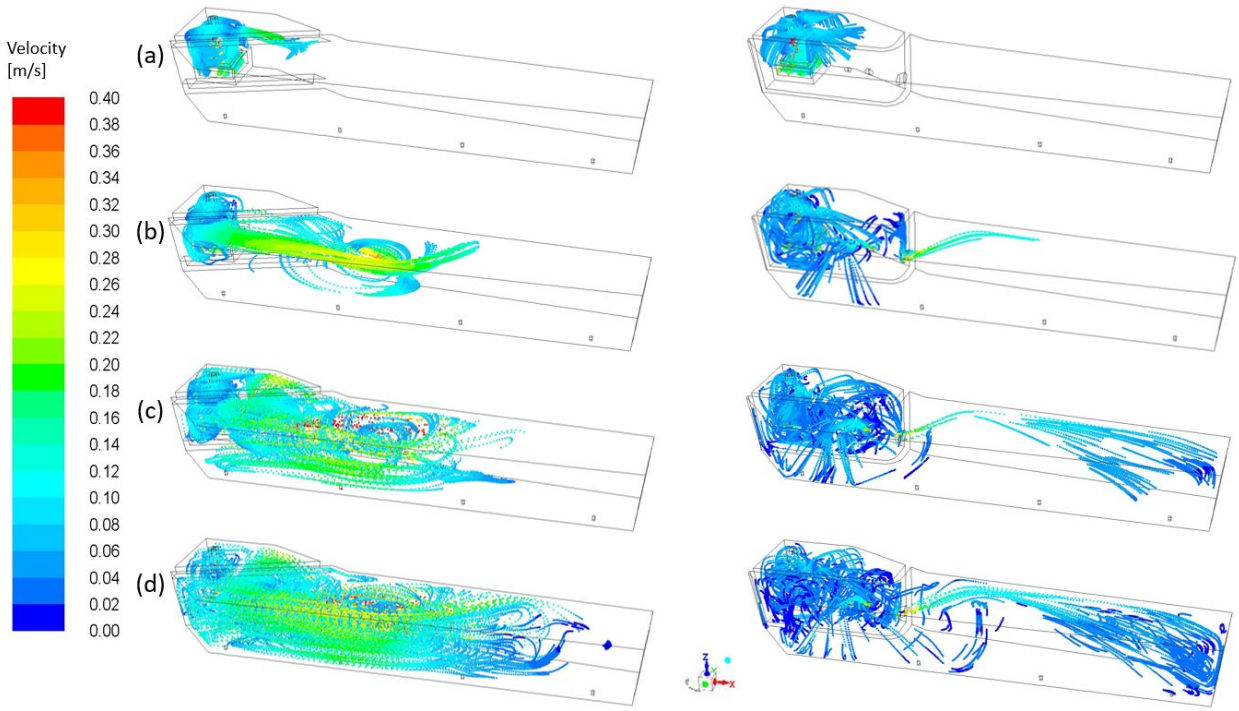

Fig. 6. Massless DPM tracers to visualize the mixing process for case no. 3 with 100% of EMS, reversed direction of stirring (left), and for case no. 4 without EMS, with baffle wall at (a) 20 [s], (b) 50 [s], (c) 100 [s], (d) 200 [s].

Summary

Based on the presented research, the following conclusions can be formulated:

- CFD simulations enable to understand the issues in the steelmaking industry and optimize the continuous casting process to improve the effectiveness of the work of metallurgical devices.
- The molten steel flow inside the tundish can be highly improved by the electromagnetic stirrers. In this case relatively low power input significantly improves the effectiveness of the mixing. As a result the homogenization of the structure and purity of the steel is improved. At the same time, agglomeration of inclusions into the slag occurs due to the prevention of the dead zones. So areas with stagnant flow influencing the velocity, temperature and inclusions distribution are minimized. All those aspects directly influence the final products' quality,
- The EMS stirring also prevents uncontrolled solidification and sedimentation, which is dangerous from a safety point of view due to the risk of clogging and faults of the production line.
- The above-mentioned advantages confirm that the structure of the molten steel can be controlled by the usage of electromagnetic stirrers, which also influence further metal forming operations .

Keywords: Interpolation, Monte Carlo, Finite Element Method, Welding

Abstract. The processes of microstructure evolution under thermal loading occurring during welding or additive manufacturing are highly complex and challenging to observe experimentally. Therefore, in this work, to support experimental investigation, a hybrid numerical model based on the combination of the Monte Carlo (MC) and Finite Element (FE) method was developed to simulate both temperature profiles and corresponding grain growth phenomena at a micro scale explicitly. The welding simulation was selected as a case study. The discrete MC microstructure evolution model is based on the temperature distribution provided by the FE simulation with the Goldak heat source model. The temperature data are transferred from 3D FE space to cubic MC Pott's domain in each time step. Direct coupling between the MC cells and FE cubic elements provides accurate results but significantly increases the simulation time. Therefore, coarser FE meshes are used in the research, but this requires applying reliable data interpolation techniques between the two methods. As a result, the temperature field stored in a coarse FE cloud of points is interpolated into regular high-resolution MC cell space in each time step. Evaluation of the influence of various interpolation methods, along with their parameters on the final microstructure morphology after welding, is presented within this work.

Introduction

Modern industry requires efficient and durable methods of joining various metallic parts. The most popular techniques in this area are the welding operations [1], which are based on melting both materials in the joining zone by the focused heat sources, e.g. laser or electron based. However, similar material processing routes are also used in other applications like additive manufacturing or soldering [2,3]. Despite the final application, phenomena controlling microstructure evolution in all those processes are very complex to analyze experimentally. During the high-heat loading of metallic materials, various phenomena should be considered, involving melting, crystallization, grain growth, phase transformation, etc. Most of the time, experimental observations of these phenomena are done after the end of the process. As a result, drawing direct conclusions about local microstructure behavior during the process is not straightforward. Therefore, numerical simulations are frequently used to support experimental observations and visualize phenomena that are difficult or impossible to observe in laboratory conditions [4].

To investigate both the temperature evolution and corresponding microstructural changes in the welding and heat-affected zones, a hybrid Finite Element (FE) - Monte Carlo (MC) model was developed. The FE part based on the classical Goldak movable heat source model is responsible for the evaluation of the temperature fields during the process. The MC model is used as a full-field approach allowing explicit representation of complex grain morphology in the weld line area [5–7]. The MC method was selected in this case due to a straightforward definition of cell transition rules. However, in this case, coupling both methods is a crucial stage in successful model development.

The direct coupling assumes linking each cubic FE element with a corresponding cubic MC cell, as presented in Fig. 1a. In this case, the data transfer is straightforward as both computational domains operate on the space discretized exactly in the same way. However, a high-resolution MC space is required to capture the grain growth during the process, which directly leads to a high-resolution FE mesh. As a result, the computational times for large-scale models may be quite excessive. Therefore, the solution is to use a coarser FE mesh that does not directly correspond to the MC cells. However, in this case, the data transfer between the two incompatible meshes in each time step has to be developed based on the interpolation technique, as seen in Fig. 1b.

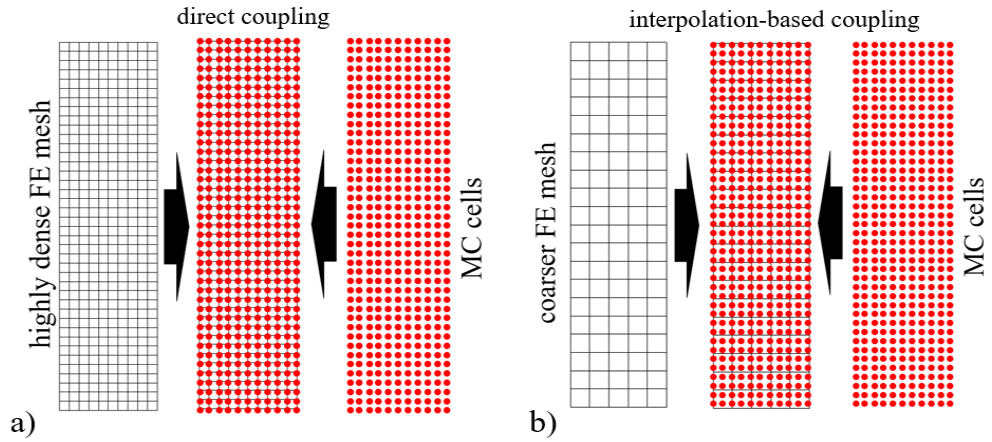

Fig. 1. Concepts of the FE-MC models based on a) direct and b) interpolation-based coupling.

Evaluation of the influence of various interpolation methods and their parameters on the final microstructure morphology after welding simulated by the MC model is the primary goal of the current research to confirm the quality of the results.

Hybrid FE-MC Model Description

The essential step in simulating the effect of thermal loading on the microstructure evolution during welding is to acquire sensible temperature data in specified conditions. The presented approach assumes that the thermal loading during welding is performed by the moving heat source incorporated into the FE framework. The welding operation of two high-purity aluminium plates was selected as a case study for the current investigation. The applied moving heat source model is based on Goldak's ellipsoid [8] in the form of:

$$q(x,y,z,t)=\frac{6\sqrt{3}Q}{abc\pi\sqrt{\pi}}e^{\frac{-3x^2}{a^2}}e^{\frac{-3y^2}{b^2}}e^{\frac{-3[z+v(\tau-t)]^2}{c^2}} \tag{1}$$

where: q – heat flux at a given point in the coordinate system; a, b, c – semi-axes of the ellipsoid; Q – energy input rate; v – welding velocity; τ – lag factor.

The FE model provides information on the temperature evolution during the subsequent process stages, as presented in Fig. 2.

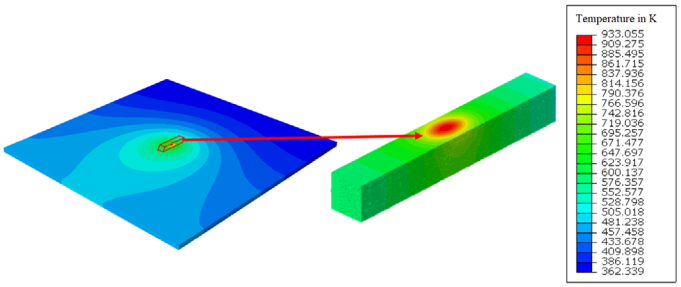

Fig. 2. FE temperature field in [K] during welding with the highlighted section of interest for interpolation analyses.

The acquired data for a particular time step is called a frame in the current work. Data from each frame has to be then transferred to the regular cubic MC space. To reduce the computational time, the MC space is associated only with the heat-affected zone during the welding.

The developed MC microstructure evolution model is based on Pott's approach [9]. The initial microstructure morphology required for simulation (Fig. 3) is generated using the cellular automata grain growth algorithm from the DigiCore library [10]. The average grain diameter is 0.143 [mm], and the resolution of generated MC space is 102×92×701, with the cell's edge length set to 0.02 [mm] to properly capture grain boundaries geometry (Fig. 3). The main idea of the MC method is to calculate the probability p of, a randomly selected, cell state change and set it to a new state according to the following equation:

$$p = \begin{cases} M(T_i)e^{\frac{-\Delta E}{kT}} & \Delta E \le 0 \\ M(T_i) & \Delta E > 0 \end{cases} \tag{2}$$

where: ΔE – change in the energy; kT – model factor; $M(T_i)$ – grain mobility; T_i – temperature of a cell.

The Eq. 3 describes change in the free energy:

$$\Delta E = E_{new} - E \qquad E = \sum_{j=1}^{Z} 1 - \delta_{SS_j} \tag{3}$$

where: E – free energy for an initial state, E_{new} – free energy for a new state, Z – number of neighbors, δ – Kronecker delta of state between current and neighboring cell. The probability p is calculated for every cubic cell in MC space. This computation is applied for every FE frame of welding simulation by performing an arbitrary set number of iterations known as the Monte Carlo Steps (MCS).

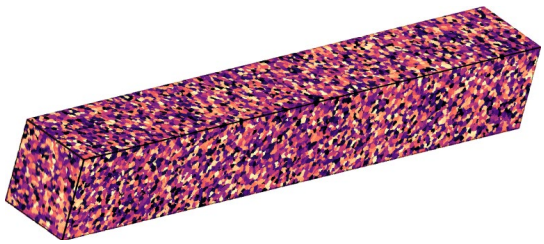

Fig. 3. Initial microstructure.

Materials Research Proceedings 28 (2023) 1551-1558 https://doi.org/10.21741/9781644902479-167

The temperature field from the FE model is used to calculate the grain mobility $M(T_i)$, which involves activation energy Q for specific material and given temperature T_i of MC cell in Arrhenius equation (Eq. 4). In the current model Eq. 4 is normalized to 0 – 1 range by M_0 scaling factor, where 1 means the value for a melting point:

$$M(T_i) = M_0 e^{-\frac{Q}{kT_i}} \tag{4}$$

Data transfer between the two models is performed by interpolating temperature values from FE cloud of points into regular high-resolution 3D MC space. As pointed out, selecting appropriate interpolating functions is crucial to reproduce a final microstructure representation after welding. Four different methods were implemented and used in the current FE-MC hybrid model. The first is an Inverse Distance Weighting (IDW) method [11]. This approach is based on the evaluation of the temperature value in a particular cell by averaging the values of neighboring FE data points (Eq. 5). The weights from Eq. 6 depend on the distance and the parameter n (Eq. 6):

$$u(x) = \begin{cases} \dfrac{\sum_{i=1}^{N} w_i(x) u_i}{\sum_{i=1}^{N} w_i(x)} & d(x, x_i) \neq 0 \\ u_i & d(x, x_i) = 0 \end{cases} \tag{5}$$

$$w_i(x) = \frac{1}{d(x, x_i)^n} \tag{6}$$

The second interpolation algorithm is based on Smoothed-Particle Hydrodynamics (SPH) approach [12], where the evaluated value u depends on the weighting kernel function k (Eq. 7). The kernel function determines the weight of value using the neighborhood radius r and distance d between the current point x and neighboring one x_i. Two different kernel functions: *Epanechnikov* (Eq. 8) and *Quartic* (Eq. 9), were used during the current investigation:

$$u(x, r) = \frac{\sum_{i=1}^{N} k(x_i, r) u_i}{\sum_{i=1}^{N} k(x_i, r)} \tag{7}$$

$$k_{epanechnikov}(x, r) = \frac{3}{4}\left(1 - \left(\frac{x}{r}\right)^2\right) \tag{8}$$

$$k_{quartic}(x, r) = \frac{15}{16}\left(1 - \left(\frac{x}{r}\right)^2\right)^2 \tag{9}$$

Additionally, two other approaches are considered due to their simplicity and low computational complexity. The third interpolation method is a particular variant of the IDW method with n set to 0. This provides a simple average method (AVG) that only takes unweighted values into the computations. The last interpolation technique is based on finding the nearest point and applying its value (NEAREST).

Comparison of Interpolation Methods

In order to study the impact of interpolation methods and their parameters on the evolution of microstructure in the MC space, two simulations of the thermal loading of an aluminium plate were carried out. The first computation was made with the most time-consuming direct coupling where FE points are equidistant from each other, and the size of the FE elements is the same as MC cells (Fig. 1a). In this case, the data are directly transferred from the particular FE integration point into the corresponding MC cell, and there is no interpolation. The simulation results from Fig. 4 are assumed to be a benchmark for further investigation. The second set of simulations is realized on a coarser FE mesh, and as described earlier, different interpolation methods were used to transfer the data into the MC model.

Fig. 4. Final microstructure obtained from the direct coupling between FE and MC models.

Each interpolation test was then conducted according to the parameters collected in Table 1. Corresponding final microstructure morphologies from hybrid FE-MC simulations are gathered in Fig. 5 – 9. For presentation purposes, only the middle section of the heat-affected zone is presented. Besides that, skeletonization of the top view of the microstructure was done to emphasize the difference in the shape of grains. Finally, obtained computational times and average grain sizes are summarized in Table 2.

Table 1. Combination of applied interpolation methods and their parameters.

Case no.	1	2	3	4	5	6	7	8	9	10	11	12	13
Interpolation method	IDW	IDW	IDW	SPH/ Q	SPH/ Q	SPH/ Q	SPH/ E	SPH/ E	SPH/ E	AVG	AVG	AVG	NEARES T

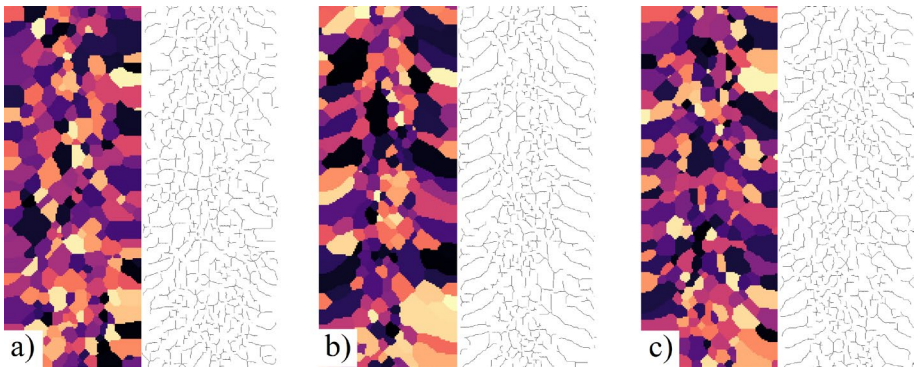

Fig. 5. Top view of the microstructure and its skeletons after thermal loading using IDW method: a) Case 1, b) Case 2, c) Case 3.

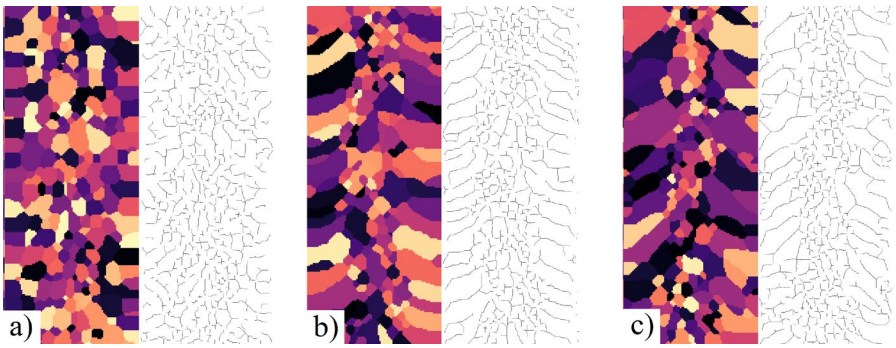

Fig. 6. Top view of the microstructure and its skeletons after thermal loading using SPH-Quartic method: a) Case 4, b) Case 5, c) Case 6.

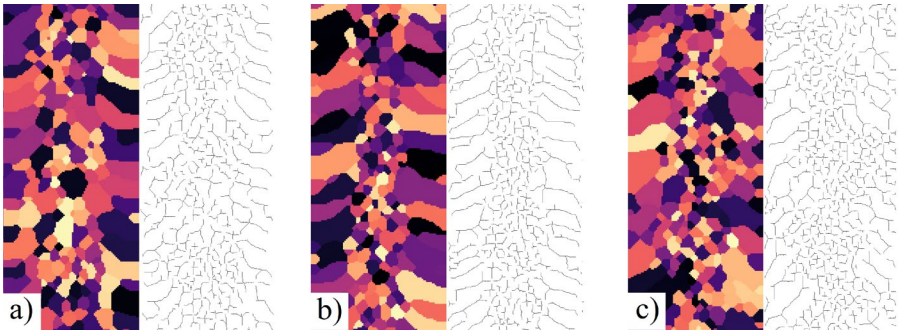

Fig. 7. Top view of the microstructure and its skeletons after thermal loading using SPH-Epanenchnikov method: a) Case 7, b) Case 8, c) Case 9.

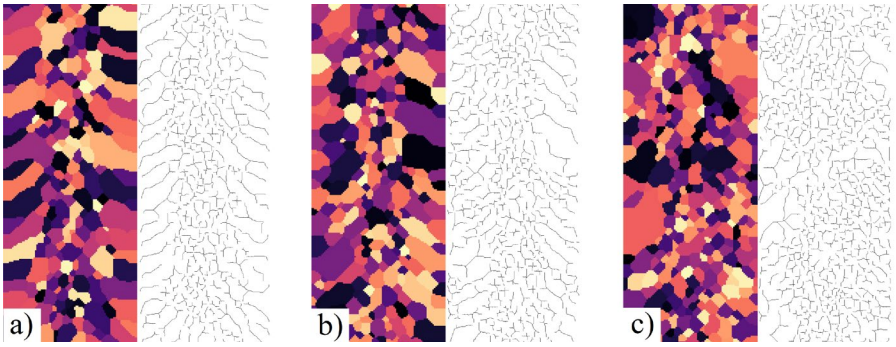

Fig. 8. Top view of the microstructure and its skeletons after thermal loading using AVG method: a) Case 10, b) Case 11, c) Case 12.

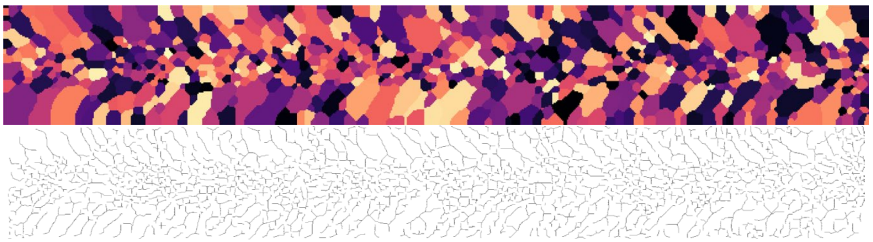

Fig. 9. Top view of the microstructure and its skeletons microstructure after thermal loading using NEAREST method (Case 13, entire model).

As presented, the applied methods and their parameters highly impact the resulting microstructures. Presented top views of the microstructures (Fig. 5 – 9) can be easily distinguished into two sections: the central part, which results in new and not fully grown grains, and the second one, with elongated grains after the grain growth. This division is particularly evident in the presented skeletons. Size, curvature, and a fraction of elongated grains depend on selected interpolation algorithms and their parameters. It is observed that SPH method in both variants produces the most elongated and curved shapes of grains that are related to the number of points taken into account in the neighborhood. However, at 0.8 [mm] neighborhood radius, the shapes of elongated grains are more irregular. According to the AVG method, if fewer values are considered in the averaging, the final structure is similar to the referenced one. The IDW approach shows the curvature of grains depends on the number of points taken into consideration, and the size relies on a parameter $\boldsymbol{n}$ value. The NEAREST method, despite its simplicity, provides a very similar microstructure to the reference one. From the presented approaches, similar microstructures are produced by the SPH (Fig. 6b and Fig. 7b), the AVG (Fig. 8a), and the NEAREST. These methods differ in two points: the shape and size of elongated grains, which are the largest in the SPH, and the angle of direction of grain growth from the fusion zone to HAZ boundary, which is more perpendicular in the case of SPH and AVG. These methods present significantly different results from the reference, especially regarding the elongated-to-center grains ratio. Despite this, it seems that the NEAREST method most closely reflects the reference microstructure relative to the others.

Summary

Based on the presented research, it can be concluded that:

1) temperature fields mapped from macro to micro scale by interpolation methods slightly vary from the direct transfer case. There are also minor differences in the shape and size of new grains.

2) the most similar microstructure can be obtained by using an appropriately tailored method. The most effective results are produced using SPH interpolation (using *Epanechnikov* and *Quartic* kernel functions with 0.4 radii of range), AVG method (with the application of 0.2 radii of range) and the nearest neighbor approach. NEAREST provides the closest results to the benchmark case among these three methods.

3) approaches based on averaging (all cases of the IDW and the AVG second and third case) introduce some disorder in temperature fields, which results in a lack of elongated grains.

More simulations will be carried out on a larger computational MC domain as the subject of future work. The research will also include an examination of geometric parameters and velocity of the heat source and its influence on the microstructure evolution.

Keywords: Random Cellular Automata, Dynamic Recrystallisation, Microstructure

Abstract. Numerical simulations can help predict microstructure morphology evolution under hot forming conditions and support final material properties determination. Cellular Automata (CA) is a commonly used full-field method to model changes in microstructure morphology during different metal-forming processes. However, in the case of microstructure evolution changes during high deformation levels, at higher temperatures, the CA method has some limitations related to computational domain geometry changes. The use of random cellular automata (RCA) allows for a more realistic representation of this phenomenon. However, it involves much more effort during model implementation to optimise the algorithm in terms of execution time, which has to be at an acceptable time. This paper is a part of a larger research aiming at developing the dynamic recrystallisation model (DRX) using the RCA directly incorporated into the finite element (FE) framework. The main goal of the current work is to evaluate the efficiency of data transfer approaches between the two mentioned coupled model components. Particular attention is on shortening the execution time thanks to data streams opened in binary mode.

Introduction

Because of the rapid development of computer technology, current numerical methods can consider not only the macroscopic response of the material but also can track the microstructural changes explicitly. Advanced multiscale models often use different numerical simulation methods to reflect given phenomena at subsequent scales. In general, three major phenomena are responsible for microstructure evolution during the deformation of metallic materials: recrystallisation, phase transformation, and texture development. The former group of phenomena, particularly dynamic recrystallisation (DRX), is critical when evaluating hot metal forming conditions. This phenomenon leads to microstructure restoration during hot working conditions, which eventually influences their final mechanical properties [1].

In principle, DRX consists of two main stages: nucleation and growth of new dislocation-free grains. It is a process driven mainly by a reduction of the dislocation density accumulated in the material during plastic deformation conditions under elevated temperatures. This process occurs directly during deformation at high temperatures, so its direct experimental observations are very demanding. Therefore, various numerical models are used to support and complement experimental analysis [2,3]

The cellular automata (CA) is one of the advanced full-field numerical methods commonly used to represent the microstructure evolution during plastic deformation. This method has been used for DRX simulations for many years, starting from the first simple model that did not consider computational domain deformation developed by Goetz and Seetharaman [4]. They showed that even a straightforward model could approximate the material properties observed during experiments. More and more advanced models appeared over the following years. Xiao et al. [5] introduced the DRX model based on the CA coupled with the topology deformation technique to

account for the influence of grains' topology change during deformation on the kinetics of the DRX. Gawad and Pietrzyk introduced the Cellular Automata Finite Element model (CAFE) [6] with a simplified way to account for the microstructure's evolution in the FE simulation. Complex and more flexible models combining the CA method with FE were also developed [7]. However, all these examples also showed that an accurate description of the deformation of the cellular automata computational domain under plastic forming conditions is a significant limitation of the classic CA approach, which is based on a regular grid of cells (Fig. 1a). Many solutions have been proposed to deal with that issue in recent years. In some works, authors introduced a simple CA space elongation algorithm along a selected axis [8], and as a result, new recrystallised grains were also artificially elongated. Another research developed a technique based on mapping the computational space between two separate coordinate systems [9]. It eliminated many disadvantages of previously reviewed approaches but still considered a series of geometrical assumptions during simulation. An exciting concept of space deformation was introduced in [10]. The authors coupled the CA method with the FE approach and introduced the CA space deformation algorithm directly based on FE mesh geometry. However, because of the regularity of CA space, the remeshing operations were limited in FE software at higher deformation degrees. Therefore, the current paper's authors introduced the concept of coupling the FE deformation model with the random cellular automata (RCA) model of microstructure evolution presented in [11].

In this case, the RCA modifies the definition of a regular CA space and considers it as a cloud of points (Fig. 1).

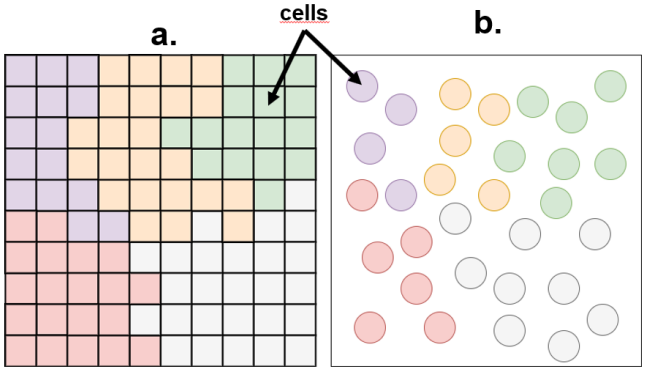

Fig. 1. Comparison of a) CA and b) RCA computational space.

The method retains all general properties of CA without introducing errors during coupling with finite element integration points, which deal with deformation calculations. As a result, the coupled RCAFE model reflects the material's behaviour during deformation more accurately, as it directly considers CA space deformation.

RCAFE DRX Simulation

The material deformation simulations are carried out in the classical J2 plasticity FE framework of Abaqus software. Additionally, each RCA cell from the microstructure evolution model is associated with a single FE integration point (Fig. **2**). Therefore, coordinates of integration points, their displacements and equivalent plastic stresses are transferred from the FE to RCA models in each time step. The described coupling between RCA with the FE model carries the risk that some areas of the material may not be discretized with the correct number of cells, and it can influence the final results. Proper initial FE mesh discretization and remeshing operations should overcome this issue. The RCA model presented in this work can easily incorporate changes introduced by FE remeshing algorithm.

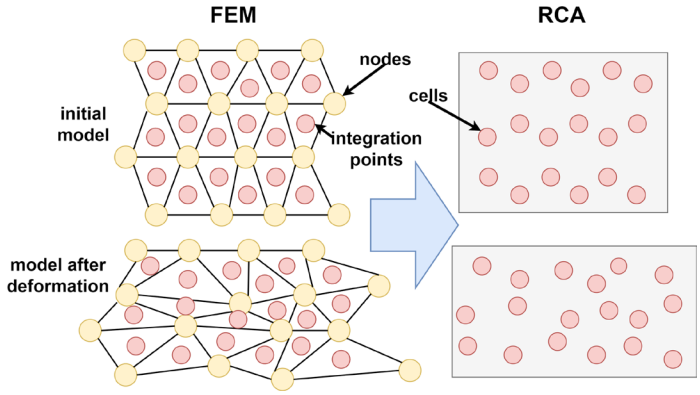

Fig. 2. Transformation of integration points into RCA cells.

In general, the simulation in such a coupled RCAFE model consists of several steps. A the beginning of each iteration, cells in the RCA space are translated based on corresponding integration points coordinates in the FE model. After that, dislocations in each cell are evaluated based on the stress value from Abaqus software:

$$\overline{\rho} = \frac{1}{\rho_0}\left(\frac{\sigma_i}{a_6 G b}\right)^2 \tag{1}$$

where: G is the shear modulus, σ_i is the equivalent stress value calculated by the Abaqus, a_6 is the model constant, b is the magnitude of the Burgers vector, and ρ_0 is the initial dislocation density. When the critical value of dislocation density is reached, new nuclei are incorporated into RCA space with the nucleation rate described by:

$$\dot{N} = c\dot{\varepsilon}\exp\left(-\frac{Q_n}{RT}\right) \tag{2}$$

where: c is constant, $\dot{\varepsilon}$ is the strain rate, Q_n is the activation energy for nucleation, T is the temperature, and R is the universal gas constant.
Finally, in each time step, the cell changes its state from unrecrystallised to recrystallised based on its size and growth velocity value calculated as:

$$V = M_0 \exp\left(-\frac{Q_m}{RT}\right) 2\alpha\tau\left(\rho_{(k,l)} - \rho_{(i,j)}\right) \tag{3}$$

where: M_0 is the initial grain boundary mobility, Q_m is the activation energy for grain boundary motion, α is a coefficient from the range (0,1), $\rho_{(k,l)}$ - dislocation density in the analysed and neighbouring cell, and τ is the energy required for dislocation movement.

The flow of the simulation in such a basic version of the DRX model is presented in Fig. 3.

Materials Research Proceedings 28 (2023) 1559-1564 https://doi.org/10.21741/9781644902479-168

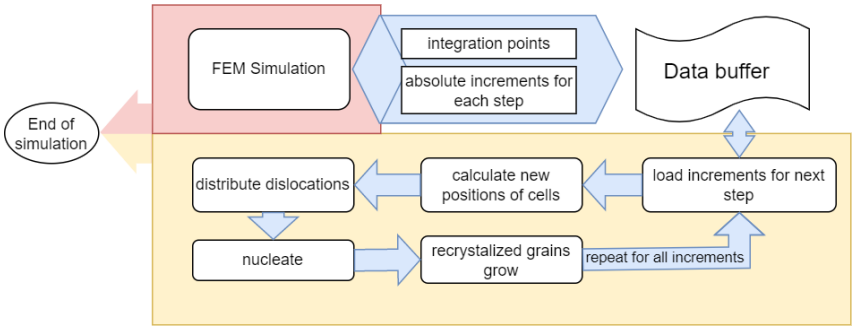

Fig. 3. Flow of implemented DRX simulation process.

Initial research on this topic clearly pointed out that the major disadvantage of the coupled RCAFE solution is the excessive computational time. The improvements in the RCA code itself, related to designing specific neighbourhood types and neighbourhood search algorithms, have already been carried out in [15]. Therefore, the current research is directly focused on further optimising the algorithmic solution to increase the model efficiency, particularly developing effective data transfer mechanisms between the RCA and FE methods.

Results

A two-dimensional digital material representation (DMR) model consisting of six grains discretised by 50 000 elements was selected as a case study for the current research (Fig. 4). The DMR model was deformed by 30% at 1100°C within the FE framework. In each FE element time step, the data from FE integration points were directly transferred to the corresponding RCA points, where the progress of dynamic recrystallisation was simulated within the in-house code.

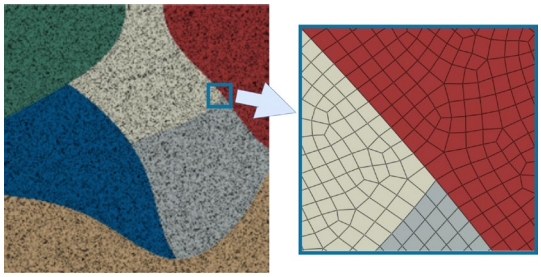

Fig. 4. Illustration of the DMR model used for the FE simulations.

Obtained microstructure evolution results in the RCA computational domain are presented in Fig. 5; blue cells represent unrecrystallised grains, and cells in the red-scale colours represent new, recrystallised ones. It is seen that nucleation starts from grain boundary regions, where higher dislocation densities are expected. The nuclei can also appear inside grains, but only after reaching significant deformation levels, which replicates well-known experimental observations. It should be clearly pointed out that despite the very small model used as a case study, the calculation time was quite long, reaching approx. 28 s. This time in the case of models with a larger number of grains and significantly refined FE mesh in 3D space, will lead to unacceptable simulation times. While the RCA simulation itself can be accelerated with the use of parallelisation techniques, the bottleneck of the coupled RCAFE solutions is transferring a large amount of data between the two models. In the evaluated case, the data transfer took about 30% of the entire simulation time.

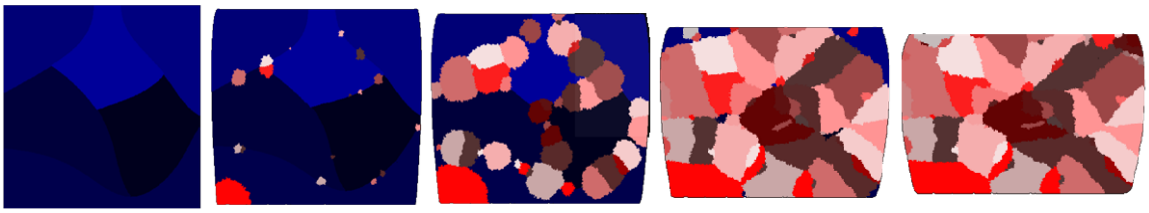

Fig. 5. The results of subsequent simulation steps for a model consisting of 50 000 elements.

As mentioned, the described technique should ultimately simulate much larger DMR models in 3D space. Therefore, as the first step, we decided to look at the possibility of reducing the time of data transfer. Two different methods of handling data transition from FE to RCA were implemented and compared. Both approaches differ in the format of the files stored in the buffer linking the two models. In the basic approach, data files from Abaqus with subsequent changes in stress values and positions of FE integration points were saved in a standard text form. In the second approach, files were saved and loaded in binary mode. The concept of communication between FE and RCA models is presented in Fig. 6.

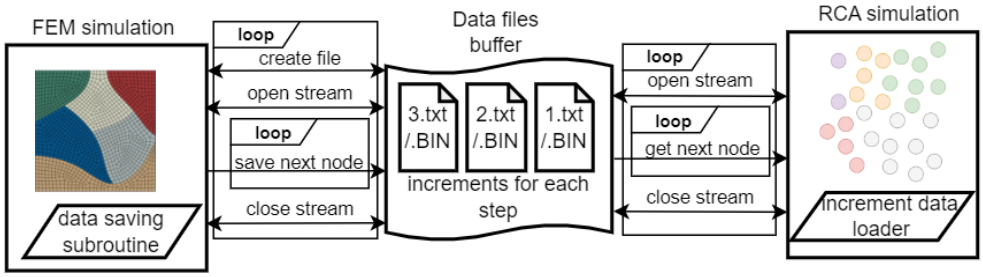

Fig. 6. Diagram of communication between FE and RCA models.

A series of simulations with increasing FE discretization levels was carried out to evaluate the differences between the two solutions. The summary of realised measurements shown in Fig. 7 proves that thanks to the application of binary files, it is possible to save up to 10% of the time for the largest model. Nevertheless, the time effort associated with the data transfer is still quite excessive in comparison to the pure simulation time.

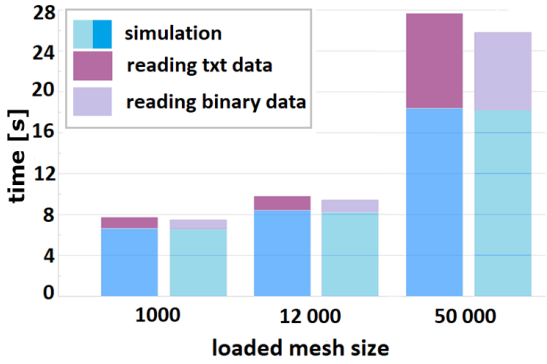

Fig. 7. Comparison of simulation and data transfer times for the text and binary files, respectively.

Summary

The use of the RCA concept allowed for the implementation of the DRX microstructure evolution model that, thanks to the flexibility of this solution, can be directly coupled with material

deformation data obtained from FE simulations. As a result, it is possible to take into account the influence of cellular automata space deformation on the progress of dynamic recrystallisation. At this research stage, the developed RCA DRX model considers only basic components like dislocation distribution, nucleation and dislocation density-driven grain growth and will be further developed. It was proven that in the coupled RCAFE simulation, the data transfer procedure between the commercial and in-house codes generates a major overhead in total simulation time. It was shown that the use of binary files could already speed up the analysis in comparison to the standard text files; however, further improvements in this aspect are also required. The further concept assumes direct information exchange inside subroutine code to eliminate the need for the files.

Keywords: Injection Moulding, Quality Prediction, Thermography

Abstract. The main purpose of this study is to control the visual quality in plastic injection moulding using an infrared camera after the ejection of the plastic part. Quality indicators have been extracted from the thermal image and from the data recorded by the sensors in the plastic injection machine and in the mould. After cooling, visual quality has been labelled by plastic experts based on 3 aesthetic defects: spot, flow line and streak mark. Three methods of reducing the dimension of the thermal image were studied: Quantiles, Principal Component Analysis (PCA), and Linear Discriminant Analysis (LDA). The visual quality can be predicted efficiently using dimension reduction of the image and Partial Least Square (PLS) regression. The PLS results allow to identify the root causes that explain the apparition of visual defects.

Introduction

The injection moulding process is one of the most used processes in the thermoplastic industry. It allows the manufacturing of parts having various shapes with low production time. The quality requirements of injected plastic parts are increasing to guarantee the final product functionality.

For this reason, quality control is widely used in this industry. Methods are often based on statistical grounds [1,[2] and multivariate analysis have been successfully used [3-[5]. In the past, neural networks coupled with fuzzy logic have shown to be efficient in predicting the quality from the parameter settings of the injection machine [6-[11].

However, these works were focused on the modelling of the injection process and have to target a dimensional quality or a weight. The visual quality is more difficult to characterize and to estimate quantitatively [12]. Existing inspection of defects in appearance relies mainly on manual visual inspection, which is neither efficient nor accurate enough to ensure the manufacturing quality. It is all the more difficult to estimate it on a plastic part right after its ejection since its appearance is not yet stabilized due to residual shrinkage.

To analyse the visual quality online, the most straightforward way to proceed is to take a picture of the plastic part right after the ejection, detect any anomaly and evaluate it in order to decide if the product should be accepted or rejected. Artificial Intelligence techniques to extract relevant information about the visual quality can be used. Since the part is still hot right after the ejection, a picture taken with an infrared camera can be a good candidate. Indeed, it has been shown in [13] that the image of the plastic part and its dimensional quality can be efficiently found by taking the hot part of the thermal image.

The most recent advances in this field were summarized in [14]. As noted in this review, studies have been mainly focused on the variation of the injection machine setting parameters. Nagorny [15] presents image analysis techniques based on neural network. It is very powerful to predict the visual quality of the part from the image but the method demands a large number of data to train the model.

In this paper, an alternative technique is introduced to handle the problem, based on dimensional reduction. It is assumed that the relevant information contained in the whole thermal image can be efficiently summarized in a small numbers of components obtained by dimensional reduction.

These components are used as inputs of a machine learning algorithm to predict the visual quality. The good results obtained with this prediction justify our assumption that the thermal image can be summarized in a few components.

This paper is organized as follows: first, the methodology of our work is explained. Secondly, the experimental setup of the work is presented. Next, the different quality criteria used to estimate the visual quality is discussed. Finally, the main results are shown and compared, and the best results are detailed in the last section.

Methods

Our approach is based on the use of dimensional reduction of the image to extract the relevant information in an automatic way.

After different attempts, two dimensional reduction methods were selected: the first one is Principal Component Analysis (PCA), which is well known in data analysis and consists in looking for the axes in the space of variables, which carry the greatest inertia. The second one is Linear Discriminant Analysis (LDA), where best representative axes are looked for taking into account the target quality to be predicted. LDA is also target oriented, since it takes into account the quality we want to predict. For this reason, LDA is expected to be more efficient. This better efficiency will be checked in the results. In this work, both of these methods are implemented using the Scikit-learn package [16] in Python [17].

These two methods provide us with components of the image ranked by decreasing order of importance. Concerning the choice of the number of components to be kept, different ways to proceed exist, but none of them has ever emerged. For this reason, the simplest method, which also seems to be the most reliable, is used [18]. This method consists in plotting the explained variance with respect to the number of components. In the obtained curve, the last inflexion point before the explained variance tends to be constant and vanishing, which gives the number of components, looked for. For instance, we keep components 0, 1, 2 and 3 in Fig. 1 below.

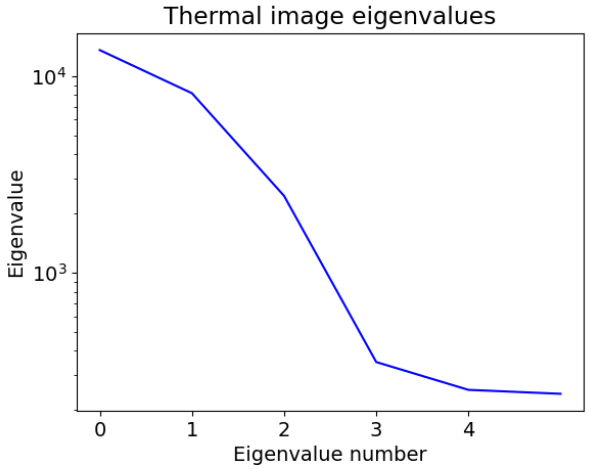

Fig. 1. Illustration of the method to choose the number of thermal image components.

To exhibit the interest of such dimension reduction methods, some quantiles of the thermal image are also computed and used in a way similar to what was done with the dimensional reduction components.

After having selected the correct number of components of the image, the next step is to use them to predict the visual quality. Since this work aims to compare the predictive power of the thermal image indicators and more classical indicators of the process, thermal image indicators and indicators given by sensors in the machine (partially from [19]) are placed in the same dataset. Prediction was then carried out using PLS (Partial Least Square) regression. This regression is

similar to an ordinary multilinear regression but is adapted to non-orthogonal input data, which is indeed the case here.

Among the results of this PLS regression, the ranking of all the input variables is shown according to their power to predict the target visual quality. This will also allow us to compare them for this goal, and to show the importance of the thermal image.

Lastly, PLS regression allows making a detailed analysis of the prediction mechanism, which leads to an interpretation of the results in terms of physical root causes. Indeed, PLS regression defines intermediate latent variables, called PLS components, which are orthogonal with each other and which are the basis for an ordinary multilinear regression. These PLS components are computed through a rigorous algorithm, and their number is fixed by prediction tests. The user has no choice to make for these prediction tests that makes the whole process very rigorous. These PLS components can be interpreted as root causes for the output variable we try to predict. PLS regression was performed using the plsRglm package [20-23].

Experimental Setup

A Billion 200T H150/470-200 plastic injection moulding machine was used for the experiments. The plastic material chosen for all the experiments was a black polypropylene "ExonMobil EXXTRAL CMU201" which is often used in the automotive industry. The plastic part was produced by an experimental mould chosen for simplicity to define quality criteria. The plastic part is shown in Fig. 2 below. Its dimensions are approximately 100×100×50 mm.

Fig. 2. Plastic part.

A Staubli robot arm takes the part out of the mould at the ejection and puts it in front of an Optris thermal camera sensitive in a wavelength range from 7.5 to 13 micrometres. For our purpose, it is enough to use the bare thermal camera image. The elapsed time between the mould opening and the image capture was constant and equal to 10 seconds.

The thermal camera picture was reshaped to isolate the plastic part from the background, especially the reflection from the robot arm. This reshaping has been performed using K-Means clustering and DBSCAN algorithm [16] in Python. This is made easy by the fact that the plastic part and the background are clearly separated on the statistical distribution of the pixels. An example of an obtained picture is shown in Fig 3. below. As can be seen on the left, the hot part is limited to the centre near the injection point and the extremity of the plastic part are the parts that have cooled down the quickest. On the right, the cumulative distribution function shows the proportion of pixels below a given temperature: this allows the easy determination of quantiles as the abscissa corresponding to a given ordinate in this curve.

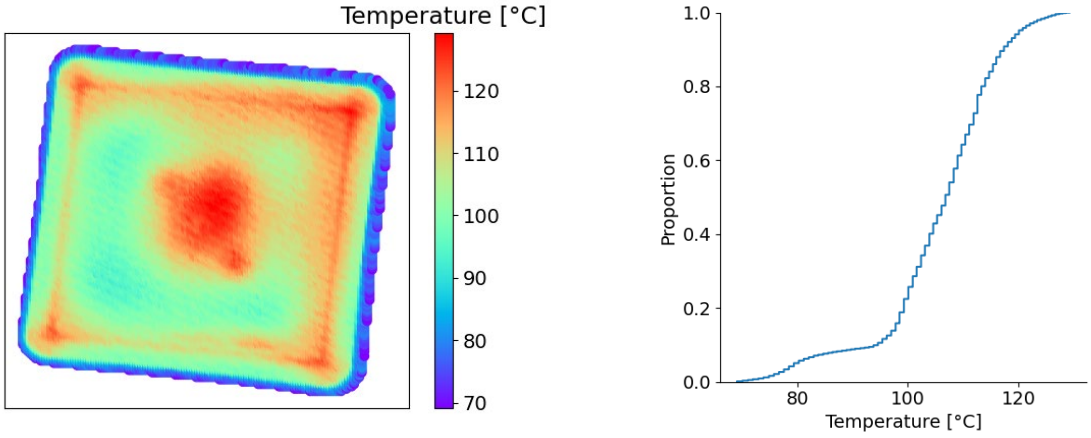

Fig. 3. Reshaped thermal camera picture (left) and empirical cumulative distribution function (right).

The dataset was produced using a L12 Plackett-Burman Design of Experiments [18]. The 11 setting parameters of the injection machine are listed in Table 1 below (together with their minimum and maximum value in this DoE), and have been chosen to ensure repeatability and automatic inline control.

Table 1. Setting parameters for the DoE.

Setting parameters	Minimum	Maximum
Clamping force	100 t	200 t
Injection stroke	80 cm^3	86 cm^3
Injection speed	50 cm^3/s	90 cm^3/s
Holding pressure	100 bars	300 bars
Controller temperature	20 °C	60 °C
Dosing delay	1 s	10 s
Screw speed	50 tr/min	150 tr/min
Barrel Temperature	220 °C	260 °C
Feeding stroke	90 cm^3	110 cm^3
Opening speed	100 mm/s	120 mm/s
Back Pressure	30 bars	70 bars

Since the thermal picture cannot vary directly, this DoE on the machine parameter setting paramters is the best way to get enough variance on the thermal pictures to be able to build a reliable statistical model to predict the visual quality.

Measurements

Once produced, the plastic parts are cooled down and plastic experts evaluate their quality 2 days later. This delay ensures that the plastic part has fully stabilized. A label is given, ranging from one (perfect) to 10 (the worse), for each of the three following criteria:

1) The presence of spots or sink marks, which come from concave zones in the part and indicate that not enough material has been injected during the holding phase to compensate for the shrinkage. This is because the holding phase was not sufficient.
2) The presence of flow lines (run-out), which come from an excessively large opening time of the mould. While the mould is open, a residual pressure exists in the nozzle that makes

the plastic material flow into the opened mould. If the opening time is long, a drop of cold material is formed and then crushed by the mould when it closes. In the subsequent process, it forms on the final part a mark around the injection point when surrounded by new material.

3) The presence of streaks around the injection point. When the plastic material is not sufficiently dried before being injected, residual humidity forms water droplets in the part around the injection point, that are visible as white marks in the part.

Finally, a total visual quality is computed as the product of the three qualities defined just above.

Overview of Results

As explained in the previous section, quantiles or dimensional reduction components from the thermal image are extracted, and concatenated to the indicators. A PLS regression is performed in order to predict a visual quality. This is done for Spots quality, Flow lines quality, Streaks quality and Total visual quality. For each quality, a separate PLS regression model is computed. Quality of the prediction is given by R2 (usual measure of quality in regression), which measures the ratio of the variance explained by regression divided by the total variance. Results are given in Table 2 below.

Table 2. Obtained R2 as a function of the considered quality and the input data.

Data Set	Spots quality	Flow lines quality	Streaks quality	Total visual quality
indicators and quantiles of the thermal image	0.780	0.647	0.148	0.349
indicators and principal components of the thermal image	0.839	0.764	0.349	0.343
indicators and LDA components of the thermal image	0.919	0.950	0.830	0.400

As can be seen from Table 2, a much more powerful way to predict the visual quality is to use the dimensional reduction instead of using only quantiles from the thermal image. In fact, R2 is better for each quality in the last two lines of Table 2 rather than in the first one, which concerns quantiles. For each quality, Table 2 shows that the best R2 result is obtained for LDA reduction. This is expected, since LDA reduction computes the components taking into account the target quality, which is not the case with the other dimension reduction methods.

In the last column of Table 2, it is noticed that the prediction performance of the total visual quality remains poor (R2=0.4) whatever the dimensional reduction of the thermal image is. This is because the total visual quality is the product of the three basic qualities (spots, flow lines and streaks). This product has great uncertainty compared to the uncertainties of the basic qualities since some values of the basic qualities can be important. This makes the total visual quality more difficult to predict.

Detailed Results

As seen in Table 2 above, LDA dimensional reduction provides the best regression. In this section, these results are analysed using the interpretation allowed by PLS regression.

Spots quality.

With the criterion of the inflexion point in the explained variance (see section “Methods”), six LDA components are kept. Main standardized coefficients (i.e. those greater than 0.1 in absolute value) of the PLS regression for spots quality prediction are given in Table 3 below.

Table 3. Main standardized coefficients for spots quality prediction.

Variable	Standardized Coefficient
First LDA component	0.259
Viscosity during the holding phase	0.241
Third LDA component	0.202
Mould viscosity during the holding phase	0.180
(…)	(…)
Second LDA component	-0.275

This table shows that the thermal image summarized by LDA component is highly relevant to explain spots quality: the interpretation of each LDA component is not available, but it can be noticed that the highest positive coefficient is held by the first LDA component and the smallest negative coefficient is held by the second LDA component. Since they are the most important LDA components, they are connected to the global homogeneity of the image and spots are connected with visual defects that have an importance on the global scale. This is expected from a visual inspection of the plastic parts.

Moreover, spots are due to a lack of material caused by an insufficient holding. In Table 3, it is found that a high viscosity in the holding phase, in the machine and in the mould, increases the spots quality. The viscosity is computed as the pressure integral in the holding phase. So Table 3 says that having a high pressure during holding increases the spots quality, that is what is expected from the definition of spots (sink marks) in section “Measurements”.

In the next table, such an interpretation is examined to identify the root causes of the spots quality in a more detailed way than with the standardized coefficients (Table 3). For the spots quality, the algorithm tells us to keep 4 PLS components.

The root causes to improve the spots quality provided by PLS components are summarized in Table 4 below. To keep the paper brief, we shall skip the detailed analysis and the justification of these results.

Table 4. Summary of PLS component interpretation for spots quality.

PLS component	Interpretation
1	Increase the pressure integral during the holding phase
2	Same as 1, plus increase the volume of polymer available for injection; also look at the thermal image in detail
3	Analyse the thermal image
4	Same as 3

Flow lines quality.

With the criterion of the inflexion point in the explained variance (see section “Methods”), 6 LDA components are kept. Main standardized coefficients (i.e. those greater than 0.1 in absolute value) are shown in Table 5 below.

Table 5. Main standardized coefficients for the flow lines quality prediction.

Variable	Coefficient
First LDA component	0.659
Fifth LDA component	0.149
Injected volume during the dynamic phase	0.106
(…)	(…)
Third LDA component	-0.109
Fourth LDA component	-0.121
Viscosity during the holding phase	-0.159
Viscosity during the dynamic phase	-0.196
Second LDA component	-0.307

The Table 5 shows that the standardized coefficients are clearly dominated by the thermal image and, in particular, the first and second LDA components. This shows that flow lines are visible on a global scale on the thermal image, and so that the thermal image is very relevant to explain the presence of flow lines (the LDA components have been calculated with respect to the flow lines quality, and have also changed compared to the spots quality case). Compared with the spots quality, it is noticed that the viscosity in the holding and dynamical phase acts negatively this time. Indeed, to have a good flow lines quality, the residual pressure after mould opening must be low, that is easier if the pressure imposed during the injection and the holding has been low (see section "Measurements" for physical causes).

Statistical tests on prediction power indicate to keep 4 PLS components. The root causes obtained for the interpretation of the four PLS component are summarized in Table 6 below.

Table 6. Summary of PLS component interpretation for flow lines quality.

PLS component	Interpretation
1	Inject the polymer early and not during the holding phase right before the mould opening, which may cause some flow of the polymer in the opened mould
2	Cool down the plastic part efficiently to avoid flow lines, which means that an efficient cooling must solidify the sprue
3	Inject a large quantity of polymer for the residual quantity of polymer in the machine to become low, and to have a low residual pressure
4	Inject all the available polymer volume, so there remains nothing to flow in the mould during mould opening

Streaks quality.

With the criterion of the inflexion point in the explained variance (see section "Methods"), we keep 4 LDA components. Main standardized coefficients (i.e. those greater than 0.05 in absolute value) are shown in Table 7 below.

Table 7. Main standardized coefficients for the streaks quality prediction.

Variable	Coefficient
First LDA component	0.831
Viscosity during the dynamic phase	0.095
Thermal controller mean flow rate	0.076
Fourth LDA component	0.072
(…)	(…)
Third LDA component	-0.055
End of feeding time	-0.069

What is visible in this Table 7 is that almost everything is explained by the first LDA component. For consistency with other analysed qualities, we look also at the PLS components. Statistical tests on prediction power tell to keep 4 PLS components.

The interpretation of the four PLS component as root causes are summarized in Table 8 below.

Table 8. Summary of the PLS component interpretation for streaks quality.

PLS component	Interpretation
1	Lower the polymer temperature at all stages to avoid the formation of water vapour bubbles
2	Increase the pressure during the holding phase to avoid droplets to form.
3	Augment the pressure drop in the nozzle to avoid shear in the mould (which causes heating and formation of water vapour bubbles)
4	Decrease pressure and injected volume during the holding phase, which decreases the shear in the mould and so the polymer heating.

Total visual quality.

The PLS regression leads to a R2 equal to 0.4, which is too small for the interpretation of the coefficients to be possible.

Summary

In this paper, the visual quality prediction of injected plastic boxes based on dimensional reduction is studied. Three methods of reducing the dimension of the thermal image are studied: quantiles, Principal Component Analysis (PCA), and Linear Discriminant Analysis (LDA). The prediction of the quality marks is achieved from a dataset gathering dimensional reduction and from indicators calculated from the machine and mould sensors. The best results are obtained with the LDA dimensional reduction whose interpretation enable to define root causes explaining the phenomena.

The presented work shows that the dimensional reduction method is validated and is a much simpler alternative for visual quality prediction than neural networks, which demand a huge amount of data. The statistical analysis interpretation shows also that it is possible to refine human experts' evaluation and knowledge, to evaluate their notation and can help ~~to~~ define a human evaluation procedure.

Keywords: Rolling Simulation, PyRolL, Monte Carlo Method, Process Variations

Abstract. Rolling simulation, especially for groove rolling, is heavily dominated by use of finite element methods, but simulating a full pass sequence often takes several hours. Simpler models offer high-speed simulation within seconds at the expense of resolution and accuracy. In mechanical engineering, Monte-Carlo approaches are well known for analysis of fabrication tolerances in component assembly. By usage of fast simulation cores, this technique becomes available for analysis of process variations in groove rolling, since computational costs are crucial due to the need of hundreds or thousands of simulation runs. Rolling process variations can be classified in two groups: first, variations of the input material, such as actual dimensions, temperature and microstructure state; second variations occurring during processing, such as transport times, environment temperature and tool wear. The regarded process was the operation of the experimental semi-continuous rolling plant at the Institute of Metal Forming (IMF). Simulations were carried out by use of the open source rolling framework PyRolL, developed at IMF. The main part of process parameters was considered as constant, but some were described as a statistical distribution. For each simulation run a set of actual sample values of the distributed parameters was drawn using a random number generator. Selected result values were described by use of statistical methods to analyze the variational behavior of the process in behalf of the two variation classes.

Introduction

The term Monte Carlo Method (MCM) generally refers to a class of methods, which are characterized by the use of random numbers. These methods are rather diverse and serve different purposes. Here, the term shall be used for the concept of drawing random numbers as input for a function and analysing the results of several evaluations of this function, with different random inputs, with statistical methods. A detailed overview on this type of Monte Carlo methods is given by Lemieux [1]. The nature of the function can be complex, even of a black-box type, where nothing about the internals of the function is known but the input and output interfaces. In this case, Monte Carlo methods can provide valuable information about the behavior of the function while altering inputs.

Here, the function equals the simulation procedure, so it is generally known, but complex. For example, it is generally not possible, to compute derivatives of the outputs in dependence on the inputs in an analytical way. Even numerical derivation is hard, due to the multi-dimensional nature of most natural or technical systems.

The use of Monte Carlo methods for the analysis of variations in technical processes was reported before in the field of assembly of complex structures, like in mechanical engineering and building construction (f.e. [2-7]). However, in the field of rolling processes, there was no such attempt yet to the knowledge of the authors. The authors have previously used a similar approach to model powder morphology influences in sintering processes [8, 9]. The current work shall show

the possibility of the application of Monte Carlo methods for the analysis of process variations in rolling processes. The focus lies hereby on the estimation of the workpiece temperature evolution. The temperature evolution is crucial for the microstructure development of the workpiece, which shall be investigated in a following work. The influence of variations in the initial workpiece and within the regarded process route is analysed and evaluated. Due to the need of a large number of function evaluations (simulation runs), the evaluation speed of the process model is crucial to the applicability of this approach.

Rolling simulation is currently dominated by the use of finite element (FE) based models. These are offering high accuracy and high resolution results at the expense of high computational resource usage. So, these methods are inconvenient for the current need. Therefore, one-dimensional approaches shall be used here. These offer less accuracy and limited resolution, but are computable within fractions of seconds on typical personal computer systems. The current work is based on the open-source rolling simulation framework PyRolL [10], developed by the authors, which is a fast, open and flexible software package mainly aimed at groove rolling in reduction passes. The models used for the different parts of the problem can be exchanged and extended with low effort to the user's needs.

Method

The Institute of Metal Forming operates a semi-continuous pilot rolling plant, which is the object of the current investigation. It consists of a two-high reversing roughing stand and four continuous finishing stands. The pass schedule of the current work consists of 10 oval-round reversing passes followed by 4 oval-round continuous finishing passes. A 50 mm round workpiece made of a mild structural steel is rolled down to 8 mm diameter. Details of the schedule are provided in the supplemental material [11], as the exact properties of the pass schedule are of minor importance for the statements of this work.

Monte Carlo Approach.

The basic idea of the approach shown here is to simulate the rolling process several times with different input values, which are drawn by a random number generator according to predefined statistical distributions. Afterwards, the distribution of the results can be analysed by classic methods of descriptive statistics to obtain information about the process' variational behavior. The principle is shown in Fig. 1.

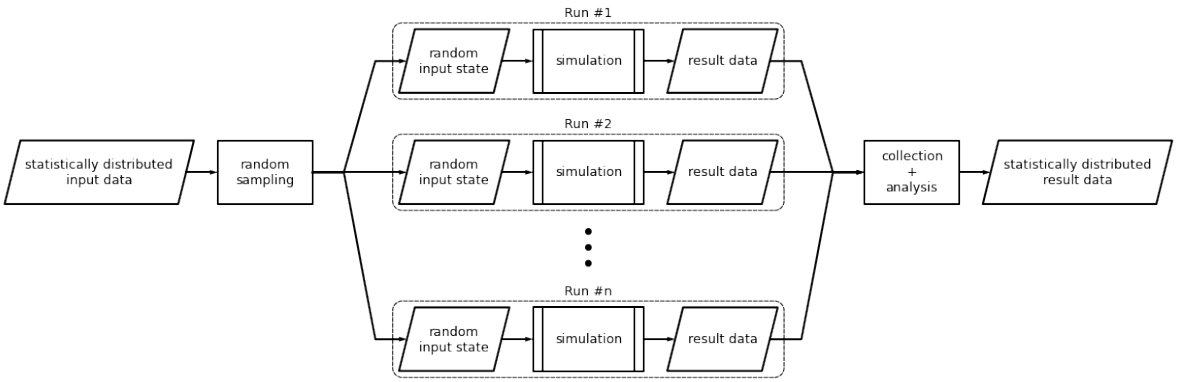

Fig. 1. Chart of the Concept of Variation Estimation Using Monte Carlo Techniques.

This approach provides information about the overall variational behavior of the process. If a single source of variation is introduced in the input, the reaction of the process on this variable can be analysed. The count of variation sources introduced is generally unbounded. The tracing back of result variations to the input can be done using classic correlation methods of descriptive statistics, however, with the same typical caveats. The main benefit of the approach is, that no information about the internals of the simulation procedure is needed for variational analysis,

especially there is no need for derivatives of result values in dependence on the input. The simulation procedure can generally be treated as black box with defined input and output interfaces.

The key problem is to obtain data describing the variations of the input variables. In this work two showcases shall be regarded: first the variation of the initial workpiece in diameter and temperature, second the variation of the inter-pass durations between the reversing passes. This choice was taken, since two fundamentally different types of variation sources were suspected. First, sources in the initial workpiece, which are applied only once, but traverse the whole process line. Second, variations in the process itself, which affect the workpiece state in each process step anew.

The question of varying inter-pass durations is crucial for scientific experiments on microstructure evolution, but currently often neglected. Mostly, only flat durations between the reversing passes are included in the design calculations. Due to manual transport and feed of the workpiece to the following roll pass, the scheduled inter-pass durations are never realized in practice. Although, these deviations from the schedule influence the microstructure evolution of the sample, as well as the actual conditions in the roll passes. The current approach is aimed to help quantifying these deviations.

Data Acquisition.

The pilot plant at IMF is equipped with several measurement and data collection systems. Data from a number of rolling trials have been collected and analysed to obtain the inter-pass durations t between the reversing passes. The complete dataset and analysis routines are available in the supplemental material [11].

For the approximative description of the durations' distribution, a gamma distribution was used, which is a generalized exponential distribution. The probability density function (PDF) of the gamma distribution is defined as in Equation 1, where Γ is the gamma function and $\alpha > 0$ and $\beta > 0$ are parameters.

$$f(x) = \frac{\beta^{\alpha}}{\Gamma(\alpha)} x^{\alpha-1} \exp(-\beta x) \tag{1}$$

Since the gamma distribution is only defined for $x > 0$, but no inter-pass durations below a certain value occur due to technical restrictions, the distribution was modified by introducing a minimal inter-pass duration t_0 with $x = t - t_0$. So, there are three free parameters α, β and t_0 for fitting of the distribution function. The fitting was done using least squares optimization of the resulting PDF function on the density histogram of the data. Statistical analysis and model fitting were done by use of the SciPy [12] and Pandas [13, 14] software packages.

Core Simulation Procedure.

In the current work, the open-source rolling simulation framework PyRolL [10] was used to simulate the rolling process. Generally, the shown approach can be used with every rolling simulation software available, since the procedure does not depend on any internals of the simulation. A fast simulation approach, however, is favourable, since the simulation has to be done several, up to hundreds of, times. The models used here are of one-dimensional type, thus, they lack of resolution in other directions as the rolling direction and provide only limited accuracy, but at the benefit of high solution speed. They typically combine empirical approaches with simplified analytical solutions. PyRolL is designed to offer simple exchangeability of the used model approaches. The model set can be chosen in a modular way by loading plugin packages. The current simulation was done with the basic configuration of PyRolL, which includes the empirical roll force and torque model of Hensel and Spittel [15], an integral thermal model approach according to Hensel et al. [16], contact area estimation according to Zouhar [16] and roll flattening

according to Hitchcock and Trinks [18]. Spreading was simulated using the equivalent flat pass according to Lendl [19-21] in conjunction with the spreading equation of Wusatowski [22]. The calculation time of one simulation run is below 1 s on typical current desktop computer systems. Details of software construction and model equations are provided in the documentation of PyRolL [10].

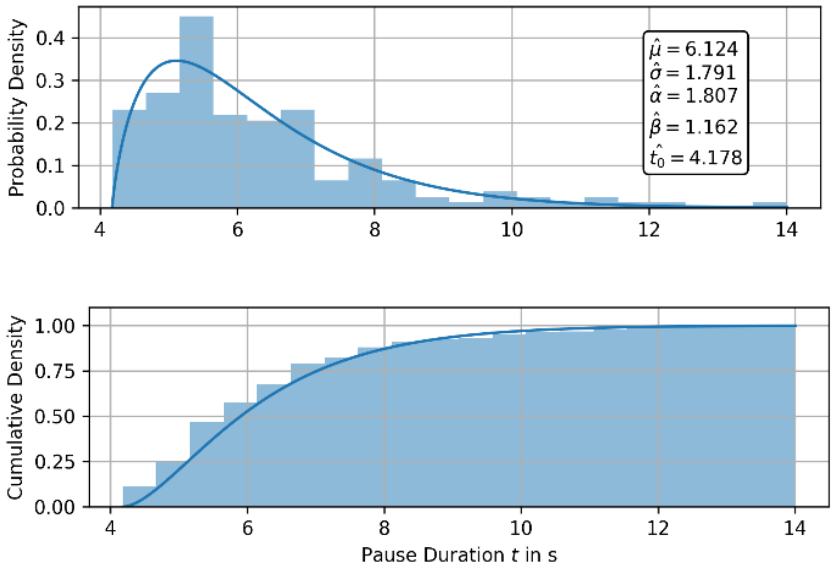

Fig. 2. Histograms of Inter-Pass Duration Between Roll Passes of the Reversing Mill.

Results

Inter-pass Durations For the analysis of the inter-pass durations a set of 29 rolling trials was analysed. The histograms of the obtained dataset are shown in Fig. 2 in conjunction with the fitted distribution parameters. The mean inter-pass duration was about $\mu(t) = 6.1$ s. The 90 % confidence interval is between 4.50 s and 9.32 s. Data points larger than 15 s were capped as outliers, since they occurred very rarely and are related to operational problems.

Simulation Showcases.

In the following, two showcases of the Monte Carlo approach described above shall be shown. For each case 100 sample conditions were drawn using a random number generator. The current analysis was limited to the aspect of temperature evolution as example for the possibilities of the method, although other key problems such as roll force and torque, spreading and filling, as well as elastic rolling stand behavior are included in the simulation core. The temperature evolution was selected, because it is the most vivid property of the process to show the importance of variation analysis. It influences directly and substantially the plastic material behavior and the evolution of the microstructure, while it is quite sensitive to most process conditions. More detailed data is included in the supplemental material [11].

The first showcase is the analysis of variations solely in the input workpiece. Exemplary, the diameter d of the round profile and the mean initial temperature T of the workpiece were chosen. Their variations were modelled using normal distributions with the nominal values as mean $\mu(d) = 50.0$ mm resp. $\mu(T) = 1373$ K and standard deviations of $\sigma(d) = 1.0$ mm resp. $\sigma(T) = 10$ K. The inter-pass durations were here chosen as an approximate constant of $t = 6.1$ s (corresponding to the mean inter-pass duration above) for the reversing passes, but were calculated directly from rolling velocity and distance for the continuous passes.

The resulting temperature evolution is shown in Fig. 3. The variations of the incoming and outgoing temperatures at each roll pass are plotted as boxplots in the respective positions. Two

line plots show the results of the simulation using only the nominal values and the mean curve of the Monte Carlo results. These were rather equivalent in this case. The variations of the simulation results tended to decrease along the pass schedule, compare also Fig. 5. In the continuous passes, the variations of the workpiece temperatures were rarely significant. This is in accordance to practical experience.

The second showcase is the consideration of the varying inter-pass durations during operation of the reversing mill due to manual feeding. The durations were drawn from the gamma distribution created above. The remaining parameters were the same as in the first case.

The resulting temperature distribution is shown in Fig. 4 similarly to the first case. The standard deviations of both cases are compared in Fig. 5. In contrast to the first case, the variations of the workpiece temperature are not decreasing along the pass schedule but in the finishing passes, since additional variation is introduced between each pass of the reversing mill. So the variation of the utput workpiece is higher than that of the input. Additionally, the mean of the Monte Carlo results tends to deviate from the nominal results, unlike the first case.

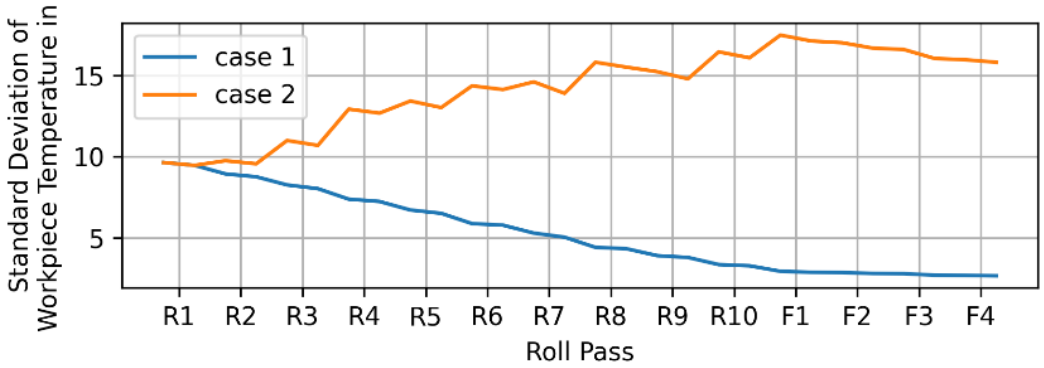

Fig. 3. Evolution of the Temperature Standard Deviation.

Summary

The current work showed the general applicability of Monte Carlo method based variation estimation techniques on the variational behavior of rolling processes. Two different kinds of variation sources in rolling processes were identified: first, variations in the input workpiece, second, variations within the process. They showed fundamentally different behavior. While variations in the input workpiece tend to vanish along the process, variations in the process itself accumulate and lead to high variations in the product. This leads to the conclusion, that the control of variations within the process is crucial in comparison to variations in the input material.

Especially in the case of manual feeding of a reversing mill, as common in pilot plants, this has to be kept in mind. It can be stated, that a well-controlled process should tend to decrease the variations of its input workpiece. These findings are in accordance to practical experience. In following work, the concept will be extended by the use of more advanced models within the simulation core. However, this has to be done always with the computational effort in mind, since the core simulation must be carried out up to hundreds of times. With the use of locally resolved models, estimations regarding the variation of local workpiece state can be carried out. Especially in terms of microstructure evolution, this would be a valuable contribution to the interpretation of

experimental results. In the future, this approach can help to identify sources of variations within a process and evaluate their influence on the resulting output variations.

A key is the acquisition of a statistical description of the process parameters. A first estimate can be given by a normal distribution with a certain standard variation around the nominal parameter value. For more accurate results, the collection of data in the running process may be appropriate, as was shown for the inter-pass durations. The method's reliability is dependent on both, the accuracy of the simulation models and the statistical parameter description.

Keywords: Incremental Bulk Forming, Flow Forming, Meshing, Coarse Meshing

Abstract. Flow forming is an incremental bulk forming process used to produce tubular components from high-strength alloys. One of the features complicating its modelling is the small contact area of the workpiece with the tools. Taken along with cyclic non-monotonic loading from three rollers deforming the workpiece with complicated kinematics, this demands a very fine mesh and time step throughout the simulation. The typical approach of using a tetrahedral mesh with strain-based remeshing can introduce errors in the results due to the highly localized deformation and can also prolong the computation time. In the present study, in parallel to using tetrahedral mesh with remeshing, two different approaches of hexahedral mesh without any remeshing were also modelled for the workpiece, retaining all the other setup parameters, and the results compared. In both cases, local mesh adaptations were used to ensure a very fine mesh in the zone of contact with the rollers. Results from the simulations clearly showed that the key outputs such as stress state parameters (triaxiality and Lode stress parameters) and plastic strain values were very sensitive to the mesh and remeshing method used and careful consideration is required before employing the outputs for further analysis.

Introduction

Flow forming is an incremental bulk forming process employing two or three rollers that produce localized zones of deformation to manufacture near-net shape tubular components [1,2]. It is a flexible and effective method to produce parts from high-strength alloys with limited ductility at room temperature[3]. It is highly flexible as it affords the possibility of independent setting of up to seven process parameters (mandrel rotation speed, axial and radial displacement speeds of three independent rollers) as detailed in [4,5] and this enables different forming strategies depending on the material, component shape and machine capabilities. In addition, for large thickness reduction ratios of thick-walled workpieces with wall thinning of up to 80–90%, the process can be carried out in several passes [5,6].

However, the process is innately complex and deciding on a forming strategy or solving particular problems such as component fracture are not straight-forward. Finite-element (FE) modelling of the process can provide some much needed insight into the complicated process mechanics, but it is not without its fair share of complications, as detailed in the work of Bylya et al. [7]. One of the features of the flow forming process that complicates its modelling is the small contact area of the workpiece with the rollers. This circumstance imposes special requirements on the choice of the finite element mesh and the time step of the calculation. Consequently, the choice of mesh size and time step influences the output from the model considerably. The inaccuracy and errors resulting from the choice of mesh will impact further analysis such as fracture prediction

that uses the outputs from the simulation and therefore cannot be overlooked in the case of robust modelling required for industrial applications.

For finite deformations in bulk forming processes, typically, a tetrahedral mesh is employed in many commercial metal forming software and a strain-based remeshing algorithm is used to remesh the nodes and elements when the strain reaches a certain value, which can be set by the user. The remeshing is helpful to avoid distortion of meshes at very high strains and can be beneficial is most metal forming modelling for improving the accuracy of the model. However, in incremental bulk forming processes, such as flow forming, remeshing can introduce errors in the results due to highly localized deformation and can also prolong the computation time. The influence of mesh size and remeshing formulation has been reported in few earlier works [8,9]. The focus therein was limited to sensitivity analysis against a specific output value (von Mises stress) [9] or the differences between different formulation of the problem, i.e., Euler, Lagrangian or ALE[8]. In the present work, in parallel to the typical approach of using tetrahedral mesh with remeshing, alternative use of hexahedral mesh for the workpiece without any remeshing was also modelled, using the same Lagrangian formulation and retaining all the other setup parameters. The key output parameters from the models were analyzed and compared against actual experimental findings.

Experimental Data Used for Modelling

A relatively short process involving a single pass flow forming of Ti6Al4V tube of thickness 12 mm is taken for simulation and for comparison of the models. It was found experimentally with repeatability that Ti6Al4V preforms fractured before the roller reached a final depth of 9 mm (i.e., reduction of 3 mm (25%)). A finite-element simulation of the process will play a crucial role in understanding the reason behind the failure. Furthermore, owing to the short duration of the actual process prior to failure, i.e. 16 s, the process can be simulated completely using a full 3D elasto-plastic formulation and with fine mesh and time-step settings. A schematic of the process and process parameters used in the model setup are provided in Fig. 1 and the kinematics parameter used for the model setup are summarized in Table 1.

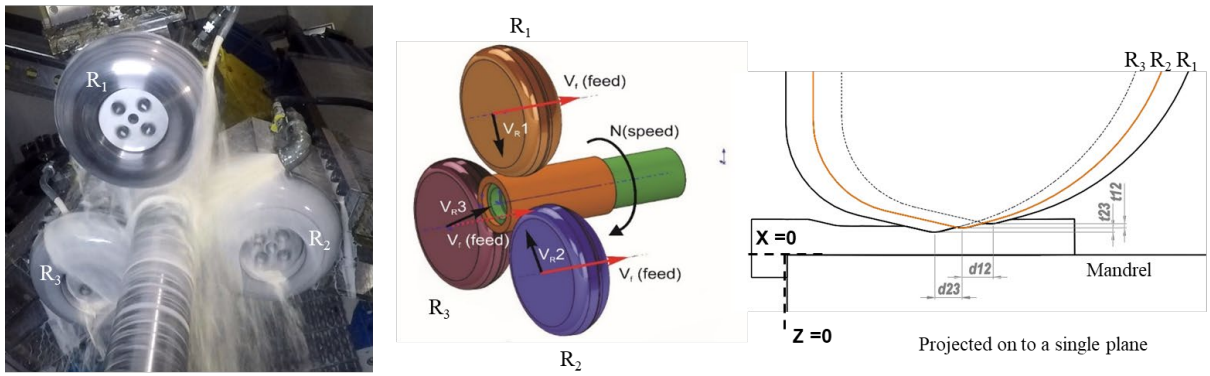

Fig. 1. Three-roller flow forming process - (a) capture of process carried out at AFRC, University of Strathclyde, (b) schematic of the process representing the main process parameters and (c) schematic showing the axial and radial positions of the three rollers when projected on to a single axial plane.

The rollers are located 120° apart in the circumferential direction as shown in Fig. 2 (a) and (b), with Roller 1 directly above the workpiece in what is designated as the vertical axis for the whole setup. The rollers are staggered both axially and radially. The total reduction is split between the rollers in such a way that Roller 1 has a bite of 1 mm, Roller 2 goes further deep with a radial

offset of 1 mm between Roller 1 and 2 (t_{12}) and Roller 3 goes even further deep with a radial offset of 1 mm between Roller 2 and 3 (t_{23}); in summary, the total bite of Roller 2 and Roller 3 are set to be 2 and 3 mm, respectively. In addition, Roller 2 trails behind Roller 1 by 4 mm (d_{12}), and Roller 3 trails behind Roller 2 by 4 mm (d_{23}) in the axial direction. When projected onto a single plane the roller offset will appear as shown in Fig. 2(c). A constant rotation speed of 150 RPM is prescribed to the mandrel and a tailstock is used to apply pressure across the face of the workpiece such that the workpiece rotates along with Mandrel without slipping. The rollers do not have their own spindle drives but rotate only due to the friction on contact with the workpiece.

Table 1. Summary of main process parameters used in experimental trials studied.

Speed, N [RPM]	Feed, V_f [mm/s]	Initial Thickness, t_0 [mm]	Final Thickness, t_f [mm]
150	1	12	9
Radial offset b/w Roller 1 and 2, t_{12} [mm]	Radial offset b/w Roller 2 and 3, t_{23} [mm]	Axial offset b/w Roller 1 and 2, d_{12} [mm]	Axial offset b/w Roller 2 and 3, d_{23} [mm]
1	1	4	4

Modelling Approach

To obtain a smooth deformation field when simulating the process, the roller must pass the contact zone in at least three time steps. The typical size of the contact spot according to experimental measurements for the case of the simulated process is approximately 9 × 16 mm, please refer to Fig. 2(a). With a workpiece rotation speed of 150 rpm and the external diameter of the part being 164 mm, the calculated time step should not exceed 4 ms. In order for at least 8–10 workpiece nodes to be in contact with the roller (blue dots in Figure 2a), the required size of the finite element mesh element should not exceed 2 mm; this is also necessary for the correct modelling of the plastic deformation gradient, and the resulting residual stresses, across the thickness of the workpiece (Fig. 2(b)). Furthermore, elastic deformation of the rest of the workpiece and secondary plastic deformation of the already deformed regions also play a crucial role, and therefore a relatively fine mesh is also required in regions that are in the vicinity of contact with rollers and also in already deformed regions.

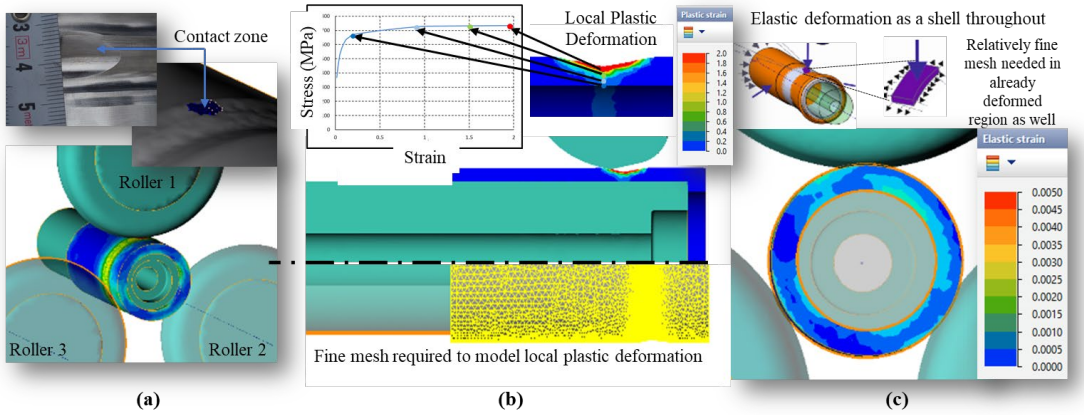

Fig. 2. Factors influencing the finite element mesh when modelling flow forming: a) small contact area between the workpiece and rollers (inset: measurement from experiment and that observed in FE simulation), b) local plastic deformation (showing the gradient of plastic strain along thickness), c) elastic deformation of workpiece as a shell throughout.

To analyze the influence of mesh settings, 3 different cases were simulated as shown in Fig. 3: Case I - default tetrahedral mesh with strain-based remeshing (Fig. 3 (b)); Case II – a coarse hexahedral mesh with less than 2 mm element size in the contact zone without remeshing through the process (Fig. 3 (c)); Case III - a finer hexahedral mesh with less than 1 mm element size in the whole deforming region of workpiece without remeshing through the process (Fig. 3 (d)). Only the first 16 s of the process leading to the fracture were simulated in each case. In Case I and II, a local mesh adaptation covering the expected contact zone with the three rollers through the process was used to refine the initial mesh to 1 mm and 2 mm, respectively. In regions outside the mesh adaptation, an average mesh sizes of 5-8 mm were used in both cases. In Case III, a fine mesh with average element size of 1 mm was used in the region covering the expected start of contact with rollers to the end of the workpiece as shown in Fig. 3 (d). The nose region in the rollers, which typically contact the workpiece, were also meshed fine as shown in Fig. 3 (a) to ensure proper contact area calculations.

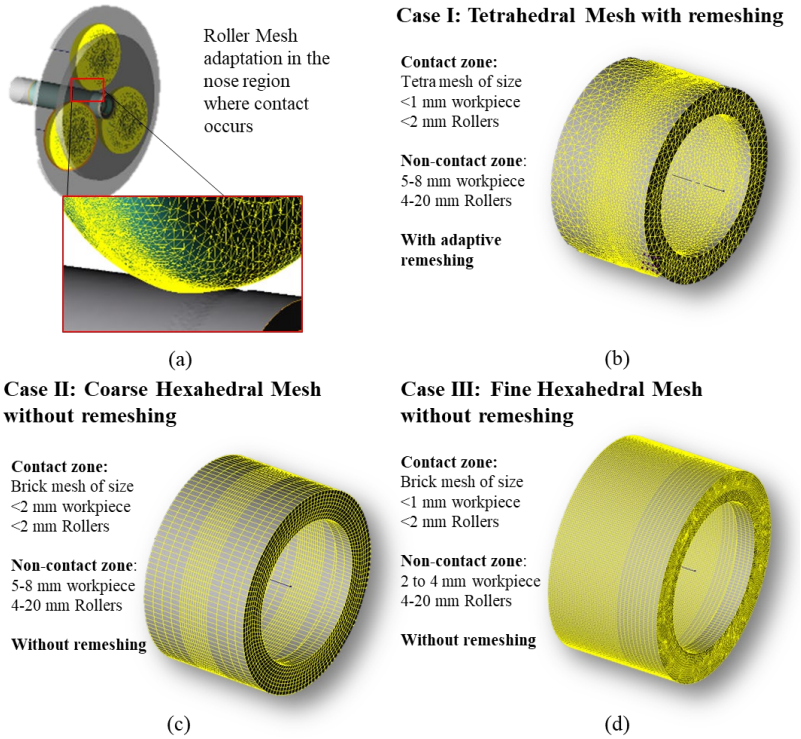

Fig. 3. Mesh settings used in the study – (a) Mesh adaptation used in the nose region for meshing of rollers to simulate accurate contact with workpiece; Workpiece mesh settings used in (b) Case I with tetragonal mesh and strain-based remeshing, (c) Case II with relatively coarse hexagonal mesh and without remeshing through process, and Case III with finer hexagonal mesh and without remeshing through process.

All the cases were simulated using commercial metal-forming software, QForm. The tool kinematics in the model setup were maintained as close to the real process as possible and were the same in all 3 cases. A full 3D elasto-plastic model with isotropic hardening material model obtained from room-temperature tensile tests carried out with the same batch of Ti6Al4V as used in the flow forming trials was used for the simulations. A constant timestep of 1 ms was used everywhere. The friction condition at mandrel and roller contact were maintained the same in all cases well. A low friction (Levanov friction factor of 0.2) and high friction (Levanov friction factor of 0.2) condition were specified at the workpiece interface with mandrel and rollers, respectively.

The temperature in the workpiece was observed to not rise beyond 50°C in experiments owing to strong coolant flow. Hence, the thermal simulation was neglected in all cases.

Results and Discussion

All three simulated cases showed reasonable agreement with roller reaction forces and final geometry observed in the experimental trials. In the experiments, it was observed that the fracture initiated on the inner surface of the workpiece in contact with the mandrel, as shown in Fig. 4(a). The trials were stopped at different instances and the fracture was identified to originate just under where roller 3 would be when it reached a depth of approx. 10 mm. Three points in the same axial plane at different depths along the thickness – Outer (surface), Mid (6 mm deep), and Inner (12 mm deep, in contact with mandrel) – corresponding to this section were identified in the simulations for further analysis, with Inner marking the location of fracture, as shown in Fig. 4(b). The same three points with exact XYZ coordinates in all three cases of simulation were tracked through the whole process, and the history of key output parameters, particularly accumulated plastic strain, triaxiality and Lode angle parameters, were traced. Furthermore, the timestamps of key events during the process, namely, Roller 1 Contact, Roller 2 Contact, Roller 3 Contact and the instance of fracture initiation with respect to the 3 identified points were recorded as shown in Fig. 4(c) and these were converted to mandrel revolutions for easy comparison.

A through-process comparison of the key output parameters from all 3 cases for the 3 identified points are presented in the following section:

Accumulated Plastic Strain.

Accumulated plastic strain or the Odquist parameter, calculated using Eq. 1 below, is an important representative scalar of the total strain path during the process and is often used in further calculations such as residual stress and fracture prediction.

$$\varepsilon^P = \int_0^t \dot{\bar{\varepsilon}}^p dt \tag{1}$$

Fig. 5 below shows a comparison of the history of accumulated plastic strain in the three cases simulated. As can be seen from Fig. 5(a), the ε^P in Case I exhibits kinks or jumps in values, which are absent in Case II and III. This can be attributed to the remeshing in Case I, wherein remeshing introduces errors in plastic strain value when remapping the calculated strain from previous time step to the newly generated mesh. Transportation of tensor values from old mesh to the new mesh poses considerable challenges and different software employ different assumptions to carry out this operation, and this introduces small errors during remapping. On repeating the operation for a few times in the case of large deformations, the errors become pronounced. This issue is not limited to QForm but is observed in other commercial FE software as well and is a challenge that warrants further in-depth study.

In addition to this, the calculated values for plastic strain in Outer and Mid points in Case I are considerably higher than those calculated in Case II and III. Given that the total reduction in thickness was 2 mm at failure, and the Mid point is 6 mm from the initial surface of the workpiece, the extremely high value of plastic strain, $\varepsilon^P = 2$, predicted for the point in Case I appears erroneous.

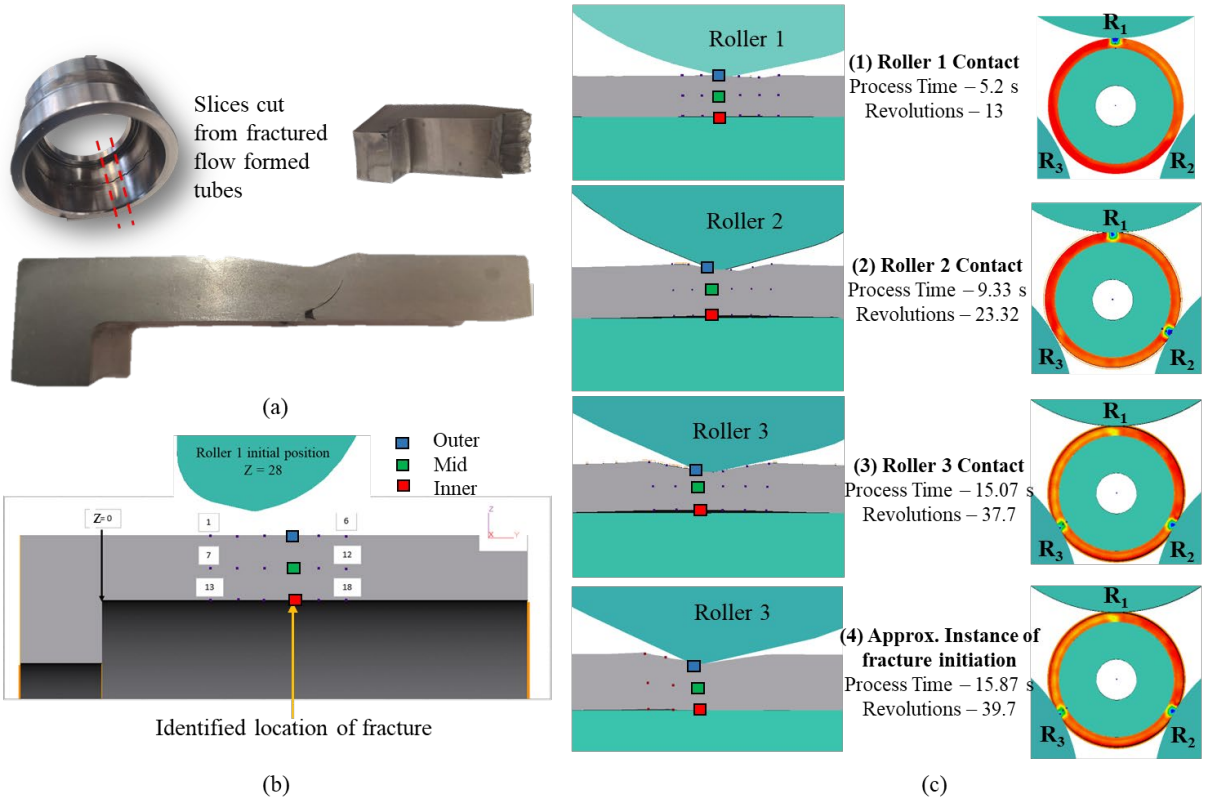

Fig. 4. Tools used for analysis of results – (a) fracture observed in experimental trials showing the location of fracture initiation, (b) points traced through the whole process in all three simulations, and (c) the timestamps of key events during the process, namely, Roller 1 Contact, Roller 2 Contact, Roller 3 Contact and instance of Fracture initiation w.r.t the points traced.

The ε^P values predicted in Case II and III appear more reliable. The difference observed in values between those calculated in Case II and Case III shows the sensitivity of the results to the mesh size used. Case III with a finer mesh can be expected to provide more accurate results in this case. Unfortunately, since the value of plastic strain cannot be directly measured but only inferred through other measurements and observations, novel calibration strategies are required to further validate the results, which are beyond the scope of this present work.

Stress-state Parameters.

Triaxiality and Lode angle parameters are important stress-state parameters that are most commonly used in fracture criteria [10, 11]. Triaxiality parameter (η), defined as the ratio of mean stress (σ_m) to equivalent or effective stress ($\bar{\sigma}$), as expressed in Eq. 2 below, is a useful parameter to represent the 3D stress-state in a point. A Triaxiality parameter of $\eta = -1/3$ represents purely uniaxial compressive stress, $\eta = 0$ represents pure shear, $\eta = 1/3$ represents purely uniaxial tensile stress and intermediate points represents a combined stress state in a point. Experimental investigation on fracture locus in Ti6Al4V show that the material is prone to fail under a tensile stress state earlier than in other conditions and $\eta >= 1/3$ are unsafe [12].

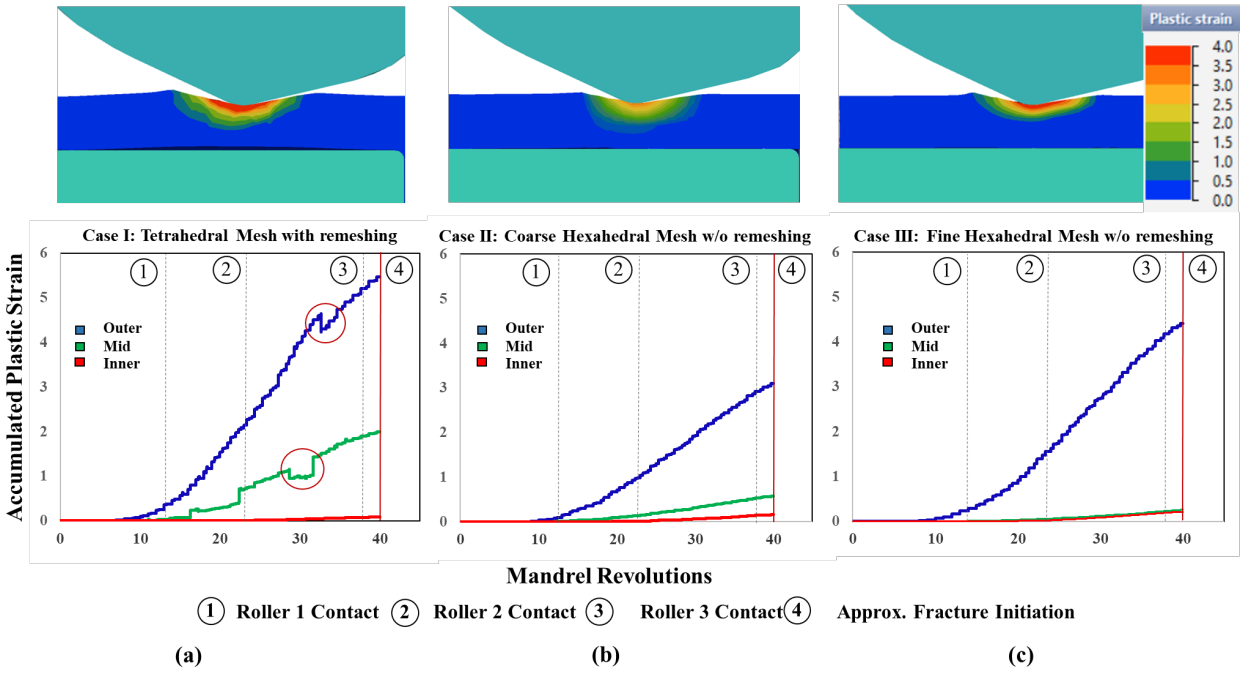

Fig. 5. Comparison of history of accumulated plastic strain in all 3 cases simulated: (a) Case I – tetrahedral mesh with remeshing, (b) Case II – Coarse hexahedral mesh, (c) Case III – fine hexahedral mesh. (Top inset: Plastic strain profile across thickness at the instance of fracture initiation in all 3 cases).

Looking at the fracture observed in flow formed Ti6Al4V tubes, the fracture appears on the inner surface where plastic strain is almost 0 and fracture surface was observed to be brittle and most probably resulted from the tensile stress state along the inner edge of the tubes directly under the rollers (refer to Fig. 6(a) and 6(b)).

$$\eta = \frac{\sigma_m}{\bar{\sigma}} \tag{2}$$

Fig. 6(c-e) shows a comparison of the history of triaxiality parameter for the same three points in all three cases studied. As can be observed, the history is considerably different in the three cases, and in Cases I and III employing a fine mesh, the deviations about the mean values are higher compared to Case II with a relatively coarser mesh. Case II and III using a Hexahedral Mesh show a trend with predominantly tensile stresses ($\eta = 1/3$) in the Inner point where fracture occurred and also in the Mid point in the initial stages closer to the contact with Roller 1. The stress state in the Mid point then transitions towards compressive stress ($\eta = -1/3$) as the reduction increases under Roller 2 and 3, which appears logical.

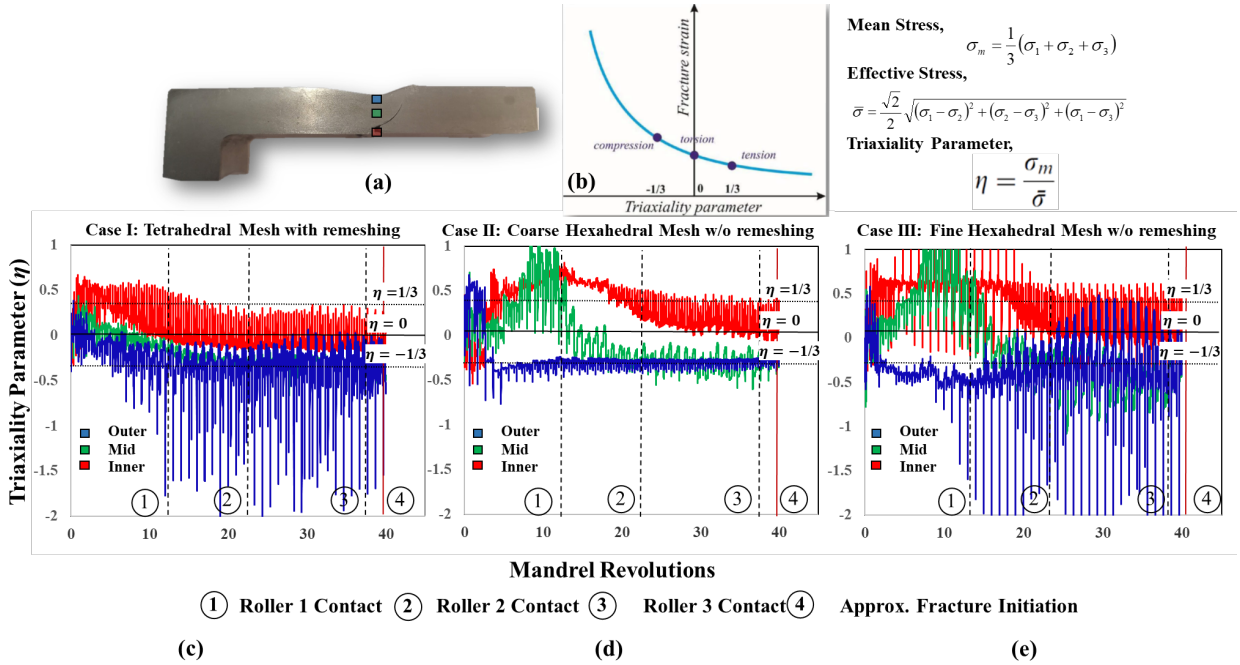

Fig. 6. Comparison of history of triaxiality parameter in all 3 cases simulated: (b) Case I – tetrahedral mesh with remeshing, (c) Case II – coarse hexahedral mesh, (d) Case III – fine hexahedral mesh. (Top inset: (a) Key: Location of points with respect to observed fracture, (b)) relationship between fracture strain and triaxiality parameter).

The duration from Roller 3 contact (Revolution 38) to the time of fracture initiation (Revolution 40) was examined further in-depth as shown in Fig. 7. The three peaks observed within a single revolution corresponds to the instant when the points are directly under the influence of the 3 rollers. As can be clearly seen in the figure, Case II and III predict tensile stresses in Inner Point, which correlates well with the main hypothesis that fracture originated in this location due to unsafe tensile stress-state prevalent at this point, while Case I does not. Case III predicts higher triaxiality and additional peaks, which warrants further investigation to be taken up in future work. Similar differences were observed in the case of Lode angle parameter as well but are not presented herein for brevity.

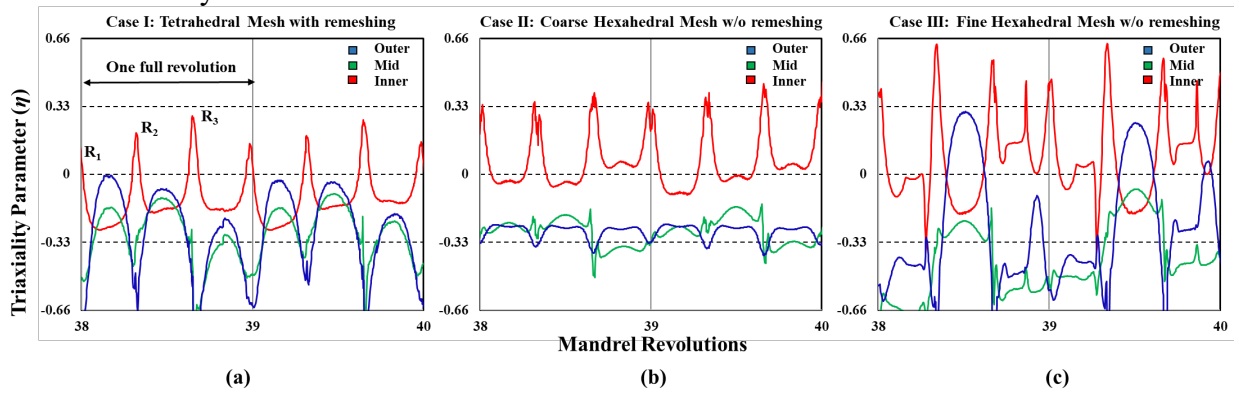

Fig. 7. In-depth comparison of history of triaxiality parameter in all 3 cases simulated in the last 2 revolutions leading up to fracture initiation.

Computation time.

The total simulation time for the three cases differed considerably and were – (i) Case I – 93 hr 24 min 48 s; (ii) Case II - 24 hr 17 min 59 s; (iii) Case III – 63 hr 49 min 13 s. It is understood that the total node count dictates the number of equations to be solved and directly influences the computation time. The total node count in the three cases simulated were - (i) Case I – 22525; (ii) Case II - 13806; (iii) Case III – 40956. As can be observed, the total simulation time in Case III was lower than that in Case I, despite having higher node count. This implies that remeshing is the chief time-consuming operation. Furthermore, in the case of hexahedral meshes, the absence of errors introduced by the remeshing operation could also lead to faster convergence of solution.

For the present case involving flow forming of Ti6Al4V tubes, hexahedral mesh appears to provide more reliable results. For cases involving large deformations and multiple passes of forming, distortion of mesh cannot be avoided without remeshing and appropriate strategies for restoring the mesh and more accurate methods for remapping the results to the restored mesh have to be investigated.

Summary

Flow forming an incremental bulk forming process with localized plastic deformations, owing to the process nature, imposes special requirements on the choice of finite element mesh and time step in simulations. Therefore, the results are highly sensitive to the mesh used. To gain a better understanding of the influence of mesh settings, 3 different cases were simulated herein - tetrahedral mesh with strain-based remeshing and two hexahedral mesh settings (relatively coarse and fine) without remeshing. A relatively short process involving a single pass flow forming of Ti6Al4V tube exhibiting fracture in the initial stages was used as the basis for model development and comparison.

- Although all cases modelled displayed comparable prediction of roller forces and output geometry, they exhibited stark differences in key output parameters, namely, accumulated plastic strain and triaxiality and Lode angle parameters that are used in critical analysis such as fracture prediction.
- For the process considered, hexahedral mesh without remeshing provided more reliable results in terms of accumulated plastic strain. Tetrahedral with remeshing provided erroneous plastic strain values in critical points in the workpiece and also introduced jumps in plastic strain history when remapping the calculated strain from previous time step to the newly generated mesh during remeshing. For short single pass flow forming, use of hexahedral mesh without remeshing is suggested as a reliable method. However, for cases involving large deformations and multiple passes of forming, distortion of mesh cannot be avoided without remeshing and more accurate methods for remapping the results during remeshing needs to be researched.
- Triaxiality and lode angle parameter from hexahedral mesh simulations without remeshing also indicate tensile stress state in the point of origin of failure, supporting the hypothesis that the fracture in question originated due to unsafe tensile stress state along the inner edge of the tube during roller penetration. The history of triaxiality and Lode angle parameters predicted using tetrahedral mesh simulation with remeshing exhibit a different trend to that observed in hexahedral mesh simulations. Before employing the results for particular problem solving such as fracture prediction, it is required to make sure that the results obtained are robust and trustable.
- Although the differences between the results are apparent and results from hexahedral mesh appear reliable when compared with experimental observation, further validation is required to improve trustworthiness of the results. Novel and intelligent validation techniques are required for this as these key output parameters are not readily measurable from experiments.

Keywords: Phase Field Fracture, Ductile Fracture, Finite Element Method

Abstract. A phase field model for ductile fracture is coupled with the Modified Mohr Coulomb (MMC) model for plastic damage evolution and subsequent crack growth. An energy-based damage threshold is applied to control degradation due to ductile damage. The model is implemented through a user subroutine. MMC parameters from the literature are utilized and found to be compatible with the model, accurately reproducing material response curves in a variety of loading conditions for 6016-T4 aluminum alloy. The influence of model parameters is demonstrated and additionally the Nakazima test is simulated to demonstrate the capability of the model predicting the formability of the material through a failure locus. The model is found capable of reproducing experimentally observed crack paths and quantitative material behavior.

Introduction

The phase field methodology has been applied to an increasing variety of fracture cases over the last few years. Based on Griffith's energy balance [1], the variational approach to fracture was developed by Francfort and Marigo [2], providing solutions to several limitations of the original theory. Bourdin et al. [3] regularized this approach through the introduction of a functional to describe the crack surface and this became the basis for the phase field model for brittle fracture, later formalized by Miehe et al. [4]. The framework is expanded to encompass more complex mechanisms such as dynamic crack growth (e.g. [5]), anisotropic crack growth (e.g. [6]) and fatigue crack growth (e.g. [7]) among many.

Adapting the phase field method to a ductile fracture framework involves the introduction of a plasticity related component in addition to the elastic energy density and fracture surface energy terms. The defining characteristic of the various models introduced in the literature is the coupling mechanism for plasticity. Duda et al. [8] opted to not couple the plastic damage with phase field evolution, leading to a model described as a brittle fracture model applied to an elastoplastic solid, with limited plastic deformation at the crack tip before failure. Ambati et al. [9] coupled their model by introducing a coupling term that acts through the degradation function. Models in [10,11] act through the introduction of a separate degradation function for the plastic dissipation term. It should be noted that the latter incorporates non-local plastic effects as well in their formulation. In a framework inspired by the phase field approach to fatigue, Yin et al. [12] degrade the fracture toughness through the accumulated plastic strain. To control the degradation over the material loading history, some models introduce a plastic damage threshold, where plastic damage influences the material response once this value is passed. Both plastic strain thresholds (e.g. [13]) and energy thresholds (e.g. [10]) have been employed in the literature.

The micromechanical mechanisms of ductile fracture demonstrate a high dependency on the stress state characterized by stress triaxiality and Lode parameter (see [14,15]). Ductile fracture models incorporating both parameters have been applied to numerical studies of metal forming (e.g. [16,17]). Recently, attempts have been made to incorporate these effects in ductile phase field models. Borden et al. [10] incorporate stress triaxiality through the addition of a section of the

Johnson-Cook damage model to the plastic damage accumulation. Li et al. [18] introduced a damage threshold that evolves with the modified Mohr Coulomb model (MMC). Vajari et al. [19] introduced a model that degrades the fracture toughness through the Stress-Weighted Ductile Fracture Model.

While most studies are focused on demonstrating the ability of various ductile models to recreate known crack paths from literature, quantitative studies accurately capturing the load-displacement response of the material remain limited. This study aims to simulate a ductile phase field model, capable of reproducing crack paths for various boundary value problems as well as the material response as accurately as possible. In the scope of this study, we introduce the MMC model to the plastic damage evolution, potentially allowing the model to accurately capture the material response in a broad range of loading conditions.

In this work, a non-linear J2 plasticity model is coupled with the phase field paradigm through coupled-temperature displacement elements, with temperature acting as the phase parameter. This is done by employed by exploiting a similarity between the phase field driving force and steady state heat transfer equation (see [20]). The in-built finite strain framework in the commercial finite element (FE) solver Abaqus is employed in conjunction with user subroutines. The framework is assessed through a comparative study with the experimental and numerical data from [21] while utilizing their hardening and MMC parameters. Load displacement curves are corroborated for various specimens. Furthermore, to demonstrate the utility of the phase field framework in metal forming processes, we utilize the Nakazima test [22], which is employed to determine a material's formability for deep drawing operations. Sheet specimens of various dimensions are subjected to a punch test, with the results subsequently used to plot a failure limit curve for the studied material.

The paper is organized as follows. Section 2 addresses the theory behind the ductile fracture phase field model employed in this paper and its various features. Section 3 covers several benchmark examples, as well as their load-displacement curves recreated through simulations. Section 4 includes the Nakazima test simulations and the achieved failure limit curve. The paper is concluded with a summary.

Theory and Methodology

Phase field fracture relies on the introduction of an auxiliary variable known as the phase field parameter $\phi \in [0,1]$ where a value of 0 represents undamaged material and 1 represents a complete loss of stress carrying capacity. The incorporation of plasticity in the phase field paradigm is based on an additional plastic term introduced to the variational form of Griffith's energy balance, as

$$E=E^s+E^e+E^p \tag{1}$$

where E^s is the fracture surface energy, while E^e and E^p refer to the elastic and plastic energy components of the total energy functional, respectively. Both the fracture and elastic contributions may be studied in more detail from [4]. The plastic contribution is thus defined by

$$E^p(\phi,\varepsilon^p)=g(\phi)W^p(\varepsilon_p) \tag{2}$$

where W^p is the energy corresponding to the plastic damage and g is the degradation function taken identical for both elastic and plastic contributions of energy. This brings certain computational advantages, allowing the retention of the original yield function without any phase field components as the yield surface and equivalent stress degrade identically. A very simple alteration to the brittle strong form becomes adequate to incorporate plastic damage leading to

$$G_c\left(\frac{\phi}{l_0}-l_0\Delta\phi\right)+g'(\phi)(H+W^p)=0 \tag{3}$$

where G_c represents the fracture toughness and l_0 is the length scale parameter governing the diffusiveness of the crack. H is the local history variable given by the maximum elastic energy over the deformation history. The definition of W^p is the dominating factor in the evolution of damage as it quantitatively dominates H. Commonly represented by plastic energy dissipation, it is given as follows:

$$W^p = \int \sigma_{eq} \dot{\varepsilon}^p_{eq} dt \tag{4}$$

where $\dot{\varepsilon}^p_{eq}$ is the equivalent plastic strain rate and σ_{eq} is the equivalent stress. This particular formulation has its drawbacks. In the case of brittle fracture, the elastic damage accumulates at an accelerating pace due to the linear elastic nature of the problem. Plastic contribution to damage, however, accumulates significantly slower, leading to a gradual degradation over a large strain range rather than a dramatic drop past a critical strain level, which is a far more realistic representation. The addition of a plastic dissipation threshold W^p_c solves this problem, with significant changes made to the role of existing parameters. G_c no longer represents the fracture toughness of the material, with this role passed on to W^p_c. Furthermore, the length scale is demoted back to a regularization parameter, no longer influencing the material fracture toughness. Instead, G_c only influences the rate of degradation past the threshold, controlling the reduction in stress following critical damage, where it may be inflated to ease convergence issues. W^p is now replaced by $\langle W^p - W^p_c \rangle$ where $\langle . \rangle$ is the Macaulay operator. An alternative family of degradation functions proposed by Alessi et al. [23] was chosen over the more common quadratic function.

$$g = \frac{(1-\phi)^2}{(k-(k-1)(1-\phi)^2)} \tag{5}$$

where k=1 retrieves the original quadratic function. Lower values of k delay premature degradation, though lowering the value has consequences in terms of convergence issues. A value of 0.5 was found to sufficiently reduce premature degradation while presenting no serious convergence problems.

Furthermore, the equivalent plastic strain at failure, ε_f, for the MMC model (see [21]) is given as follows:

$$\varepsilon_f = \left\{ \frac{K}{\widehat{C}_2} \left[\widehat{C}_3 + \frac{\sqrt{3}}{2-\sqrt{3}} (\widehat{C}^*_4 - \widehat{C}_3)\left(\sec\left(\frac{-L\pi}{6}\right) - 1 \right) \right] \times \left[\sqrt{\frac{1+\widehat{C}_1^2}{3}} \cos\left(\frac{-L\pi}{6}\right) + \widehat{C}_1 \left(T + \frac{1}{3}\sin\left(\frac{-L\pi}{6}\right)\right) \right] \right\}^{1/n} \tag{6}$$

$$\widehat{C}^*_4 = \begin{cases} 1 & \text{for } -1 \le L \le 0 \\ \widehat{C}_4 & \text{for } 0 < L \le 1 \end{cases}$$

where K, n and $\widehat{C}_i$ are material specific constants. L is the Lode parameter and T is the stress triaxiality with both defined as

$$T = \frac{\sigma_h}{\sigma_{eq}}, \qquad L = \frac{2\sigma_2 - \sigma_1 - \sigma_3}{\sigma_1 - \sigma_3} \tag{7}$$

where σ_1, σ_2 and σ_3 are principal stresses while σ_h and σ_{eq} are the hydrostatic and equivalent stresses, respectively.

The incorporation of the MMC model opens up the range of specimens and deformation cases that may be studied, where the model can accurately capture damage at evolving stress states.

While in the classic approach, damage evolves through equivalent plastic strain and failure strain, as

$$D=\int \frac{\dot{\varepsilon}^{p}_{eq}}{\varepsilon_f} dt \tag{8}$$

where D=1 represents complete fracture and ε_f is the failure strain. In the context of the phase field paradigm, damage evolves through plastic dissipation that drives the phase field parameter to retain an energy-based framework. We employed the following definition for W^p:

$$W^P=\int \frac{\sigma_{eq}\dot{\varepsilon}^{p}_{eq}}{\varepsilon_f} dt \tag{9}$$

In the current implementation, the addition of the MMC model helps scale the plastic contribution in regard to the stress state. While classical uncoupled fracture models, employ a strain-based incremental measure of damage where the material is considered fully broken at a damage value of 1, this framework uses W_c^p as the fracture indicator. J2 plasticity model with non-linear isotropic hardening is coupled with the phase field paradigm through a staggered scheme, where plastic and elastic damage contributions from the previous increment influence the evolution of the phase field parameter in the current one. An extended Voce hardening rule given below is utilized to define isotropic hardening.

$$\sigma_y=\sigma_0+\sum_{i=1}^{3} Q_i (1-\exp(-C_i\varepsilon^{p}_{eq})) \tag{10}$$

where σ_y is the yield stress, σ_0 is the initial yield stress value, and Q_i and C_i are hardening parameters. The plasticity framework and the phase field evolution are coupled through the degradation function $g(\phi)$. J2 plasticity model is solved with classical radial return algorithm in the user subroutine (UMAT) and at the end of each increment stress and material stiffness are degraded through $g(\phi)$ retrieved from the previous converged increment, as

$$\sigma=g(\phi)\sigma_{0,} \quad \mathbb{C}=g(\phi)\mathbb{C}_0 \tag{11}$$

where $\sigma_{0,}$ and $\mathbb{C}_0$ are the undegraded stress tensor and material tangent stiffness tensor, respectively, retrieved from the J2 plasticity solution. The phase field evolution is solved by using the heat generation subroutine (HETVAL) exploiting the similarities between the phase field strong form (Eq. 3) and steady-state heat transfer equation (see [20] for the details of the implementation). Elastic and plastic energy contributions from the previous converged increment are used to drive the phase field evolution in the current increment.

Ductile Failure Simulations

Several benchmark examples are simulated to gauge the proposed model's ability to capture ductile failure crack paths as well as the material response. Firstly, 4 specimen geometries, namely notched tension (NT3, NT10), plane strain tension (PST) and in-plane shear (ISS), are solved using the proposed phase field formulation for 6016-T4 aluminum alloy. The details of the specimen dimensions and experimental data are given in [21]. The MMC model variables, calibrated and tested in the aforementioned paper, are used in the ductile fracture phase field model. The parameter set given in Table 1 is employed in the presented phase field framework.

Table 1. Material and model parameters.

E [MPa]	ν	l_0 [mm]	G_c [N/mm]	W_c^p [N.mm]		
70000	0.3	1	50	275		
σ_0 [MPa]	Q_1 [MPa]	C_1	Q_2 [MPa]	C_2	Q_3 [MPa]	C_3
135	19.04	87.05	142.22	10.06	75	3.08
K	$\widehat{C}_1$	$\widehat{C}_2$	$\widehat{C}_3$	$\widehat{C}_4$	n	
0.9969	0.01	0.5075	0.8820	1.0056	0.01122	

All simulations are performed with the implicit finite element solver Abaqus. Models are meshed with a fully integrated 3D (hexahedral) temperature-displacement coupled element (C3D8T in Abaqus) as shown in Fig. 1. NT3, NT10 and ISS are pulled from the center of the top pin and held from the center of the bottom pin while allowing for rotation around the pins. Pin centers are connected to the specimen with the MPC beam constraint. For the PST specimen, the clamped regions are assumed to be rigid and modeled as rigid bodies in FE as shown in Fig. 1. The PST specimen is pulled upwards from the top rigid section and held fixed from the bottom rigid section. Only the middle portion of the ISS specimen is modeled for FE simulations to save computational time. In order to apply boundary conditions, top and bottom pin centers are connected to the FE mesh with the MPC beam constraint as shown in Fig. 1 with black lines. The details of the specimen dimensions and experimental procedure can be found in [21]. The average element size in the gauge section is 0.05 mm with 5 elements in the thickness direction in all FE models. Solutions are performed using automatic step size control with a maximum step size of 0.001 s and a total time of 1 s which is found to be an efficient value in terms of solution time and convergence.

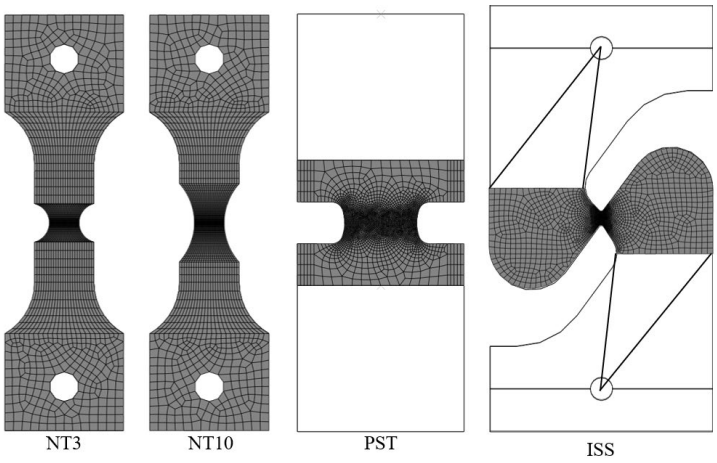

Fig. 1. FE models of the tensile test specimens.

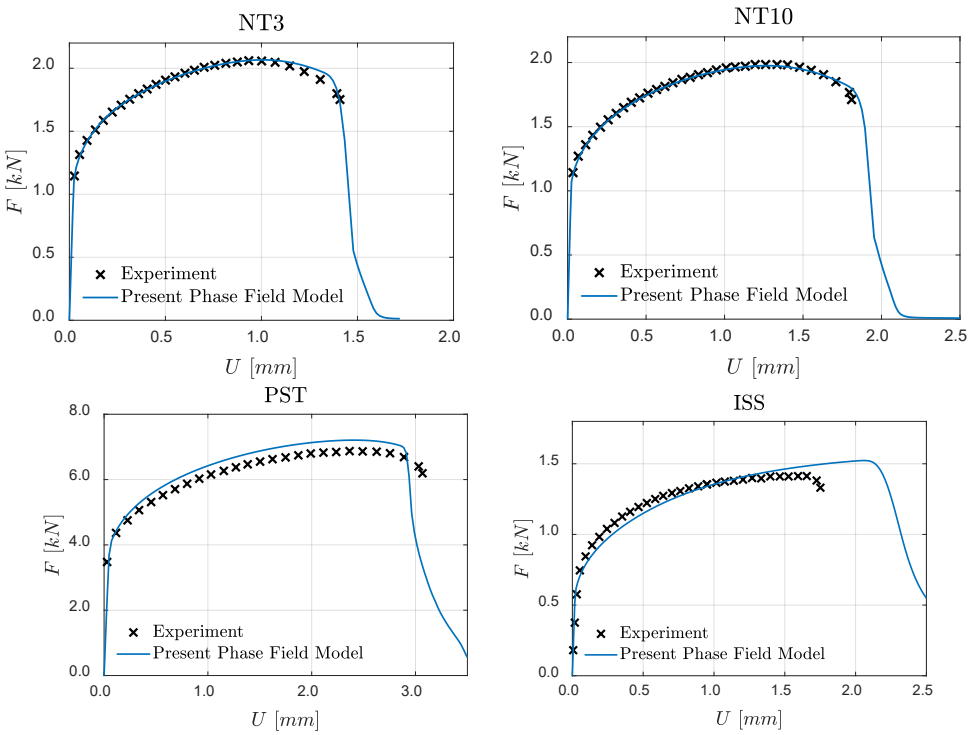

Fig. 2. Comparison of experimental [21] and the present phase field results. Load vs. Displacement curves for 4 specimen geometries.

In Fig. 2, the comparison of force vs. displacement is depicted for 4 specimens. For the given MMC parameters, the material response performed well for each of the four specimens compared to experimental data. The fracture strain for the ISS specimen is exaggerated slightly, but referring to [21] confirms that this is a feature of the MMC fit, not the phase field model. It can be concluded that the developed phase field framework is compatible with classical uncoupled ductile failure models such as Johnson-Cook and MMC. The simulated crack paths are shown in Fig. 3. A straight horizontal crack is developed in the tension specimens resulting in a cup-cup fracture surface. For the ISS test, a slanted crack is developed in the gauge region. All crack paths are compatible with the experimental results presented in [21].

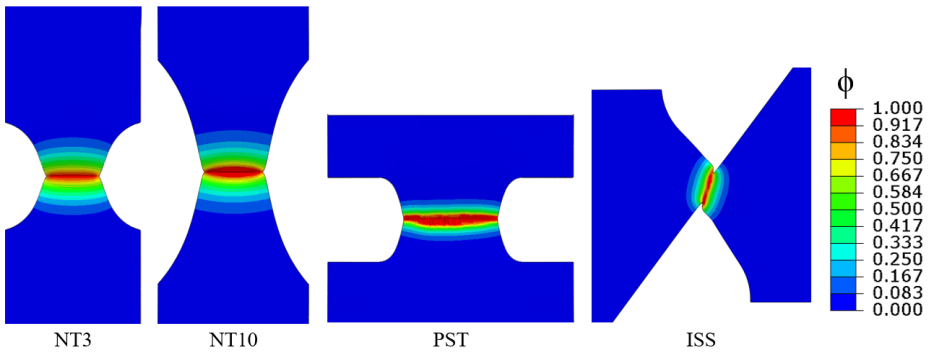

Fig. 3. Distribution of phase field parameter (ϕ) after fracture.

In order to illustrate the effect of length scale in the current model, two additional simulation results are shown in Fig. 4 with the PST specimen. It is clear that the length scale has an insignificant effect on the failure strain but the diffusiveness of the phase field is increased with increasing length scale. Using a smaller length scale is desirable to have relatively precise crack

paths; however, this requires an equivalently finer mesh as comparable scales for both can lead to the mesh distribution influencing the crack path. In all simulations, we set the length scale as 1 mm. Furthermore, in Fig. 4, the effect of critical plastic dissipation, W_c^p, is depicted. This is the main calibration parameter of the proposed model that defines the ductility limits of the material where larger critical dissipation delays the fracture strain value.

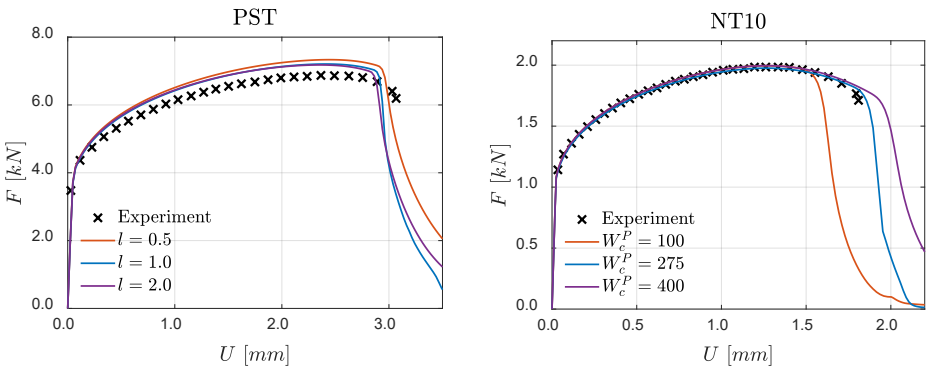

Fig. 4. Effect of length scale and critical plastic dissipation, W_c^p, on fracture.

Nakazima Forming Test Simulations

In order to demonstrate the capability of the presented framework in predicting material formability, the Nakazima test [22] is simulated to reproduce a failure limit curve which assesses the formability of a material in the context of the deep drawing process. The dimensions of the Nakazima setup are adopted from [24]. Specimen thickness is taken as 1mm. The finite element model of the test is given in Fig. 5. Both the punch and the die are taken as rigid bodies and the test sample is meshed with fully integrated 3D (hexahedral) temperature-displacement coupled elements. Outer edge of the Nakazima sample and the die is fixed in all three directions. Displacement boundary condition is applied to the punch while fixing the displacement in transverse directions. Incrementation is retained from the previous section. Frictionless contact is assumed between all interacting surfaces. The punch is pushed vertically until the specimen experiences crack initiation and subsequent crack growth.

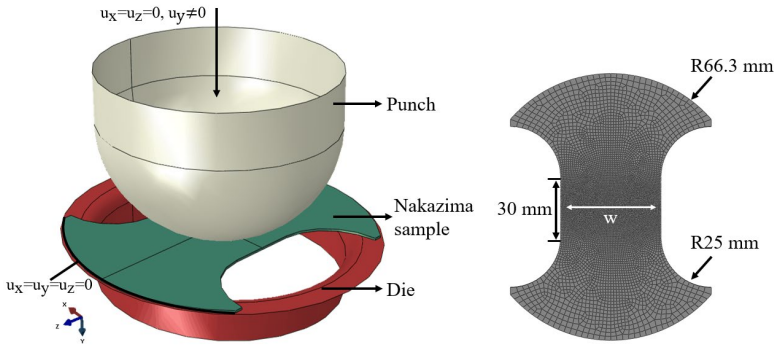

Fig. 5. Finite element model of Nakazima test setup. For the dimensions of the setup see [24].

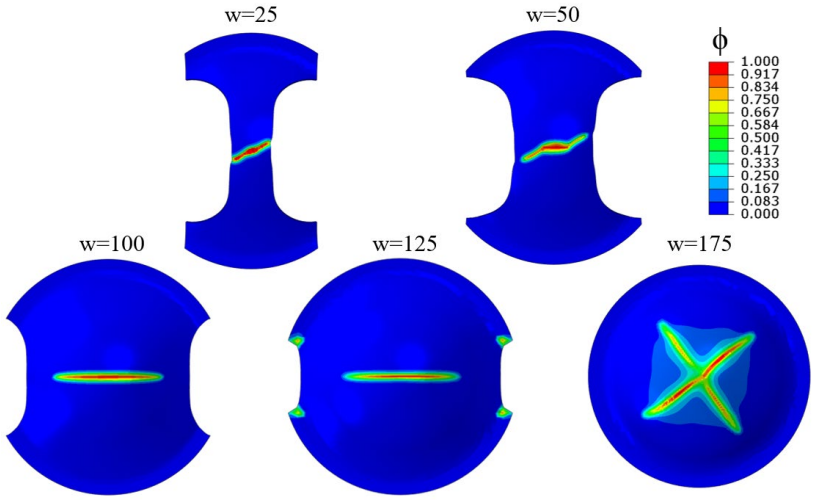

Fig. 6. Crack paths for the Nakazima simulations. Here, w refers to the specimen width.

In Fig. 6, the crack pattern developed for the various specimens may be observed. For narrow specimens, the crack initiates horizontally at the center followed by slanted crack growth which is a pattern that can be observed experimentally (see [24,25]) but most damage models fail to capture it. A horizontal crack development is obtained for wider specimens in agreement with the experimental observations.

The failure limit curve is plotted by taking the major and minor strain histories at the center point of each specimen. The curves are depicted in Fig. 7. A critical facet of plotting a forming limit curve (FLC) is choosing the failure point for the specimen. In this study, we choose the point right before the crack initiation predicted by the phase field model. Hence, we preferred to refer to the curve as a failure limit curve rather than a forming limit curve. The shape of the curve obtained matches the prevalent trend in the literature. A possible source of inaccuracies in the current study may be the assumption of isotropic hardening behavior as sheet metals tend to be anisotropic. The study in [25] compared the performance of an anisotropic yield function vs. an isotropic one and concluded that the anisotropic yield function is found to be more successful at reproducing major-minor strain history curves.

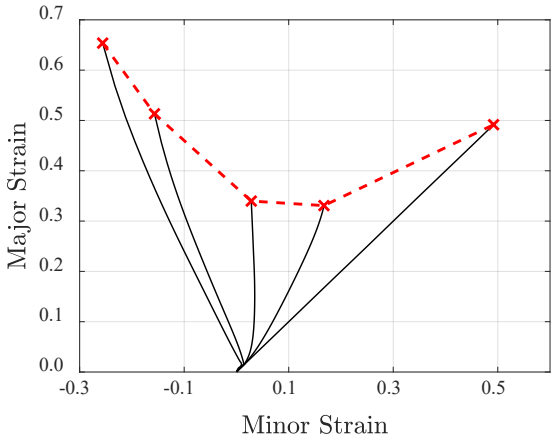

Fig. 7. Failure loci plot for Nakazima specimens.

Summary

A ductile phase field fracture model is developed to simulate crack paths and accurate material responses for various benchmark cases. It demonstrates compatibility with the MMC model allowing the use of existing calibrated parameters for various materials. The framework provides

a route for the non-local coupled implementation of classically uncoupled damage models. Finite element simulation results demonstrated good correspondence with experimental data in terms of both crack paths and material force-displacement response. The Nakazima test is analyzed in FE to show a possible forming application of the developed phase field model, and the results are found to be promising. The framework is a simplistic implementation of a non-local coupled ductile failure model functioning with an implicit solver. The versatility of this methodology could allow future works to simulate more complex ductile fracture behavior such as anisotropic plasticity and damage models.

Keywords: Ductile Damage to Fracture Transition, Phase Field, Forming Processes

Abstract. In this work we present a phase-field based method to accurately predict the nucleation and evolution of damage. The damage pattern is then used as a criterion for automatic, remeshing-based, 3D crack insertion and propagation. The proposed framework has been implemented in Forge® finite element software and it offers a robust numerical tool for the modeling of damage to fracture transition in complex industrial processes. A bar shearing simulation will be used to show the robustness and efficiency of the approach. The flexibility of the approach is presented through the use of different damage criteria introduced into the phase-field formulation.

Introduction

Material forming processes take advantage of the ductility of materials, in particular metals, to obtain a given geometry of a part. Depending on the complexity of the part, different stages might be needed. From a mechanical perspective, the material will be submitted to a non-proportional loading path and large deformation. As a result of these processes damage and fracture might appear within the material. Depending on the process, damage, and subsequent fracture, should be either avoided or controlled. In either case the simulation of the kinetics of the evolution of damage is fundamental in order to design new parts and manufacturing processes. The damage to fracture transition becomes particularly necessary in order to study processes where damage should be controlled (*e.g.,* blanking and cutting processes). To this end, the first step consists in being able to predict the damage kinetics. Then the damage prediction should be used to initiate and propagate cracks into the material.

Regarding the prediction of damage, when dealing with brittle materials Griffith theory can be used to explain the evolution of fracture. In fact, this energetic approach can be used to reproduce experiments of fracture of brittle materials [1]. On the other hand, when dealing with ductile materials the literature about models that allow to predict the evolution of damage is often restricted to specific material and/or particular loading conditions. It is thus fair to say that there is no unified theory that quantitatively explains the kinetics of ductile damage and fracture phenomena. However, we can say that there are three main stages on the process:

1. void nucleation
2. void growth and distortion
3. void coalescence.

Voids are nucleated due to stress concentrations and the presence of defects in the materials. These voids will grow under plastic deformation and their growth will be significantly affected by the

material's stress state. And finally void coalescence is the result of the merging of previously nucleated voids [2,3].

The numerical modeling of these ductile damage mechanisms has been done by using different numerical approaches: *uncoupled* and *coupled* approaches. Uncoupled approaches can be seen as a post processing tool that allows to compute the local damage state of the material by using a set of thermomechanical variables integrated over time. These approaches are easy to implement and do not affect the convergence of the finite element solver[1]. They present an important drawback: uncoupled approaches do not allow to reproduce the drop of stress experimentally observed once damage has been initiated. On the other hand, coupled models link the evolution of damage to the elastoplastic properties of the material. This allows to capture the softening behavior experimentally observed but this brings along some drawbacks. The softening of the materials leads to numerical difficulties that are well documented in literature [9] and the numerical solver must be adapted to tackle these challenges.

Extensive literature can be found in the context of ductile fracture applied to material forming as in [5] and [6] (and the references therein). The phase-field community has also proposed remarkable contributions to the field such as [7,8]. Such approaches often focus on capturing the drop of loading carrying capacity of the material. However, the degradation of the material is taken into account within a continuum mechanics framework and thus no actual crack is introduced in the computational domain.

Once damage has developed in the material, a discontinuity should be introduced. Early attempts to introduce the discrete cracks based on a remeshing approach in 2D were proposed in [9]. Crack propagation direction is given by the maximum damage at different distances from the crack tip, which led to wrong crack directions especially in the case of complex crack patterns (*e.g.,* merging, branching and multiple cracks) and its extension to 3D was complicated. An alternative to this approach based on the marching ridges method was introduced in [10]. The idea was to find the local maximum of the damage field and propagate the crack by introducing a segment linking these local maximum points. It is worth mentioning that there exist alternatives to discrete crack insertion methods (such as the XFEM [11] or the GFEM [12]) which suffer from difficulties when it comes to large plastic strain and remeshing. But these methods will not be covered in this work.

In this article, the phase-field based damage modeling strategy proposed in [13] is briefly discussed. The proposed method, based on a phase-field-inspired approach to predict the evolution of damage, will be presented in the next section. Then the phase-field damage is used to drive the crack insertion and propagation following the *Crack Insertion and propagation using the Phase Field and Adaptive Remeshing* (CIPFAR) algorithm introduced in [14]. Finally, some results are presented.

Phase-Field Inspired Damage Formulation

Phase-field approaches to simulate damage and fracture can be seen as an extension of the generalized formulation of Griffith theory introduced by Francfort and Marigo [15]. The idea is to use a regularized representation of the crack by introducing a damage variable (d). The evolution of this damage problem is driven by the minimization of an energy functional that links the mechanical behavior of the material to its damage evolution. The energy functional is given by:

$$\mathcal{E}_l(u,d) = \int_\Omega g_e(d) W_e(\epsilon^e) d\Omega + \int_\Omega \frac{G_c}{2l_c}\left(d^2 + {l_c}^2 \nabla d^2\right) d\Omega \quad (1)$$

Materials Research Proceedings 28 (2023) 1603-1610 https://doi.org/10.21741/9781644902479-173

Where ε^e is the elastic strain tensor, W_e is the elastic energy density, G_c is the fracture toughness, l_c is the regularization length and $g_e(d)$ is the degradation function given by:

$$g_e(d) = (1-d)^2 \tag{2}$$

The choice of the degradation function satisfies the following conditions: $g_e(0) = 1$, $g_e(1) = 0$ and $g'_e(d) = 0$. The minimization of the energy functional leads to the following set of equations:

$$d - {l_c}^2 \nabla^2 d = -g'_e(d)H \qquad \text{(Phase-field evolution)} \tag{3}$$

$$H = \frac{2l_c}{G_c} max W_e(\epsilon^e) \qquad \text{(Local history functional)} \tag{4}$$

$$\nabla d.n = 0 \qquad \text{(Neumann boundary condition)} \tag{5}$$

A similar set of equations is found when a non-local continuum damage formulation is used. The main difference is that phase-field evolution includes the term $g'_e(d)$ which vanishes when the material is completely damaged ($d = 1 \rightarrow g_e(d = 1) = 0$). This vanishing term prevents spurious diffusion of the damage variable [13].

The previous set of equation corresponds to the classic phase-field damage formulation for brittle materials. If we were to extend this formulation to ductile damage modeling while keeping the phase field philosophy, we would need to come up with an energy functional that accounts for the plastic dissipation which should also account for the plasticity-damage coupling. Real material exhibit complex damage behavior often involving a strong coupling damage, stress triaxiality and/or even the Lode parameter [2]. Obviously proposing a general energy functional that fulfills all these requirements is not an easy task.

In order to overcome this problem of finding an appropriate energy functional, we simply replace the local history functional by a phenomenological law. The idea is to introduce any of the existing *Uncoupled* damage criterion into the local functional:

$$H = \eta_c \langle D - D_{thresh} \rangle \tag{6}$$

Where D is the local damage (damage criterion), η_c is a material parameter used to control the post-peak stress response of the material by controlling the amount of effective energy needed to create the crack surfaces once the crack is initiated and D_{thresh} is a damage threshold value used to delay the softening of the material. The effect of η_c and D_{thresh} is shown in Fig. 1, which corresponds to the 1D homogeneous solution of the phase-field equation.

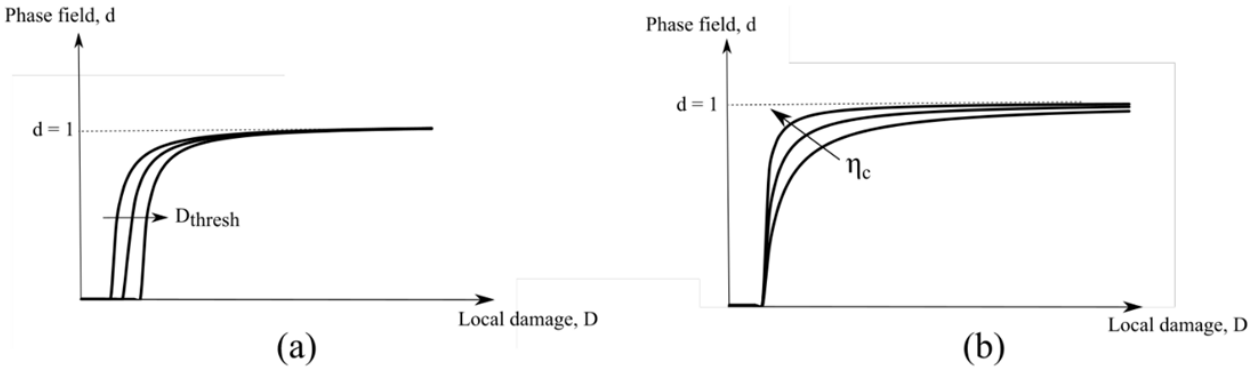

Fig. 1. The effect of model parameters on the evolution of the phase field in a 1D homogeneous solution [16].

Once the phase-field is computed, the crack insertion strategy presented in [14] is used in order to introduce the crack discontinuity into the mesh. In the next section, a forming application is presented and discussed.The implementation and validation of the different building blocks of the proposed approach has been done in Forge®.

Results

The proposed strategy has already been validated and tested [13,14]. It has been proven that the approach is very robust and flexible as different damage criterion could be used to study a given problem. In fact, as it has been mentioned before, there is not a unified theory that explains the evolution of ductile damage and therefore the choice of the damage criterion is done depending on the material and the loading conditions.

Here we will present a simple case of a bar shearing. The boundary conditions of the problem are shown in Fig. 2. Depending on the choice of damage criterion, the failure pattern predicted by the model will be different. The different failure criteria tested are listed in Table 1 and the corresponding properties used in the simulations are shown in Table 2.

Table 1. Damage criteria used for the coupled phase-field simulations [16].

Model number	Damage criterion	Driving force (DF)	Parameters
1	$D = \int_0^{\bar{\varepsilon}} \frac{\sigma_1}{\bar{\sigma}} d\bar{\varepsilon}$	Maximum principal stress σ_1	-
2	$D = \int_0^{\bar{\varepsilon}} \frac{\bar{\sigma}}{A} d\bar{\varepsilon}$	Von Mises stress $\bar{\sigma}$	A
3	$D = \int_0^{\bar{\varepsilon}} C_1 exp C_2 \eta d\bar{\varepsilon}$	Stress triaxiality η	C_1 and C_2
4	$D = \int_0^{\bar{\varepsilon}} \frac{\sigma_1 - \sigma_3}{\bar{\sigma}} d\bar{\varepsilon}$	Maximum shear stress $2\tau_{max} = \sigma_1 - \sigma_3$	-

Materials Research Proceedings 28 (2023) 1603-1610 https://doi.org/10.21741/9781644902479-173

Table 2. Material and model parameters [16].

Quantity		Value	Units
Young's modulus	E	200 000	MPa
Poisson's ratio	ν	0.3	-
Yield stress	σ_y	$A\,\overline{\varepsilon}^{\,0.1845}\,\dot{\overline{\varepsilon}}^{\,0.012}$	MPa
A		818	MPa
Charasteristic length	l_c	0.5	mm
Damage model 1			
Damage threshold	D_{thresh}	0.1	-
Fracture parameter	η_c	200	-
Damage model 2			
Damage threshold	D_{thresh}	0.1	-
Fracture parameter	η_c	50	-
Damage model 3			
Damage threshold	D_{thresh}	0.05	-
Fracture parameter	η_c	200	-
C_1		2	-
C_2		1	-
Damage model 4			
Damage threshold	D_{thresh}	0.2	-
Fracture parameter	η_c	100	-

The different crack patterns are shown in Fig. 3 for each of the models in Table 1. For each model the upper row shows the phase-field damage level (d) and the lower row represents the cracks that have been inserted. Fig. 3a shows the results obtained when using the Normalized Latham-Cockcroft model (number 1 in Table 1) at different macroscopic loading states. It can be seen that two cracks are initiated at the left and right boundaries of the sheared zone. It is important to highlight that the approach is robust enough to handle the two cracks that propagate independently and that end up merging into a single crack that breaks the rod into two pieces.

Crack patterns obtained when using models 2 and 4 in Table 1 present a similar kinetics: first two cracks near the boundary of the rod are initiated and these cracks merge at the end in order to fully break the rod. Interestingly the crack initiation region from these two models is different from the one observed in model 1. This time, the two branches are initiated in the upper and lower boundaries of the rod. This change on the initiation region can be explained by the driving term of the damage criterion used (Column 3 in Table 1).

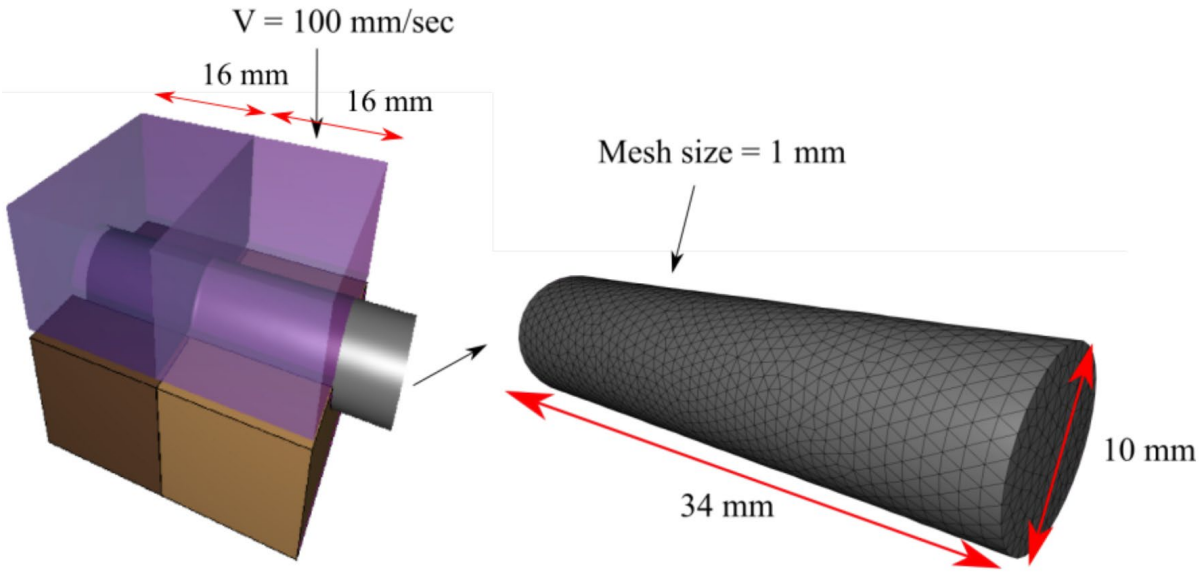

Fig. 2. Geometry and boundary conditions of a bar subjected to shear loading [16].

The von Mises stress as well as the maximum shear stress are concentrated over the regions that are in contact with the tools in the shearing regions. On the other hand, the normalized maximum principal stress is maximum over the left and right boundaries of the rod, which explains the pattern observed in model 1. Finally, model 3 (triaxiality driven) leads to a completely different crack pattern. In fact, the regions that present high triaxiality are located behind the shearing region. Therefore, the crack nucleates in the upper and lower regions of the rod but inside of the tool.

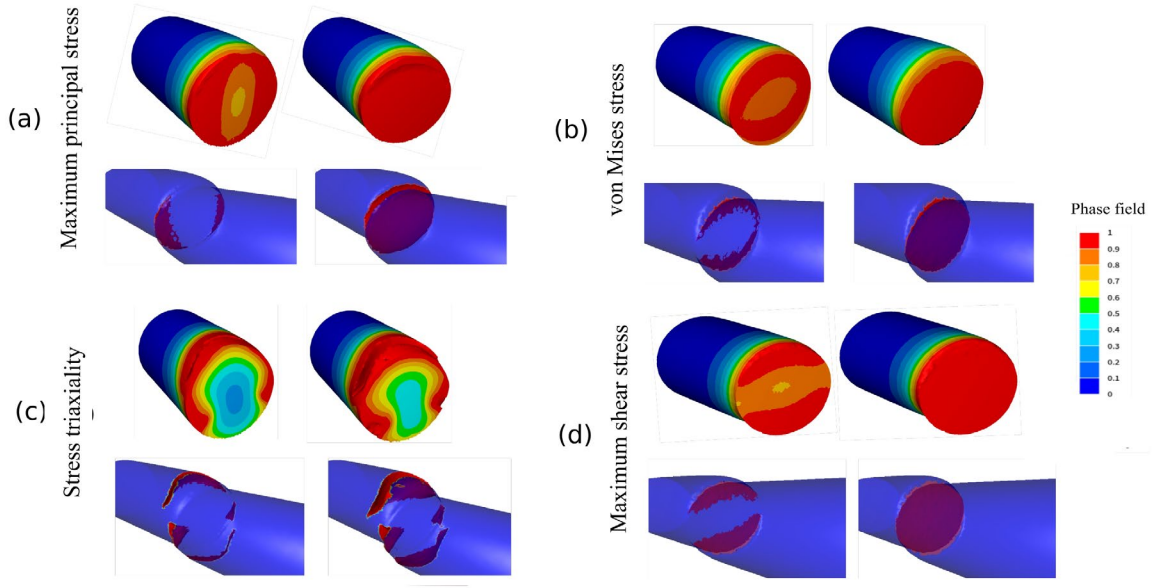

Fig. 3. Illustration of the phase field damage evolution (upper row) and the inserted cracks surfaces (lower row) for the four different damage criteria introduced in Table 1.

Summary

To conclude, the presented examples confirm the ability of the proposed approach to accurately model the damage to fracture transition under complex loading conditions. In addition, the model provides a general framework for crack initiation and propagation in 3D that can be adopted for different applications. Since there is no a universal model that accurately predicts the ductile damage evolution, the use of custom damage criteria (often developed in the context of *uncoupled* approaches) combined with the phase-field formulation allows to account for complex damage phenomena experimentally observed. Once the damage has initiated, the CIPFAR algorithm is used to insert cracks into the computational domain while being robust and reliable. Further developments and tests should be carried out in order to study the impact of different damage criteria in the case of multistage non-proportional loading processes.

Keywords: Cooling Bed, Steel Bars, Thermo-Mechanics, Strong Form Meshless Method

Abstract. After the continuous hot-rolling process, steel bars are immediately placed on the cooling bed. At the beginning of the cooling, the material is at high temperatures, and the yield strength is low. Due to thermal load, yield strength can be exceeded, and permanent plastic strains start accumulating, resulting in possible unwanted shape changes and residual stresses. The present paper aims to develop a thermo-mechanical model for studying and eliminating undesirable phenomena before the products leave the cooling bed. The governing equations are solved for the two-dimensional slice in a strong form, and a modified version of the radial basis function generated finite difference (RBF-FD) method [1]. The initial bar geometry is obtained from the existing meshless hot-rolling simulation system [2]. The thermal and mechanical models are one-way coupled, i.e. the temperature solution represents a driving force for the stress and strain solution. The temperature field is obtained with explicit propagation in time. The convective and radiative heat fluxes on the boundary are updated at each time step using the ray tracing procedure to determine the radiative heat flux. The mechanical part is solved by considering the small strain elasto-plasticity, where the isotropic von Mises temperature-dependent hardening is employed. The global system of nonlinear equations of the mechanical part is solved by the Newton-Raphson method. The closest point projection method is used to solve the constitutive relations. A sensitivity study is performed on the influence of cooling intensity on a rectangular steel bar's temperature, stress and strain field. We defined the most influential factors for defect formation. For the first time, a novel meshless RBF-FD method is successfully used for solving such a complex industrial problem. The model will be perspectively upgraded from the slice to the three-dimensional model to enable also bending.

Introduction

The meshless strong form radial basis function generated finite difference (RBF-FD) method has gained popularity in modelling different steel production processes. It has been successfully applied to solve large spectra of continuous casting problems, such as diffusion-convection with phase change [1], natural convection influenced by magnetic stirring [3], turbulence phenomena [4], 2D microsegregation with grain growth [5], and 2D thermo-mechanics [6]. Also, multi-pass hot-rolling has been successfully modelled with RBF-FD [2,7], including the grain size prediction [8].

This work represents the first use of RBF-FD for solving the thermo-mechanical response of the last stage of hot-rolling, where the hot-rolled steel bars are cooled. Previous attempts at modelling this step were performed in 1D [9], 2D [10,11] and 3D [12,13]. In [9], the friction with the supports was investigated. In [12], a simple thermo-elastic description has been used and later

extended in [13], including contact with the supports and gravitational load. In [10], the bending of the bars and the residual stresses were computed, and in [11], the flow of surrounding air was included to better predict heat transfer at the boundary. All of the above studies were performed for symmetric and asymmetric rail profiles where the geometry significantly impacts the bending and residual stress formation.

An example of round steel bars cooling on the cooling bed (CB) is shown in Fig. 1 left. A cross-section scheme with rectangular bars (80×39 mm) used in this work is presented in Fig. 1 right. The heat shield with the length of p_l is positioned on top of the CB, raised by p_y from the lowest point of the CB. Each bar starts from the left at the position p_1. After a time t_p, the bar is moved for a distance x_{bp} to the position p_2, and a new bar occupies the position p_1. This movement is repeated until the final position p_n is reached, where the bars leave CB.

The influence of the position of the heat shield above the bars p_y and the distance between the bars x_{bp} on the thermo-mechanical response is investigated.

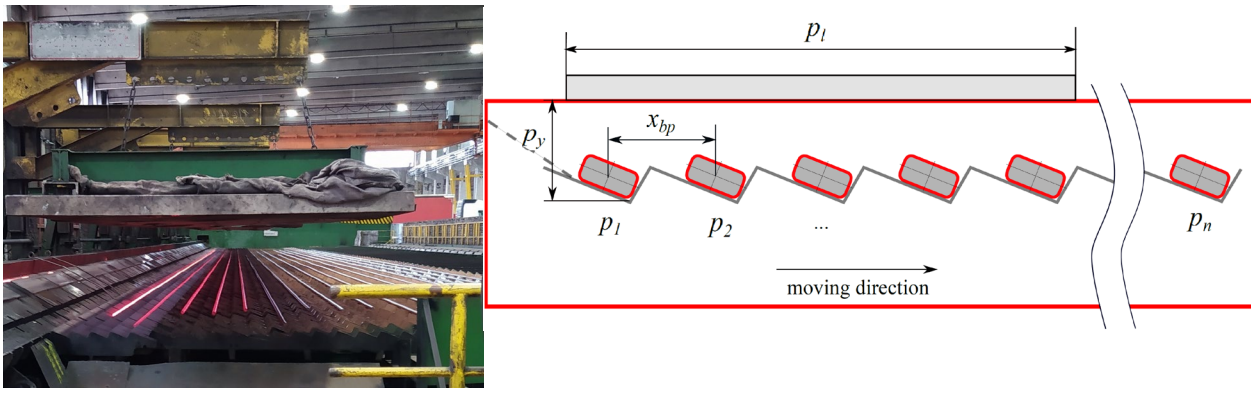

Fig. 1. Left: Photo of the cooling bed. Right: cross-section of the cooling bed with rectangle steel bars present on each position p_i.

Thermal Model

Cooling of the steel bars is governed by the heat diffusion equation

$$\frac{\partial}{\partial t}(\rho c_p T) = \nabla k \cdot \nabla T + k\nabla^2 T \tag{1}$$

where ρ, c_p, k and T stand for the density, the specific heat at constant pressure, the heat conductivity and the temperature, respectively. Material parameters ρ, c_p and k are temperature-dependent. Neumann boundary condition is employed as

$$\mathbf{q}\cdot\mathbf{n} = -k\frac{\partial T}{\partial \mathbf{n}} = q_{conv} + q_{rad} \tag{2}$$

where **q** represents the total heat flux and **n** is normal at the boundary. The prescribed value on the right-hand side is composed of convective q_{conv} and radiative q_{rad} terms, defined as

$$q_{conv} = h(T - T_{amb}), \qquad q_{rad} = \varepsilon\sigma(T^4 - T_{amb}{}^4) \tag{3}$$

Materials Research Proceedings 28 (2023) 1611-1620 https://doi.org/10.21741/9781644902479-174

where h, T_{amb}, ε and σ stand for the heat transfer coefficient, the ambient temperature, the emissivity coefficient, and the Stefan-Boltzmann constant, respectively. Since the bars are positioned close to each other, and a heat shield is present above the cooling bed, information about the geometry and the positioning is effectively introduced in q_{rad}. The boundary of the system, composed of the bars and heat shield, is discretized and enclosed inside another discretized closed-loop virtual boundary. The net radiative heat flux of the i-th discretized boundary surface $q_{rad,i}$ is defined as a difference between the emitted heat flux from the surface and the received heat flux from the surroundings as

$$q_{rad,i} = \varepsilon_i \sigma T_i^4 - \sum_{j=1}^{J} \varepsilon_j \sigma T_j^4 \frac{A_j}{A_i} F_{j \to i} \tag{4}$$

where the received part is defined as a sum over all J discrete surfaces (DSs). DS visibility is defined by the view factor $F_{j \to i} \in [0,1]$. It represents the portion of the radiation emitted by the surface A_j received by the surface A_i [14].

Mechanical Model

This work considers small strain elasto-plasticity with von Mises flow rule and isotropic hardening. The mechanical equilibrium of the steel bar is described by the balance law

$$\nabla \cdot \boldsymbol{\sigma} = \mathbf{f} \tag{5}$$

where $\boldsymbol{\sigma}$ is the stress tensor and f is the body force. The strain tensor is defined in terms of displacement $\mathbf{u}$ as $\boldsymbol{\varepsilon} = 1/2\left(\nabla \mathbf{u} + \nabla \mathbf{u}^{\mathsf{T}}\right) = \nabla^s \mathbf{u}$. It can be split into elastic $\boldsymbol{\varepsilon}^e$ and plastic $\boldsymbol{\varepsilon}^p$ terms $\boldsymbol{\varepsilon} = \boldsymbol{\varepsilon}^e + \boldsymbol{\varepsilon}^p$. The relationship between stresses and strains is defined by the Hooke's law

$$\boldsymbol{\sigma} = \mathsf{D}^e \boldsymbol{\varepsilon}^e = \mathsf{D}^e (\boldsymbol{\varepsilon} - \boldsymbol{\varepsilon}^p) \tag{6}$$

where D^e represents the fourth-order elasticity tensor. The employed von Mises yield criterion states that the material yields when von Mises stress $\sigma_{vm} = \sqrt{3J_2}$ exceeds the yield stress obtained from the uniaxial tensile test σ_y. J_2 represents the second invariant of the deviatoric part $\mathbf{s} = \boldsymbol{\sigma} - \mathbf{I}\mathrm{tr}(\boldsymbol{\sigma})/3$ of the stress tensor, where $\mathbf{I}$ is the identity tensor. The evolution of the yield stress is defined by a hardening law $\sigma_y = \sigma_y(\bar{\varepsilon}^p, T)$, assumed to be a nonlinear function of the temperature and the accumulated plastic strain $\bar{\varepsilon}^p = \sqrt{2/3}\,\|\boldsymbol{\varepsilon}^p\|$. Johnson-Cook strain rate independent hardening law is used

$$\sigma_y(\bar{\varepsilon}^p, T) = \left(A + B\left(\bar{\varepsilon}^p\right)^n\right)\left(1 - \left(\frac{T - T_0}{T_m - T_0}\right)^m\right) \tag{7}$$

where all constants are determined by fitting 46MnVS5 steel data obtained by the JMatPro software. Admissible stress states are compactly specified with a yield function

$$\Phi(\boldsymbol{\sigma},\sigma_y)=\sqrt{3J_2(\mathbf{s}(\boldsymbol{\sigma}))}-\sigma_y\le 0 \tag{8}$$

where $\Phi(\boldsymbol{\sigma},\sigma_y)<0$ holds in the elastic regime and $\Phi(\boldsymbol{\sigma},\sigma_y)=0$ holds in the plastic regime. The evolution of the plastic strain is defined in the rate form by a plastic flow rule

$$\dot{\boldsymbol{\varepsilon}}^p=\dot{\gamma}\frac{\partial\Phi}{\partial\boldsymbol{\sigma}}=\dot{\gamma}\sqrt{\frac{3}{2}}\frac{\mathbf{s}}{\|\mathbf{s}\|} \tag{9}$$

where γ represents the plastic multiplier and connects the strain and the stress space. Lastly, a set of loading/unloading conditions is given as

$$\Phi(\boldsymbol{\sigma},\sigma_y)\le 0,\quad \dot{\gamma}>0,\quad \Phi(\boldsymbol{\sigma},\sigma_y)\dot{\gamma}=0 \tag{10}$$

that have to be fulfilled. Since the material response is path-dependent, Eq. 5 is solved incrementally. For a $(n+1)$-th load increment, it can be written in the form $\mathbf{f}^{\text{int}}|_{n+1}-\mathbf{f}^{ex}|_{n+1}=\mathbf{r}(\mathbf{u}_{n+1})=0$, where $\mathbf{r}$ represents the residual that should be zero, $\mathbf{f}^{ex}$ external load, and $\mathbf{f}^{\text{int}}$ internal force defined as $\mathbf{f}^{\text{int}}=\nabla\cdot\boldsymbol{\sigma}\left(\nabla^s\mathbf{u}\right)$. Due to a nonlinear relationship between stress and strain, the residual is linearized as

$$\nabla\cdot\left(\mathsf{D}\nabla^s\right)\Big|_{n+1}^{k}\delta\mathbf{u}=-\mathbf{r}\Big|_{n+1}^{k} \tag{11}$$

where $\mathsf{D}=\partial\boldsymbol{\sigma}/\partial\boldsymbol{\varepsilon}$. Eq. 11 is iteratively (index k) solved for $\delta\mathbf{u}$. After each k-th iteration, the displacement increment is updated as $\Delta\mathbf{u}^k=\Delta\mathbf{u}^{k-1}+\delta\mathbf{u}$. From here, the strain increment $\Delta\boldsymbol{\varepsilon}^k$ is determined and inserted into the integration model, where all other state variables are updated, solving Eqs. 6-10. When $\delta\mathbf{u}$ is sufficiently small, the displacement is updated as $\mathbf{u}_{n+1}=\mathbf{u}_n+\Delta\mathbf{u}$. Since only temperature load is applied on the steel bars, the external load is defined as $\mathbf{f}^{ex}_{n+1}=\nabla\cdot((3\lambda+2G)\alpha\Delta T\mathbf{I})\big|_{n+1}$, where λ,G,α and ΔT stand for the first and the second Lamé's constants, the linear expansion coefficient, and the temperature difference ($\Delta T=T_{n+1}-T_n$), respectively. Between bars and the cooling bed, no contact is assumed. The Neumann type of boundary condition is prescribed on the whole boundary $\mathbf{t}=\boldsymbol{\sigma}\cdot\mathbf{n}=0\,\text{N/m}$, where $\mathbf{t}$ represents the traction vector. Since only the derivatives of the displacement field are defined, two additional conditions are enforced to obtain a unique solution

$$\int_\Omega\mathbf{u}(\mathbf{r})d\Omega=0\quad,\quad\int_\Omega\left(\mathbf{u}(\mathbf{r})\times\mathbf{r}\right)d\Omega=0 \tag{12}$$

where Ω represents the bar cross-section area, and $\mathbf{r}$ is a position vector. The posed equations are solved within a plane strain assumption.

Numerical Method

Spatial discretization is performed using the RBF-FD method. The observed domain is discretized by a homogeneous distribution of the scattered discretization nodes - collocation nodes (CNs). For each CN, a set of closest local neighbours is determined that constructs the so-called local

subdomains ${}_l\Omega, l \in [1, N_{all}]$, where N_{all} represents the number of all CNs. Inside each ${}_l\Omega$, the interpolation of a general function can be written as

$$ {}_l y_\xi(\mathbf{r}) \approx \sum_{i=1}^{{}_l N} {}_l\alpha_{i,\xi}\ {}_l\Phi_i(\mathbf{r}) + \sum_{i=1}^{M} {}_l\alpha_{({}_l N+i),\xi}\ p_i(\mathbf{r}) = \sum_{i=1}^{{}_l N+M} {}_l\alpha_{i,\xi}\ {}_l\Psi_i(\mathbf{r}) \tag{13} $$

where ξ is the index that runs over space dimensions n_d, ${}_l N$ is the number of CNs inside ${}_l\Omega$ and is here set to ${}_l N = 13$, ${}_l\alpha_{i,\xi}$ represents weight coefficients, and ${}_l\Phi_i(\mathbf{r})$ is the Radial Basis Function (RBF). Various types of RBFs can be used in the RBF-FD method. Here, 3rd order polyharmonic splines [15] (PHSs) are employed as ${}_l\Phi_i(\mathbf{r}) = (\| \mathbf{r} - {}_l\mathbf{r}_i \| / {}_l h)^3$, where ${}_l h$ represents the average distance from the centre of ${}_l\Omega$ to its neighbours inside ${}_l\Omega$. The interpolant is augmented with monomials $p_i(\mathbf{r}), i \in [1, M]$, where $M = 3$ for the 2nd order augmentation $p_1 = x, p_2 = y, p_3 = 1$ used here. Eq. 13 can be compactly written as a system of $n_d({}_l N + M)$ linear equations

$$ \sum_{\chi=1}^{n_d} \sum_{i=1}^{{}_l N+M} {}_l A_{ji,\chi\xi}\ {}_l\alpha_{i,\chi} = {}_l\gamma_{j,\xi} $$

where

$$ {}_l A_{ji,\xi\chi} = \begin{cases} \Psi_i({}_l\mathbf{r}_j)\delta_{\xi\chi} & \text{if } {}_l\mathbf{r}_j \in \Omega \cup \Gamma \\ p_{j-{}_l N}({}_l\mathbf{r}_j)\delta_{\xi\chi} & \text{if } j > {}_l N \text{ and } i \le {}_l N \\ 0 & \text{otherwise} \end{cases}, \quad {}_l\gamma_{j,\xi} = \begin{cases} y_\xi({}_l\mathbf{r}_j) & \text{if } {}_l\mathbf{r}_j \in \Omega \cup \Gamma \\ 0 & \text{otherwise} \end{cases} \tag{14} $$

Application of a linear differential operator L on the interpolation function Eq. 13 acts only on the basis functions

$$ L_l\mathbf{y}(\mathbf{r})_\xi = \sum_{\chi=1}^{n_d} L_{\xi\chi}\, {}_l y_\chi(\mathbf{r}) \approx \sum_{\chi=1}^{n_d} \sum_{i=1}^{{}_l N+M} {}_l\alpha_{i,\chi}\ L_{\xi\chi}\, {}_l\Psi_i(\mathbf{r}) \tag{15} $$

Expressing weight coefficients from Eq. 14, we arrive at

$$ L_l\mathbf{y}(\mathbf{r})_\xi \approx \sum_{\zeta=1}^{n_d} \sum_{j=1}^{{}_l N+M} {}_l\gamma_{j,\zeta} \sum_{\chi=1}^{n_d} \sum_{i=1}^{{}_l N+M} {}_l A^{-1}_{ij,\chi\zeta}\ L_{\xi\chi}\, {}_l\Psi_i(\mathbf{r}) = \sum_{\zeta=1}^{n_d} \sum_{j=1}^{{}_l N+M} {}_l\gamma_{j,\zeta}\ {}_l W_{j,\xi\zeta}(\mathbf{r}) \tag{16} $$

where the operator's action on a function is now expressed as a weighted sum of known values ${}_l\gamma_{j,\zeta}$ and operator coefficients ${}_l W_{j,\xi\zeta}(\mathbf{r})$. So, in order to discretize differential operators, the operator coefficients (OCs) should be determined for each ${}_l\Omega$. This is done as a pre-prosses step only once.

Regarding the governing equation of the thermal model Eq. 1, OCs for the gradient and the Laplacian operator of the scalar field are computed. Time marching is performed with the forward Euler method. View factor matrix **F**, which includes the view factor $F_{j\to i}$ for each (j,i) DS pair,

is computed with the Monte Carlo method. Here $N_{vf} = 10^5$ particles are shoot in random directions from *j*-th DS and checked which *i*-th DS is hit. Based on the number of hit particles in the *i*-th DS the $F_{j \to i}$ component is determined. In case DS is reflective, the $N_{vf} \cdot \zeta$ number of random particles is bounced off, where ζ is the reflection coefficient.

Discretization of the differential operators in the governing equation Eq. 11 of the mechanical model is performed slightly differently than in the thermal model for increasing stability. OCs of ∇^s operator are not evaluated in CNs but on the 2nd order finite difference (FD) stencils prescribed separately to each CN when CN lies inside the domain. Then, the divergence operator is evaluated via the FD method. The distance between CN and its nearest point on the FD stencil equals $h/2$, where h is the distance to the nearest CN. On the boundary, where only OCs of ∇^s are needed, the position of evaluation of COs is moved for $h/2$ in the opposite side of the outward-facing normal vectors. With the OCs computed, a sparse global system of equations is assembled and solved to obtain the solution. Our future work will publish a more detailed description of the procedure.

Simulation Procedure

The thermal simulation starts by importing the bar's discretized domain (CNs), placing it on the first stage p_1, and setting the material parameters based on the initial temperature $T_{bar,0}$. For the determination of radiative heat fluxes, the CB is enclosed inside the virtual rectangle shown with the red contour in Fig. 1. The boundary of the first bar (also shown with the red contour in Fig. 1) is discretized on DSs. Then, the view factor matrix **F** is computed with DSs of the rectangle and the first bar. Three types of DSs are considered: the first one belongs to the heat shield with reflectivity ζ_{pl}, the second to the steel bars with reflectivity ζ_{bar}, and the third to all other surfaces with reflectivity ζ_{sur}. The heat shield temperature and ambient temperature are set to T_{pl} and T_{sur}, respectively. With **F** computed, heat fluxes on the boundary are calculated using the remaining parameters shown in Table 1. The simulation runs until t_p is reached, where during time marching, the heat fluxes on the boundary and material parameters are updated before each time step. After that, the bar is moved to p_2, and a new bar is positioned on p_1. Since 2 bars are now included, a new **F** is computed. The simulation runs again until t_p where 2 bars are now cooled. This process is repeated with 3, 4, and so on bars until the last position p_n is reached. Then a new cycle is run where the bar on p_n position is removed from the system. Adding the bars on the CB (from the left side) and removing them (from the right side) is repeated until the temperature difference at the time t_p in the centre of the bar on the last stage p_n between two cycles is less than $\Delta T_{\max}$. With this procedure, the quasi-steady state temperature solution is obtained.

The temperature solution is position (or stage) dependent $T(\mathbf{r}, t_j, p_i), t_j \in [0, t_p]$. For mechanical simulation, it is transformed to $T(\mathbf{r}, t_j), t_j \in [0, t_p\ p_n]$ since an arbitrary bar can be picked for the analysis. The mechanical model then incrementally applies the temperature load and considers the updating of the material parameters.

In this work, we show the influence of the distance between bars x_{bp} and the position of the heat shield p_y on the thermal and mechanical solution fields. The study is performed for three different x_{bp} s (R1, R2, R3). To study the same time window $t_{\max} = t_p \cdot p_n$, different times on each stage t_p and a different number of maximum stages p_n are applied. Also, three different p_y s (P1, P2, P3) are investigated, as shown in Table 2.

Results of the Thermal Model

In Fig. 2, the temperature solution in the centre of the bar for the P1R1 case (T_{P1R1}) and the difference to other cases $T_{\mathrm{diff}} = T_{\mathrm{P1R1}} - T_{\mathrm{PiRi}}$ are shown over time. In the P1R1 case, the bars are close to each other, and the heat shield is at its lowest point. Due to that, the slowest cooling is obtained. In all cases, the temperature sensitivity to the position of the heat shield is small. With a larger p_y, the bar's centre is additionally cooled for ~1°C. A comparison of R1 and R2 shows that x_{bp} has a more significant impact on the solution than p_y. In the end, the centre point is cooled for ~5°C more. In case of increased spacing between the bars (compare R2 and R3), the temperature drop is much lower ~1°C.

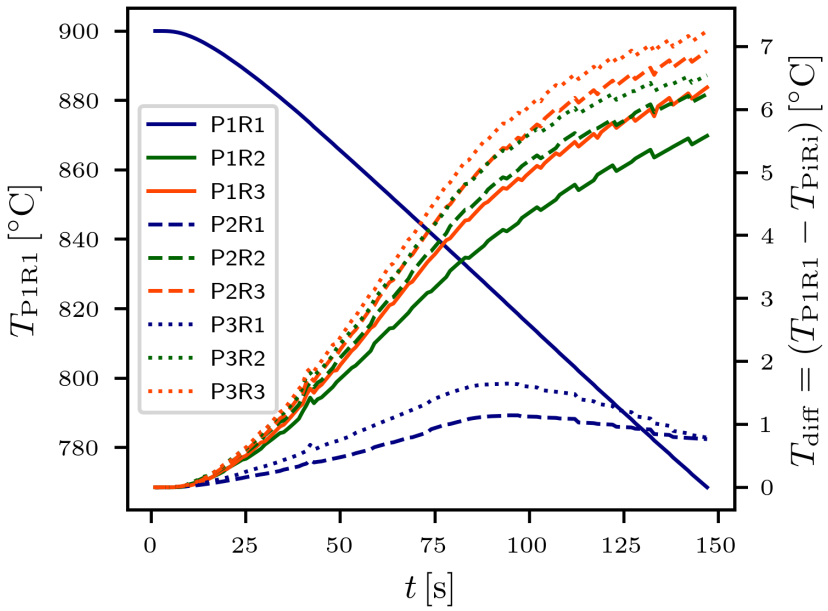

Fig. 2. P1R1 temperature solution in time at the centre of the bar and the difference to other cases.

Fig. 3 shows the temperature solution at the end of the simulation over the field for all investigated cases. As shown before, observing cases from left to right (increasing x_{bp}), the temperature decreases more than changing the cases from top to bottom (increasing p_y). One can also observe that the field is not symmetric. This is a consequence of nonuniform heat fluxes that change with time. In all cases, the right half of the bar is cooled more. This happens since a bar on the right-hand side of some other observed bar is colder than the bar on the left-hand side, so the heat flux on the right is larger.

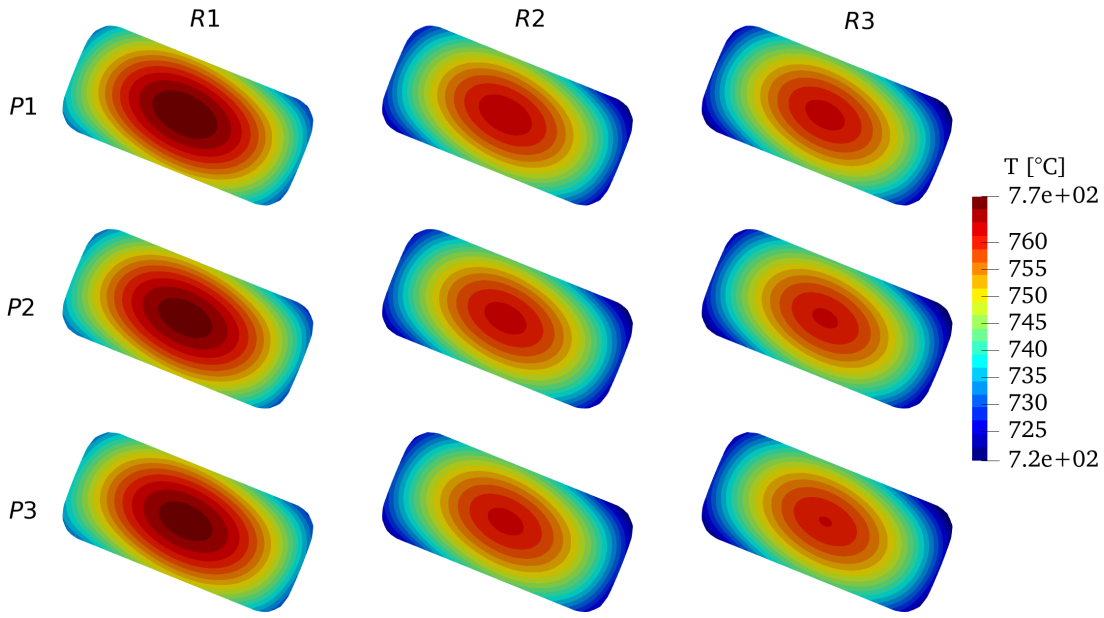

Fig. 3. Temperature of all cases as a function of x_{bp} and p_y at $t_{max} = 150$ s.

Results of the Mechanical Model

In Fig. 4, the results of the von Mises stress σ_{vm} and the accumulated plastic strain $\bar{\varepsilon}^p$ are shown over time obtained in the centre point of the bar. Up to $t \approx 5$ s, the elastic response occurs where no plastic strain is present. Then the slope of the σ_{vm} changes and the bar is plastically deformed. One can see that σ_{vm} and $\bar{\varepsilon}^p$ are changing mostly linearly with time. Small differences in solutions at the end of the simulation are obtained. As in the temperature solution, cases with the same x_{bp} have a similar solution.

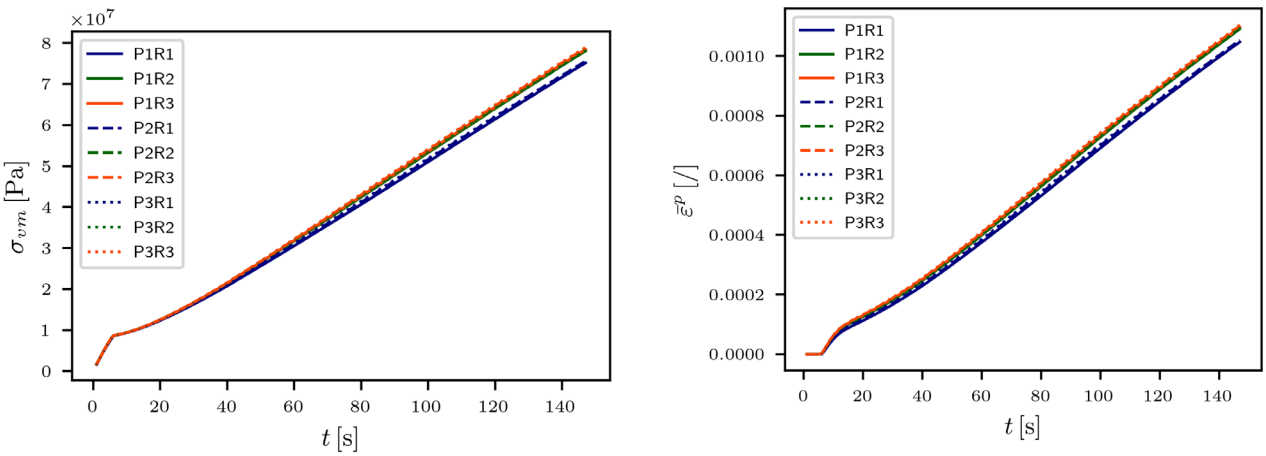

Fig. 4. Von Mises stress (left) and accumulated plastic strain (right) in the centre of the bar over time.

In Fig. 5, the von Mises stress is shown over the field for all cases at the end of the simulation. Similar asymmetry as in the temperature field can be observed. The highest stresses occur in the same area as the lowest temperatures.

In Fig. 6, the initial shape is shown with a grey colour contour. For comparison with deformed shapes, it is shrunk by a factor of 16. The deformed contours, also shown in Fig. 6, are obtained by applying the displacement field solution, multiplied by 300, onto the initial geometry to make

the change visible. In the R1 case, the shrinkage is the smallest, and in the R3 case is the largest. All deformed shapes have a more elliptic shape and are also slightly tilted to the left.

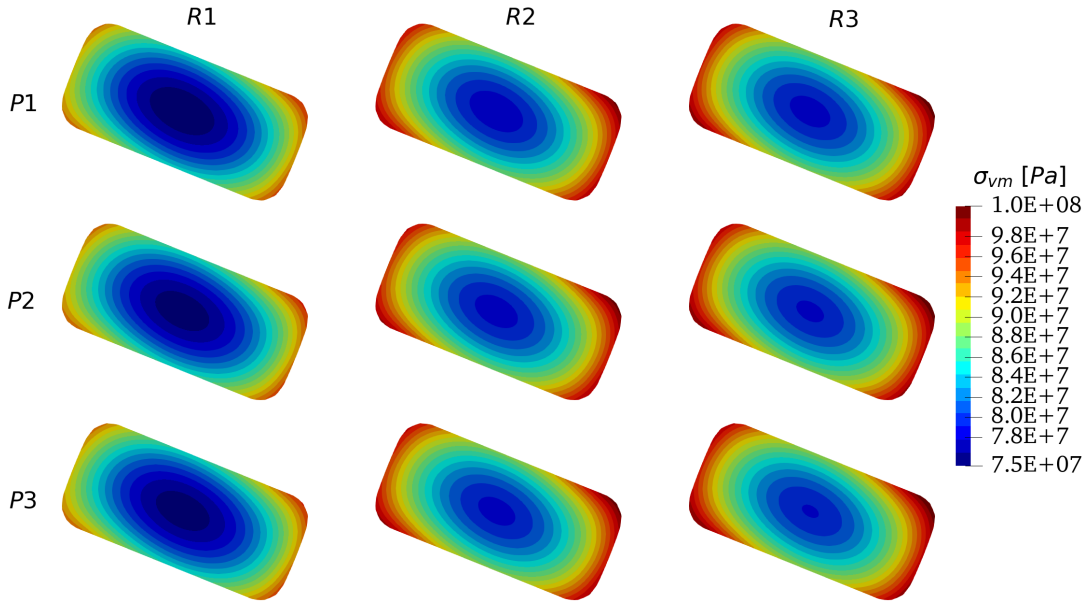

Fig. 5. Von Mises stress of all cases as a function of x_{bp} and p_y at $t_{\max} = 150$ s.

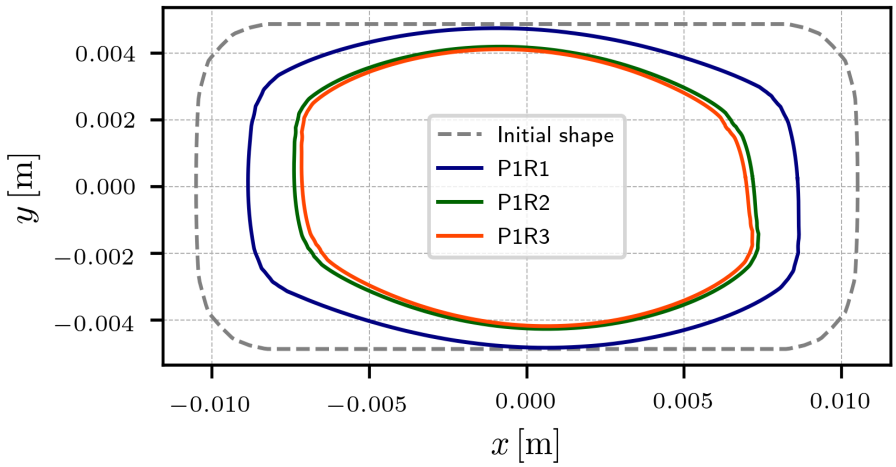

Fig. 6. Initial shape contour shrank by a factor of 16. Deformed contours are obtained by applying the displacement solution multiplied by a factor 300.

Summary

In this work, we presented the modelling of a thermo-mechanical response of steel bars on the cooling bed with the RBF-FD method. Nine cases with varying distances between bars and the position of the heat shield were investigated. We have shown that the solution fields and the final geometry are not symmetric. A reduction of distance between bars has proven to be much more dominant in reducing the cooling rate than the reduction of spacing between bars and the heat shield. The calculated accumulated plastic strain in all considered cases ranges up to ~0.1%, and the maximum von Mises stresses obtained are ~100 MPa.

With this work, we have successfully demonstrated the use of the RBF-FD method on a complex industrial problem. In future work, a three-dimensional model will be implemented to capture also bending of the bars.

Keywords: PINNs, Computational Homogenization, Thermomechanics, Effective Properties

Abstract. We determine the effective (macroscopic) thermoelastic properties of two-phase composites computationally. To this end, we use a physics-informed neural network (PINN)-mediated first-order two-scale periodic asymptotic homogenization framework. A diffuse interface formulation is used to remedy the lack of differentiability of property tensors at phase interfaces. Considering the reliance on the standard integral solution for the property tensors on only the gradient of the corresponding solutions, the emerging unit cell problems are solved up to a constant. In view of this and the exact imposition of the periodic boundary conditions, it is merely the corresponding differential equation that contributes to minimizing the loss. This way, the requirement of scaling individual loss contributions of different kinds is abolished. The developed framework is applied to a planar thermoelastic composite with a hexagonal unit cell with a circular inclusion by which we show that PINNs work successfully in the solution of the corresponding thermomechanical cell problems and, hence, the determination of corresponding effective properties.

Introduction

Accurate prediction of the effective (macroscopic) material properties is crucial for the high-fidelity simulation of the deformation processes of heterogeneous media. Although there exist analytically derived bounds, e.g., (arithmetic) Voigt and the (harmonic) Reuss averages;
and effective-medium theories, e.g., the Maxwell, self-consistent, and differential effective-medium approximations, these fall short of providing accurate predictions for materials systems, including high property contrast and varying phase volume fractions [1]. This is due to the limited microstructural descriptors considered in their formulation, e.g., the phase volume fraction and shape. As a remedy, full-field computational micro-macro transfer techniques, e.g., finite element method-based computational homogenization schemes, have been proposed [2-5]. This requires solving the boundary value problem, in this context also referred to as the *cell problem*, over the discretized periodic unit cell, or, in general, a representative volume element (RVE).

Since the founding work of Lagaris *et al*., [6] deep neural networks (DNNs) have emerged as an alternative method to solve partial differential equations (PDEs). Physics-informed neural networks (PINNs) use the universal approximation property [7-9] of DNNs in approximating the solution of PDEs in physical problems[10]. This is accomplished through an optimization procedure in which the DNN hyper-parameters are found by minimizing loss functions.
Whereas the classical machine learning approaches identify the corresponding error in terms of distance to a dataset, it is the residual norm of the governing differential equation and associated initial and boundary conditions (BCs) which forms the loss function in PINNs [6, 11-13]. As opposed to standard discretization techniques, e.g., the finite element method (FEM), which

requires domain discretization and construction of a weak form, PINNs allow solving the PDE in its strong form and in a meshless manner providing a differentiable solution which proves helpful in subsequent calculations[6]. For an extensive survey regarding the state of the art of PINNs, the reader is referred to [14].

This work considers the determination of the effective thermomechanical properties of periodic two-phase composites. This is accomplished by two-scale asymptotic and computational homogenization. Unlike many references that conventionally use FEM in the solution of the cell problem, see, e.g., [2-5], we use PINNs by considering that the micro- (constituent-level) \MP{scale} is described by Duhamel-Neumann and Fourier laws. Solving the unit cell problems up to a constant and an exact imposition of the periodic boundary conditions eliminates loss contributions from the boundary conditions of different kinds. It should be noted that the property tensor computations rely on the integrals of the gradient of the corresponding solutions.
DeepXDE is used as the scientific ML and physics-informed library[10]. A 2D periodic hexagonal unit cell with a central circular inclusion is selected as an application problem. Our work shows that PINNs successfully solve the cell problem, i.e., the local thermomechanical boundary value problem, and determine corresponding effective properties. For an extended treatment of the framework in generic elliptic PDEs, with $n-$dimensional applications including phase contrast and interface sharpness effects on the solution accuracy, see [15].

Planar Thermoelasticity

We consider planar thermoelasticity in which the relation between mechanical and thermal fields is constructed through the following Duhamel-Neumann law [16,17] for *i,j,k,l* = 1,2

$$\sigma_{ij} = \mathrm{C}_{ijkl}\epsilon_{ij} - \beta_{ij}\Theta \tag{1}$$

$$\beta_{ij} = \mathrm{C}_{ijkl}\alpha_{kl} \tag{2}$$

Here, C_{ijkl}, β_{ij}, and α_{kl} denote components of the fourth-order planar elasticity tensor C, and planar second-order thermal expansion tensors β and κ, respectively. The temperature field is denoted by Θ whereas σ represents the stress tensor. Letting x denote the position vector, the components of the strain tensor ϵ are computed from the displacement field u with

$$\epsilon_{ij} = \frac{1}{2}\left[\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right] \tag{3}$$

Letting κ denote the second-order thermal conductivity tensor; it is assumed that Fourier law relates the heat flow vector to the temperature with

$$q_i = -\kappa_{ij}\frac{\partial \Theta}{\partial x_j} \tag{4}$$

In view of Eq. 1 and 4, and letting b and f denote the internal body force and heat source density, respectively, the linear momentum balance and the stationary heat balance equations respectively read

$$\frac{\partial \sigma_{ij}}{\partial x_j} = b_i \qquad and \qquad \frac{\partial q_i}{\partial x_i} = f \tag{5}$$

Considering planar thermoelastic isotropy, we have

$$C_{ijkl} = \lambda\delta_{ij}\delta_{kl} + \mu\left[\delta_{il}\delta_{jk} + \delta_{ik}\delta_{jl}\right], \qquad \beta_{ij} = \beta\delta_{ij}, \qquad and \qquad \kappa_{ij} = \kappa\delta_{ij} \tag{6}$$

for *i, j, k, l* = 1, 2. Here, λ and μ represent planar Lamé constants, whereas β and κ denote isotropic thermal expansion and heat conduction coefficients. In matrix notation, the isotropic property tensors C, β, and κ whose indicial representations are given in Eq. 6, correspond to the following 3 x 3, 2 x 2, and 2 x 2 matrices, respectively

$$[C] = \begin{bmatrix} \lambda + 2\mu & \lambda & 0 \\ \lambda & \lambda + 2\mu & 0 \\ 0 & 0 & \mu \end{bmatrix}, \quad [\beta] = \begin{bmatrix} \beta & 0 \\ 0 & \beta \end{bmatrix}, \quad [\kappa] = \begin{bmatrix} \kappa & 0 \\ 0 & \kappa \end{bmatrix} \tag{7}$$

First-Order Asymptotic Homogenization

We are interested in material systems of two periodically distributed phases showing linear physical properties. For such systems, a repeating material domain *v*, which is also referred to as a unit cell, encapsulates all material characteristics. Henceforth, let *x* denote the cell-scale (microscale) position and capture fast field variations. It is linked to the macroscale position ${}^{M}x$ which captures fields slow variations, with $x = {}^{M}x/\epsilon$, where $0 < \epsilon << 1$ scale separation parameter. Following [17], we apply a two-scale asymptotic expansion of the *nondimensional* thermoelastic problem-solution in terms of the displacement and temperature fields $u^{\epsilon}({}^{M}x)$ and $\Theta^{\epsilon}({}^{M}\boldsymbol{x})$ results in the following representation

$$u^{\epsilon}\left({}^{M}x\right) = u^{(0)}\left({}^{M}x, x\right) + \epsilon u^{(1)}\left({}^{M}x, x\right) + \epsilon^2 u^{(2)}\left({}^{M}x, x\right) + O(\epsilon^3) \tag{8}$$

$$\Theta^{\epsilon}\left({}^{M}x\right) = \Theta^{(0)}\left({}^{M}x, x\right) + \epsilon u\Theta^{(1)}\left({}^{M}x, x\right) + \epsilon^2 u\Theta^{(2)}\left({}^{M}x, x\right) + O(\epsilon^3) \tag{9}$$

Here, $u^{(i)}$ and $\Theta^{(i)}$ are *v* periodic functions in *x*. Using Eq. 1 and 4 to derive the expansions for the stress tensor and heat flux vector, σ^{ϵ} and q^{ϵ}, substituting the expansions in Eq. 5 and comparing coefficients of powers in ϵ and applying separation of variables, we reach the following macroscopic property tensors $C^{\star}$, $\beta^{\star}$, and $\kappa^{\star}$, respectively

$$C^{*}_{ijkl} = \frac{1}{|v|}\int_{v} \left[C_{ijkl} + C_{ijmn}\frac{\partial U^{kl}_{m}(x)}{\partial x_n}\right] dV \tag{10}$$

$$\beta^{*}_{ij} = \frac{1}{|v|}\int_{v} \left[\beta_{ij} - C_{ijmn}\frac{\partial L_m(x)}{\partial x_n}\right] dV \tag{11}$$

$$\kappa^{*}_{ij} = \frac{1}{|v|}\int_{v} \left[\kappa_{ij} - \kappa_{nj}\frac{\partial M^{i}(x)}{\partial x_n}\right] dV \tag{12}$$

In Eq. 10, 11 and 12, ${U^{kl}}_{m}$, L_m and M^i for *m, k, l, i* = 1, 2 correspond to v - periodic corrector functions which constitute the solutions of the following cell-problems, respectively

$$\frac{\partial}{\partial x_j}\left[C_{ijkl}\frac{\partial U^{mn}_{k}(x)}{\partial x_l}\right] = -\frac{\partial C_{ijmn}(x)}{\partial x_j} \tag{13}$$

$$\frac{\partial}{\partial x_j}\left[C_{ijkl}\frac{\partial L_k(x)}{\partial x_l}\right] = \frac{\partial \beta_{ij}(x)}{\partial x_j} \tag{14}$$

$$\frac{\partial}{\partial x_j}\left[\kappa_{jl}\frac{\partial M^{i}(x)}{\partial x_l}\right] = -\frac{\partial \kappa_{ij}(x)}{\partial x_j} \tag{15}$$

Physics-Informed Neural Networks (PINNs)

In the representation of the corresponding theory, we follow the works by Lu *et al.* [10] and Haghighat *et al.* [13]. Let $N^L(x;\Theta) : \mathrm{R}^{\dim_{in}} \rightarrow \mathrm{R}^{\dim_{out}}$ represent the surrogate model, an L-layer neural network with L - 1 number of hidden layers, that gives the approximate solution for the unknown u of the differential equation. Let x and y denote the input and output vectors, respectively, and $\Theta := \{W, b\}$ represent the set of trainable network parameters, i.e., the weight matrix W and the bias vector b. $\dim_{in}$ and $\dim_{out}$ denote the network input and output dimensions, respectively. With the input-output relations $z^0 \leftarrow x$ and $y \leftarrow z^L$, the propagation of the input through the layers of a feed-forward network is accomplished with the following sequence of operations

$$z^k = \sigma(W^k z^{k-1} + b^k), \qquad 1 \leq k \leq L-1 \tag{16}$$

$$z^L = W^L z^{L-1} + b^L \tag{17}$$

Here, σ is the nonlinear activation function, and q_k, $z^k \in \mathrm{R}^{q_k}$, $W^k \in \mathrm{R}^{q_k \times q_{k-1}}$ and $b^k \in \mathrm{R}^{q_k}$ denote the number of neurons, the outputs, the weight matrix, and the bias vector of each layer k, espectively.

Fig. 1 depicts a schematic plot of a PINN used in the solution of PDEs for the input x and output $\hat{u}$, as an approximation of the actual solution u. P and B respectively denote the differential and boundary operators and the subscripts P and B associations with the PDE and the boundary operators, respectively. For a given training set (collocation points) T, the loss function $L(\boldsymbol{\theta}; T)$ then comprises a weighted sum (with ω_P and ω_B denoting the loss weights) of the residuals of the PDE and the boundary terms which are denoted by $L_P(\boldsymbol{\theta}; T_P)$) and $L_B(\boldsymbol{\theta}; T_B)$), respectively, to give

$$L(\theta; T) = \omega_P L_P(\theta; T_P) + \omega_B L_{PB}(\theta; T_B) \tag{18}$$

The neural network minimizes the loss function by varying the network parameters θ by means of a process referred to as training. At the end of the training, a converged parameter set $\boldsymbol{\theta}^\star$ is reached, providing the optimum output.

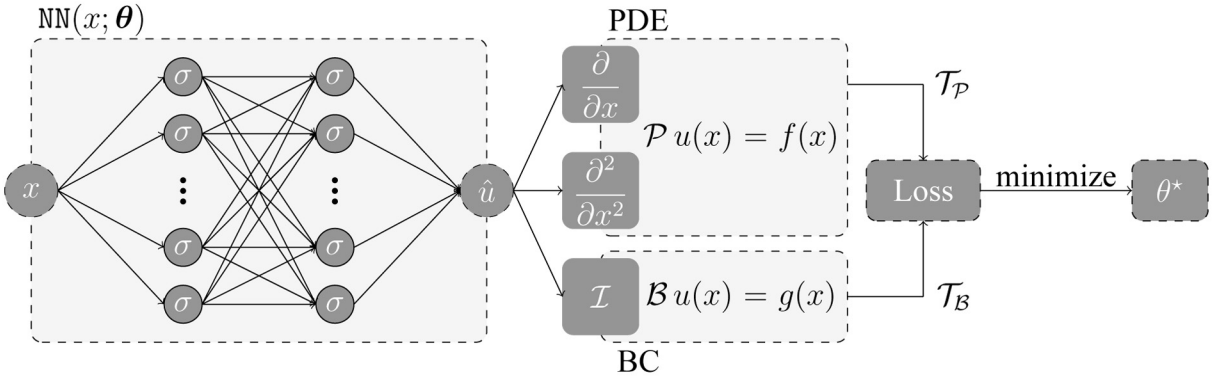

Fig. 1. Schematics of a PINN used in the solution of a PDE with P and B denoting differential and boundary operators, respectively. The image is adapted from [10].

Applications

As an illustrative example, we consider a two-dimensional hexagonal composite domain with a circular inclusion. The selected unit cell corresponds to the Wigner-Seitz cell of the hexagonal Bravais lattice; see Fig. 2. An inclusion volume fraction of $\phi_i = 0.30$ is selected.

Letting $a(x)$ denote a generic isotropic property; the inclusion and matrix properties are denoted as a_i and a_m, respectively. For convenience we consider the values $a_i = \lambda_i = \mu_i = \beta_i = \kappa_i = 2$ and $a_m = \lambda_m = \mu_m = \beta_m = \kappa_m = 1$. This corresponds to a property contrast of 2. The case for phase interchange with $a_i = 1$ and $a_m = 2$ is also investigated.

Considering Eq. 13, 14 and 15, the computation of the source terms requires property derivatives with respect to position. To make this possible, we use a diffuse interface approach given by

$$a(x) = a_m + \frac{a_i - a_m}{2}\left[1 - \tanh\left(\frac{|x|-r}{\xi}\right)\right] \tag{19}$$

where the regularization parameter ξ is chosen to satisfy $L/\xi = 200$. In view of Neumann's principle [18, 19], the macroscopic thermoelastic properties of the material system represented by the periodic composite unit cell given in Fig. 2 possess planar isotropy. Consequently, we can compute the thermoelastic property tensor components through the solutions $U^{kl}{}_m$, L_m and M^i of Eq. 13, 14 and 15 using only one source term in each, which we denote by b^U, b^L and f^M, respectively, and are given in matrix form as

$$[b^U] = \begin{bmatrix} \frac{\partial[\lambda(x)+2\mu(x)]}{\partial x_1} \\ \frac{\partial \lambda(x)}{\partial x_2} \end{bmatrix}, \qquad [b^L] = \begin{bmatrix} \frac{\partial \beta(x)}{\partial x_1} \\ \frac{\partial B(x)}{\partial x_2} \end{bmatrix}, \qquad and \qquad f^M = \frac{\partial \kappa(x)}{\partial x_1} \tag{20}$$

The above problem is implemented into DeepXDE, a scientific ML and physics-informed library [10]. As for the NN hyperparameters, the density and depth of the neural network are selected as 50 and 3, respectively. 25000 collocation points are selected over the problem domain. In optimization studies, a learning rate of 0.01 is used with 30000 epochs. The first 5000 of the 30000 epochs belong to adam optimizer, whereas the remaining 25000 to the L-BFGS optimizer.

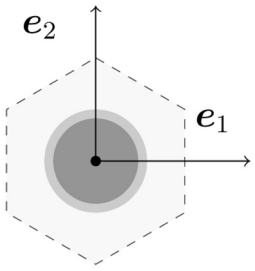

Fig. 2. The selected hexagonal unit cell centered at the origin of the selected Cartesian plane (e_1, e_2). The regular hexagon has an edge length of L and the circular inclusion a radius of r. A diffuse phase interface formulation makes the function differentiable when computing the source terms.

Results and Discussions

Using the PINNs framework, the cell problems dictated by Eq. 13, 14 and 15 are solved for the load cases given in Eq. 20 considering phase properties with $a_i/a_m = 2$ and $a_m/a_i = 2$. Fig. 3 gives the normalized loss function training histories for the PINN solutions. During the iterations, the

first 5000 epochs belonged to the first-order and stochastic adam optimizer. It is observed thatat the latter stages of adam optimization, the loss hardly improves. Reverting to L-BFGS optimizer considerably reduces loss by providing a monotonic convergence.

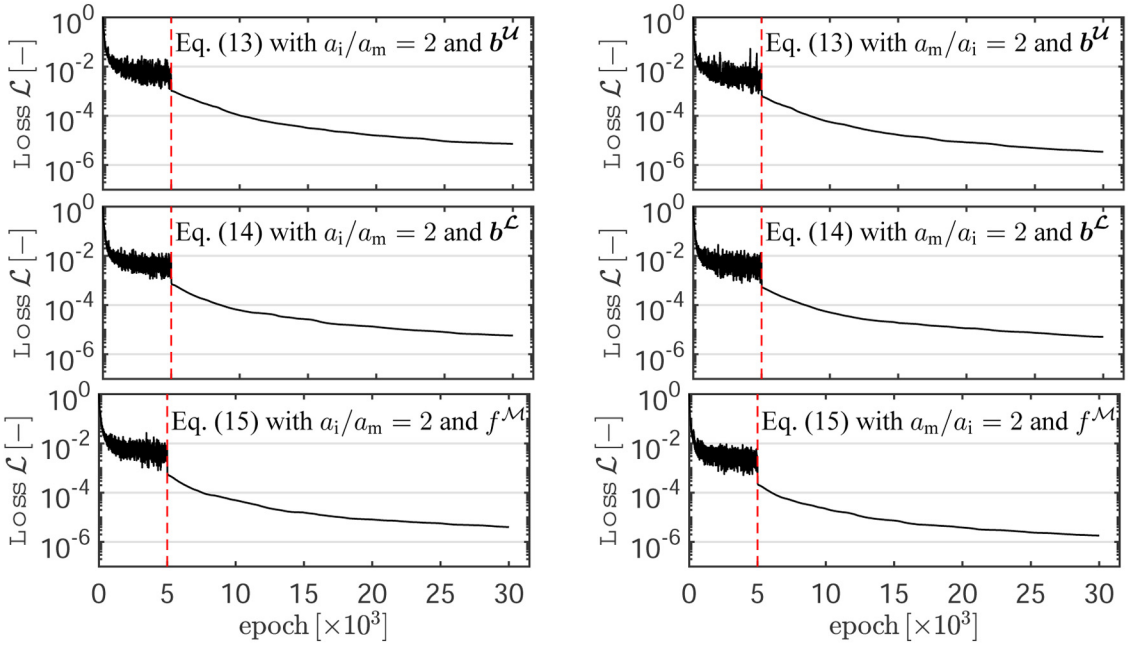

Fig. 3. Training histories of the loss function for the PINN solution of the cell problems given in Eq. 13, 14 and 15. The first 5000 epochs (marked with a red dashed line) belong to adam optimizer, whereas the remaining to L-BFGS. All results are normalized with respect to the initial state.

Resultant contour plots for the property, as well as resultant fields, are given in Figs. 4, 5, and 6. The symmetry and periodicity in the solution fields match that of the composite unit cell. The phase interchange results in the interchange of zones of maximum and minimum in the field distributions.

Computing the integral expressions given in Eq. 10, 11 and 12, we determine the effective property tensors. For $a_i/a_m = 2$ and phase content of $\phi_i = 0.30$, the (arithmetic) Voigt and the (harmonic) Reuss averages yield $a^*_V = 1.300$ and $a^*_R = 1.176$, respectively, which also correspond to upper and lower bounds, respectively.

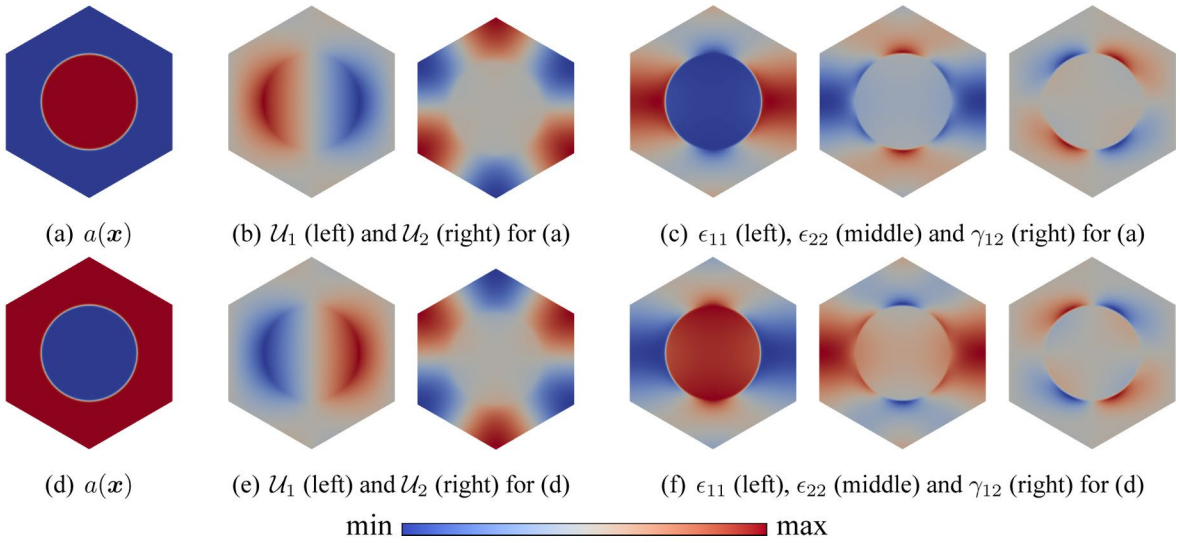

Fig. 4. The contour plots for the solution of Eq. 13 considering the load case b^U given in Eq. 20. The property field a(x) is given for $a_i/a_m = 2$ in (a) and for $a_m/a_i = 2$ in (d). The strain components are computed using the corresponding corrector function U with $\epsilon_{11} = \partial U_1/\partial x_1$, $\epsilon_{22} = \partial U_2/\partial x_2$ and $\gamma_{12} = [\partial U_1/\partial x_2 + \partial U_2/\partial x_1]$.

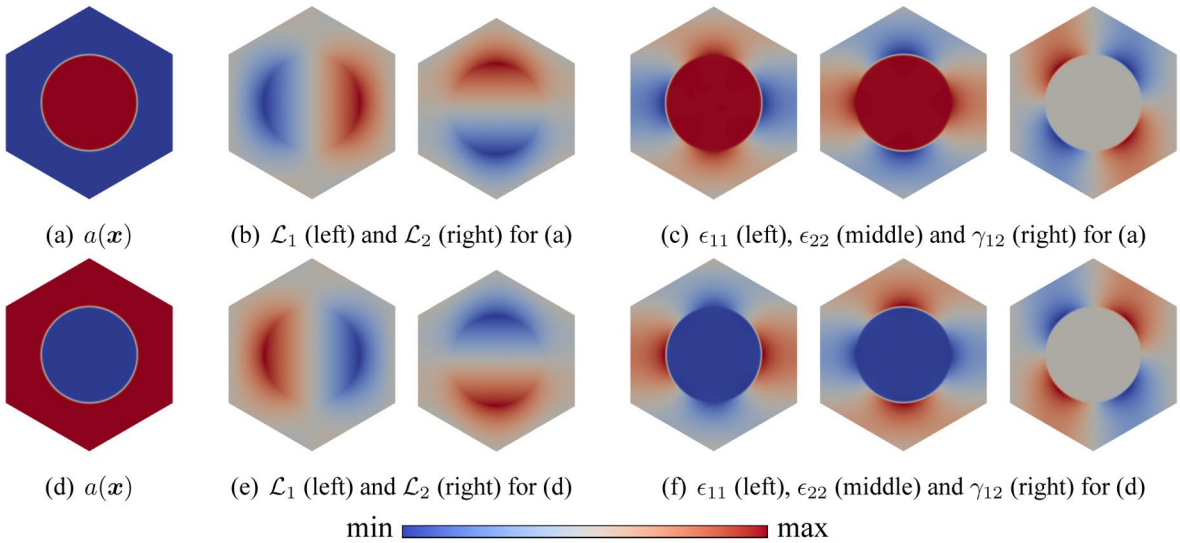

Fig. 5. The contour plots for the solution of Eq. 14 considering the load case b^L given in Eq. 20. The property field a(x) is given for $a_i/a_m = 2$ in (a) and for $a_m/a_i = 2$ in (d). The strain components are computed using the corresponding corrector function L with $\epsilon_{11} = \partial L_1/\partial x_1$, $\epsilon_{22} = \partial L_2/\partial x_2$ and $\gamma_{12} = [\partial L_1/\partial x_2 + \partial L_2/\partial x_1]$.

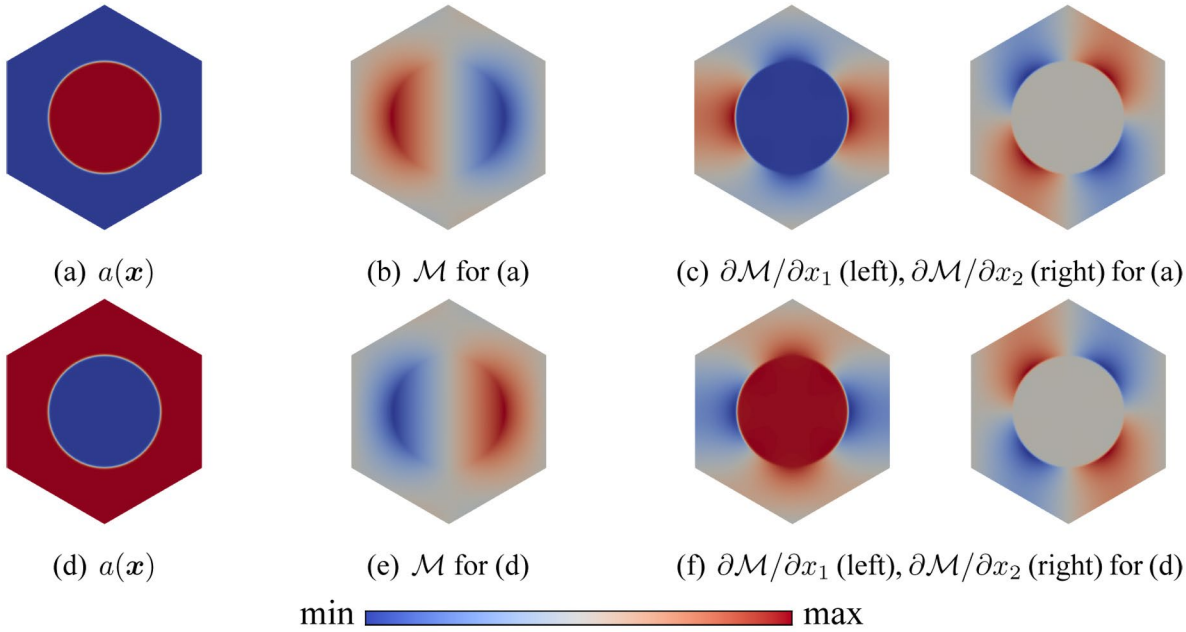

Fig. 6. The contour plots for the solution of Eq. 15 considering the load case $f^{\mathcal{M}}$ given in Eq. 20. The property field a(x) is given for $a_i/a_m = 2$ in (a) and for $a_m/a_i = 2$ in (d).

This is, however, under sharp interface conditions, which is not the case in our PINN computations. In our PINN solution, we have the following matrix representations

$$[C^*] = \begin{bmatrix} 3.621 & 1.207 & 0 \\ 1.207 & 3.621 & 0 \\ 0 & 0 & 1.207 \end{bmatrix}, \quad [\beta^*] = \begin{bmatrix} 1.207 & 0 \\ 0 & 1.207 \end{bmatrix}, \quad [\kappa^*] = \begin{bmatrix} 1.224 & 0 \\ 0 & 1.224 \end{bmatrix}$$

This corresponds to the effective planar Lamé constants of $\lambda^* = \mu^* = 1.207$. Selecting $\lambda = \mu$ and keeping a constant ratio between the λ, μ, and β values of the matrix and the inclusion corresponds to the assumption of an identical thermal expansion coefficient α for the phases. Consequently, one expects to recover $\alpha^* = \alpha_i = \alpha_m = 1/4$ as the effective thermal expansion coefficient for the composite. Our solutions with $\beta^* = \lambda^* = \mu^*$ agree with this statement and confirm our computations. Taking $a_m/a_i = 2$ and phase content of $\phi_i = 0.30$, the (arithmetic) Voigt and the (harmonic) Reuss averages, considering sharp interface conditions, yield $a^*_V = 1.700$ and $a^*_R = 1.538$, respectively. In our PINN solution, we have the following matrix representations

$$[C^*] = \begin{bmatrix} 4.830 & 1.610 & 0 \\ 1.610 & 4.830 & 0 \\ 0 & 0 & 1.610 \end{bmatrix}, \quad [\beta^*] = \begin{bmatrix} 1.610 & 0 \\ 0 & 1.610 \end{bmatrix}, \quad [\kappa^*] = \begin{bmatrix} 1.638 & 0 \\ 0 & 1.638 \end{bmatrix}$$

This corresponds to the effective planar Lamé constants of $\lambda^* = \mu^* = 1.610$. As before, our solutions with $\beta^* = \lambda^* = \mu^*$ agree with the condition of $\alpha^* = \alpha_i = \alpha_m = 1/4$. Although these results show that the emerging effective properties lie between those of the constituent phases and the analytical bounds, the computed magnitudes do not follow conventional rules of mixtures.

Summary

We presented a physics-informed neural network-based first-order two-scale periodic asymptotic computational homogenization framework to determine the effective (macroscopic) thermoelastic properties of two-phase composites. The developed framework allowed the exact imposition of the periodic boundary conditions. Solving the relevant thermomechanical unit cell problems up to

a constant was sufficient to compute the integrals giving the effective properties. These allowed the training loss terms devoid of boundary condition contribution, eliminating the need for identifying the associated weights. We applied the developed framework to a planar composite with a circular inclusion of a hexagonal periodic unit cell. We showed that PINNs work successfully to solve emerging cell problems yielding the determination of effective thermomechanical properties.

Keywords: Internal Variables, Stochastic Model, Hot Strip Rolling, DP Steel, Microstructure Evolution

Abstract. Advanced numerical models, which predict heterogeneity of microstructural features, are needed to design modern multiphase steels. Models based on stochastic internal variables meet this requirement. Our objective was to account for the random character of the recrystallization and to transfer this randomness to equations describing the evolution of the dislocations and the grain size during hot deformation. The idea of the internal variable model with the dislocation density and the grain size being stochastic variables is described briefly in the paper. Histograms of the grain size measured in the experimental compression tests were used to identify the coefficients in the model. Inverse analysis with the objective function based on the distance between histograms was applied. The model was used to simulation of the various technological routes in the industrial process of the hot strip rolling.

Introduction

Continuous development of the industry is associated with the search for new construction materials that combine high strength with good formability, as well as high strength-to-density ratio. These features can be obtained for steels with heterogeneous microstructures, in which hard constituents of bainite, martensite and retained austenite are dispersed in a soft ferrite matrix [1]. Advanced numerical models are needed to gain knowledge on the local heterogeneities of the microstructural features and resulting properties. As it was shown in [2] internal variable stochastic models, which can predict heterogeneity of the microstructure, would be a support for the design of multiphase materials.

Majority of the models, which can predict heterogeneity of the microstructure, is based on the explicit representation of the microstructure using Representative Volume Elements (RVE). These models require long computing times. Development of the fast mean field model with a capability to predict distributions of the selected microstructural features is the motivation for our research. The papers, which deal with an application of the mean-field stochastic approach to describe heterogeneity of the microstructure, are rare and they usually consider problem of a correlation between material microstructure and in-use properties of products. Among the recent papers, authors of [3] used statistics for geometry description in homogenization methods and in [4] *n*-point statistics was applied to predict crack probability. In few papers random distribution of selected parameter is used as an input for the deterministic material model, e.g. the Authors of [5] studied an influence of various distributions of the austenite grain size prior to recrystallization on the recrystallization kinetics. Our objective was to account for the random character of the recrystallization which occurs during deformation and after deformation at elevated temperatures and to transfer this randomness to equations describing evolution of the dislocation populations

and the grain size. The idea of the model is presented in [6] and its identification for hot deformation processes is described in [2,7]. Since the model incorporates stochastic character of the phenomena, it may predict the distribution of parameters instead of their average values. The general objectives of the present work were twofold. The first was identification and validation of the stochastic approach to modelling hot deformation of the dual phase (DP) steel including dynamic processes during deformation and static processes during interpass times. The second was application of this model to the simulation of various technological routes for the hot strip rolling process. Application of the results from the stochastic model as input for the simulation of phase transformations during laminar cooling recapitulates the paper.

Model

Description of the model.

The model is discussed in details in [6] and only main equations are repeated here for a completeness of the presentation. The model origins from Kocks-Estrin-Mecking (KEM) approach [8,9] with the stochastic dynamic recrystallization term added. After discretization in time, the evolution of the dislocation density is governed by the equation:

$$\rho(t_i) = \rho(t_0)\left[1-\xi(t_i)\right] + \left\{\rho(t_{i-1}) + \left[A_1\dot{\varepsilon} - A_2\rho(t_{i-1})\dot{\varepsilon}^{1-a_7}\right]\Delta t\right\}\xi(t_i) \tag{1}$$

where: t - time, $\dot{\varepsilon}$ - strain rate, a_7 - coefficient accounting for the influence of the strain rate on the recovery, Δt - time step, A_1, A_2 - coefficients responsible for hardening and recovery defined in [6] and in Fig. *1*.

The parameter $\xi(t_i)$, accounts for a random character of the recrystallization and its distribution is described by the following conditions:

$$\begin{aligned} &\mathbf{P}\left[\xi(t_i)=0\right] = \begin{cases} p(t_i) & if\ \ p(t_i)<1 \\ 1 & otherwise \end{cases} \\ &\mathbf{P}\left[\xi(t_i)=1\right] = 1-\mathbf{P}\left[\xi(t_i)=0\right] \end{aligned} \tag{2}$$

In Eq. 2 $p(t_i)$ is a function, which bounds together the probability that the material point recrystallizes in a current time step and present state of the material:

$$p(t_i) = a_4\rho(t_{i-1})^{a_6}\frac{3\gamma(t_i)\tau}{D_\gamma(t_{i-1})}\exp\left(\frac{-a_5}{RT}\right)\Delta t \tag{3}$$

where: D_γ - grain size in μm, τ - energy per unit dislocation length, a_4, a_5, a_6, a_{17} - coefficients.

In Eq. 3 variable γ represents a mobile fraction of the recrystallized grain boundary and depends on the distribution of $\xi(t_{i-1})$ in previous step, as it is explained in [6]. In the work [7] the model was further extended by including interpass times and static phenomena into simulations. Several trajectories of Eq. 1 were calculated, each time using randomly generated values of $\rho(t_0)$ and $D_\gamma(t_0)$. These individual trajectories were then aggregated into histograms at consecutive time steps t_i. Strictly speaking, we start with the grain size $D_\gamma(t_0) \equiv D_0$ which is a random variable described by the Weibull distribution with the shape parameter $k = 10$, which was determined on the basis of measured grain size distributions shown in [2]. The scale parameter of the distribution was established as the average grain size measured after roughing rolling.

The changes of the grain size during deformation and during the interpass times were calculated based on the fundamental works of Sellars [10], who proposed equations describing grain size after static and dynamic recrystallization, as well as after grain growth.

When during the calculation the random parameter $\xi(t_i) = 0$, the considered point recrystallizes and its new grain size $D_\gamma(t_i)$ is drawn from the Gauss distribution with the expected value of the grain size calculated by the deterministic model either for the static or for the dynamic recrystallization [10]. The standard deviation in the Gauss distribution is an optimization variable a_{16} in the model. The chart showing flow of calculations in the model is shown in Fig. *1*, where: *Np* - number of the Monte Carlo points, *Nt* - number of the time steps, $\dot{\varepsilon}$ - strain rate, *b* - module of the Burgers vector, *l* - mean free path for the dislocations, - *R* - universal gas constant, *T* - temperature in K.

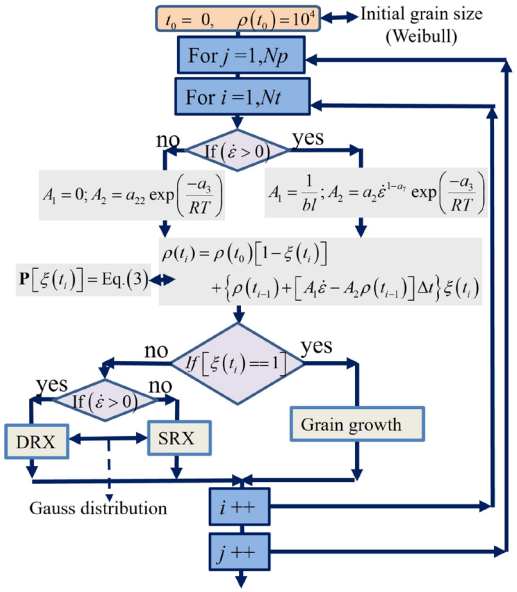

Fig. 1. Selected results of a comparison of measured and calculated flow stress in uniaxial compression.

Beyond the histograms of the selected parameters, the model allows calculation of the average dislocation density ρ_{av} and further the flow stress σ_p, as follows:

$$\sigma_p = \alpha G b \sqrt{\rho_{av}} \qquad \rho_{av} = \frac{1}{Np}\sum_{i=1}^{Np}\rho_i \quad (4)$$

where: *G* - shear modulus, *b* - module of the Burgers vector, *Np* - number of points in the Monte Carlo solution, α - coefficient.

The model contains 22 coefficients, which are grouped in the vector **a**. These coefficients were identified on the basis of the experimental data.

Identification and validation of the model.

Details of the identification procedure are described in [2,6]. Inverse algorithm developed in [11] was applied.

The conventional objective function used in the identification of the deterministic models [11] was extended by including the metric of the distance between measured and calculated histograms of the grain size. The experimental data published in [12] were used. Steel DP600 with the symbol S406 in that publication was considered. The tests composed uniaxial compression of the samples measuring ϕ10×12 at various temperatures and strain rates. The total strain was 1 in all the tests and the expected value of the austenite grain size after preheating was 30 μm. Full set of the experimental data for these test, including micrographs taken at various stages of the deformation and after the deformation, can be found in the RFCS report [13]. The model with optimal coefficients was validated and the selected results are shown in Fig. *2* for the flow stress and in Fig. *3* for the austenite grain size. The experimental flow stress was calculated by the inverse solution [11] for the forces measured in the uniaxial compression tests. Reasonably good agreement between measurements and predictions of the model was obtained for all the experiments.

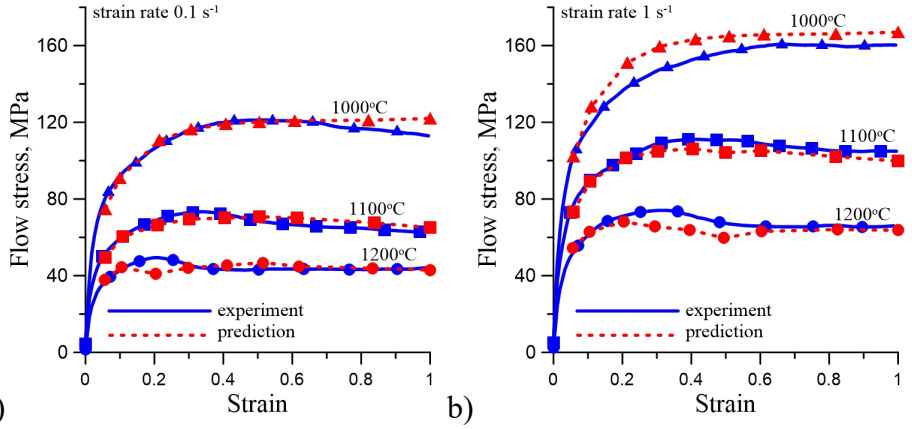

Fig. 2. Selected results of a comparison of measured and calculated flow stress in uniaxial compression.

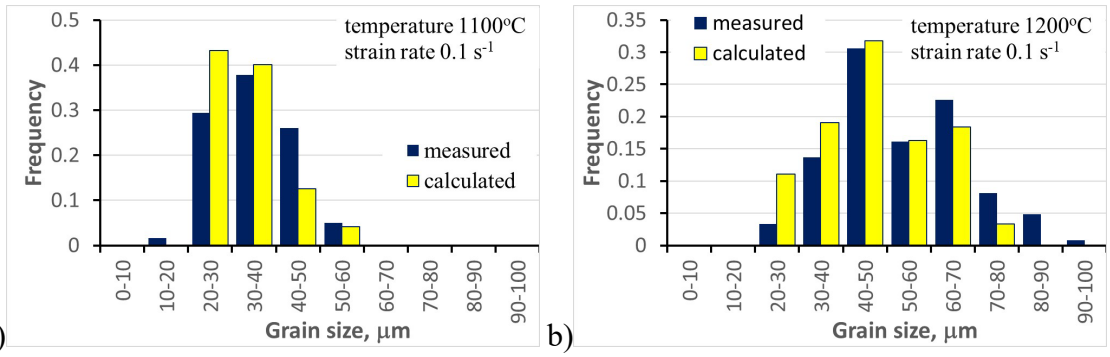

Fig. 3. Selected results of a comparison of measured and calculated histograms of the grain size after uniaxial compression at the strain rate 0.1 s^{-1} and temperature 1100°C (a) and 1200°C (b).

We assumed further that the model, which was validated in the laboratory experiments for various deformation/temperature cycles, will give good results for the industrial conditions.

Numerical Tests of the Model

Numerical tests were performed to evaluate model's predictive capability in the varying conditions of deformation. The stochastic model was implemented into the finite element (FE) program [14] and it was solved in selected points of the FE mesh. The two experiments were simulated: i) Interrupted compression of the uniaxial samples with various holding times between deformations, ii) Varying strain rate test.

Interrupted compression of the uniaxial samples [15].

This test is usually used to develop static recrystallization model. In the present work simulation of the 2 step compression of the sample measuring ϕ10×12 mm were performed. Results for the strain of 0.4 in both deformations and various interpass times are shown in Fig. *4* and in Fig. *5*. The deformation temperature was 1000°C and the strain rate was 1 s^{-1}. Changes of the flow stress calculated following Eq (4) are shown in Fig. *4*. The flow stress during the interpass time decreases asymptotically to zero but it can be concluded that the recrystallization is completed in 2 s after the end of deformation. Histograms of the grain size and dislocation density at the beginning of the second deformation for various interpass times are shown in Fig. *5*. It is confirmed that after 2 s the static recrystallization is completed.

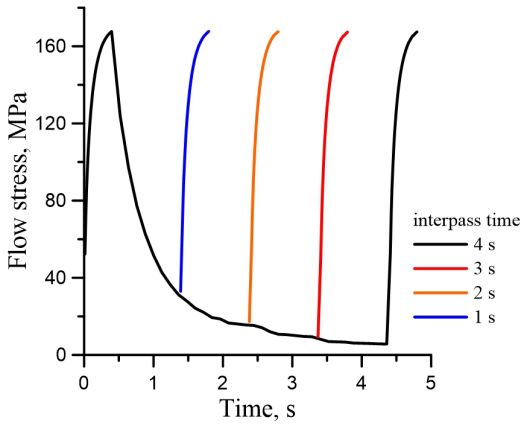

Fig. 4. Results of simulations of the interrupted compression of the cylindrical samples with different interpass times.

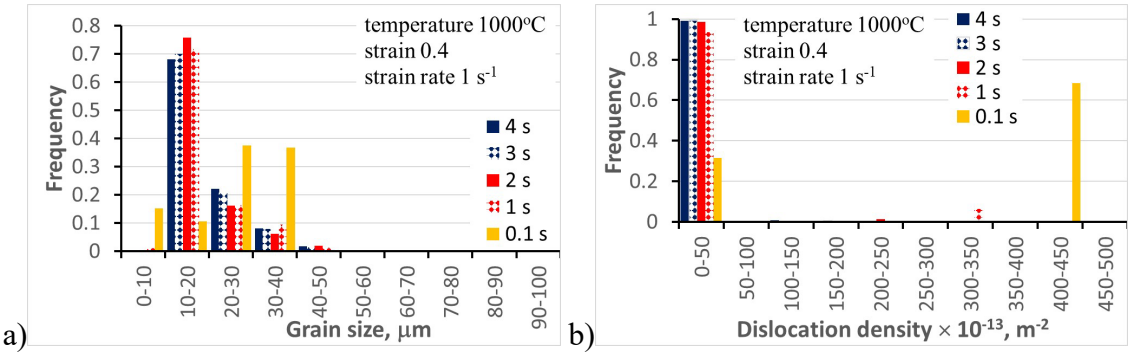

Fig. 5. Histograms of the grain size (a) and dislocation density (b) calculated for various times after the end of deformation.

Varying strain rate test.

In this test the strain rate was changed by an order of magnitude at various stages of the deformation. When external variable models are used, after the change of the conditions the response of the model moves immediately to a new equation of state. On the other hand, it was observed experimentally by many researchers that the response of the material is delayed [16]. This delay is larger for pure metals but it is also observed for alloys (steels) [17]. Below we present the results for the tests when at the strain of 0.4 the strain rate is changed by an order of magnitude (between 0.1 and 1 s^{-1}). The test temperature was 1100°C what means that at the strain of 0.4 the dynamic recrystallization has already begun. Changes of the flow stress during varying strain rate tests are shown in Fig. *6*a. Delay of the material response is well seen in this figure. Histograms of the dislocation density during these tests are shown in Fig. *6*b. Full bars represent dislocation density at the strain 0.4, when the strain rate was changed. The bars with a pattern represent dislocation density at the strain 0.5 (additional strain of 0.1 after the strain rate was changed). It is seen that after this additional strain the state of the system has not reached the state, which was predicted for the constant strain rate.

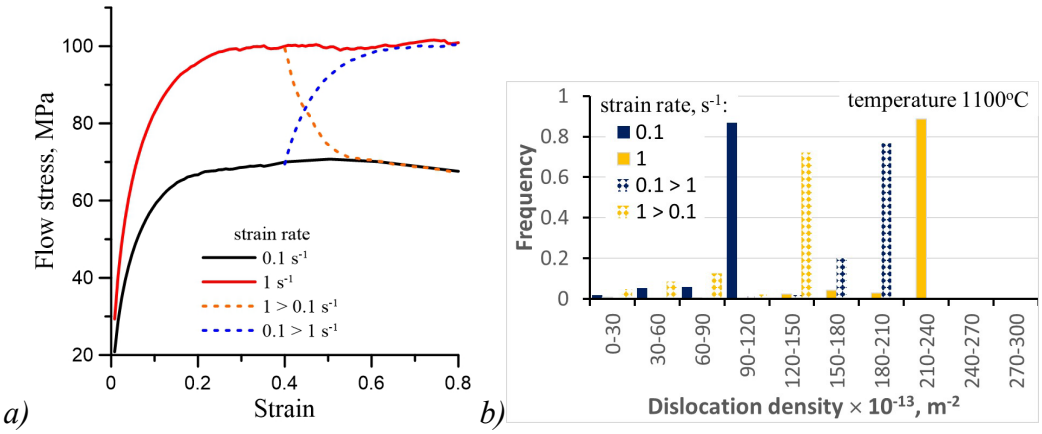

Fig. 6. Changes of the flow stress (a) and histograms of the dislocation density (b) during varying strain rate tests.

Hot Strip Rolling

The hot strip mill composed of reverse roughing mill, 6-stand continuous finishing mill and 2-section laminar cooling was considered. Rolling of the strip 1500×3 mm was simulated. The results for the finishing mill only are presented below. The work roll radius was 400 mm in all stands and the distance between stands was 5 m. The rolling schedule is given in Table 1, where: *h* - thickness, *r* - reduction, *v* - velocity, *t* - interpass time, *rpm* - rotational velocity of the rolls.

Table 1. Rolling schedule considered in the paper.

pass	*h*, mm	*r*	*v*, m/s	*t*, s	*rpm*
0	67	-	0.36	-	-
1	40.6	0.385	0.59	8.5	14.1
2	19.1	0.53	1.26	4	30
3	9.4	0.508	2.56	2	61
4	5.4	0.426	4.44	1.1	106.2
5	3.7	0.315	6.49	0.8	154.9
6	3	0.189	8	0.6	191.1

Two rolling strategies were considered: i) Classical rolling with the end of rolling temperature about 900°C followed by a laminar cooling (V1); ii) Rolling with intensive cooling in finishing mill between 4th and 5th stands as well as between 5th and 6th stands. The end of rolling temperature is below 850°C (V2). Laminar cooling followed and phase transformation model for partially recrystallized material was applied. The objective of V2 was to show the model's capability to predict effect of the austenite deformation on the kinetics of transformations. Calculated time-temperature profiles and load parameters for both variants are shown in Fig. *7*. An effect of additional cooling between stands on loads was evaluated, as well, and it was small.

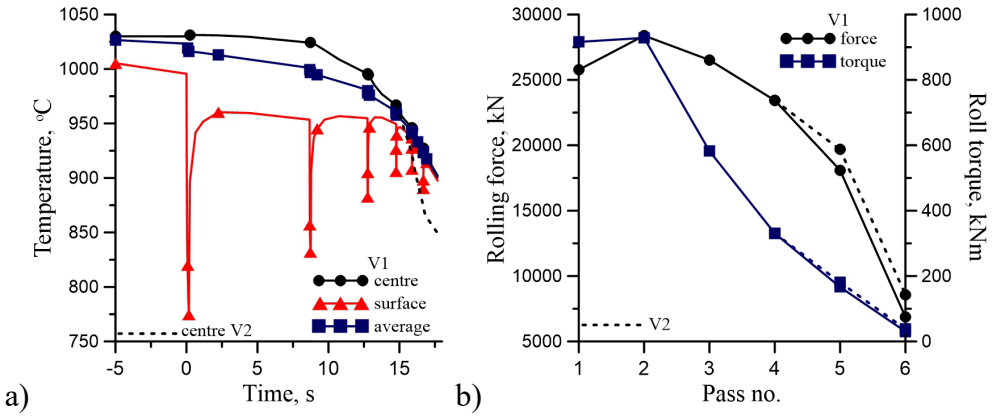

Fig. 7. Calculated time-temperature profiles (a) and load parameters (b) for the two rolling routes.

The stochastic model was applied to calculate distribution of the microstructural parameters during rolling. The selected results for the last 2 passes are shown in Fig. *8*. These results show that decrease of the end of rolling temperature leads to an increase of the dislocation density at the beginning of transformations. These results were used as an input data for simulations of the phase transformations during laminar cooling. At this stage the deterministic model of phase transformations described in [12] was applied but the input data were stochastic. The typical laminar cooling system composed of 2 sections and described in [18] was considered. This system allows a 3-stage cooling sequence: fast/slow/fast cooling. In consequence the DP microstructure composed of ferrite and martensite can be obtained. Since the input data for the deterministic phase transformation model were stochastic, calculated phase composition was obtained in the form of histograms, which are shown in Fig. *9*a. It is seen in this figure that deformation of the austenite (V2) results in an increase of the ferrite volume fraction. Beyond the ferrite, martensite and small amount of bainite (below 0.02) was predicted by the model.

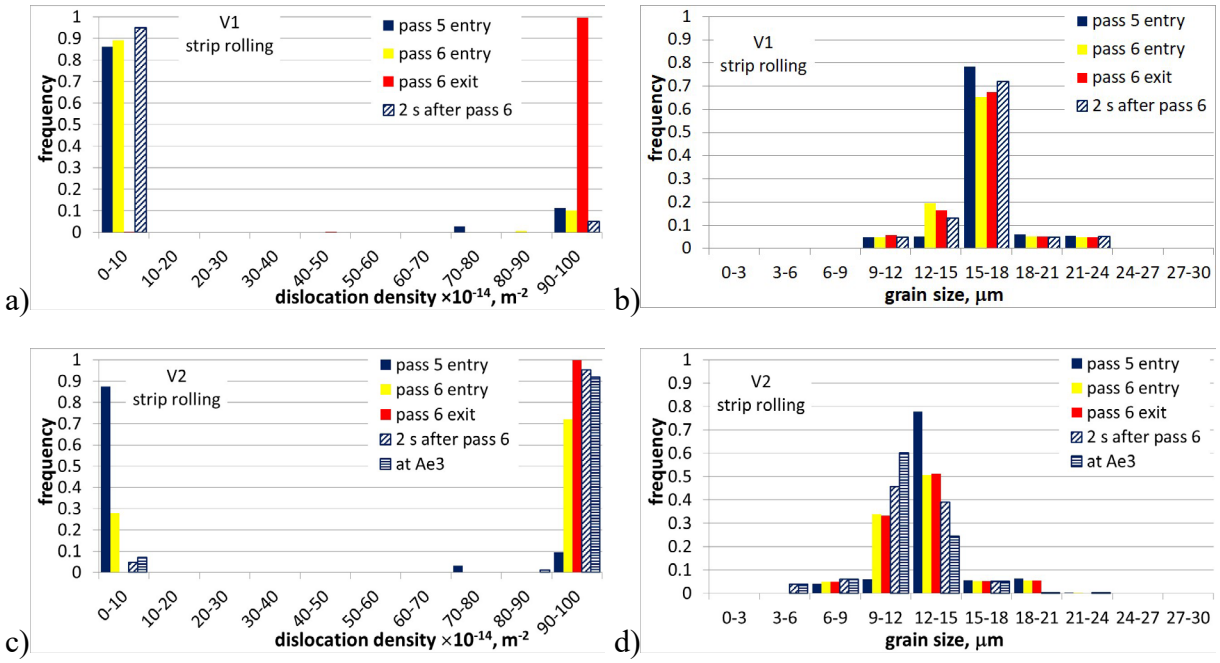

Fig. 8. Calculated histograms of the dislocation density (a,c) and the grain size (b,d) in the last 2 passes of the hot strip rolling according to the rolling schedule V1 (a,b) and V2 (c,d).

Ferrite grain size was calculated by the model, as well. The following deterministic equation proposed in [19] was used:

$$D_\alpha = \left(1-0.45\varepsilon_r^{1/2}\right)\left\{\left(-0.4+6.37\,\mathrm{C_{eq}}\right)+\left(24.2-59\,\mathrm{C_{eq}}\right)C_r^{-0.5}+22\left[1-\exp\left(-0.015D_\gamma\right)\right]\right\} \quad (5)$$

where: ε_r - deformation of the austenite at the beginning of transformation, C_{eq} - carbon equivalent for the steel calculated as C_{eq} = C + Mn/6 + (Cr + Mo)/5, C_r - average cooling rate during ferritic transformation, $D\gamma$ - austenite grain size prior to transformations in μm.

Deformation of the austenite was zero for the V1 and for the V2 it was evaluated from the dislocation density using reverse KEM model. Although Eq. 5 is deterministic, the input parameters (grain size, dislocation density) are stochastic. In consequence the ferrite grain size was obtained in the form of histograms, which are shown in Fig. *9*b. As expected, deformation of the austenite accelerates nucleation of the ferrite and finer grain size was predicted for the rolling schedule V2. Accounting for the random character of the nucleation during phase transformation will be an objective of our future works.

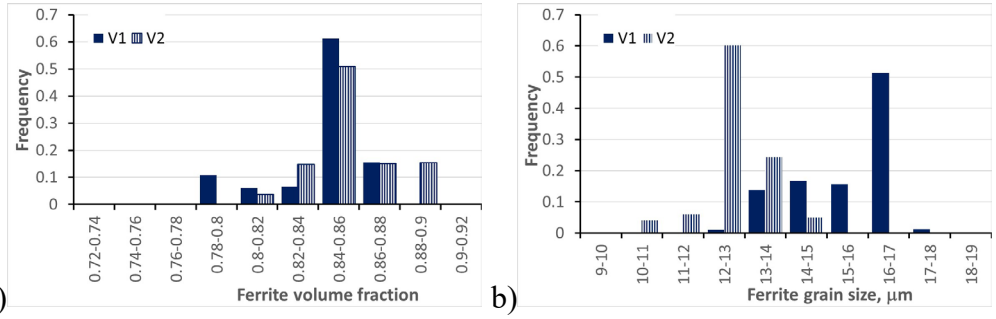

Fig. 9. Calculated histograms of the ferrite volume fraction (a) and the ferrite grain size (b) after laminar cooling of the steel strip.

Summary

The stochastic model describing evolution of the microstructure during hot strip rolling and laminar cooling is presented in the paper. Numerical tests of the model allowed to draw the following conclusions:

- Identification based on the inverse analysis for the compression tests yielded coefficients in the model, which give good agreement between predictions and measurements of both average values and distributions of various parameters.
- Capability to predict histograms of different microstructural features instead of their average values is the main advantage of the model.
- The model was validated in the interrupted compression test and in the varying strain rate test. Prediction of the model were in qualitative agreement with published information about these tests.
- The model is classified as mean-field model and it does not need explicit representation of the microstructure. In consequence, its computing costs are low.
- The model was applied to simulation of various novel strategies for the industrial hot strip rolling. The results are in agreement with our knowledge about this process, what confirmed model's capability to support a design of the optimal rolling technology.
- The stochastic model for the hot deformation is completed. When this model is coupled with the FE program, it can be applied to any hot forming process. In the phase transformations part it is still the work in progress. In the present work we used deterministic phase

transformation model with stochastic input data (histograms of the dislocation density and the grain size calculated by the hot deformation model). Accounting for the random character of the nucleation during phase transformations will be the objective of future works.

Keywords: Human Machine Interface, Jet-ECM

Abstract. Electrochemical machining with a closed free jet (Jet-ECM) is a flexible ablating manufacturing technology. With this manufacturing technology, surface structures in the micrometer range can be generated without tool wear occurring. Until now, the technology has mainly been developed in research institutions. Therefore, the aspect of a user-friendly human machine interface has not been in the focus of the machine tool design. The aspect of a user-friendly human machine interface was considered in the construction and development of a new Jet-ECM prototype system at the Otto von Guericke University Magdeburg (OVGU). The prototype system is intended for teaching and research purposes. Users, who will operate the prototype system, have different knowledge of the Jet-ECM process and machine control. Therefore, it was necessary to develop a user-friendly interface, that is easy to learn and easy to use.In the present study, the procedure for creating a user-friendly human-machine interface will be introduced, and the resulting design will be explained. The design was developed according to established design guidelines for machine systems and can also serve as a template for industrial operation. To arrange the operating elements ergonomically and according to the material, energy and information flow, a suitable mask layout was developed. Furthermore, the user interface is suitable for future expansion. Based on the realised user interface, the main components of the Jet-ECM prototype system can be controlled, various process functions can be executed, and different process variables can be analysed.

Introduction

To create a graphical user interface (GUI) for Jet-ECM, the fundamental understanding of this manufacturing technology is necessary to conduct various user tasks. Jet-ECM is an electrochemical machining process based on the anodic dissolution of the workpiece under the influence of electric charge exchange [1,2]. The dissolution takes place between the workpiece and the liquid ion conductor, called electrolyte. Reaction products are carried out by the continuous electrolyte flow. In Jet-ECM an electrolyte jet localises the electric direct current between the anodic workpiece and the cathodic tool, as seen in Fig. 1. The nozzle is positioned at a defined position above the workpiece surface. This nozzle is made of stainless steel and has an inner diameter of e.g. 100 µm [3]. An electrolyte is pumped through the nozzle and hits perpendicular upon the surface of the workpiece. The ejecting jet is forming a closed free jet, because there is no mixing between the surrounding fluid and the ejecting jet, due to the lower density of the atmospheric air in comparison to the electrolyte [4].

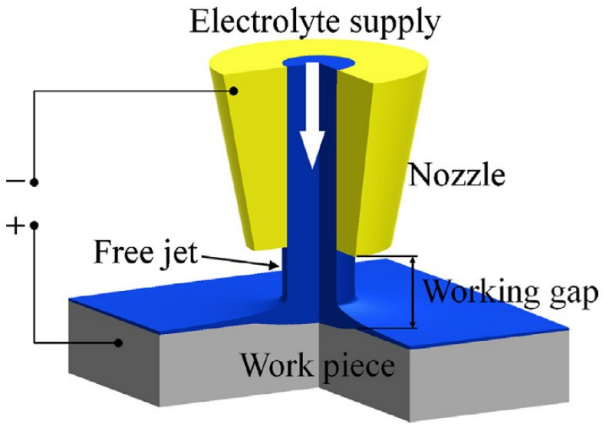

Fig. 1. Scheme of Jet-ECM [3].

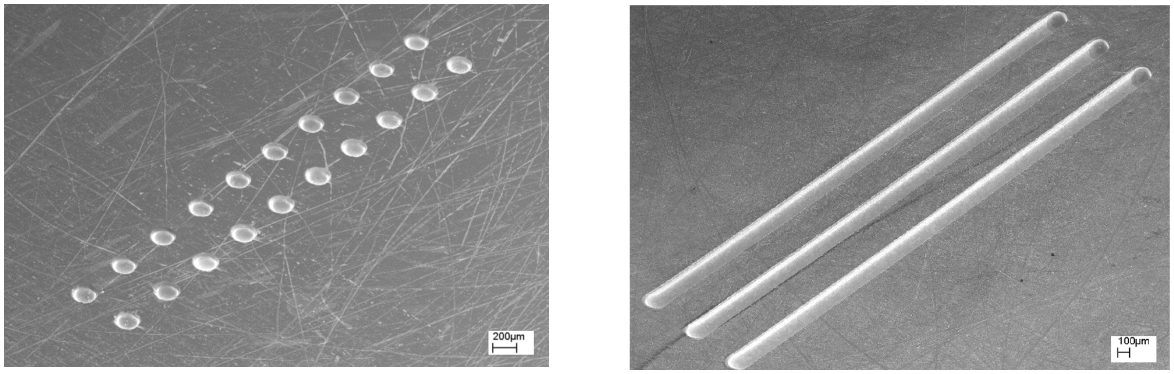
The current density, which amounts up to 1000 A/cm², is localised due to the shape of the closed free jet [5]. Therefore, a high localisation and a high precision of the removal geometry can be achieved. Different removal geometries can be realised by changing the movement strategies of the nozzle and the on-time of the electric current.

Machined examples are shown in Fig. 2 and Fig. 3. Without movement of the nozzle in the machining process, point removals can be generated. The depth of a point removal depends mainly on the on-time of electric current. An array of point removals shows Fig. 2a). The shape of a point removal is a typical calotte geometry.



a) Point removals b) Line removals

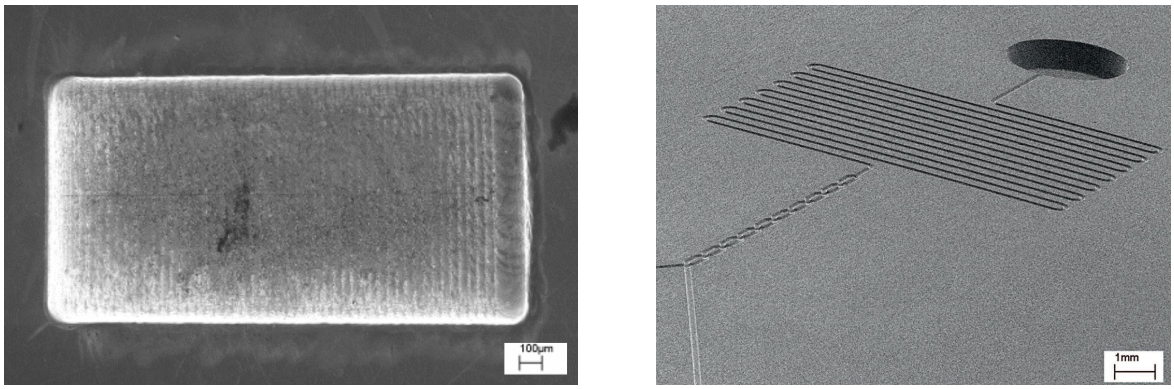
Fig. 2. SEM images of point and line removals generated with Jet-ECM [6].

With movement of the nozzle and constant process parameters, different forms of removal geometries can be machined, such as line removals, plane surfaces and contour removals. Line removals occur during a line movement of the nozzle with a switched-on electric current. The depth of a line removal depends on the dwell time over the machined workpiece surface and can be influenced by nozzle velocity and number of repetitions of the same line removal. By using complex nozzle geometries, the whole line removal geometry can be affected [7]. The line removals, as seen in Fig. 2b), were each machined with three superimposed lines [6]. Noticeable is the reproducibility and the high quality of the line removal.

A machined plane surface can be realized by an overlay of line removals, as seen in Fig. 3a). The line removals have a defined distance to each other. This defined line distance is caused

through a specific motion in one direction. In order to avoid additional removal, this motion takes place without switched-on electric current. To reach a high surface quality, the kinematic roughness has to be considered. Hackert [8] shows, that the kinematic roughness is nearly steady, if the line distance is smaller than the inner diameter of the nozzle. By a rise of the line distance, the kinematic roughness increases to a maximum. The maximum is reached if the line distance has the width of 1.9-fold of the nozzle diameter [8].

Another removal movement is the contour removal, where the removal takes place along a contour path. The contour removals can be executed through a programmed trajectory with different motion commands. Contour removals are applied to machine for example channels for a microreactor. To get a constant depth for the microstructure, the nozzle velocity has to be equal for each motion commands. Fig. 3b) shows an example of a machined microstructure in form of a microreactor. The cavities are machined in stainless steel with a depth of 60 µm and a width of 200 µm [2].



a) Plane surface removal [8] b) Contour removal (microreactor) [2]

Fig. 3. SEM images of a plane surface and a microreactor generated with Jet-ECM.

Jet-ECM prototype system

The design of the Jet-ECM prototype system at the OVGU is shown in Fig. 4. The prototype system is housed in a casing to prevent reaching into the system during processing. The extraction system vacuums and filters the removal gases. A granite portal is mounted on the carrying frame. The linear stages are mounted on this granite portal, that is designed in a gantry design. The nozzle system is mounted on the z-axis and the processing chamber is mounted on the x-axis. To separate the processing area and the electrolyte system, a partition wall is implemented. The electrolyte system consists of fresh electrolyte tank, filter, pump and measurement system for electrical conductivity, electrolyte temperature and pH-value.

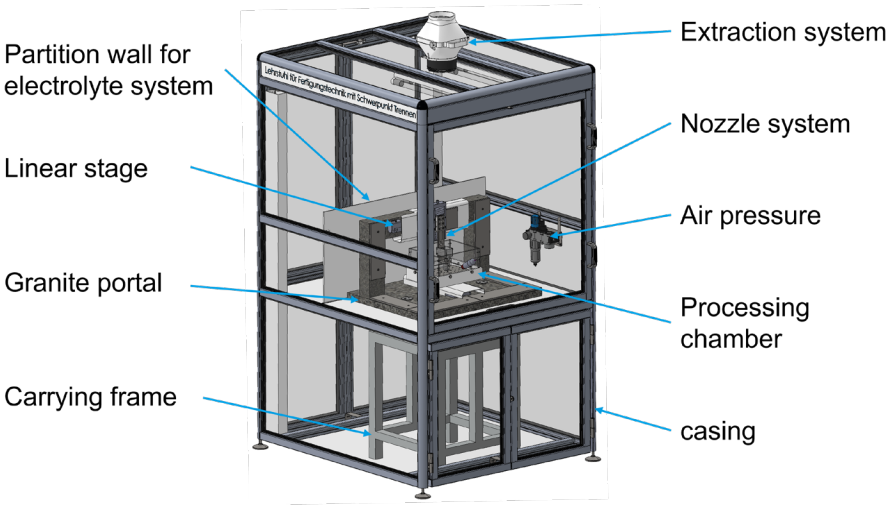


Fig. 4. Design of the Jet-ECM prototype system.

According to Fig. 5 the Jet-ECM prototype system consists of different components, that can be divided into the main parts electrolyte system, power supply, nozzle system, data acquisition, positioning system and control system.

The electrolyte system supplies the Jet-ECM prototype system with an electrolyte. A micro annular gear pump pumps the electrolyte through a filter out of an electrolyte tank. The flow rate of this micro gear pump is in range of 0.048 ml/min to 288 ml/min. The electrolyte is transported to the nozzle system and is ejected perpendicular to the workpiece surface. The used electrolyte is collected in the processing chamber. Afterwards, the electrolyte is discharged to the disposal tank.

A maximum voltage of 50 V and a maximum current of 7 A can be set with a digital laboratory power supply, which is locally and remotely programmable.

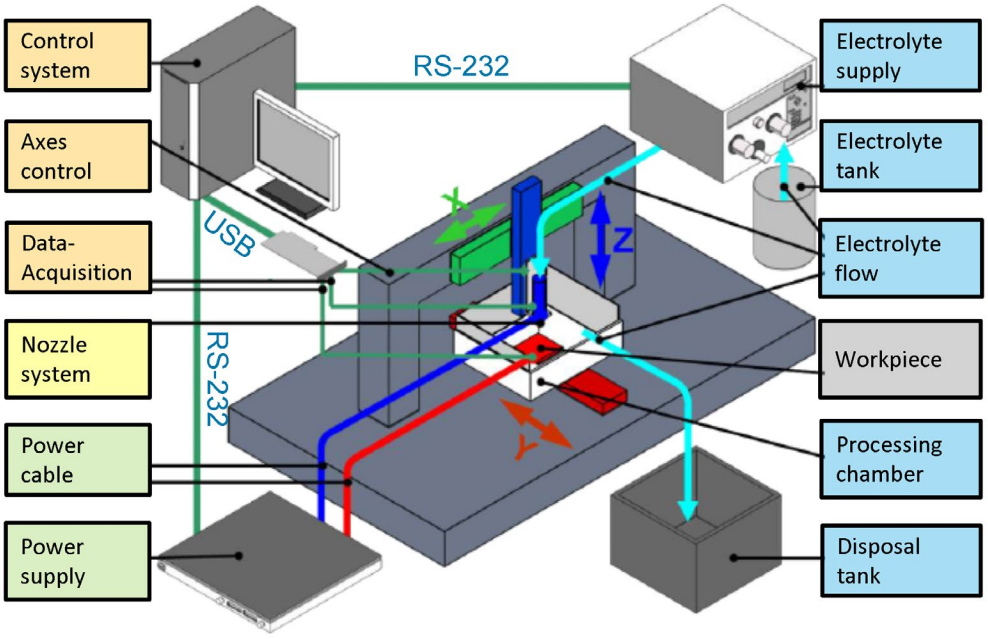

Fig. 5. Components of the Jet-ECM prototype system according to [2].

The nozzle system consists of a nozzle, nozzle holder, cathode contact and connections for the electrolyte and air pressure. The nozzle system defines the position of the nozzle to the workpiece. Furthermore, the nozzle system supplies electrolyte and electric current.

To measure analogue signals and to generate digital output signals, a data acquisition device is used. Through analogue inputs for instance the process voltage, working gap voltage and the process current are measured. The digital outputs are used to switch the process voltage and the air pressure.

The positioning system consists of three linear stages and a motion control. A motion controller is utilized to control the nozzle movement in three axes. Various motion profiles, e.g. multi-axis point-to-point, multi-axis segmented motion or third order profiles can be executed.

To control the whole machining process, a control system, called Jet-Control, was programmed based on the commercial software LabVIEW. All process operations and tasks can be controlled by using Jet-Control. To add a possibility for the user to interact with the Jet-ECM process, a user-friendly human machine interface was designed. Based on the interface, the user can observe, adjust and control the Jet-ECM process. Caused by the variety of different components and by adding new features, the GUI becomes quickly too complex and confusing. Therefore, the GUI was redesigned, using established design guidelines for machine systems.

Concept of the Human Machine Interface

To design a human machine interface, it is recommended to consider the function first and the presentation later [9]. Therefore, the user tasks have to be analysed and sorted due to their importance and their frequency. Accordingly, a task flow is analysed, that shows the sequence for machining a microstructure. As seen in Fig. 6 the task flow can be separated in three main tasks: preparation, processing and post-processing. In the preparation task, the user has to enter the motion commands of a trajectory into a process file. The user loads the process file into the software Jet-Control. Furthermore, the process parameters, for example process voltage, nozzle velocity, flow rate, etc., have to be set. To set the working gap, the user can choose an assisted program which is included in the GUI. To do this, the user manually moves the nozzle to a desired position over the workpiece and enters the required distance of the working gap. With starting of the assisted program, the nozzle is moved into the workpiece direction until an electrical contact is determined. After reaching the electrical contact with the workpiece surface, the working gap is set automatically. For this purpose, the nozzle is moved in opposite direction from the electrical contact position and positioned at the required distance from the workpiece surface.

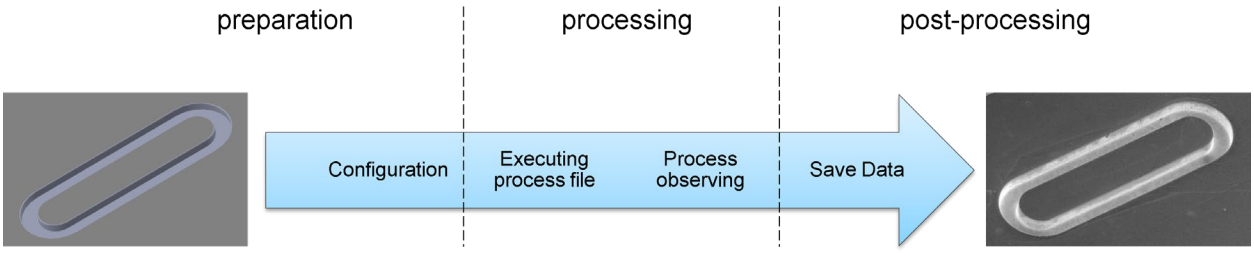

Fig. 6. Task flow to generate a microstructure with Jet-ECM from CAD to machined sample (picture on right hand side from [6]).

After the preparation, the processing task can be started by the user. During the processing task, the removal process takes place based on the set process parameters and the process file. The user

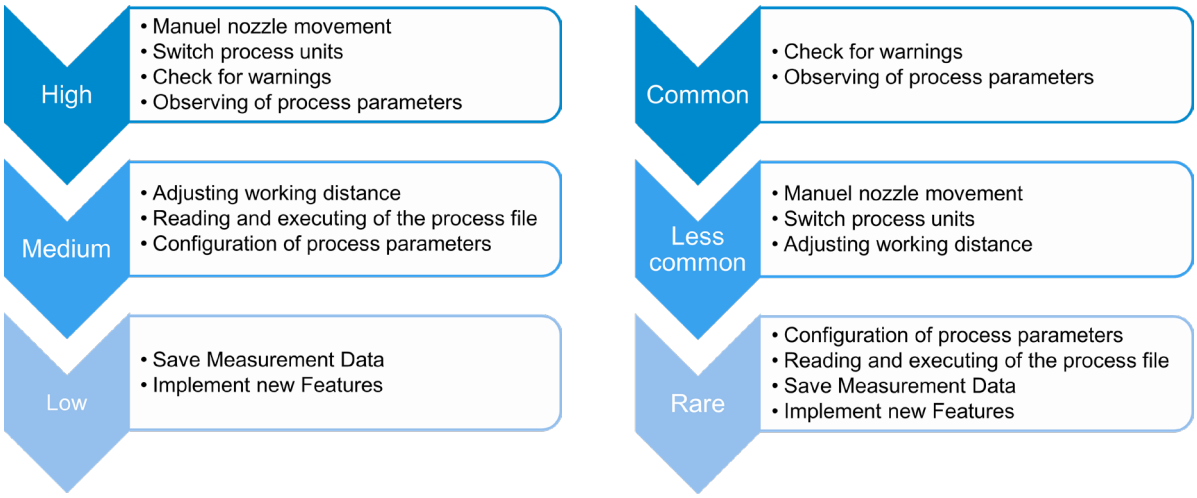
can observe the process via GUI by checking different diagrams, LED's, text or number inserts. Furthermore, the user can interact anytime for warnings and errors.

After the removal process, the post-processing task begins. In the post-processing task, Jet-Control saves selected measurements, such as process current, nozzle position or nozzle velocity, that were recorded during the machining process. Based on the stored measurements, the current characteristics can be determined and the electric charge can be calculated.

Throughout the analyses of the task flow, the common user tasks can be derived. These tasks are listed in Fig.7 and are weighted of their importance and their frequency. Fig. 7a) shows the importance of user tasks. For the Jet-ECM process, it is necessary to switch the process units, such as power supply or electrolyte supply, check for warnings, observing the process parameters and control manually the movement of the nozzle. These functions should always be visible during the whole process.

Less important tasks are configuration or adjusting the working gap, because these tasks have to be performed once during the process. That's why, these tasks shouldn't be visible during the whole process and should be selectable than needed.

Tasks such as save data or implement new features are not required for the process or for the user. Accordingly, these tasks should play a minor role and not be focused or visible.



a) Importance of user tasks b) Frequency of user tasks

Fig. 7. List of common user tasks weighted by their importance and frequency.

Fig. 7b) shows the frequency of the user tasks, according to which the visibility should be based. Therefore, the warnings and process parameter should take up the most space. The less common user tasks, such as manual movement or switching process units, should be less visible. The rare user tasks shouldn't be visible, only visible during selecting.

To design the presentation of the GUI, a layout is being used according to Zühlke [10]. The presentation consists of a two-dimensional mask layout, which covered the whole window, as seen in Fig.8. The window is separated into single sections. Each section has its own unique function or task. The section on the top right is called status domain. This domain shows the operating mode of the prototype system. Next to the status domain are the error domain and the command domain. The error domain displays the warning and error messages. The command domain displays, which operations are currently executed. These three domains are located on the top and are always visible. On the right side, the domain of direct functions is located. This domain is used to trigger direct operation functions, that are independent of the activated mask, but dependent on the state

of the prototype system. An example of an independent function is the emergency stop, which is always useable.

The domain of direct functions is also visible and operable during the whole machine process. The working domain is placed in the centre of the window. The working domain displays specific functions, which contains the main tasks and information. The navigation domain is located below the working domain. Due to the navigation domain, the user can choose specific functions, that are displayed in the working domain.

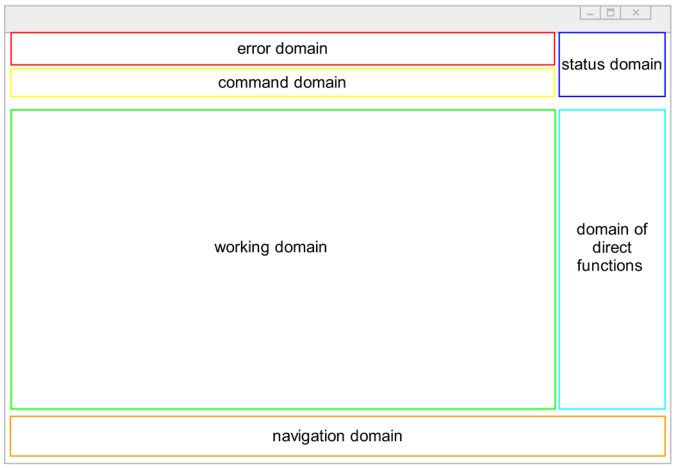


Fig. 8. Conceptional mask layout according to [10].

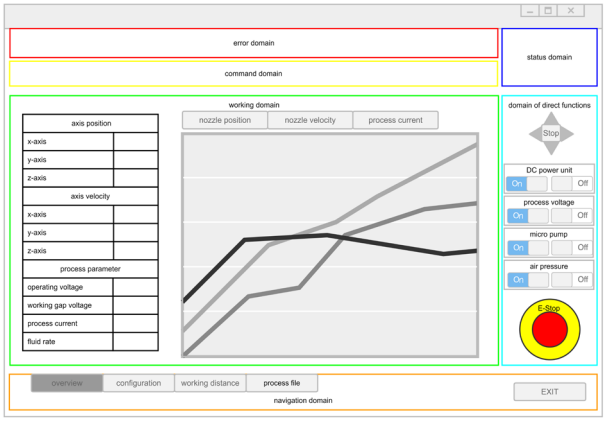
Based on the mask layout, the GUI was designed. The GUI consists of four different mask layouts, that can be chosen by the navigation domain. The mask layouts are differentiated by the working domain, which are: *overview*, *configuration*, *working gap* and *process file*. The mask layouts for the working domains *overview* and *configuration* are shown in Fig 9.

As described before, the error domain, command domain and status domain are placed on the top, because there is the biggest attention of the user [10]. The domain of direct functions is used for the manual movement of the nozzle, for switching the process units like power supply or electrolyte system and for the emergency stop. The emergency stop is configured to abort the removal process at any time as quickly as possible. When pressed, movements are stopped immediately and all process units, e.g. power supply and electrolyte system, are switched off.

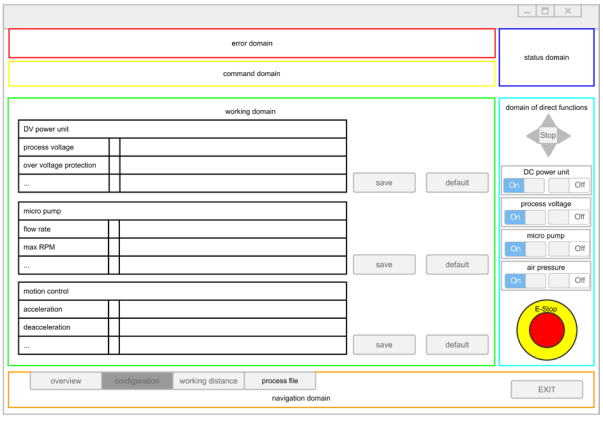
The navigation domain consists of different buttons. Four of these buttons are actually assigned with domains and two of them can be used to add new functionality. The *EXIT* Button on the right is used to end Jet-Control. As seen in Fig. 9a), the working domain *overview* is selected. The overview displays all the important information and measurements in tabular form. In addition, process parameters are visualized in various diagrams that the user can select. Fig. 9b) shows the working domain *configuration*. At the configuration, the user can select different parameter to adjust the processing units. Furthermore, the user has the possibility, to save new process parameters via a save button for each system. To undo the change, the user can click on the default button.

At the mask layout for the working domain working gap, as seen in Fig. 10a), the user can operate the function to adjust the working gap. Firstly, the user starts to select a strategy and set a distance for the working gap. Under the dropdown field, the user can activate the process. Due to the domain of direct functions, the user can move the nozzle to a position, there the user wants to set the defined working gap. After clicking the button *approach contact*, the touching process begins. Through diagrams and LED's, the user can observe the process. The user could cancel the

process anytime. After setting the working gap, each touched position will be display in tabular form for the x, y and z position and could be used for the following removal process.



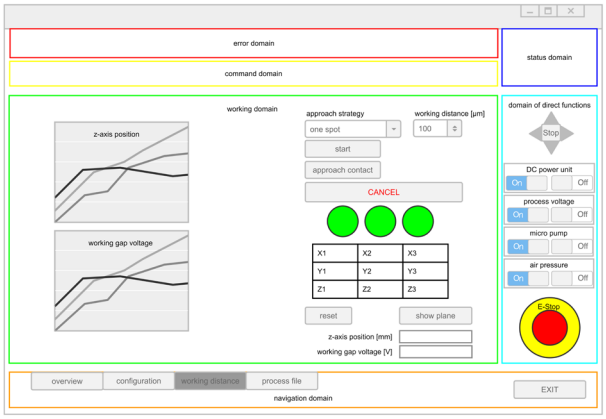
a) Overview-mask: Compilation of process parameters in tabular and diagram form



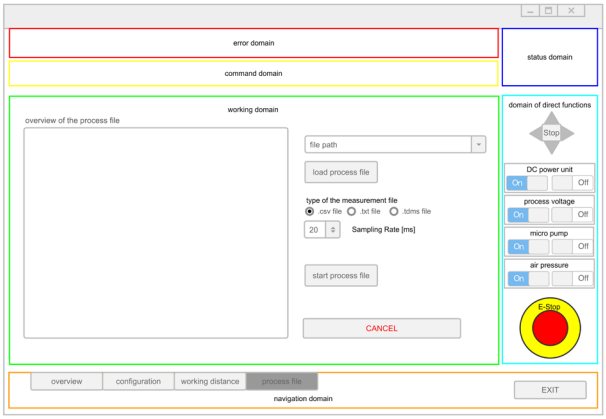
b) Configuration-mask: Setting of process variables

Fig. 9. Mask layouts for the working domains: overview and configuration.

Fig. 10b) shows the mask layout for the working domain *process file*. This working domain is needed to load and execute a process file. The process file contains movement commands and switching commands for the removal process. In the dropdown field, the user chooses the desired process file and load the file over the button *load process file*. Afterwards, the file displayed at the window on the left side. Due to the radio buttons, the user can select different file types for saving the measurement data and can adjust the sampling rate. With clicking on the button *start process file*, the machining process will start and can be stopped with *CANCEL* or the *emergency stop*.



a) Working gap-mask: Program-assisted setting of the working gap



b) Process file-mask: Visualisation and executing of commands for machining

Fig. 10. Mask layouts for the working domains: working gap and process file.

Designed User-Friendly Human Machine Interface

Based on the GUI concept, a human machine interface was designed and implemented with LabVIEW, as seen in Fig. 11. To ensure user-friendliness, the mask layouts are kept minimalist, that each mask only contains the information, that the user needs. Furthermore, identical information is placed at the same location. Operating elements are arranged according to the material, energy and information flow. In Fig. 11 the different sections are framed in colour for a

purpose of presentation. For example, the error domain is framed in red and the command domain is framed in yellow. Due to the importance of these domains, they are additionally placed at the top. Through text inserts, the GUI displays error messages in the error domain and displays executing tasks in the command domain. The status domain consists of an Enum-ring, which contains the status messages: initialization, ready, running and error. These messages represent the status of the machining process and are presented accordingly in text and colour. Green for the status initialization and ready, flashing green for the status running and red for the status error.

On the right side, the domain of direct functions is placed and is framed in light blue. In order to highlight the actors of the process unit, the actors are grouped into clusters. The first cluster contains arrow keys to manually move the nozzle. Furthermore, in the cluster are different buttons located, to set the type of movement, velocity and increment. By clicking the checkbox *automatic control of z-axis,* the readjustment movement of the *z*-axis can be activated or deactivated. The following clusters contain the process units, that can be controlled by *ON* and *OFF* buttons. To highlight the switching state, the background colour of the cluster changes to green when a process unit is activated.

The navigation domain is framed in orange and is realized using a tab control. Each tab activates a different working domain, which is framed in green. With adding new tabs, new features or functions can be implemented to the GUI.

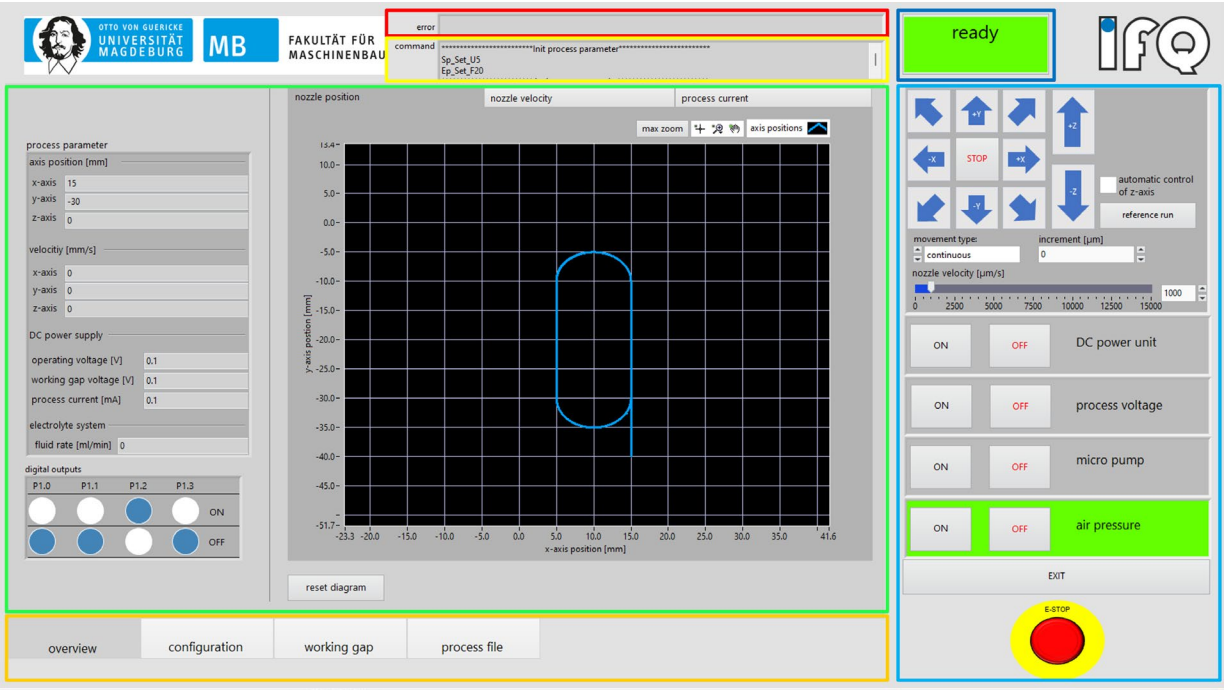


Fig. 11. Implemented GUI concept in LabVIEW with outlined section.

As seen in Fig. 11 the working domain *overview* is selected. On the left side, all process parameters grouped into a cluster. At the bottom, a table is located, which displays the state of the digital outputs. On the right side, a tab control is placed, from which the user can select which diagram to activate.

Summary

The study focused on a design of a user-friendly human machine interface for jet electrochemical machining. Through the developed interface, the Jet-ECM process can be controlled as well as

user tasks can be assisted, for example for the working gap setting. Caused by the variety of different components and by adding new features, the GUI becomes quickly too complex and too confusing. Therefore, established guidelines were applied to design a human machine interface for the Jet-ECM process. To ensure a user-friendly interface, the interface was designed minimalistic and the operating elements were arranged according to the material, energy and information flow. To determine the order and the visibility of user tasks, a task flow of the Jet-ECM process was analysed. Therefore, the frequency and the importance of the user tasks were worked out. The GUI was designed based on a two-dimensional mask layout. The interface can be extended for later functions or features by adding new mask layouts.

Keywords: Electrochemical Machining, Multiphysics Simulation

Abstract. The ablation results with electrochemical precision machining (PECM) are essentially influenced by the material to be processed and by the current density distribution in the working gap. Therefore, ablation experiments according to DIN SPEC 91399 are essential to determine the material-specific removal characteristics and to derive process input variables for the process design. A main limitation of these experiments is the lack of accessibility at crucial surfaces on the workpiece and on the device, which means that relevant information such as the local current density distribution or the local temperature field cannot be measured. To face the mentioned limitation, the aim of this work was to develop a digital twin for an experiment for PECM according to DIN SPEC 91399. The digital twin is based on a commercial multiphysics simulation software with the main property that the calculation time of the model is less than the real time for the experiment to allow a simultaneous processing of experiment and simulation. Via suitable interfaces, experiment and simulation can be interconnected in future. Based on this, the digital twin can be applied to evaluate parameters, monitor the process in real time and adapt it accordingly. The design and the properties of the digital twin will be shown exemplary for an experiment with the workpiece material steel 1.4301.

Introduction

Electrochemical Machining (ECM) is the generic term for a number of machining processes in which material removal is based on the principle of anodic metal dissolution. The workpiece is polarised as an anode and the tool electrode as cathode. An electrolyte, as a sufficiently electrically conductive medium, provides an electric charge transport between the electrodes. The ECM process is a non-contact machining process without heat input. Disadvantages of conventional cutting methods such as tool wear, negative influence on the component properties or burr formation can be avoided if ECM is applied.

A further development of the EC-countersinking process is electrochemical precision machining (PECM), in which the precision can be further increased by applying an oscillating cathode and a pulsed direct current. The PECM process is a separating manufacturing process and is classified according to DIN 8580 in the 3. main group Machining and further in the groups Ablation and Electrochemical Ablation [1]. Fig. 1 shows the principle of the PECM-process with oscillating cathode.

Materials Research Proceedings 28 (2023) 1653-1662 https://doi.org/10.21741/9781644902479-178

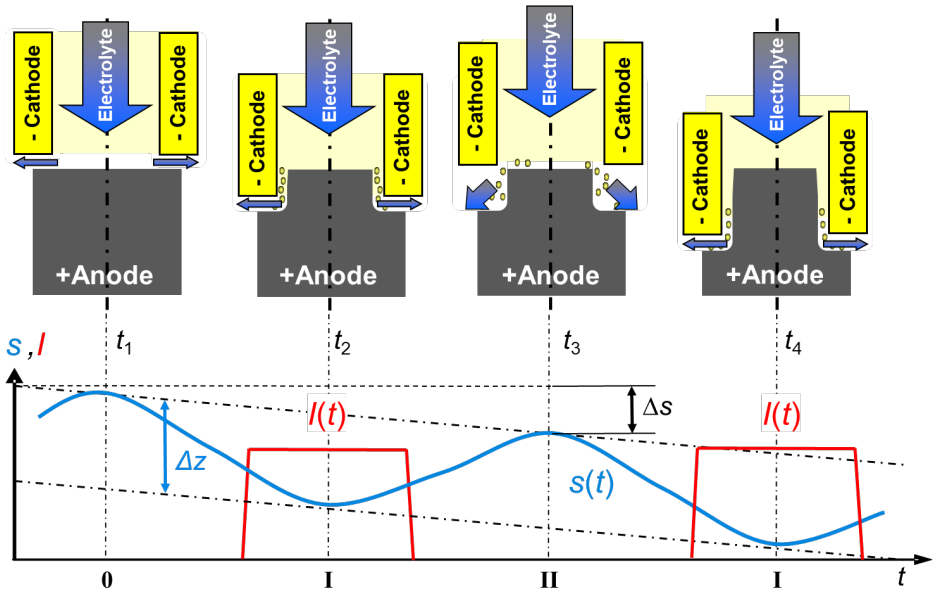

Fig. 1. Principle of a pulsed ECM-process with oscillating cathode according to [2].

In the initial state (0), the cathode is at top dead center, so that a maximum working distance is established between the anode and the cathode. Thus, the working distance is sufficiently supplied with electrolyte. State I describes the time of material removal. Here, the cathode geometry is transferred in the anode.

Shortly before the bottom dead center of the oscillation movement is reached, the machining voltage is switched on so that a current pulse with almost constant current is formed for a defined current pulse width. In the lower dead position of the oscillation movement, the working distance reaches the minimum. After exceeding the bottom dead center, the material is removed until the machining voltage is switched off.

The working distance is extended in state II until the top dead center is reached. This ensures that the working distance is sufficiently supplied with fresh electrolyte to remove reaction and removal products, which are created in state I.

The sequence of state I and state II is repeated until the target sink depth is reached. For this purpose, the oscillation of the cathode is superimposed with a feed movement. [3–5] Due to the reduced working distance in the PECM process, the production of complex shapes in the micrometer range is possible (structure size ≥ 5 µm). [6]

EC-removal is based on a complex mechanism. Material-specific removal parameters and the current density distribution in the working distance are essential process input variables, that cannot be derived with sufficient accuracy from literature values.

The DIN SPEC 91399 describes a method, which is based on determining the material-specific removal rate during PECM using an industrial machine tool. Applying a special removal device and complying with defined boundary conditions, the velocity of the relative movement between the cathode and anode can be evaluated as a comparison variable for determining the material-specific removal parameters.

With the help of systematic ablation experiments, the ablation functions of the material-specific ablation rate and the change of state in the working distance can be determined. From this, process input variables can be determined for the PECM process. [7]

Method

In addition to the time and cost issues, the challenge in PECM ablation experiments is the measurement of physical variables such as the distribution of the current density during the PECM process. A simulation model can serve as a digital twin, that provides missing measurement variables or make ablation experiments more efficient through preliminary investigations. With FEM-based simulation software, such as the commercial software COMSOL Multiphysics, it is possible to build a digital twin, obtain missing information from a PECM process and analyse it. A digital twin is the digital model of physical objects and has the task of generating a comprehensive exchange of information. The basis for this is, that the model not only includes anode, cathode and electrolyte region, but is designed in such a way, that the entire device unit is represented. The aim of the work is to build a simulation model, that confirms the results of a previous experiment with the workpiece material 1.4301. In order to monitor the process in future, it is also necessary for the digital twin to calculate the simulation results in a time which is lower than the machining time of the real process. This should enable real-time data exchange between the digital twin and the real process in future by help of the development of suitable interfaces.

Model Description

In order to create the digital twin, materials and PECM input parameters were taken from previous ablation experiments [8]. The design and the geometry dimensions of the simulation model are based on the recommendations of DIN SPEC 91399. Fig. 2 shows a cross-section of the PECM device and the derived geometry of the simulation model.

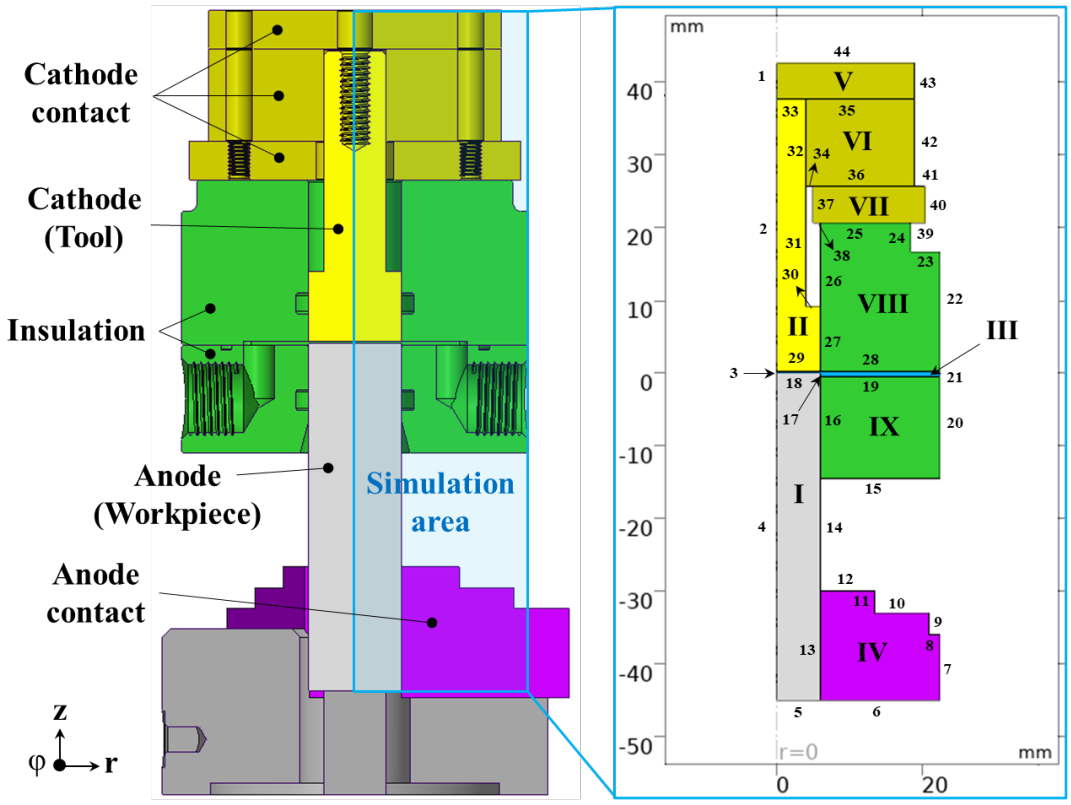

Fig. 2. Cross section of the PECM device and derived *2D axisymmetric model geometry with defined domains and boundaries.*

In the simulation model, the experimental end front working distance $s_{f\text{-}E}$ was set at the beginning of the simulation. The cathode unit was assigned a constant feed with superimposed oscillation

movement for a period $T = 0.02$ s. Electric current flows through the application of a pulsed voltage with a pulse duration $t_p = 1$ ms at the dead center of the oscillating movement of the cathode. In order to keep the simulation time of the digital twin below the real process time, the oscillating movement and pulsed power supply were interrupted after the simulated period. The surface of the workpiece was then removed with calculated velocities for further 30 s. A process time of 30 s was selected in order to comply with DIN SPEC 91399, according to which the removal experiment run for further 30 s after the end front working distance $s_{f\text{-}E}$ has been established [7].

The model is evaluated according to simulation duration and working distance at the end of the 30 s simulated process time.

Due to the desired model solution time below 30 s and the almost rotationally symmetrical design of the device, the model was designed as an axisymmetric model with the coordinates r, φ and z, with the axis of symmetry at r = 0. The two electrodes, can be seen in gray (anode/workpiece) and yellow (cathode/tool). Both electrodes are cylindrical in shape. The workpiece has a diameter of 12 mm and a length of 45 mm. The cathode consists of a stepped shaft with diameters of 7.5 mm and 12 mm and a length of 37.5 mm. In the simulation the electric conduction processes in the cathode and in the workpiece as well as in the electrical contact geometries were considered, since otherwise some effects can be underestimated [9].

The oscillating movement of the tool unit occurs in z-direction. The allocation of the materials to the model domains and the material parameters used for the simulation are summarized in Table 1.

Table 1. Material parameters of the simulation model derived from [8].

Domain	Material	σ [mS/cm]	ε_r
I, II, IV-VII	1.4301	$1.4 \cdot 10^{10}$	1
III	Electrolyte ($NaNO_3$)	67.4	65
VIII, IX	POM	10^{-10}	4

In order to analyse the ECM-specific parameters, the electrical conductivity σ and the relative permittivity ε_r were assigned to the domains. To represent the desired PECM process, 3 physics modes of COMSOL Multiphysics were applied. *Electric Current* mode was applied to supply the PECM process with external electric potential. The *Moving Mesh* was applied to simulate the oscillating motion of the cathode assembly and the flushing chambers as well as the removal of the surface of the workpiece. The *Events Interface* was applied to simulate the various PECM parameters in a precisely timed manner.

Eq. 1 describes the electrical potential $U_{\text{pulsed}}(t)$ which connects and disconnects the voltage according to the lower- and upper time limits. The electrical potential is determined by subtracting the process voltage U_{min} with the sum of overpotentials ΔU [4].

$$U_{pulsed}(t) \begin{cases} 0\,V, if\ t < t_{Low} \\ U_{min} - \Delta U, if\ t_{Low} \leq t \leq t_{Upp} \\ 0\,V,\ if\ t > t_{Upp} \end{cases} \quad (1)$$

with

$$t_{Low} = \frac{T}{4} - \frac{t_p}{2} \quad (2)$$

and

$$t_{Upp} = \frac{T}{4} + \frac{t_p}{2} \quad (3)$$

The pulsed current parameters used in the simulation model are summarised in the Table 2 below.

Table 2. Pulsed electric potential parameters derived from [3,8].

Definition	Symbol	Value	Unit
Process voltage	U_{min}	6.7	[V]
Sum of potentials	ΔU	4.6	[V]
Pulse width	t_p	0.001	[s]
Lower Limit	t_{Low}	0.0045	[s]
Upper Limit	t_{Upp}	0.0055	[s]

The electrical potential $\varphi_{el} = U_{pulsed}(t)$ was applied at boundary 6 and ground at boundary 44 and it was switched via the event interface. Boundary conditions of the electric current mode defined in the model are listed in the Table 3.

Table 3. Boundary conditions of electric current mode.

Condition	Boundary	Property
Axial Symmetry	1-4	-
Electric Insulation	5, 7-12, 14, 15, 20-24, 26, 30, 31, 34, 37-43	-
Ground	44	$\varphi_{el} = 0$ [V]
Electric Potential	6	$\varphi_{el} = U_{pulsed}(t) \cdot C_2$ [V]

The moving mesh mode was applied to simulate the movement of the cathode unit, including the flushing channel and flushing chambers. The oscillation of the cathode was defined as a harmonic oscillation superimposed with a constant movement in z-direction, which is explained in Eq. 4.

$$z(t) = \left(\hat{Z} \cdot \cos\left(2\pi \cdot f \cdot t + \frac{\pi}{2}\right)\right) \cdot C_1 - v_f \cdot t \quad (4)$$

$\hat{Z}$ is the range of the oscillation (amplitude), f is the frequency and v_f the lowering velocity. The discrete variable C_1 is a logical auxiliary variable to control which expression to use in an equation. C_1 is explained in more detail in the Events Interface section. When the oscillation has reached its lowest point in z-direction, $s_{f\text{-}E}$ is set. Table 4 allocates the motion parameters of the cathode.

Table 4. Motion parameters of the cathode derived from [8].

Definition	Symbol	Value	Unit
Period	T	0.02	[s]
Frequency	f	50	[Hz]
Amplitude	$\hat{Z}$	0.185	[mm]
Working distance	$s_{f\text{-}E}$	0.048	[mm]
Feed rate	v_f	0.01	[mm/min]

For numerical reasons, period *T* starts after 1 s simulation time. Figure 3 illustrates the cathode oscillation and the pulsed electrical potential in a period *T*, here the oscillation graph $z(t)$ marked with blue line is plotted as in Eq. 4 and the pulsed voltage $U_{pulsed}(t)$ graph marked with red line is characterized as in Eq. 1.

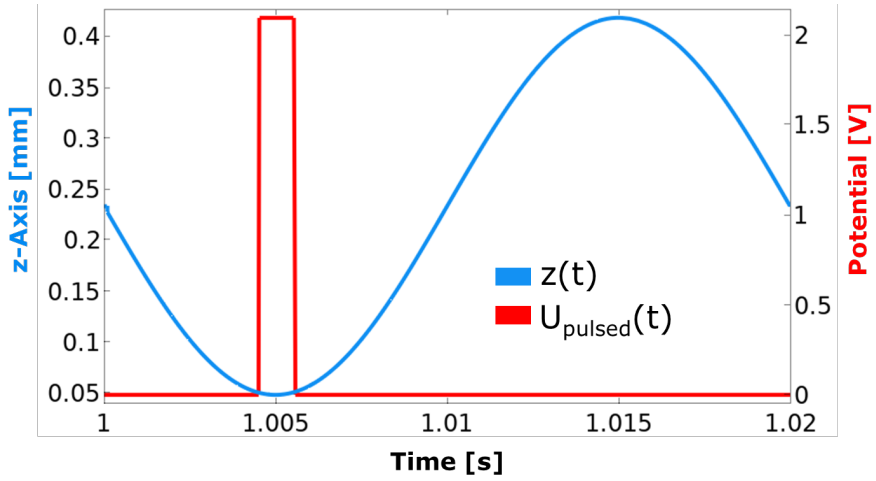

Fig. 3. Cathode oscillation and pulsed potential in one period.

The surface of the workpiece is removed with 2 different removal rates. According to [3,4], the removal rate is recorded as follows during the pulse on time t_p.

$$v_a(J) = ((V_m \cdot J + v_0) \cdot c) \cdot C_2 \tag{5}$$

with

$$c = f \cdot t_p \tag{6}$$

The removal rate is therefore strongly dependent on the current density distribution J [A/cm²] on the workpiece surface. The pulsed current flow is characterized by the duty cycle c, which is composed of the multiplication of the frequency f and the pulse on time t_p. V_m ($0.0106 \frac{mm/min}{A/cm^2}$) and v_o ($-0.063 \frac{mm}{min}$) result from the removal experiment and are described in more detail in [8]. V_m, v_0 and c are thus constant values, while J is calculated during the pulse on time. In order to save computing time of the model, an average removal rate $\hat{v}_a$ is calculated after the time period *T*, with which the workpiece surface is removed for another 30 s.

$$\hat{v}_a = \frac{1}{T} \cdot \int_{1.0045\ s}^{1.0055\ s} v_a(J)dt \cdot C_3 \tag{7}$$

Boundary conditions of moving mesh mode defined in the PECM simulation model are listed in the Table 5.

Table 5. Boundary conditions of moving mesh mode.

Condition	Boundary	Property
Fixed Boundary	5	-
Prescribed Mesh Displacement in Normal Direction	3, 4, 13, 14, 17, 21	$d_n = 0$ [mm]
Prescribed Mesh Displacement	1, 2, 15, 16, 19, 20, 22-44	$d_r = 0$ [mm] $d_z = z(t)$ [mm]
Prescribed Normal Mesh Velocity	18	$v_n = -v_a(J) - \hat{v}_a$ [mm/min]

The event interface is used to trigger events. When an event occurs, the solver stops and provides a possibility to reinitialize the values of variables. The events are controlled with the state variables C_1, C_2 and C_3, which can assume the values 0 and 1. The course of the variables can be seen in Fig. 4.

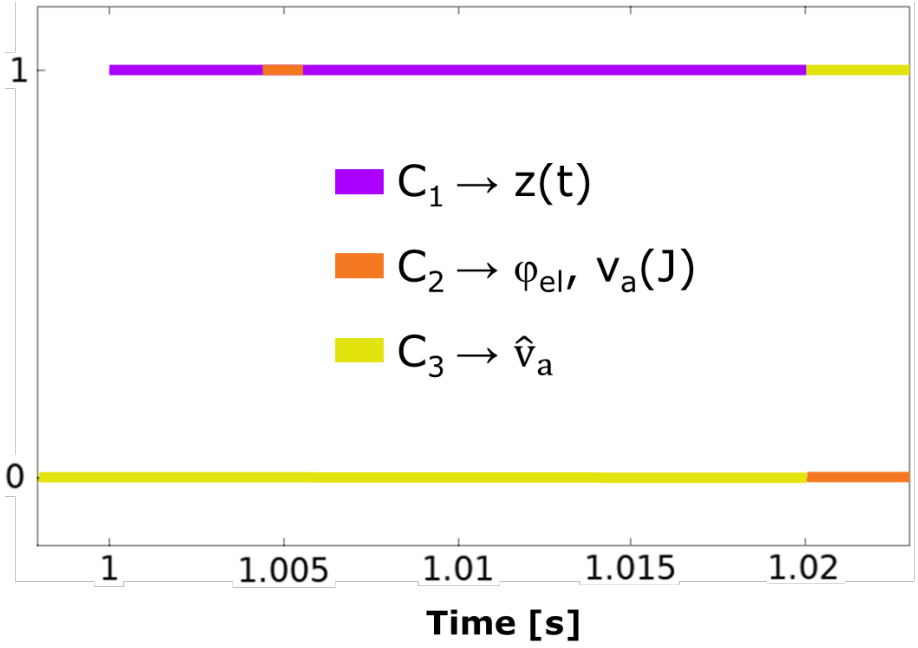

Fig. 4. Discrete auxiliary variables as function of the time.

The variables are linked to the equations and boundary conditions. C_1 triggers the oscillation from $t = 1$ s to $t = 1.02$ s, after that the first term of Eq. 4 becomes zero and the cathode moves on without oscillation with the constant feed motion v_f. C_2 switches from 0 to 1 at $t = 1.0045$ s and back to 0 at $t = 1.0055$ s ($t_p = 0.001$ s). The electrical potential φ_{el} (see Table 3) and the removal rate $v_a(J)$ (Equation 5) are linked to the state variable C_2. Variable C_3 is coupled to $\hat{v}_a$ (Equation 7). The average removal rate is calculated during the pulse, then the workpiece surface is removed with the calculated velocity $\hat{v}_a$ for 30 s.

The mesh for the model was generated using a physics-driven mesh as the sequence type. The physics-controlled mesh is the default mesh setting in COMSOL Multiphysics, which in turn distinguishes different element sizes from very fine to very coarse. The mesh encloses an area of

1356 mm² with 1155 triangular elements. The maximum and minimum element sizes are 5.8 mm and 0.026 mm.

Results

Fig. 5 shows the current density distribution in the entire model at the bottom dead center of the oscillation.

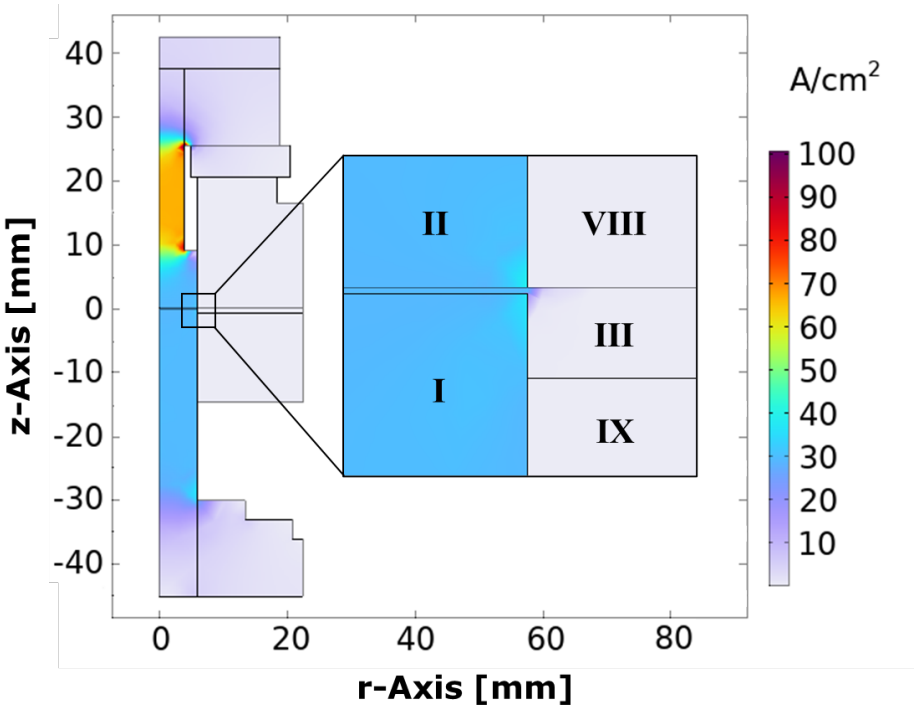

Fig. 5. Current density distribution at time t = 1.005 s.

In the model, a maximum current density J of 101 A/cm² occurs during the pulse on time, which can be attributed to peak effects at points on the cathode. A current density J of 29 A/cm² is established in the working gap between the cathode and the workpiece surface during t = 1.005 s. The removal rate v_a depends on the current density distribution on the workpiece surface (boundary 8). Figure 6 shows the 3 applied velocities, of which v_f represents the constant feed of the cathode while v_a (J) and $\hat{v}_a$ are calculated during the simulation.

Since $v_a(J)$ depends on the current density acting in the pulse, the curve is not linear but increases as the cathode approaches the workpiece surface due to the oscillating movement. The maximum removal rate is reached at the bottom dead center of the oscillation.

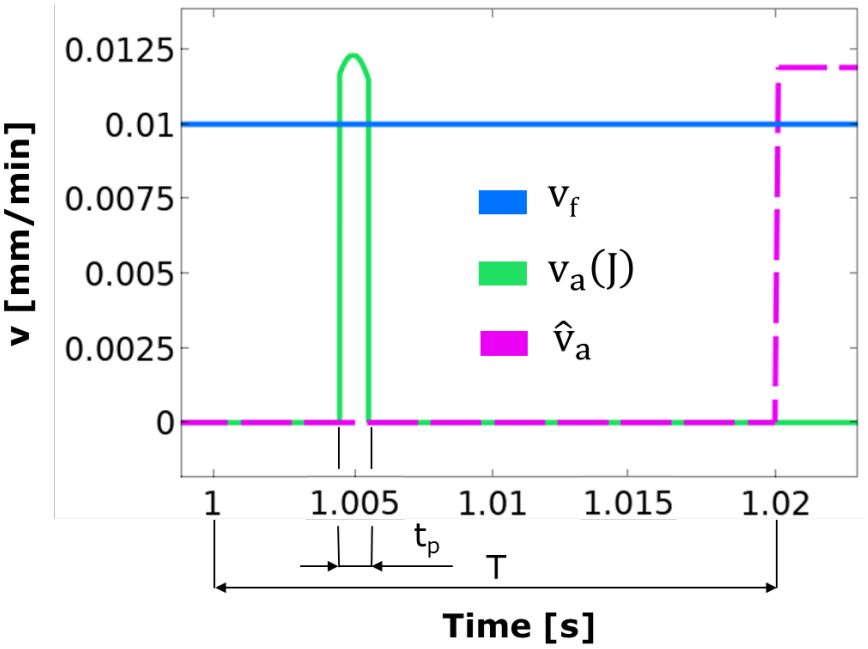

Fig. 6. Course of the velocities vf = 0.01 mm/min, va(J) = 0.0115…0.0123 mm/min and $\hat{v}_a$ = 0.0119 mm/min.

If the cathode moves away from the workpiece surface, the removal rate drops until the pulse ends and no more removal takes place. The effect of the course of $v_a(J)$ is thus an effect of the combination of feed and oscillation of the cathode. After t = 1.02 s, the cathode moves at a constant speed v_f in the z-direction and the workpiece is removed at the average velocity calculated from $v_a(J)$. In Figure 7, the evaluation is based on the final working distance after t = 31.005 s.

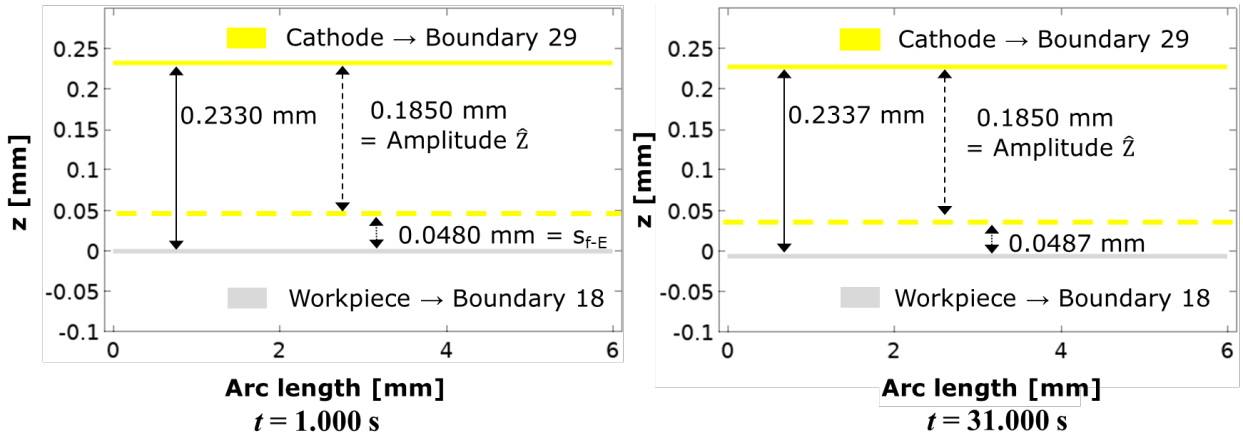

Fig. 7. Comparison of the end front working distance at the initial state and after the process time.

The end front working distance is set at the bottom dead center of the oscillation. After the process time of 30 s, the working distance between the surface of the cathode and the surface of the workpiece is 0.0487 mm. The difference between the defined end front working distance and the calculated working distance after a process time of 30 s is therefore 0.7 µm. The computing time of the simulation model for a real removal time of 30 s was 25 s.

Summary
In this study, a digital twin for the determination of process input variables for electrochemical precision machining according to DIN SPEC 91399 was developed. For this, a simulation model for a PECM process according to DIN SPEC 91399 was build up in COMSOL Multiphysics based on the geometry of an entire device unit. To design the PECM process, the oscillation of the cathode and the current pulse conditions were integrated in the model. The input parameters were set according to previous ablation experiments. A validation was carried out by maintaining the working gap after the process time of 30 s. It was shown, that the simulation time of the developed model is less than the real time of the machining process. The model can be expanded in further work. For example, the effective electrical conductivity of the electrolyte, which is influenced by the generation of heat and the formation of gas bubbles, is also decisive for the removal process in the PECM process. Approaches would be the coupling of further physical interactions like thermodynamics and fluid dynamics, multiscale approaches and the implementation of current control characteristics. In order to carry out parameter studies with this model, it is essential to integrate further ablation periods into the calculation. This will allow the removal rate to be updated as the process progresses, to match the feed of the tool electrode and the removal rate on the workpiece.

Keywords: Electro Discharge Machining, EDM, Dry EDM, Inconel 625 Alloy, Titanium Grade 2

Abstract. Dry EDM machining with external workpiece cooling is one of the possible modifications of dry EDM process, which enables to reduce the negative impact of EDM machining on the environment and on the machine tool operator. At the same time, it is possible to obtain relatively good machining accuracy and surface quality. Due to the problems with the effective heat dissipation from the machining gap, the application of dry-EDM is still limited to micromachining. In this paper the comparison and discussion of dry-EDM technological factors for two hard to machine materials: Inconel 625 and Titanium Grade 2 have been presented. The tests were carried out in carbon dioxide as a dielectric supplied to the machining gap through the channel in the workpiece electrode. To improve the process effectivity additional workpiece cooling were also applied, however the presence of fluid in machining area makes the process near dry-EDM. The input machining parameters were pulse time, machining voltage, current amplitude and inlet gas pressure. The main aim of this work was to show the significance of the type of machined material on the material removal rate, and surface layer (i.e. roughness, morphology and microhardness). The results analysis will be discussed considering differences in physical properties of machined materials.

Introduction

Nickel and chromium-based superalloys such as Inconel 625 and titanium Grade 2 are widely used in all the branches of industry, such as aviation, space industry, automotive and power generation industry. Inconel alloys account for more than half of the materials used to manufacture the hot sections of turbojet engines [1]. Inconel alloys are used similarly to titanium alloys for the manufacture of turbine blades of high-temperature turbo-machine engine components [2]. Titanium alloys are also used very extensively in the medical industry, particularly because of their biocompatibility, which is very important for implant materials. Due to the physical and mechanical properties of these materials, conventional machining of these materials is very difficult and, moreover, often cost-intensive due to high material losses during machining (material costs) and tool wear [3,4]. Machining methods which may be used for mentioned materials are unconventional machining methods such as electrochemical, electro-discharge or ultrasonic machining [5,6].

The physical phenomena occurring during material removal in EDM are very complex [2,7]. When the potential is applied to both electrodes (workpiece and tool electrode), a pulsed DC is generated between these electrodes. At the time when the gap width is adequate and the breakdown field strength is exceeded, the dielectric breakdown phenomena by gases occurs and electrons are emitted from the working electrode. Accelerated in the electric field electrons collide with the

atoms of the gas leading to atoms' ionization, which results in formation an ionization fronts from anode and cathode. When the fronts are connected, then a flow of high current in a small bridge occurs. It results in forming plasma channel with gas-interface. The rapid thermal processes lead to melting, boiling and evaporating of the workpiece surface and the tool electrode. As a result, a discharge channel consisting of an inner plasma channel and a transition area into the gas phase. The discharge channel close implosively, after the pulse is down and its volume increases continuously with the high internal pressure development, which enables the removal of some of the molten metal from the crater. Dielectric is poured over the molten metal in the craters, causing rapid cooling of the electrode material, so that micro-cracks can also form within the craters formed. The main function of the dielectric fluid is to cool, solidify the molten workpiece material and remove it from the machining zone [8,11].

The undoubted advantage of EDM is the dimensional and form accuracy that can be achieved during the process, even when machined feature size is below 100 μm. During stable machining the machining accuracy might be in range of the machining gap width. Disadvantages include the low machining productivity, high working electrode wear, as well as thermal stresses that occur in the surface layer after machining [12]. There are advantages of EDM such as possibility to machine any material which is electrical conductor (stainless stills, carbides, titanium and nickel alloys, etc., materials which are characterized by high hardness) it is also possible to obtain thin-walled elements, with complicated geometry and at the same time with very good accuracy (even close to 2 μm). However, one of the biggest drawback of EDM is the negative environmental impact when machining in liquid dielectrics, especially when the most commonly used hydrocarbon dielectrics are applied. One possible solution in the entrepreneurship where there is no possibility to use other machining technology than EDM, to reduce the negative influence on the environment and the machine-tool operator might be the usage one of alternative, environmentally neutral dielectrics. These include gaseous dielectrics such as air, oxygen, nitrogen, argon or carbon dioxide [13].

Due to the fact that during dry-EDM process it is still a problem with effective removal of heat from the machining gap, as well as workpiece material surface, adequate selection of process input parameters, dry-EDM is still limited to micromachining and is not used in industrial applications [14]. What is more one of the factors which has major impact on dry-EDM process it the workpiece material. Roth et al. [15] shows in his work, the influence of process stability and dry-EDM efficiency, not only because of the material's' physical properties, but mainly due to the properties which have a direct impact on the nature of the discharges produced during machining.

In this paper the results of dry-EDM milling of Inconel 625 and titanium Grade 2 in the carbon dioxide with the additional external workpiece cooling (sample immersed in the de-ionized water environment) were presented. The goal of this research was to determine the influence of material properties on dry-EDM process, considering gap working voltage, current intensity, pulse on-time, pulse off time and gas pressure. It is also worthy to mention that research of dry-EDM with carbon dioxide as dielectric medium is rarely described in the literature.

Materials and Methods

The near-dry EDM milling was conducted on the research test stand equipped with electro-discharge generator MATRIX MPS – 7163 160V/3A at the Cracow University of Technology [14]. The tool was tubular copper working electrode with an outer diameter of 1 mm. The carbon dioxide as the medium was supplied with pressure to the machining gap through thin - walled pipe electrode, while the workpiece was submerged in the de-ionised water (Fig. 1). Inconel 625 alloy and titanium Grade 2 were machined in the milling kinematics, with the parameters described in Table 1. The polarity during machining Inconel 625 was - working electrode (+), workpiece (-); during machining titanium Grade 2 - working electrode (-), workpiece (+). The electrode polarity was established on the basis of the preliminary tests, where the machining stability and working

electrode wear were verified for machining both Inconel 625 alloy and titanium Grade 2. The difference between used electrodes polarity between Inconel alloy and titanium Grade 2 is caused by the characteristic of used EDM generator type, as well as differences in the materials properties. For the samples 7A and 7B, the average values from three repetitions of the machining are presented in Table 1.

Table 1. Samples description with machining parameters, working tool: tubular copper electrode Ø1 mm, gas: carbon dioxide, external coolant type: deionised water (G= 0.01 µS), voltage: U=100 V

Inconel 625 (A)	titanium Grade 2 (B)	Pulse on-time [µs]	Voltage [V]	Current intensity [A]	Gas pressure [bar]
1A	1B	100	100	2.70	6
2A	2B	500	100	2.70	6
3A	3B	300	100	0.90	6
4A	4B	300	100	4.50	6
5A	5B	300	100	2.70	2
6A	6B	300	100	2.70	10
7A (3 repetition)	7B (3 repetition)	300	100	2.70	6

Described below analysis was focused on comparison of selected aspects of surface integrity of Inconel 625 alloy and titanium Grade 2 after dry-EDM in the milling kinematics with external workpiece cooling such as: surface roughness parameters (measured with Taylor Hobson profilometer), SEM photographs and microhardness. The detailed research methodology and research devices which were used during this research were described in [14].

Discussion of the Results

Fig. 2 shows the differences of material removal rate during (MRR) dry-EDM of Inconel 625 and titanium Grade 2 with external workpiece cooling. MRR was determined by the calculation of the workpiece material volume removed and the total milling time in each trial (each time removing 10 layers of material).

It is possible to say that in the most trials, the material removal rate is higher for Inconel 625, or material removal rates for both materials are very close. However, the exceptions are: trials 4B (where the highest current value, I=4.5 A, was used) and 3B (where the lowest current value, I=0.9 A, was used). Trial 3B was interrupted after removal of the one layer of the material, as the

total milling time for this layer exceeded the total milling time for the 10 layers of titanium Grade 2 in all other cases. It was stated that milling with these machining parameters used for trail 3B is inefficient. As a result, in all diagrams trial 3B is marked in a separate color (grey).

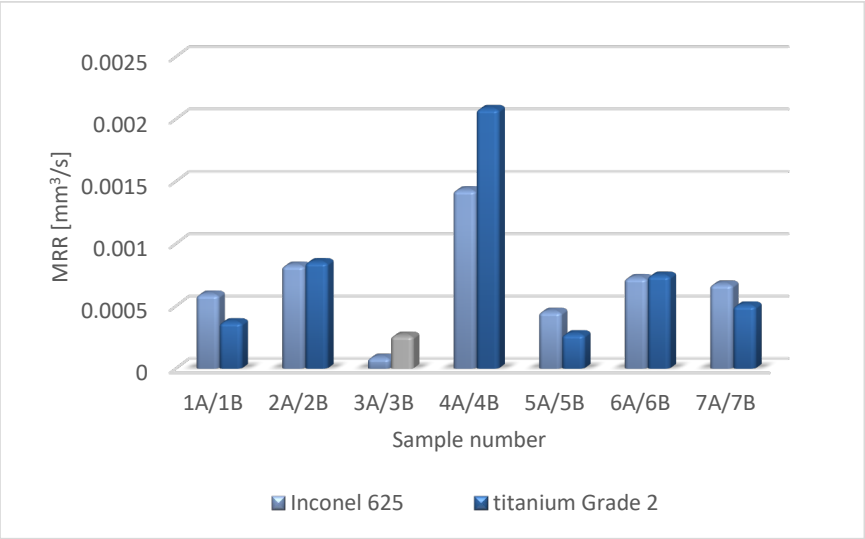

Fig 2. Comparison of material removal rate during dry-EDM of Inconel 625 and titanium Grade 2 with external workpiece cooling.

Considering the results presented in Table 2, Fig. 3, Fig. 4, one can state, that the significant differences between the results of roughness parameters of Inconel 625 and titanium Grade 2 may be observed. Much higher values of Ra and Rz parameters were obtained for Inconel 625 comparing to titanium Grade 2, when machining with higher current intensity (I=4.5 A), sample 4A, and with highest pressure (p=10 bar), sample 6A. What is more the influence of input process parameters to Ra and Rz roughness parameters can be observed. In case of the current intensity and gas pressure similar tendencies may be noticed. Strong linear correlation pattern between Ra and Rz parameters was also observed (r=0.980 for Inconel 625 and r=0.992). The examples of roughness profiles are presented in the Fig. 5.

The value of mean square deviation of the roughness profile Rq in most cases is lower for titanium Grade 2. Rsk parameter gives information about the symmetry of the profile distribution in relation to mean plane. The lower the Rsk value, the flatter the surface and the more rounded the peaks what is which is beneficial during part exploitation. Much lower values of Rsk parameter were obtained after EDM machining of titanium Grade 2.

The value of Rku (kurtosis) is a measure of the sharpness of profile peaks. When the distribution of profile peaks and valleys are normal Rku=3 µm, while for profiles with sharp peaks Rku can be higher than 20 µm. Considering obtained results one can state, that in majority cases Rku is close to 3 µm for Inconel 625, so the profile height distribution is close to normal. Similar, in most cases Rku is close to 3 µm for titanium Grade 2, however it is higher for 4B (I=4.5 A), 6B (p=10 bar) and 7B (research plan center) trial.

c) gas presurre - p

Fig. 6. Comparison of the influence of different process parameters: t_i, I and p on the surface roughness petameters Ra and Rz for Inconel 625 and titanium Grade 2 (relation based on the mean values according to Table 2), Standard deviations of Ra and Rz for samples machined with research plan central parameters (ti=300 µs, I=2.70 A, p= 6 bar): 1A: σRa= 1.65 µm; σRz=7.12 µm, 1B: σRa= 4.2 µm; σRz=21.6 µm.

Titanium grade 2 is characterized by low thermal conductivity and a single-phase α-structure, that is why no phase transformations were observed in the heat-affected zone (Fig. 7-9). The structural changes of the surface layer mainly involved the white layer, which is due to the lack of phase transformations and therefore it is difficult to observe the heat-affected zone. Of course, depending on the machining parameters used, changes in the shape of the grooves can be observed. The bottom of the groove is even and flat, the cross-section seems to reflect the actual shape of the working electrode. In the case of Inconel 625 (Fig. 7-9) surface layer morphology changes can be noticed (Fig. 7-9 A-F). With the increase of pulse time (Fig. 7 A-B), the depth of the milling grooves increases and also the recast layer becomes thicker (t_i= 500 µs). The cross-sections also

show increasing surface irregularities and deepening the discharge craters. Similar relationships can be found with increasing current intensity (Fig. 8 C-D). The increase of gas pressure causes the white layer thickness decrease (Fig. 9 E-F). At the same time discharge craters become shallower and less amount of melted material can be found on the workpiece surface.

Inconel 625 and titanium Grade 2 after dry-EDM milling with additional workpiece cooling are characterized by different hardness. In the Fig. 10 the hardness of each RAW material (Inconel 625 and titanium Grade 2) is given. It is possible to say that the values of microhardness of Inconel 625 and titanium Grade 2 in most cases are lower than for RAW materials. The Inconel 625 hardness decrease comparing to the RAW material may be caused by chipping of the recast layer during preparation of metallographic microsections or the dissolution of the carbides in the heat affected zone. In the case of titanium Grade 2, the decrease of microhardness comparing to RAW material may be related to the changes that have occurred in the material as a result of energy - electrical discharges occurring there. In the initial state, titanium Grade 2 had been cold-formed before treatment and was therefore strengthened. Energy application (electrical discharge) may cause the internal stresses removal and dislocations can be regrouped (dislocations allow the material to deform if they are free to move), as well as the density of dislocations decreases. As a result, strength and hardness decrease, while plastic deformability increases.

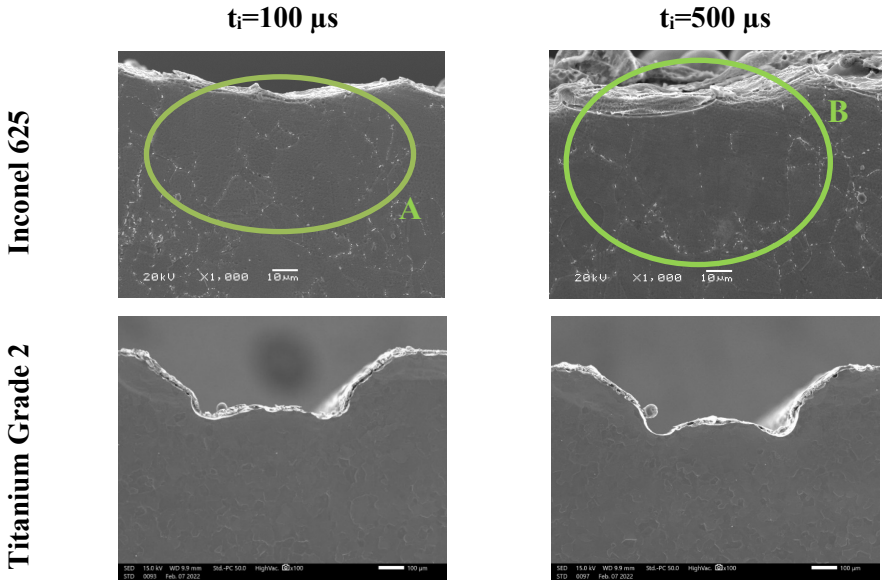

Fig. 7. Comparison of the SEM photos of Inconel 625 and titanium Grade 2 after EDM process with pulse time t_i=100 µs and t_i=500 µs with the following machining parameters: U=100 V, I=2.7 A, p=6 bar.

Summary

According to the research work carried out, the type of material (and, in particular, its internal structure, thermal and electrical conductivity) which was EDM milled in carbon dioxide, is crucial for the conducted machining process, obtained machining efficiency, working electrode wear, as well as surface roughness. However, is worth to underline that, regardless of the type of machined material, the productivity of the process is very low, which favours micro machining as an application area for the investigated process. In this application, the benefits of external cooling, such as better surface layer properties (roughness, lower thermal changes) and lower working electrode wear, result in easier designing of the machining process (it is easier to compensate the occurring lower working electrode wear) and determine the application area (better surface layer properties). It is worthy to underline, that considering the nature of the dry-EDM with additional workpiece cooling, it is hard to identify the relation between roughness parameters. It is caused by the stochastically distribution of discharge craters during the dry-EDM process. The better representation of roughness is considered to be obtained after 3D roughness measurements, which should much better represent the state of the surface roughness (especially given the randomness of the EDM discharges). Therefore, in further research it is recommended to conduct 3D roughness measurements.

Keywords: Polishing, Drag Finishing, Electrochemical Polishing, Surface Roughness, Material Removal

Abstract. This work falls within the context of very rough parts (Ra > 10 µm) polishing using a new hybrid process called PEMEC, which combines a mechanical abrasion action (tribofinishing) and an anodic dissolution action (electrochemical polishing). The study of the performances of a polishing process requires the monitoring of the surface roughness, but also the monitoring of the dimensions and the shape of the parts. This paper proposes a new method for characterising polishing operations that enables all these criteria to be monitored in a single test. This method is applied to the study of the influence of the electrolyte temperature in the PEMEC process.

Introduction

The polishing of complex shaped very rough metallic parts (Ra > 10 µm) is an old subject in industry, often related to parts produced by casting, forging, etc. However, the functional simple shaped surfaces of these parts, such as plane or cylindrical, were usually calibrated using machining processes (turning, milling, grinding, etc.). The polishing of complex shaped very rough metal parts (Ra > 10 µm) is once again becoming a major research topic in the industry with the upgrowing development of additive manufacturing techniques, such as Laser Powder Bed Fusion (L-PBF). Additive manufacturing enables the design of new parts with complex functional surfaces. These complex surfaces are difficult to access and cannot be finished by conventional machining processes. In the case of L-PBF, the surfaces are very rough, and it is common to observe surfaces with Ra roughness values ranging from 10 - 30 µm depending on the area concerned [1]. Numerous recent research projects aimed to optimise conventional polishing processes on these rough and complex surfaces (chemical or electrochemical polishing, tribofinishing, laser polishing, water polishing, plasma electrolytic polishing, etc. [2-5]). Among these recent works, Malkorra et al. [5] have shown that it is possible to reduce the roughness from an Ra of 10 µm to 1 µm using the drag finishing process. However, to achieve this goal, very long treatment times are required. Then, conventional polishing processes tend to severely deteriorate the geometry of the parts (size, shape), especially the sharp edges. In order to solve this problem, new polishing processes have appeared with the objective of reducing surface roughness without deteriorating the shape of the parts. These processes are called "hybrid" processes because they combine the simultaneous and controlled action of several mechanisms (physical, chemical, optical, etc.) and/or energy sources/tools [6]. The main objective of hybrid processes is to increase the material removal during the polishing process through a synergistic effect between the mechanisms. For example, there are several hybrid processes daily used in industry that combine

abrasion and chemical dissolution mechanisms [7-8]. In the scientific literature, there are also several processes that combine abrasion and anodic dissolution mechanisms [9-14]. Unfortunately, these hybrid processes have been designed to polish simple surfaces such as planes or cylinders and are not suitable for complex shapes.

Moreover, it can be stated that all the papers dealing with the polishing of rough and complex parts do not use any standardised method. Each paper develops a specific method for its own samples with respect to its application. It is therefore difficult to compare the performance between several processes. Additionally, the wide majority of the papers are focused on surface roughness. Only few papers have investigated the evolution of part's geometry (dimension, form, edges, …). The objective of this article is to propose a reference method for the characterisation of polishing processes on parts with complex geometries and very high initial roughness ($Ra > 10$ µm). The application case study of this new method concerns the investigation of the influence of electrolyte temperature in a new process called 'PEMEC'. This polishing process was recently proposed in [15]. This process combines an abrasive action (tribofinishing) with an anodic dissolution action (electrochemical polishing - ECP). Among the large variety of technical solutions in tribofinishing, the PEMEC process kinematic uses a drag-finishing machine kinematics that enables to polish complex surfaces thanks to its double rotation. The principle of this process is described in Fig .1

As a reminder, electrochemical polishing (ECP) is one of the most common electrochemical polishing processes used for metallic parts with complex shapes. This process involves the controlled dissolution of the surface to be polished. ECP commonly provides shiny surfaces. When electropolishing, current flows from the anode (the workpiece – Fig.1 A-D) to the cathode (the machine tank – Fig.1 A-D). The anode-cathode assembly is immersed in an electrolyte bath, the concentration and composition of which varies according to the metal being polished. The scientific community has conducted numerous studies on the sensitivity of the process parameters (temperature, electrolyte composition, agitation rate, distance between the electrodes, etc.) [3]. This process requires long treatment periods. Moreover, the concentration of the electric current lines on the sharp edges induces a modification of the geometry of the parts (Fig. 1D).

Drag-finishing is a mechanical polishing process that improves the surface roughness of parts with complex geometries. The parts are dragged through a mixture of a large number of abrasive particles (called abrasive media) immersed in a liquid. The interaction between the abrasive media and the surface to be polished induces 3 mechanisms: plastic deformation of the roughness peaks, scratches and finally it generates micro-chips. These mechanisms lead to an improvement of the surface finish. This process has been studied several times and it has been shown that the efficiency of the process depends on several parameters such as drag velocity, type of liquid and geometry, as well as size and composition of the abrasive media [5]. However, this process requires long polishing periods to achieve a low roughness. In addition, abrasives are particularly aggressive to sharp edges, which changes the geometry of the polished workpieces.

Rech et al. [15] have shown that there is a synergistic effect between abrasion and anodic dissolution during the PEMEC process. It becomes possible to reduce the roughness very quickly from a *Sa* value of 11 µm to 3 µm within 120 minutes on complex 316L stainless steel parts, without significantly modifying the shape of the parts and especially the sharp edges.

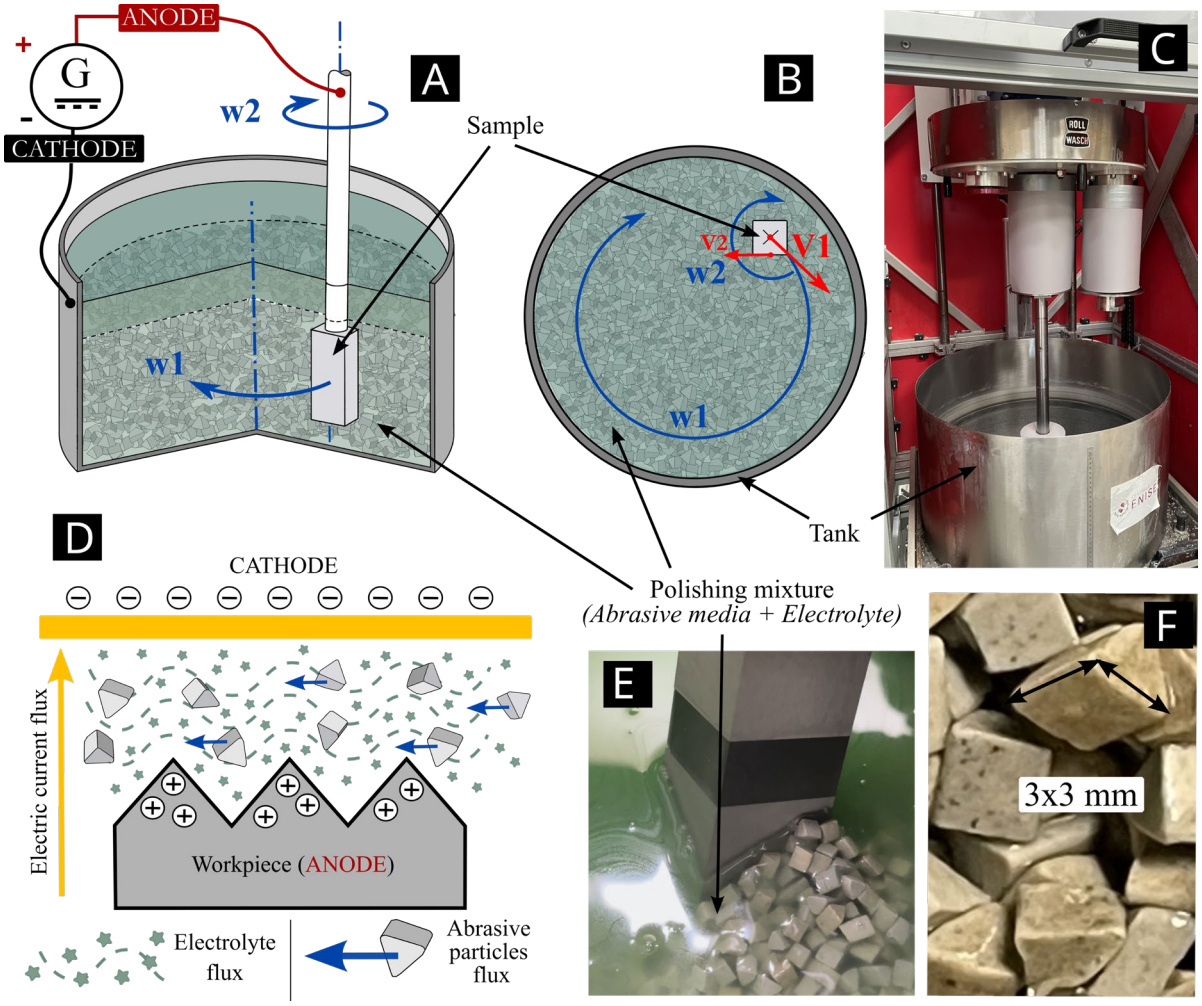

Fig. 1. PEMEC process principle: A) Schematic illustration; B) Schematic illustration; C) PEMEC machine; D) Schematic illustration of PEMEC principle; E) PEMEC polishing mixture (Abrasive media + Electrolyte); F) Elementary abrasive media used in PEMEC process.

Experimental Procedure

Definition of sample geometry.

The first step of the new method, to characterize polishing processes, is to define a new sample geometry with a calibrated geometry and roughness (Fig. 2). The part has rectangular parallelepipedal shape with two *'reference surfaces'* at its upper and lower ends. These *'reference surfaces'* are flat and smooth (Fig. 2A). During the polishing process, these surfaces will be protected and will not be affected by the polishing process (Fig. 2C). These '*reference surfaces'* enable the sample to be relocated in an absolute reference frame. Then there are two groups of so-called *'transition surfaces'* (Fig. 2C). *'Transition surfaces'* are also flat and smooth. They enable to investigate the evolution of the macro-geometry of the sample (flatness, orientation, dimension) and the evolution of edge sharpness. Both the *'reference surfaces'* and *'transition surfaces'* have been generated by grinding. Finally, in the centre of the sample, there is the so-called *'calibrated roughness area'* where a high roughness is generated with a determined shape (Fig. 2B). The analysis of the evolution of the topography in this zone enables the analysis of the polishing mechanisms (plastic deformation, abrasion, dissolution, ...). The principle of this analysis has already been introduced by Malkorra et al. [16].

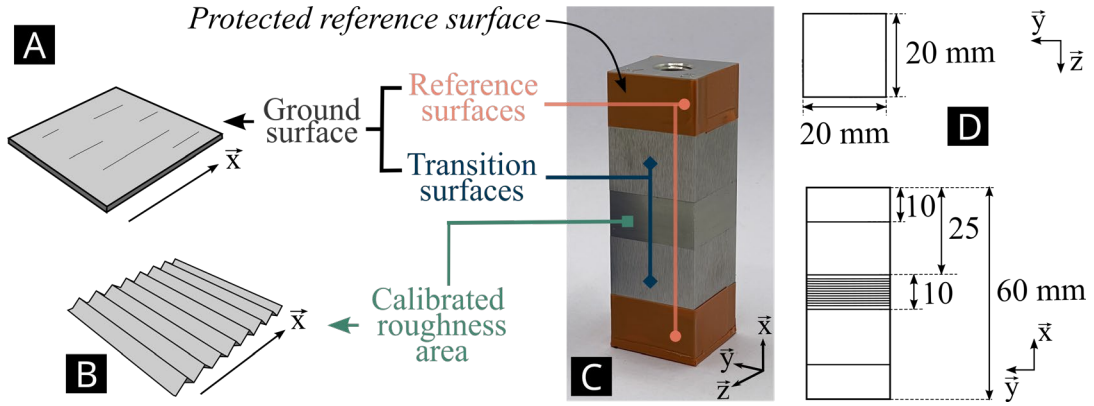

Fig. 2. A) Ground surface schematic; B) Calibrated roughness area schematic; C) Image of sample with protected reference surface; D) Sample dimensions.

Sample fabrication.

The samples were fabricated from austenitic 316L stainless steel. For logistical reasons, it was decided to use 316L stainless steel from laminated bars. After milling, *'reference surfaces'* and *'transition surfaces'* were both manufactured by fine grinding. Before polishing, the *'reference surfaces'* and *'transition surfaces'* cannot be distinguished from each other. The only difference between these two surfaces is that *'reference surface'* will be protected during the polishing process, and thus will not be modified. The edges around the transition surfaces are sharp (Fig. 3E). The so-called *'calibrated roughness area'* was machined by milling (Fig.3 A to D) with the aim of reproducing a microgeometry similar to those obtained after additive manufacturing processes. This step allowed to obtain a high roughness value ($Ra \simeq 12$ µm / $Rz \simeq 50$ µm). The results found when polishing this *'calibrated roughness area'* have the same trends as those obtained when polishing real parts produced by additive manufacturing [15].

Polishing tests.

The samples were polished by the PEMEC process for 75 minutes. The PEMEC machine is designed within a drag-finishing machine, that enables both polishing processes (abrasion + anodic dissolution) to be carried out. The main rotation (w1 in Fig. 1 A-B) induces a drag velocity V1 responsible for the abrasive mechanisms, while the second rotation (w2 in Fig. 1 A-B) leads to a homogeneous treatment around the workpiece. This kinematic induces a high sliding speed. This set-up has already been used in previous works [15]. During the polishing process, the workpiece is immersed and dragged in the polishing mixture (abrasive media + electrolyte). Table 3 shows the composition of the polishing mixture and the process parameters used. A DC power supply was installed between the tank (cathode) and the workpiece (anode).

Table 1 Polishing mixture composition and process parameters

		PEMEC process	
Drag velocity V_1 [m/s]		0.6	
Rotation speed, w_1 [rpm]		200	
V_2 [m/s]		0.69	
Sample rotation speed, w_2 [rpm]		655	
Temperatures		25 °C	62 °C
"Polishing mixture"	Abrasive particles	Pyramidal shape Al_2O_3 abrasive particles, size 3x3 mm	
	Electrolyte / Lubricant	Phosphoric acid H_3PO_4 (85 wt.%) and deionised water	
Voltage [V]		12	
Current density [A/dm²]		20	

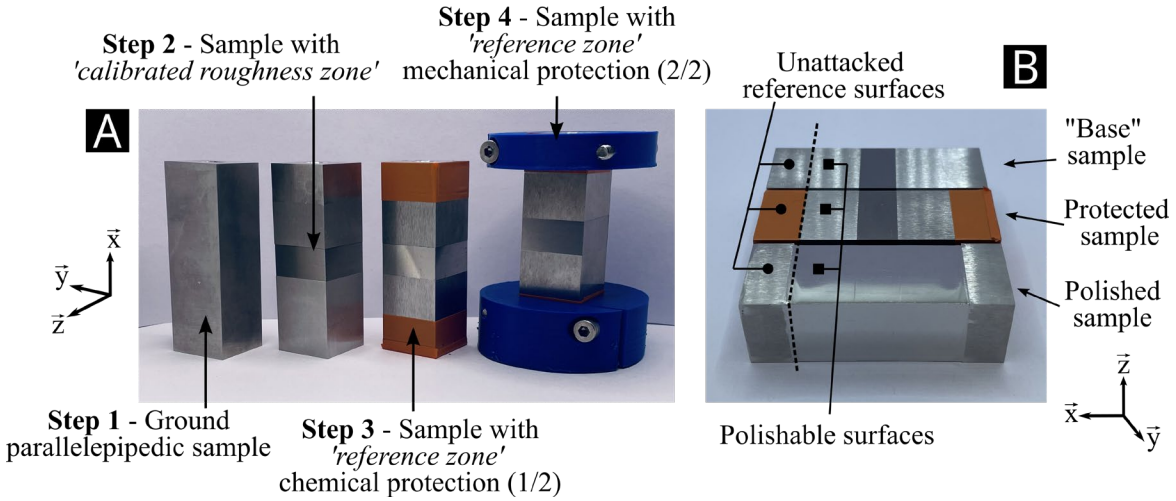

Fig. 4. A) Sample protection process; B) Protected reference surface principle.

The distance between the anode (workpiece) and the cathode (tank), and the drag speed are very influential parameters for the ECP mechanisms. The anode-cathode distance was set at around 30 mm, and this distance oscillates around this value due to the rotation of the workpiece (w2) and the geometry of the workpiece. It should be noted that the distance and drag speed used in this study are significantly higher than the values used in studies conducted by the scientific community on ECP. The temperature of the electrolyte is controlled before and during the treatment to ensure that the temperature is the same throughout the polishing process. In this study, two temperature levels were chosen: T°= 25 °C and 62 °C. The samples are mounted in the machine with a reference surface protection system (Fig. 4). The tests were interrupted every 15

minutes in order to characterise the topography evolution of the 4 calibrated roughness areas and the 8 transition surfaces and edges. This enables to obtain an average value, as well as to quantify the deviation.

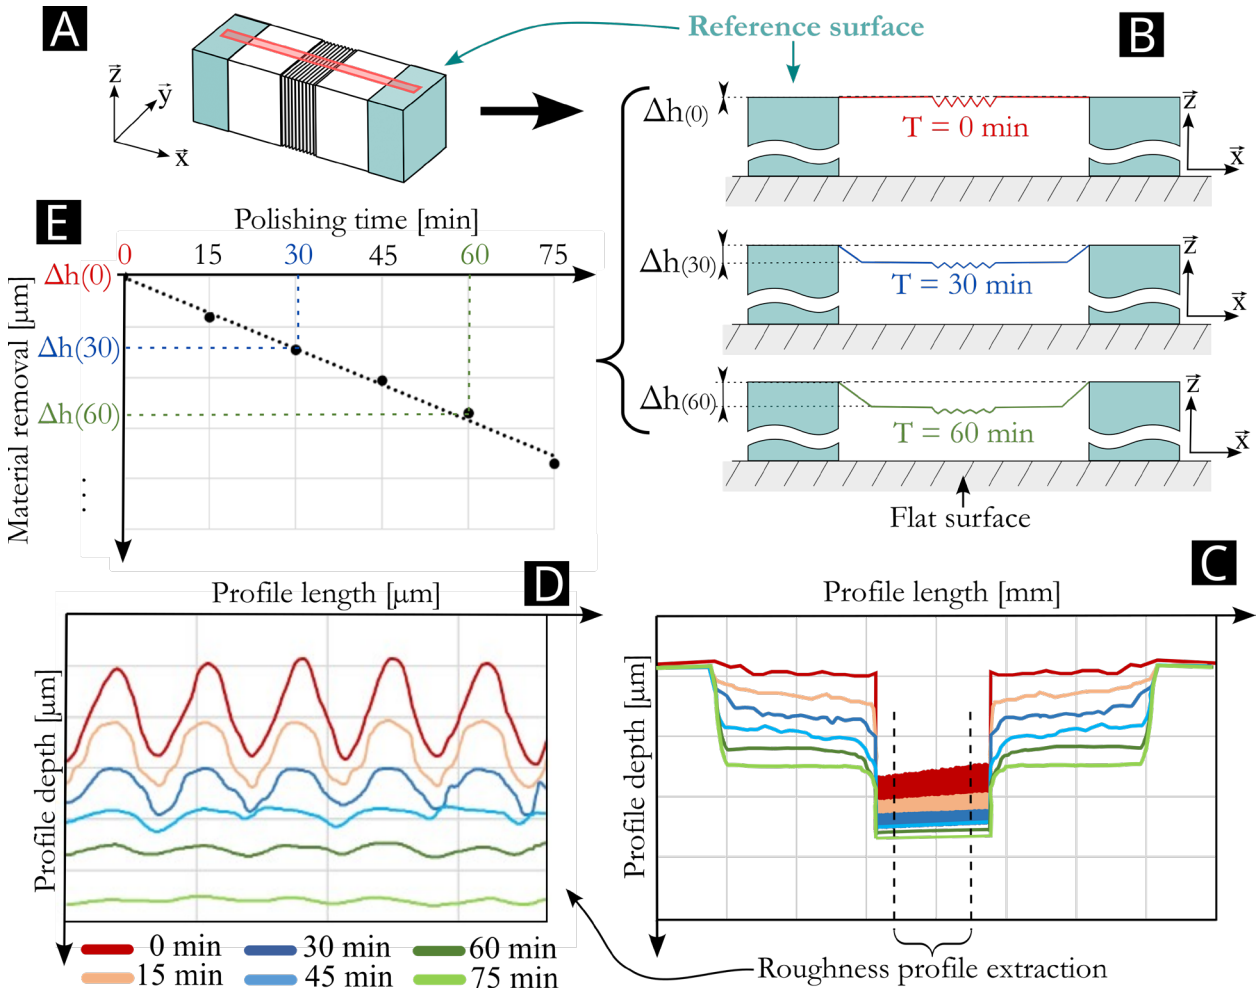

Fig. 5. A) Sample with highlighted reference surfaces schematics; B) Reference surface working principle; C) Profile overlay; D) Roughness profile extraction after profile overlay; E) Material removal evolution obtained.

Results and Discussions

The new method for characterising the performance of polishing processes was applied for two polishing conditions, corresponding to operating conditions, i.e. two different values for electrolyte temperatures. The results are presented in Figures 6, 7 and 8.

Fig. 6A shows the evolution of the amount of material removed (Δh) in the *'transition surfaces'* for both tested conditions. The process for obtaining figure 6 is explained in figures 5A, 5B and 5E. It appears that the material removal rate is much higher at high temperature. Thus, after 75 min, a value of $\Delta h \sim 384$ µm can be observed at 62 °C compared to 74 µm at 25 °C. If we analyse the evolution of material removal, we can observe that at 62 °C, the process removes nearly as much material after 15 min ($\Delta h \sim 65$ µm) as the process at 25 °C after 75 min ($\Delta h \sim 74$ µm). There is a ratio of around 4.5 on the material removal rate between the two different temperatures tested.

Fig. 6B shows the evolution of the *Ra* parameter in the *"calibrated roughness area"*. It can be observed that the roughness is improved much faster when using a high temperature. Thus, after

15 minutes only, *Ra* reaches a value of ~ 0.45 µm at 62 °C, compared to 8.22 µm at 25 °C. The PEMEC process at 25 °C only achieves a *Ra* < 1µm after 75 min.

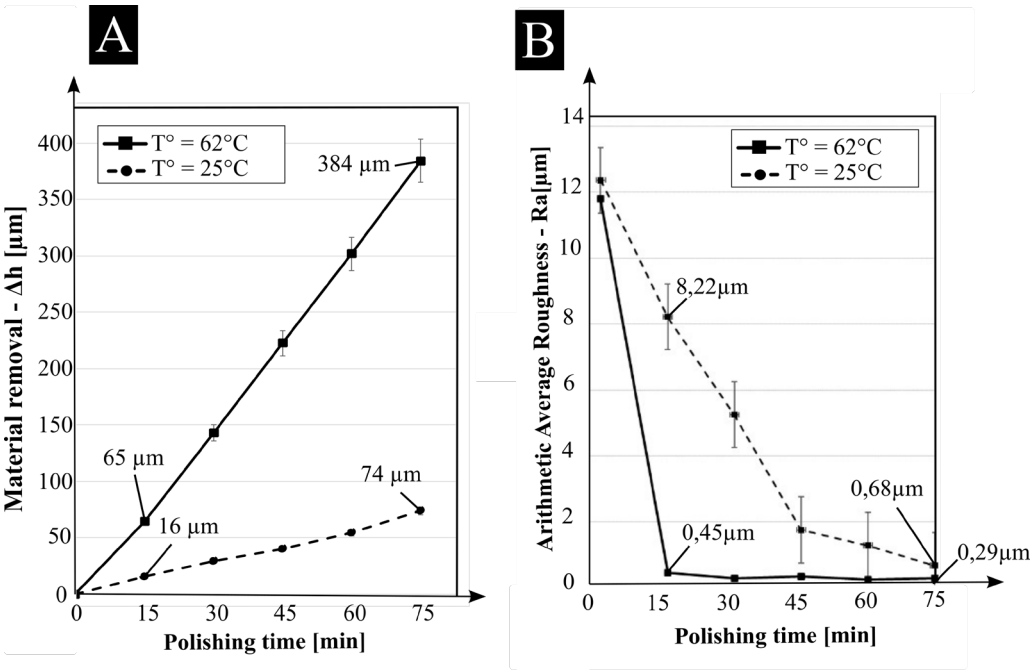

Fig. 6. A) Material removal, Δh[µm], over time; B) Arithmetic Average Roughness, Ra[µm], over time.

Fig. 7A and B show the evolution of the roughness profile, as well as their relative position compared to the reference surfaces. These figures were obtained by overlaying the different measured roughness profiles, using the *"reference surfaces"* as a reference (Fig.5 A-B). This overlay process is explained in Fig. 5 A to D. Fig. 7A and B illustrate clearly that the polishing process at 62 °C completely erases the initial roughness profile in less than 15 minutes. It can also be seen that the amount of material removed is greater than the initial height of the roughness profile. However, after a 15-minutes treatment, a slightly noticeable periodic surface remains from the initial roughness profile. The surface then becomes aperiodic from 30 minutes onwards.

In comparison, at 25 °C the profile remains periodic until 75 min. It can be observed that the valleys of the profiles are not much affected at the beginning of the treatment. This behaviour reveals the abrasion of the roughness peaks, which indicates that abrasion is probably the dominant mechanism. In sharp contrast, at 62 °C there is clearly a combination of homogeneous material dissolution and peak roughness abrasion (synergistic effect of the PEMEC process). These results confirm the findings of the literature regarding the importance of temperature control in electrochemical polishing [5].

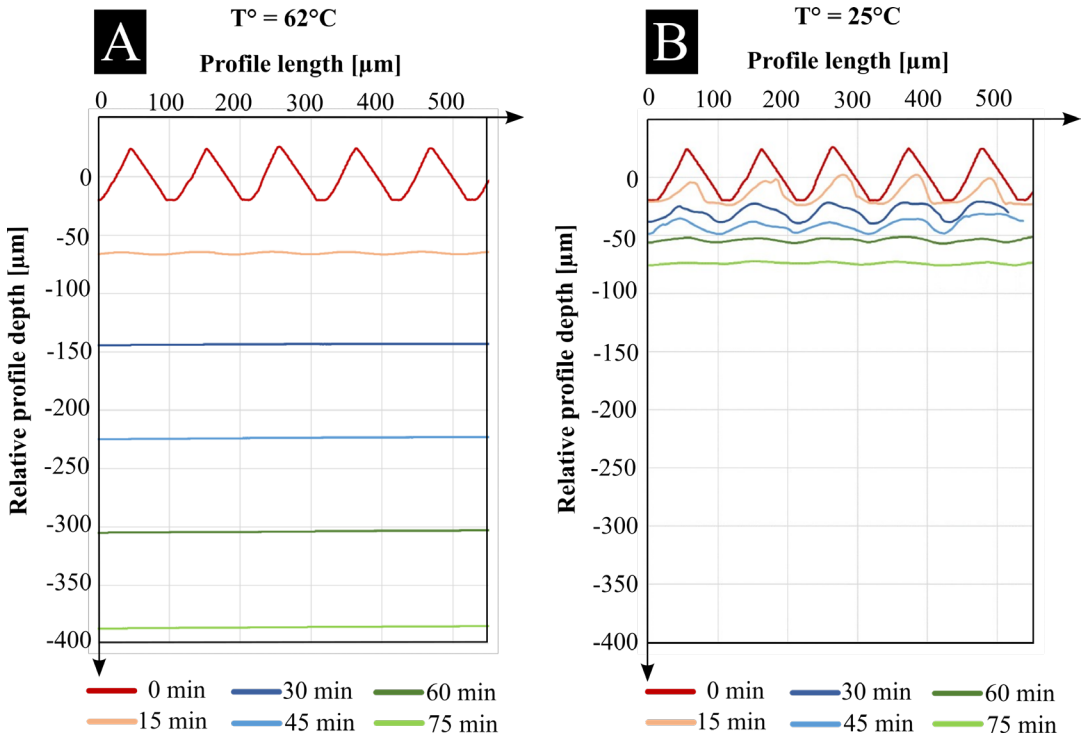

Fig. 7. A) Roughness profile evolution at 62 °C; B) Roughness profile evolution at 25 °C.

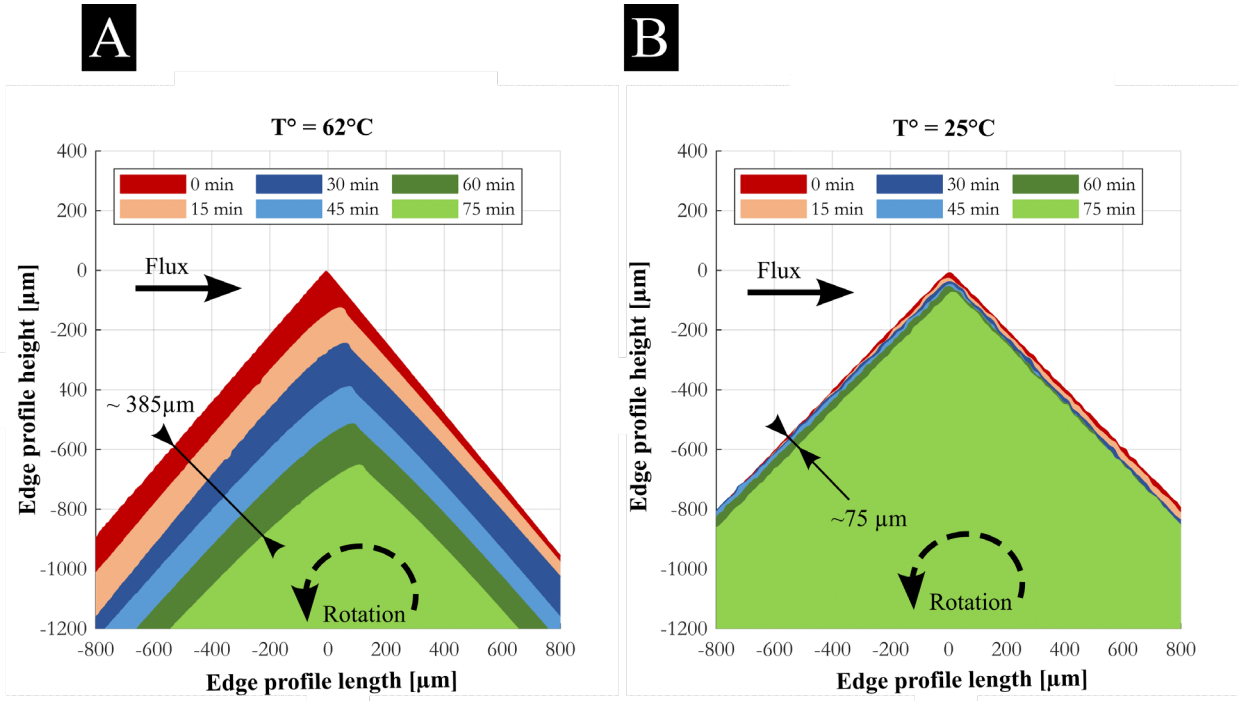

Fig. 8. A) Edge profile evolution at 62 °C; B) Edge profile evolution at 25 °C.

Fig. 8A and B show the evolution of the edge profile, were obtained by overlaying the different measured edge profiles. It is clear that at 25 °C the edges are only slightly affected by the process, while, at 62 °C the change in edge geometry is very rapid. This is in accordance with the previous

results presented in Fig. 7 and 8. A large amount of material is removed. However, the edge sharpness remains quite sharp and not rounded (~ 1 mm) as is commonly seen in drag-finishing processes. A closer look at the profiles shows that the two sides are not symmetrical. On the left side, the shape is more affected by the polishing process than on the right side leaving non-flat surfaces near the edge, as well as a slightly curved edge. This is due to the direction of rotation of the sample in the machine. The w2 speed induces a greater abrasive media impact speed on left side. This asymmetry can be counterbalanced by regularly reversing the direction of rotation in the machine. So, it can be concluded that the PEMEC process enables to preserve edge sharpness thanks to the reduced polishing duration (some minutes).

Summary

This paper has presented a new method to characterise the performance of a polishing process on complex shaped samples with high roughness. This method was applied to the characterisation of the influence of electrolyte temperature in the PEMEC process, which combines an abrasive and an anodic dissolution action. This method has shown its ability to simultaneously quantify the multi-scale evolution of the samples: roughness parameters, roughness profiles, material removal and edge macro-geometry. This method allows to reveal the mechanisms of action of polishing processes.

In the case of the PEMEC process, it was shown that temperature is a key parameter for the efficiency of material removal. While the process is essentially dominated by the abrasive action at low temperature, the dissolving action plays a major role in synergy with the abrasion at higher temperature.

The perspective of this work will now focus on a generalised use of this methodology in order to study the sensitivity of the PEMEC process to all the mechanical parameters (shape and speed of the abrasive particles, ...) and the electrochemical parameters (voltage, electrolyte, ...) so as to identify the best synergistic conditions between the two mechanisms.

This geometry of samples has the potential to compare the efficiency of various polishing processes for complex and rough parts.

Abstract. Composite materials are increasingly employed in many industrial sectors (transportation, infrastructure, electronics). Among the others, carbon fibers are used primarily as reinforcing agents in high-performance composites with synthetic resin matrices such as epoxies, polyimides, vinyl esters, phenolics, and certain thermoplastics. However, when carbon fibers were coupled with a thermosetting matrix, the resulting composites are not easily recyclable. When these products reaching their end-of-life (EoL) there are several difficulties in their recycling and in the reuse of the carbon fiber reinforce. There are several recycling process methods, but one of the most promising and investigated in the last years is the mechanical one that differently from other approaches do not require the use of high temperature or chemical substances to decompose the polymeric matrix. Respect to known mechanical recycling methods like shredding, crushing and hammer milling process, in this work is presented a mechanical recycling that mainly consists in the use of an un-conventional milling process in order to obtain carbon/epoxy chips. Different chips in terms of geometry and size were obtained by fixing the milling process parameters, so the results in terms of chip morphological characteristic were presented. CFRPs chips, after sieving, were then used to manufacture new CFRPs laminates produced starting from recycled materials.

Introduction

Carbon fiber reinforced plastic (CFRP) materials are attracting a significant interest in our day-to-day life because of their interesting mechanical properties combined with the low weight [1].

It is not a surprise that their demand over the last 40 years is grown more and more and during these last years, although the COVID pandemic, the CFRP growing demand reached a current rate of 11% per year due to the increasing need of lightweight materials in different industrial fields. It was estimated that the CFRPs demand was around 120 kTons during the present year [2,3].

It is worth to note that the growing demand of CFPRs is directly connected with an increasing production of virgin carbon fibres (vCF) with expensive and energy intensive processes that generates gases such as ammonia (NH_3), carbon monoxide (CO), carbon dioxide (CO_2) nitrogen oxides (NO_X) and other volatile compounds [4].

It was calculated by a Life Cycle Assessment (LCA) analysis that the amount of energy required for the production of vCF is almost 198 - 595 MJ/kg [5] compared with 13 - 32 MJ/kg required for the production of virgin glass fibre (vGF).

In addition to these considerations, it have to be considered that the growing demand of CFRPs will dramatically increase the amount of waste derives both from scraps produced during the manufacturing of composite products and from the end-of-life products; this latter represents the majority part. A defined waste management and a recycling policy are then required since it is estimated an increasing of CFRP waste of around 20 kTons annually by 2025 also considering that

around 6000 - 8000 commercial aircrafts (with CFRP components) will reach their end-of-life by the 2030 [6,7].

Based on these considerations, it is clear that there is a strong need to recycle CFRPs by adopting an appropriate recycling process that is in the same time cheap, eco-sustainable, suitable for the industrial scale-up and able to obtain rCF to produce recycled CFRPs with interesting mechanical properties. Among different recycling processes, usually classified in chemical, thermal and mechanical processes, one of the most promising for the future is represented by the mechanical one. Chemical e thermal methods were widely investigated in the last years [8,9] and in spite of interesting mechanical properties are achieved by composites produced using these rCF, both methods are characterized by high costs, specific laboratory apparatus that can obstacle an easy industrial scaling up, long processing time and environmental impact.

The mechanical method is usually used to indicate a broader process's categories such as shredding, crushing and hammer milling that lead to a composite fragmentation into small pieces. An overview on the mechanical recycling process [5,10] leads to the conclusion that these methods produce short recovered fibers that due to their geometrical characteristics, size and the presence of residual matrix, severely affect the overall mechanical properties of the recycled composite material [11]. All these aspects compromise the use of mechanical recycled composite as load bearing structure limiting their use sometimes as fillers in low properties composite materials such as SMC and BMC. In addition, the use of shredding or hummer-milling process implies the use of ad-hoc industrial machine with low flexibility and big size.

To overcome this limitation, in this work it is studied the possibility to use the milling process as mechanical recycling method in order to obtain carbon/epoxy chips used to produce recycled CFRP laminates.

Materials and Methods

The CFRP materials used in this experimental campaign were manufactured using 20 unidirectional carbon/epoxy prepregs (0.2 mm in thickness) supplied by Toray. Composite laminates $(0/90)_{20}$ were produced using the compression molding process under a pressure of 8 bar and a temperature of 130°C for 8 hours. At the end of the polymerization phase, the cured composite laminates (4 mm in thickness) were cut in plate 200 mm x 200 mm to allow the machining of the CFRP material. For this purpose, a CNC machine (C.B. Ferrari) and a three flute HSS end mill tool (20 mm in diameter) were used for the peripheral down-mill machining of the produced samples. A radial depth of cut of 3.00 mm with a feed rate, *f*, of 1000 mm/min and a spindle speed, *s*, of 1000 rpm were adopted as machining parameters.

The obtained CFRP chips were then sieved using a shaking table aiming to achieve a satisfying separation between fine and coarse fibers (mean size > 0.1 mm) from powders (mean size < 0.1 mm).

Therefore, in order to produced recycled CFPR samples, the obtained chips were manually impregnated with an epoxy resin and placed in a mold at room temperature for 24 hours. Different typologies of samples were produced, they mainly differ in the size of the recycled reinforcement (greater or smaller than 0.1 mm) and in its percentage weight content equal to 14, 17, 20 and 25%. Then, the flexural behavior of each sample typology was investigated according to ASTM D790 standard testing three specimens for each sample typologies. For this purpose, three-point bending tests were carried out using a universal testing machine (MTS Alliance RT/50) equipped with a 1 kN piezoelectric load cell. Specimens (120 mm x 21 mm x 4 mm) were tested using a span length of 64 mm (span to depth ratio equal to 16). Three un-reinforced samples are also tested as reference. The flexural strength was calculated by means of the following equation:

$$\sigma_f = \frac{3FL}{2bt^2} \quad (1)$$

where σ_f is the maximum stress in the outer fibers at midpoint, F is the maximum load of the load-deflection curve, b is the width of the specimen, t is the thickness of the specimen and L is the support span. The flexural elastic modulus was evaluated as the ratio, within the elastic limit, of stress to corresponding strain.

Results and Discussions

The machining operation of virgin CFRP samples produced chips of different sizes. In detail, the results after sieving are reported in Table 1 and in Fig. 1 are showed typical chip images for each sieving size.

Table 1. Size dimension distribution of CFRP chips obtained after the machining operation.

	Chip size <0.1 mm	**Chip size >0.1 mm**	**Chip size >0.3 mm**	**Chip size >1.5 mm**
Weight content [%]	3.49	20.96	40.98	34.57

In Fig. 2 is instead reported the results of the bending tests. The flexural stress-strain curves can give precious indication about the mechanical properties of the recycled samples in terms of interfacial adhesion efficiency between the surface of the recovered fibers and the new epoxy matrix. In detail, it was observed that for samples produced by using recycled materials with a mean size smaller than 0.1 mm the results were not affected by the reinforcement weight content.

Then, for a better readability of the results, in Fig. 2 it is plotted only one stress-strain curve for representing this sample category.

The results showed that all reinforced samples are characterized by a linear elastic response with a reduction of the strain at breaking in comparison with the reference sample type (pure epoxy sample); this difference decreases as the reinforcement content increases.

Looking at both Fig. 2a and 2b it is clear that the sample reinforced with rCF smaller than 0.1 mm showed the worst performances and despite a flexural modulus improvement respect to reference sample (around 40%) an evident reduction of both the strain at breaking and the flexural strength was detected. The reduction of the flexural strength is due to the small size of the reinforcement phase that acted more as defect than as reinforce, in addition it barely can stop the propagation of internal cracks nucleated in proximity of possible porosity within the sample.

Differently, when the reinforcement phase was represented by rCF chips with a mean size greater than 0.1 mm both the flexural strength and modulus were higher than those of the reference sample and they increase as the rCF chips weight content increases. In detail an increasing of about +46% of the flexural strength was detected when 25 wt.% of rCF chips was adopted.

In spite of this interesting results, it has to be considered that the mechanical properties achieved following this method do not allow the use of this recycled composite for structural applications where high performance are required. This is due to two main reasons: (i) the obtained rCF are short fiber, then the properties cannot reach those of long fibers and (ii) the mechanical recycled fibers are characterized by the presence of matrix residues on their surface and this involves a reduced adhesion efficiency between the recovered fibers and the new resin. By way of example, in Fig. 3 it is showed a magnification of a rCF chip where it is evident the presence of residual matrix on its external surface.

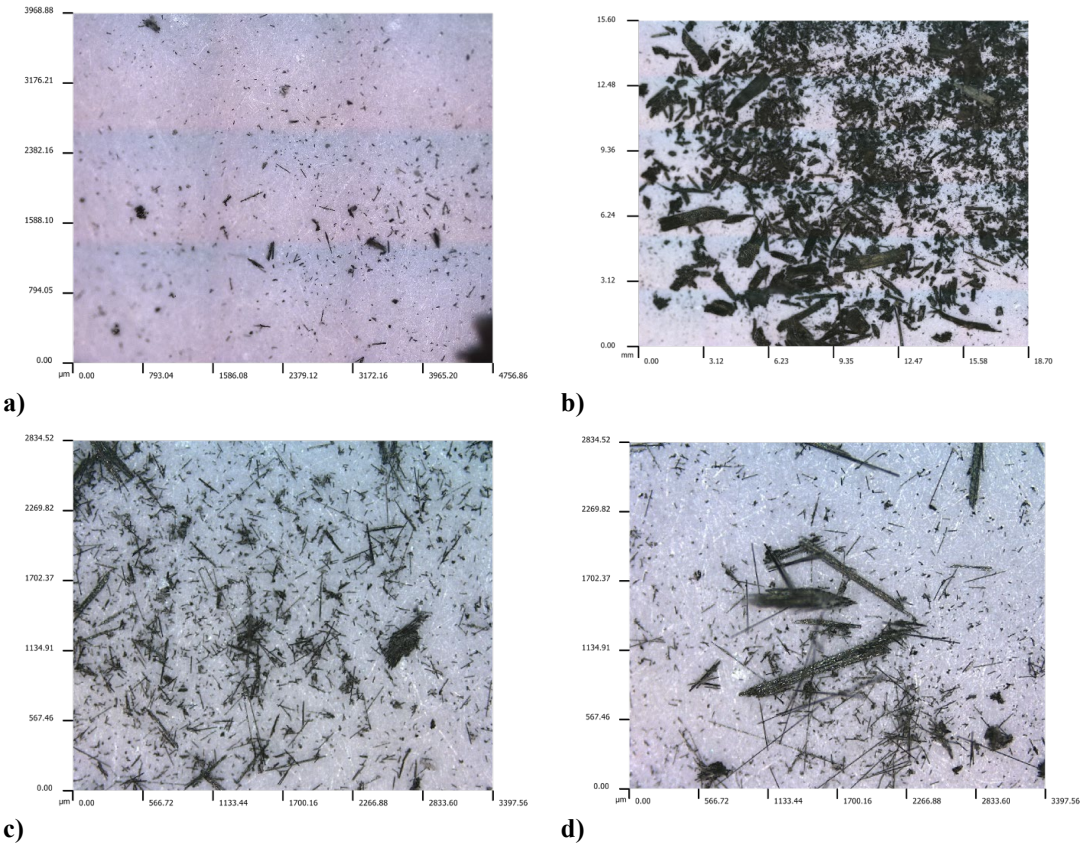

Fig. 1. Typical chips obtained after the milling process: size dimension <0.1 mm (a), size dimension >0.1 mm (b), size dimension >0.3 mm (c), size dimension >1.5 mm (d).

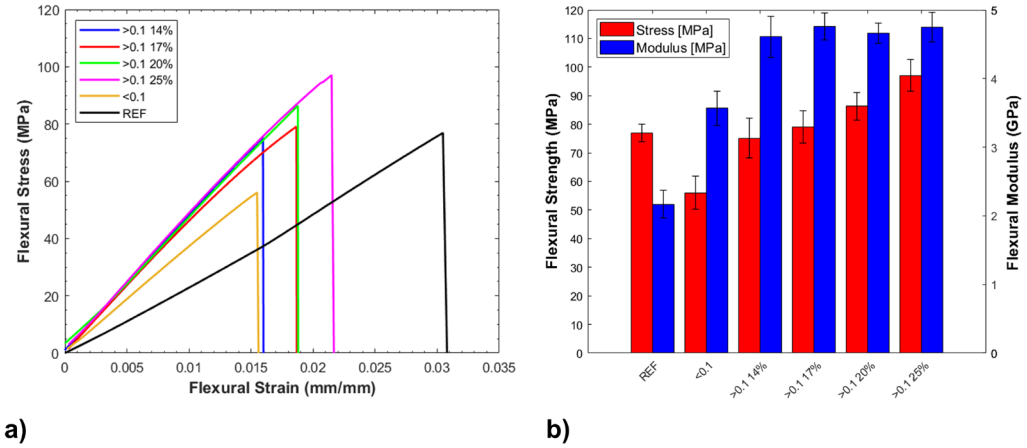

Fig. 2. Typical stress-strain curves (a) and mean flexural strength and modulus (b) for each sample category.

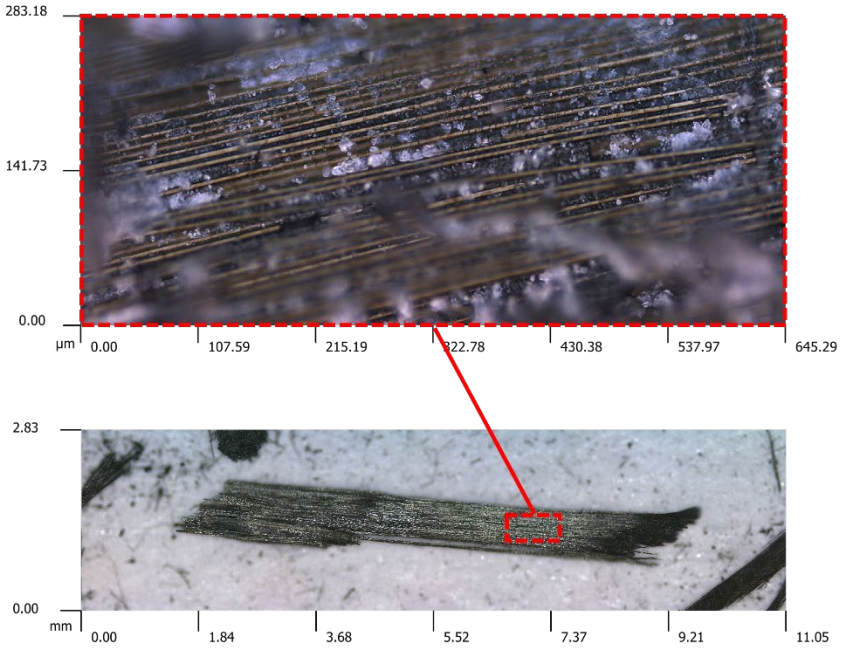

Fig. 3. Details of a rCF chip with the presence of residual matrix on its surface.

Summary

In this work it was presented a preliminary study on the use of a milling process to obtain rCF chip usable as reinforcement for the production of recycled CFRPs. The results showed that the flexural properties were affected by the rCF chip size, in particular the use of the smallest one (mean size < 0.1 mm) did not involve any advantages, contrary to what obtained when greater rCF chips were adopted. Indeed, the use of rCF chips with a mean size greater than 0.1 mm allowed the production of recycled CFRPs characterized by a flexural strength 46 % higher respect to pure epoxy sample. The results showed that according to the proposed procedure, it is possible to use the recycled carbon fibres as reinforcement of the epoxy resin reaching a flexural strength of around 100 MPa and a flexural modulus of around 115 GPa.

It is also important to note that after sieving, it was highlighted that only 3.9 wt.% of the rCF chips was comprised of those with a mean size smaller than 0.1 mm. This means that the proposed recycling procedure is characterized by a high efficiency since the 87.1 % of the obtained waste can be successfully reutilized to produce recycled CFRPs.

Keywords: Metal Matrix Composites (MMC), Compressibility, Powder Pressing

Abstract. Aluminium-matrix composites (AMC) are produced in order to improve specific properties (e.g. mechanical, thermal or tribological) of the matrix alloy using discontinuous reinforcements like fibres or particles. If functional requirements of application specific components such as brake discs have to be met, reinforcement contents of more than 35 % may be required. Therefore, a new manufacturing route is currently being investigated at the Institute for Metal Forming Technology (IFU) of the University of Stuttgart, combining powder pressing with subsequent semi-solid forming to obtain near-net-shape components. A key challenge of this process route includes compacting the green bodies. In this contribution, therefore, powder pressing of AlSi7Mg0.6 and SiC_p powders with up to 50 vol.% SiC_p are investigated in order to gain a deeper understanding of the compacting behaviour of powder with particularly high reinforcement contents. During the investigations, homogenously mixed powders were consolidated to a cylindrical green body by uniaxial powder pressing in order to determine the compressibility of different AMC powder mixtures. At first, the influence of the consolidation pressure onto the reached density was analysed, resulting in compressibility curves as well as process limits for different amounts of reinforcement particles. Subsequently, the influence of particle size onto the achieved density as well as consolidation behaviour could be identified. Furthermore, the high tool wear due to the abrasive behaviour of the reinforcement is quantified in this paper.

Introduction

In comparison to monolithic aluminium alloys, aluminium-matrix composites (AMC) exhibit advanced properties such as increased stiffness, wear resistance, specific strength and vibration damping as well as a decreased coefficient of thermal expansion [1]. However, manufacturing of particle reinforced AMC still is facing technological problems in terms of relatively high processing costs and prevailing production difficulties, which are in the focus of different current research activities [1-3]. Manufacturing processes of AMC investigated in this context in general can be divided into liquid, semi-solid and solid routes. In liquid process routes, the matrix alloy is melted, while solid reinforcement particles are distributed in the melt. This can adversely affect its castability, thus leading to porosity [4] and agglomeration [5] within the final component´s volume. The particle reinforcement content achievable with liquid process routes is therefore up to now limited to 30 vol.% in most cases [6]. In contrast, in the semi-solid (e.g. [7]) and solid (e.g. [8]) process routes, both matrix and reinforcement are solid powders. Therefore, a consolidation step is required in these process routes to produce green bodies for further manufacturing steps. Several approaches can be used for this consolidation respectively cold or hot isostatic pressing, cold uniaxial pressing or direct pressure sintering. For the solid process route, a sinter [1], sinterforging [9] or extrusion [10] step can subsequently be used in order to bond as well as further consolidate the green bodies into the final shape for solid forming. Current investigations in the

field of reinforced aluminium powder mixtures show the influence of size ratio, volume ratio between reinforcement and matrix alloy particles up to 30 vol.%. Hafizpour and Simchi displayed that a size ratio of 1:1 is recommended, especially for higher amounts of reinforcements, in order to reach a high density [3]. O'Donnell and Looney investigated the influence of lubrication onto the consolidation process using insert wall lubrication or mixed-in lubrication, showing no noticeable effects on the sintered specimens [1].

At the Institute for Metal Forming Technology of the University of Stuttgart (IFU), semi-solid routes were initially investigated in terms of producing continuous fibre-reinforced aluminium alloys [11]. Further investigations resulted in the manufacturing of a metallic end connection for pultruded fiber composite tensile rods, which were forged into a metallic end connection [12]. First investigations of particle reinforced AMC were produced by a process route combining direct pressure sintering with subsequent semi-solid forming, resulting in promising material properties as well as complex near-net shape components [2]. However, the direct pressure sintering step should be avoided in order to reduce energy costs. Therefore, a novel process route is currently investigated combining cold uniaxial compression with subsequent semi-solid forming. Thereby, particular focus is now being placed on the forming of AMC with particle loadings higher than 30 vol.% silicon carbide (SiC_p). Currently, no investigations of the compaction behavior of powders with SiC_p reinforcement higher than 30 vol.% were made, while for this novel process route further understanding of the compaction behavior is needed.

The present paper deals with the first step of the novel semi-solid process route and thus with the cold uniaxial compression of aluminium alloy powder with silicon carbide powder (SiC_p). Here, special attention is paid to the production of green bodies with as homogenous as possible particle and density distribution in the green body volume. In this paper the influence of two different composite particle sizes of the powder as well as of compression insert wall lubrication onto the consolidation behaviour is studied.

Materials and Methods

For the investigations of different AMC powder mixtures on the consolidation behaviour, two different particle sizes having a mean particle diameter of 250 µm and 63 µm respectively were analysed. For the matrix aluminium alloy (AlSi7Mg0.6), produced by Ecka Granules GmbH, Germany, nitrogen gas atomized powder with a nearly globular shape was used (Fig. 1a). During production of gas atomized powders larger particle sizes are undesirably produced, due to overspray. This normally would lead to a recycling of those larger particles, since established additive manufacturing routes commonly use particle sizes smaller than 63 µm. To utilize those larger particles for the production of green bodies, a powder particle size having a mean diameter of 250 µm was used. However, a conventional particle size for AM with a mean diameter of 63 µm was investigated as well. Commercially available SiC_p particles having an angular shape, as seen in Fig. 1b, were utilised as reinforcement particles. Dry mixing of both powders (size ratio 1:1) with a particle loading of 30, 40 and 50 vol.% SiC_P was performed by a turbular mixer. With a mixing speed of 20 min^{-1} and 15 min mixing time, a homogenous mixture of both powders could be guaranteed for all powder mixtures. The homogeneity was proven by an image analysis of the different volume fractions based on finite body tessellation and the coefficient of variance (COV) [13].

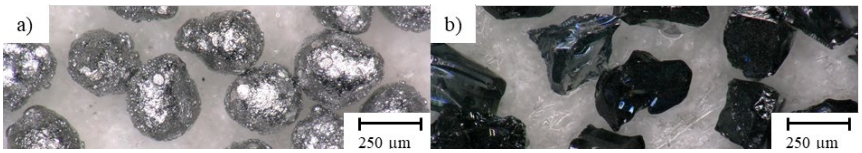

Fig. 1. a) Nitrogen gas atomized aluminium powder b) SiC powder (mean diameter 250 µm).

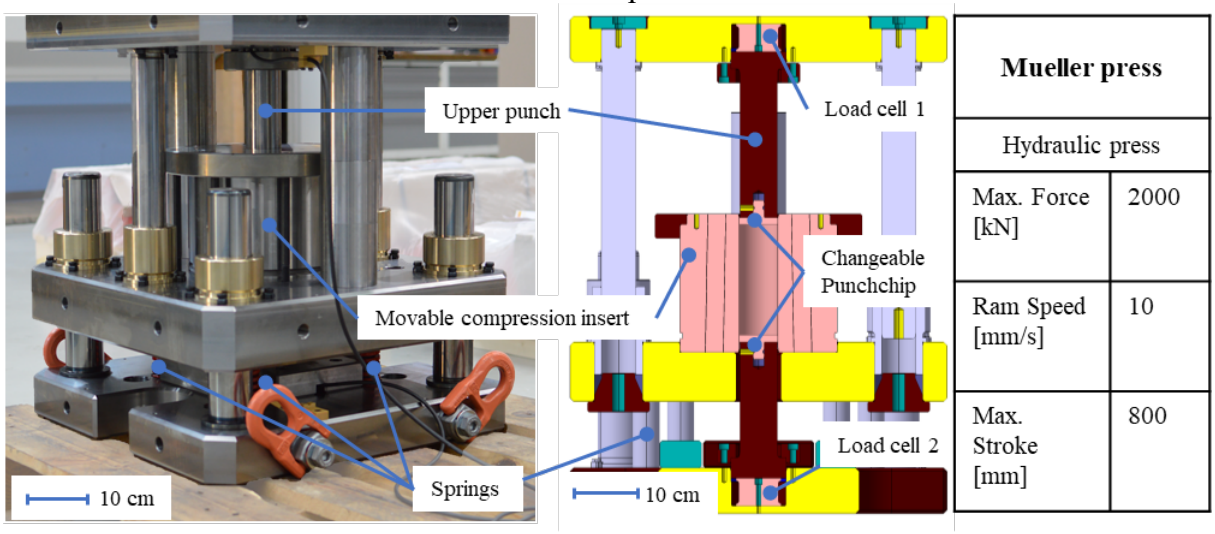
The tool used for the consolidation tests was designed with a movable compression insert mounted on four springs in order to ensure a two-sided uniaxial compression (Fig. 2). The insert diameter was 56 mm having a g6 fit, while the punches were processed to a H7 fit. The upper and lower punch was attached to a loading cell for measuring the press forces during consolidation. Contact faces of the punches to the workpiece were designed to be changeable due to the expected high abrasive wear by the SiC_p. This was achieved by using changeable punch-chips, which were mounted via a ball catch for a quick changeover. A hydraulic press was used to consolidate the green bodies with different press ram forces. Maximum force of the press is 2000 kN having a maximum stroke of 800 mm with a constant ram speed of 10 mm/s.



Mueller press	
Hydraulic press	
Max. Force [kN]	2000
Ram Speed [mm/s]	10
Max. Stroke [mm]	800

Fig. 2. Compacting tool and specification of hydraulic press used.

During the consolidation tests, mixed powders all having a size ratio of 1:1 (mean particle diameter of both powders) were compacted using pressures of 300, 450 and 600 MPa respectively (see Table 1). The coarser (F 60) powder was additionally compacted using a hydraulic press at a pressure of 1000 MPa, in order to determine the maximum force that can be applied without defects in the green body for this coarse size. In conventional powder metallurgic process routes often, lubrication is added to the powder mixture. However, for the subsequent semi-solid forming, lubrication is undesirable due to the included remaining lubrication in the final components. The presented experiments were carried out partly without lubricant and partly with molybdenum disulfide (MoS_2). Here, the MoS_2 was only applied to the inner side of the insert and the punch surfaces, aiming to minimize the amount of contamination inside of the green bodies produced. After ejection of the green bodies out of the insert, the green body density was measured using a volumetric approach. Weight measurement was performed on a precision balance with a deviation in measure of 0.001 g, while for dimensional measurement a micrometer with 0.01 mm deviation was used. For all experimental parameter combinations, three green bodies were produced and the mean deviation was used to compare the results in an objective manner.

Table 1. Experimental parameters used.

Experimental parameters				
Powder particle size [µm]	F 60 (250 – 400 µm)		F 220 (40 – 63 µm)

Compaction pressure [MPa]	300	450	600	1000 (only F60)
Lubrication	None		Molykote (MoS_2)	

Results and Discussion

At first the obtained results of the unlubricated consolidation experiments are presented. The mixtures of powders with the larger particle size (F 60) could be pressed at all compaction pressure levels to unlubricated green bodies having relative densities dependent on the pressure value. The resulting compressibility curves are shown for all three investigated proportions of SiC-particles in Fig. 3. Thereby, the relative density was calculated from the reached density (volumetric approach) compared to the ideal density of the composite of each respective powder mixture. Lower particle loadings of 30 vol.% SiC_p showed the highest reached density for all pressure values. The reason for this is that the aluminium matrix is plastically deformed during densification, while the harder SiC_p particles are only elastically deformed. At the beginning of the densification a particle rearrangement occurs, as the pressure further increases the plastic deformation and thus the particle deformation of the aluminium particle begins. Elastic deformation of the SiC_p leads to a reduction of the plastic deformation and hence an insufficient bonding strength between the aluminium particles. Given by the uniaxial compression with a movable compression insert, the area of the lowest density is in the middle of the green body. If the plastic deformation is insufficient, a delamination plane appears in the green body, consisting of nearly non-compacted powder with low cohesion. Green bodies having a density below the depicted red line indicating a relative density of 77 % in fact showed such behavior with an insufficient densification. In general, a higher portion of reinforcement amount increases the absorbed elastic pressure and further limits the densification. Green bodies with 50 vol.% SiC_p showed on average a 4% lower relative density compared to green bodies with only 30 vol.% SiC_p. Maximum reached densities were 91.86 % (30 vol.%), 89.51 % (40 vol.%) and 87.69 % (50 vol.%). During ejection, abrasive wear of the insert as well as the punch-chips appeared, while with higher compaction pressure a higher ejection force as well as a higher wear behavior was determined.

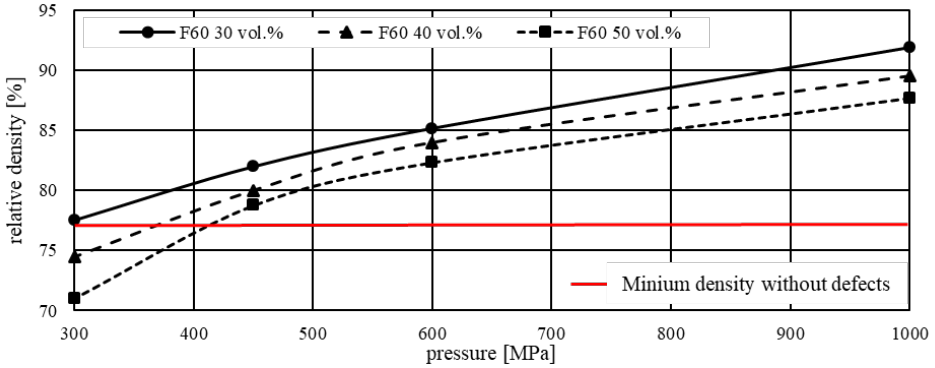

Fig. 3. Compressibility curve of the larger powder mixture without lubrication.

The finer powder of F220 could not be compacted without lubrication, since delamination and shear fractures occurred during ejection, as seen in Fig. 4 (1.). The reason for this is, on the one hand, that smaller aluminium particles have lower limiting strains, reducing the deformation ratio. On the other hand, particle rearrangement of the finer particles represents the dominant mechanism of densification as investigated by [3]. Another reason constitutes the higher friction between insert wall and powder mixture, which lead to sticking effects during ejection. Furthermore, the higher inner friction within the powder leads to a reduced deformation ratio, due to reduced force transmission. This promotes delamination and increases the density gradient inside of the green body, having areas of almost no compaction in the middle plane and highly compacted areas in the contact zones with both punches. Increasing the pressure up to 600 MPa shear cracks appear and the green body additionally cracks during ejection. Thus, the maximum pressure applied was reduced to 600 MPa for the following experiments.

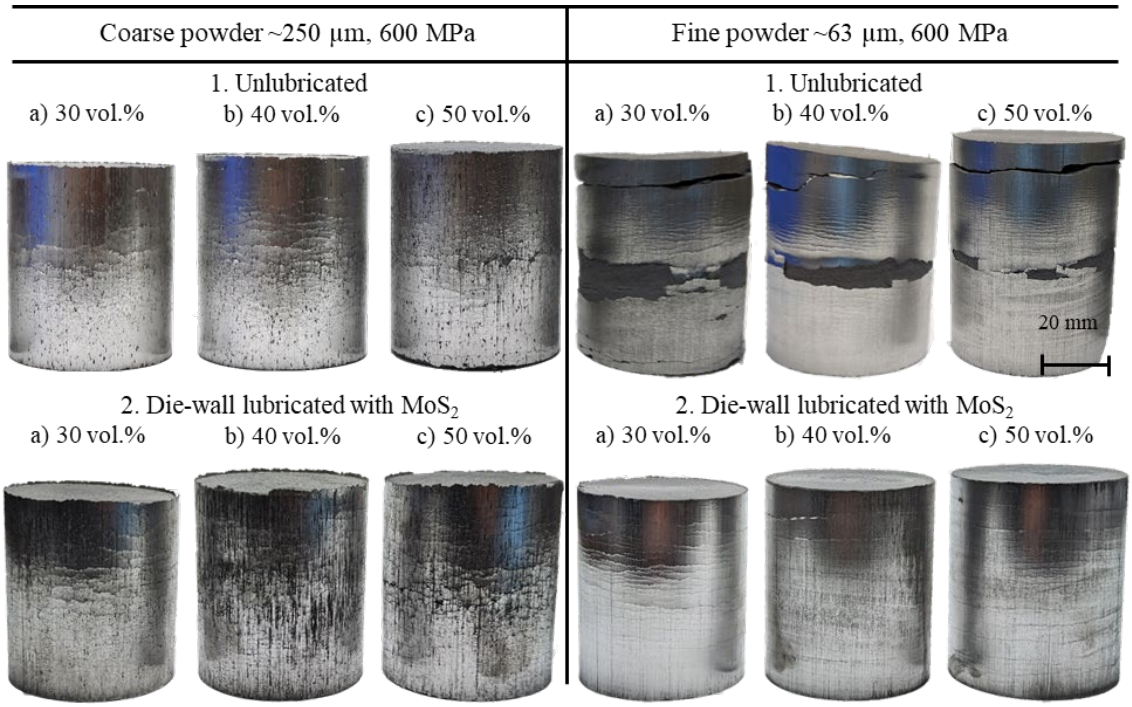

Fig. 4. Produced green billets with a constant pressure of 600 MPa, 1) Unlubricated 2) Insert-wall lubrication.

Compaction with a sprayed insert-wall lubrication, containing MoS_2, at 600 MPa achieved delamination-free green bodies for both the fine as well as the coarse powder mixtures (see Fig. 4 (2.). In the following, the resulting densities obtained from the compression experiments using insert wall lubrication (MoS_2) are presented in Fig. 5. The trend towards lower densities at higher particle loadings could be confirmed for both particle sizes and resulted from the higher amount of elastic energy absorbed by the SiC_p. Compared to the unlubricated densities of F60 particle size, an improvement in compressibility of approximately 2 % could be observed. Again, the lowest pressure of 300 MPa resulted in insufficient compaction for particle loadings of 40 and 50 vol.% as indicated by the red line in Fig. 5.

In conclusion, the fine powder showed a reduced compressibility compared to the coarser powder after consolidation. As already shown by the results of the unlubricated experiments, one reason for this is the friction between insert wall and powder, which is principally higher with fine than with coarser powder. As a consequence, higher friction results in lower consolidation

pressures during densification. In this respect, the difference between measured force of the upper punch compared to the measured force of the lower punch, which corresponds to the friction loss, was 15.2 % higher for fine powder than for coarse powder at 300 MPa. At 450 MPa, the value was 32.0 % higher, and 51.5 % at 600 MPa. Another reason for the lower densification of the finer powder is the inner friction of the powder particles, since the porous structure has more contacts as well as smaller voids in the finer powder mixture.

In addition, the experiments carried out have shown that the limit for the lowest density, at which just sufficient compaction occurs in the middle plane of the green body, in general is nearly the same for fine powder compared to coarser powder. For all three particle loadings and both particle sizes, an insufficient consolidation is reached at densities below 77 % resulting in loose powder in the middle separation plane. Particle loadings of 40 and 50 vol.% SiC_p should be manufactured with pressures of 450 MPa or 600 MPa. Higher pressure than 600 MPa favors shear and delamination cracks without lubrication as well as increases the tool wear during ejection, due to the higher elastic energy absorbed by the SiC. Therefore, higher pressures should only be used for significantly higher required green body densities.

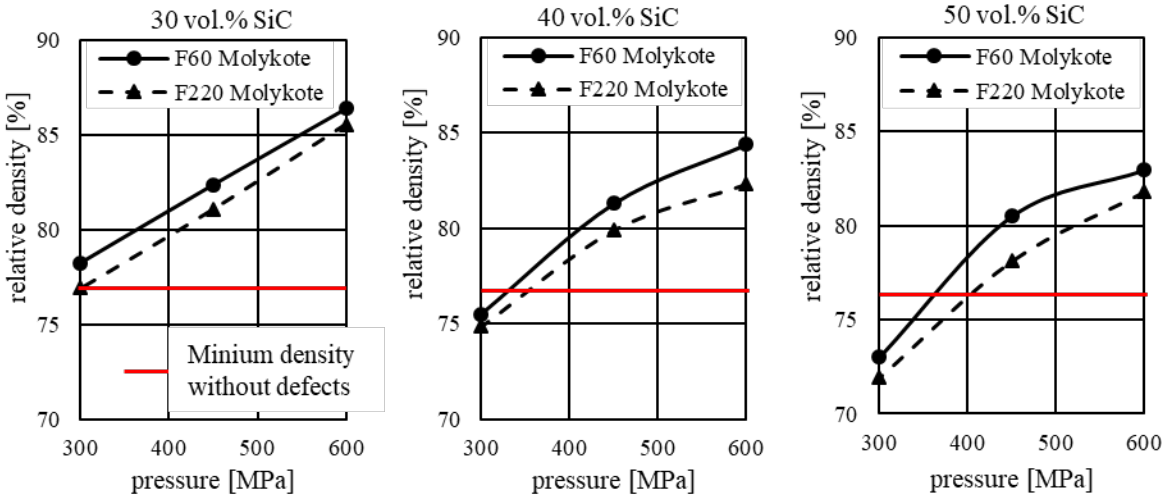

Fig. 5. Compressibility curves for both particle sizes using insert wall lubrication.

Summary

In this paper, the consolidation process of highly reinforced aluminium powders with SiC_p contents up to 50 vol.% were investigated. Thereby, the influence of particle loading and size of the powder mixture on the achieved density of the green bodies to be consolidated was analysed. Subsequently, the compaction parameters regarding compaction pressure as well as lubrication effects onto the produced densities of the green bodies were determined. The main findings are summarized according to the obtained results:

- The coarser powder mixture exhibited a lower wall friction as well as a higher compressibility during compaction, resulting from lower inner friction as well as a high plastic deformation of coarser aluminium particles. In general, it was found for all powder mixtures investigated that the green body must exhibit a density of at least 77 % after consolidation in order to ensure sufficient plastic deformation of the aluminium powder and thus avoid a delamination plane in the middle of the green body.
- Finer powder mixtures showed a higher insert wall friction, especially during the ejection of the green bodies, resulting in shear and delamination fractures. Green bodies without insert wall lubrication could not be compacted. One reason for shear and delamination defects was the higher friction inside the powder. For finer powders the main densification mechanism is particle rearrangement, resulting in high particle to particle contacts as well

as smaller voids inside the green body compared to the green bodies with coarse powder. Thereby, the inner friction reduced the force transmission inside the powder, causing high density gradients inside the green body height and failure of the form-locking bonds.

- Particle loading reduced the achieved density, due to the absorbed elastic energy by the SiC_p for both particle sizes of the powder decreasing the plastic deformation of the aluminium powder. A higher amount of SiC_p results in lower densities of the final green bodies.
- Compaction pressure improved the density achieved for both particle sizes of the powder, which can be attituded to the increased plastic deformation of the aluminium particles and the resulting bonds between the particles.
- Unlubricated experiments using fine powder mixtures resulted in delamination in the middle plane of the green bodies as well as shear cracks near the contact areas of the punches, due to high insert wall friction during compaction as well as during ejection. Insert wall lubrication enabled the manufacturing of green bodies with the finer powders, and reduced the ejection forces acting on the green body. In general, insert wall lubrication improved the achieved densities compared to the unlubricated green bodies by 2 % for the coarser powder mixtures, due to the reduced friction energy absorbed by the insert. Coarser powder reached higher densities compared to the finer powder, resulting from the higher friction energy absorbed by the insert as well as the higher inner friction in the finer powder mixture during compaction.

For future research, the process parameters of lubricated insert wall with a compaction pressure of 600 MPa will be used, as the results showed defect-free green bodies for both particle sizes with sufficient densification. For semi-solid forming of brake disc-shaped components the green bodies will be heated into a semi-solid state and subsequently formed using different process parameters. Thereby, the influence of the process parameters onto the particle distribution of the final component will be further investigated.

Keywords: Incremental Sheet Forming, Polymers, FE Analysis, Toolpath Strategy

Abstract. Incremental sheet forming is a relatively new technology with a deformation strategy that resembles the layered manufacturing principle of rapid prototyping; thanks to this, it can represent a viable way to form metal and polymer sheets, guaranteeing high customization and cost-effectiveness. On the other hand, and particularly when considering thermoplastic sheets, the components obtained by this process suffer from peculiar defects like, for example, twisting and wrinkling. A way of reducing the risk of such defects is to optimize the toolpath strategy to lower in-plane forming forces. To pursue this aim, the present work follows a numerical approach; a commercial FE code was used to simulate the incremental forming of polycarbonate sheets by varying the toolpath strategy. The investigation of some features like the forming forces and the deformation states was carried out, with the goal of determining an optimized toolpath strategy for the reduction of the incremental forming forces and the consequent expectation of reduced risk of failures and defects for incremental formed polymer sheets.

Introduction

The interest in the incremental sheet forming (ISF) of thermoplastic polymers has been experiencing a significant increase over the past few years since these important materials can be engineered to reach high specific strength and stiffness values, and the ISF technology guarantees high customization. The products manufactured with this process can cover many fields of application; for example, they are largely considered for aerospace and unmanned aerial vehicles, so as for racing and commercial cars [1], and several applications have been also found in the biomedical sector [2].

When formed by ISF, the polymer sheets (but not only) can suffer from failures and undesired deformation phenomena like, for example, twisting and wrinkling. The first one occurs as the effect of an uncontrolled twist of the sheets with respect to the clamping frame and it is caused by the in-plane shear that, in turn, is generated by the tangential component of the forming forces. The authors, in previous works, observed and quantified this phenomenon both for metal [3] and polycarbonate sheets [4], and the last ones, in the case of axisymmetric components obtained by a unidirectional toolpath, showed very high twisting angles (about 22°) if compared to the corresponding ones on metal sheets (less than 6°). On the other hand, they also observed a dramatic reduction of the twisting angle when adopting an alternate toolpath. All the same, severe forming conditions in terms of sliding forces on thin sheets of not particularly resistant materials like thermoplastics can determine the occurrence of wrinkling [5].

However, the attempt to reduce the sliding forces between the tool and the sheet can also be made for further different aims like, for example, to limit the global forming forces, to reduce the risk of failures of the forming tool and of the sheets, and to improve the surface quality of the incrementally formed parts; in addition, it could be possible to reduce the use of lubricants employed to lower friction and sticking of material to the tool.

Considering the above, this work aims to follow a numerical approach for the optimization of the toolpath strategy applied to the incremental forming of polycarbonate sheets, to reduce the forming forces and, with it, reduce the risk of failures and defects. To do this, the manufacture of cone frusta with fixed wall angle by varying the toolpath strategy was simulated by a commercial FE code; from the results of the simulations, some outputs were investigated, like the forming forces and the stress-strain states.

Materials and Methods

The manufacture of cone frusta with a fixed wall angle was simulated by means of the FE commercial code LS DYNA; the goodness-of-fit of the numerical model was evaluated in a previous authors' work [6] on the occurrence of wrinkling when thin polycarbonate sheets were worked by incremental forming.

Polycarbonate sheets with a thickness of 1.5 mm were considered; besides, the forming tool had a hemispherical head, 10 mm in diameter. The main geometrical features of the cone frusta are highlighted in Fig. 1; in particular, α represents the wall angle, h the height and R the radius of the major base.

The sheet and the tool (only its hemispherical head) were modeled, whereas the effects of the blank holder were simulated by setting fixed constraints to the nodes of the sheet periphery (a square of 100 mm × 100 mm in dimensions).

The elements of the sheet are fully integrated shells with five integration points through the thickness and a mean dimension of 1.41 mm. The material model was the MAT PLASTICITY POLYMER. For the tool head, Belytschko-Tsay shell elements with two integration points through the thickness and a mean dimension of 0.2 mm were used, while the MAT RIGID model was chosen, setting typical properties of the steel.

The main materials' properties are summarized in Table 1.

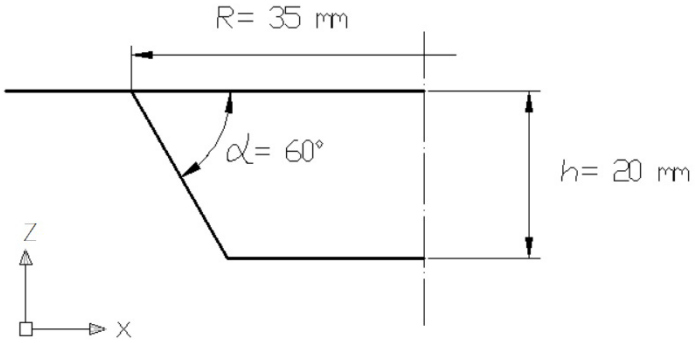

Fig. 1. Geometrical features of the cone frusta.

Table 1. Main materials' properties.

Material	Density [g/cm^3]	Young's modulus [GPa]	Poisson's ratio [-]	Yield stress [MPa]	Ultimate elongation [%]
Polycarbonate (sheet)	1.2	2.3	0.3	60	110
Steel (tool)	7.85	210	0.3	-	-

Materials Research Proceedings 28 (2023) 1697-1702 https://doi.org/10.21741/9781644902479-183

The SURFACE TO SURFACE contact card was selected for the tool/sheet interaction (consider that for this kind of test the sheets can be lubricated with mineral oil for cold forming to reduce friction and sticking of material to the tool and then, to avoid the risk of damages) and x, y, and z displacement laws were set in the BOUNDARY PRESCRIBED MOTION card to impose the tool movement (feed rate of the forming tool V_f=1000 mm/min).

Finally, the run time of the simulations was notably decreased, using mass scaling [3].

Different paths of the forming tool were considered to impress the deformation to the sheet with which comes in contact on points of a spiral path; in particular, the points were equally spaced around θ=6° from each other and the vertical step (*vs*, the vertical distance between two consecutive spirals) was equal to 1 mm (see Fig. 2; five exemplary consecutive points, from A to E, are reported).

Three solutions, reported in a not-to-scale schematization in Fig. 3, were chosen to cover the distance between two consecutive points: in particular, describing:

- one segment;
- a horizontal and a vertical segment;
- an upward (where H_r represents the ramp height) and a vertical segment.

These three typologies are labeled std_tp (standard toolpath), Hr0_tp and Hr1_tp, respectively.

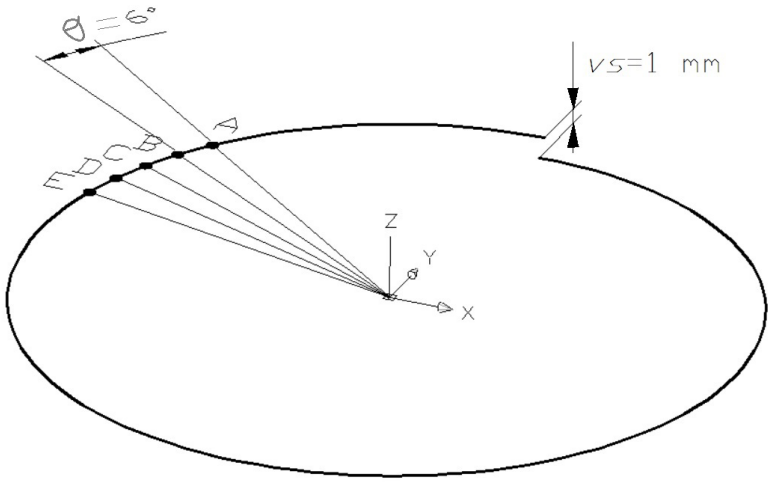

Fig. 2. Details of the spiral path.

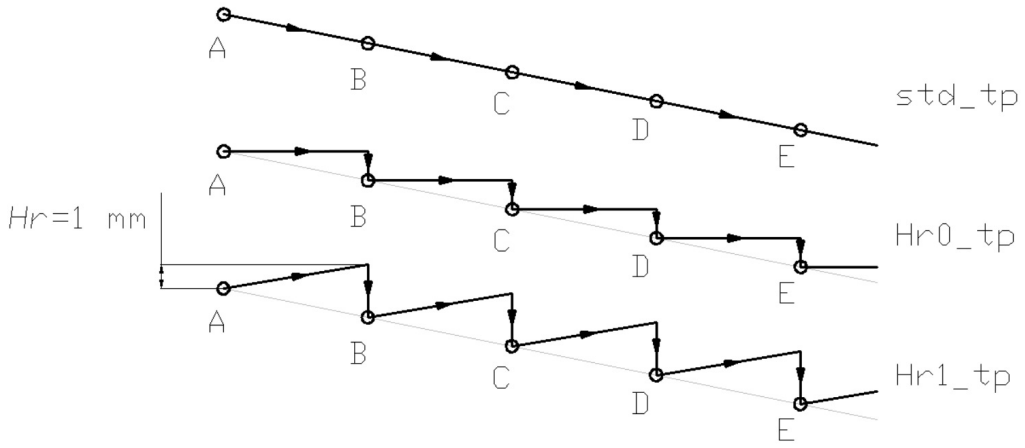

Fig. 3. Toolpath strategies.

Materials Research Proceedings 28 (2023) 1697-1702 https://doi.org/10.21741/9781644902479-183

Results

Fig. 4 shows an example of FE simulation of the ISF process for the Hr1_tp strategy; in particular, it is possible to observe the deformed sheet and the tool head for a z displacement of about 15 mm.

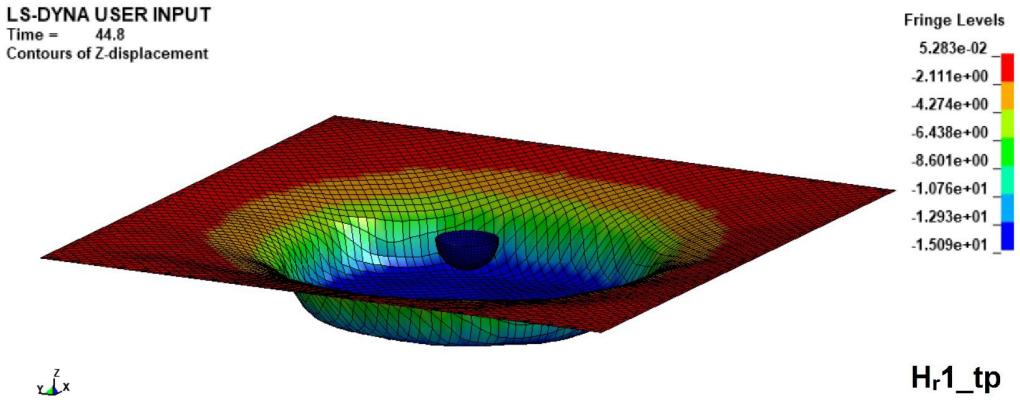

Fig. 4. FE simulation of the ISF process for the Hr1_tp strategy.

Fig. 5 reports the trend of the vertical (F_Z) and of one only horizontal force (F_X) for the different toolpath strategies. It is possible to note that the forces for the first two strategies show the typical trend for the manufacture of cone frusta by ISF with a spiral toolpath [5,7].

Moreover, they are similar, with very slightly lower values for the Hr0_tp compared to the std_tp; in detail, the maximum values of F_Z and F_X (in absolute terms) are of about 400 N and 300 N. This behaviour is an effect of the elastic springback that, despite being lower for the second toolpath, determines a significant tool/sheet contact and, consequently, high forming forces [8].

The third strategy allows a very significant reduction of both the components of the forming forces; F_Z lies below 200 N, while the absolute value of F_X does not exceed 50 N

In addition, the reduced regularity of the forces trend is representative of a noncontinuous contact between the tool and the sheet. On the other hand, the forming time for this last strategy increases, passing from about 40 s of the first two strategies to about 55 s, due to the increase of the length of the toolpath.

Moreover, Fig. 6 reports the max shear strain for three consecutive forming steps related to the std_tp and the Hr1_tp strategy. The figure highlights that the std_tp strategy determines strain accumulation on a large area of the sheet and in an asymmetric way, following the tool movement; this is not so true for the Hr1_tp strategy, which shows a more localized deformation and reduced shells distortion.

By considering the results on the forming forces from Fig. 5 and that the twisting is caused by the combination of continued strain accumulation and asymmetric stress levels [9,10], it can be assumed that the twisting can be reduced with the Hr1_tp strategy.

Finally, despite not being capable of predicting accurately wrinkling (the numerical model does not include wrinkle instability criteria), the results of the simulations let suppose that the occurrence of this defect is less likely for the Hr1_tp strategy.

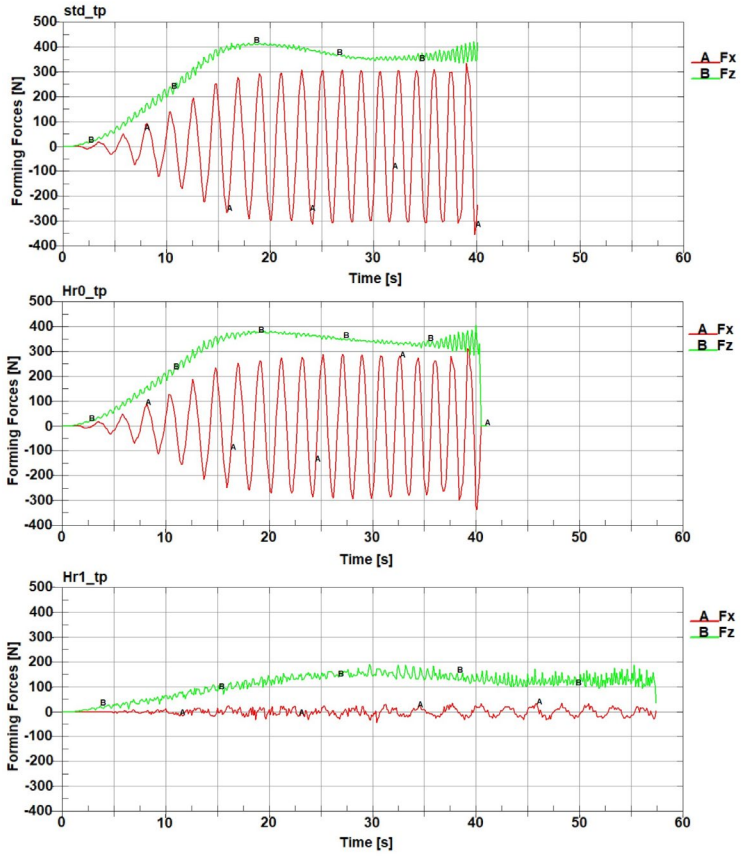

Fig. 5. Trend of the forming forces by varying the toolpath strategy.

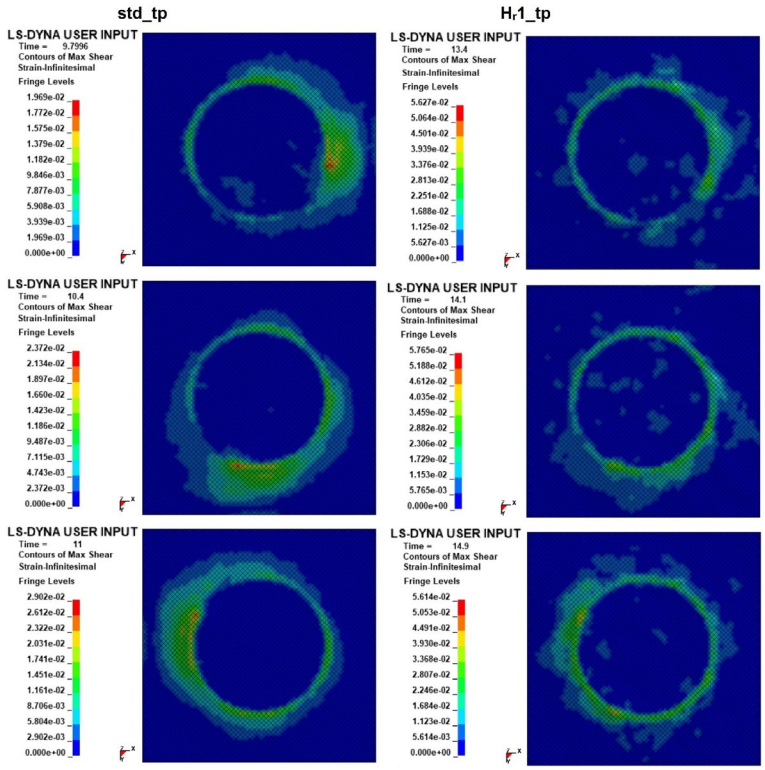

Fig. 6. Max shear strain distribution for std_tp and H_r1_tp strategy.

Summary

In the present work, a commercial FE code was used for the simulation of the incremental sheet forming of polycarbonate, with the aim of investigating different toolpath strategies. From the analysis of the results in terms of forces and strain states, it can be concluded that a stepped path, constituted by a sequence of upward and vertical segments, while showing higher forming times, can reduce drastically both the vertical and the in-plane forming forces, as well as the severity of the deformation states. Consequently, this may involve reduced risk of failures and defects like twisting and wrinkling.

Future works can focus on extending the numerical investigation by considering, for example, different forming tool shapes, and carrying out an experimental campaign for estimating what expected from the numerical analyses, in particular the reduction of the forming forces and of the twisting defect.

Keywords: Surface Topography, Laser Engraving, Nanosecond Pulsed Laser, SAE304 Steel

Abstract. Laser engraving process is widely used for various industrial applications, such as the creation of small and complex geometries with ultra-high precision. As surface topography can affect the functionality of produced surfaces in various ways, it is required to carry out comprehensive experimental work in order to correlate the laser engraving process parameters with surface topography characteristics. In the current paper, the surface topography of SAE304 stainless steel specimens in respect to laser power, scanning speed and pulse repetition rate is studied through microscope observations. The findings indicate that the scanning speed is the most dominant parameter regarding surface roughness and from the viewpoint of surface quality, it is suggested that higher scanning speed, lower power and pulse repetition rate values should be employed.

Introduction

Laser machining and laser assisted machining are a rapidly growing non-conventional manufacturing processes class, with lasers becoming gradually more and more significant as part of the modern industrial environment [1]. In general, by the interaction of the material with the laser beam, the material's electrons absorb a proportion of the laser beam energy and become excited [2]. The temperature of the excited electrons sub-system is raised and subsequently the absorbed energy is transferred to the material's atomic lattice, causing it to heat up until its melting and/or ablation. The high energy densities that are employed during laser-based processes provide a number of significant advantages over the conventional machining that include the potential to create small and complex geometries with ultra-high precision, the reduction of the Heat Affected Zone (HAZ), and the deformations due to the thermal and mechanical stress concentration [3]. Laser engraving consists one of the most widely employed laser-based processes.

In laser engraving, the material is removed layer by layer subsequent to the multiple passes of the laser beam over the material surface. Given that usually, in laser engraving, pulsed lasers are utilized, each layer of material is removed by the overlap of the generated craters that are formed due to material ablation [4]. As it was aforementioned, pulsed lasers are most commonly utilized since, although they have lower nominal power, through their pulsed operation extremely high-

power peak and power density can be achieved [5]. In laser engraving, minimum power density of 10^8 W/cm^2 is required and laser pulse durations in the order of nanoseconds are usually utilized. Finally, the operation wavelength of the laser is also an important parameter, since the material reflectivity is directly related with the laser beam wavelength, and thus, the proper type of laser has to be used for each class of material. Hence, neodymium-doped yttrium aluminum garnet Nd:YAG lasers have prevailed over other types of lasers (e.g., CO_2 lasers) for the engraving of metallic materials since the reflectivity of metals in wavelengths around 1064 nm is significantly lower, in comparison with the reflectivity in the range of 10.6 μm wavelengths where CO_2 lasers operate.

The relevant field of laser machining, including the laser engraving, is an area of active research. The laser milling of aluminum-magnesium alloy has been studied by Campanelli et al. [6] in terms of the material removal depth and the surface roughness as function of the machining parameters. Orazi et al. [7] presented a semi-empirical model regarding the Material Removal Rate (MRR) in machining of aluminum alloy 7075 and mild steel AISI 1040 with fiber pulsed laser. Teixidor et al. [8] studied the surface quality and the dimensional accuracy in respect to the process parameters in laser milling of hardened AISI H13 tool steel. In the work of Campaneli et al. [9], an experimental investigation regarding the laser milling of aluminum alloy 5754 was carried out, where the impact of machining parameters on the material removal depth, the MRR and the mean surface roughness Ra was mainly studied. The deep engraving process of AISI 1045 stainless steel was investigated by Anita Pritam [10], with the engraving depth and the surface roughness being the machining process evaluation indexes. The experimental work of Sugar et al. [11] presents a study regarding the effect of machining parameters on the surface quality of laser processed brass. The machinability of titanium alloy Ti6Al4V with laser milling has been investigated in the work of Ahmed et al. [12], with the MRR and the surface roughness being considered as representative indexes of the alloy's machinability. The MRR and the dimensional accuracy in fabrication of microchannels with Nd:YAG laser on alumina was studied by Mohammed et al. [13], while the machining quality of microchannels on Nickel-Titanium (NiTi) based shape-memory alloys was discussed in the work of Mohammed et al. [14]. From the literature review, the importance and interest on studying the surface quality after laser machining and engraving for different materials and alloys is clearly deduced.

The current paper pertains to the surface topography of SAE 304 stainless steel after its engraving with pulsed Nd:YAG laser. From the literature review it is concluded that laser engraving process is very sensitive to the machining parameters, thus, an extensive and detailed study of how each parameter affects the surface topography is scientifically interesting, but also with practical value. Hence, different laser powers, scanning speeds and repetition rates were utilized in order to cover a wide range of machining conditions and define the impact of each parameter on the surface topography. The Design of Experiment (DOE) was based on Taguchi L9 orthogonal array with three factors at three levels each. More specifically, laser power values of 8, 12 and 16 W were used, as well as scanning speed values of 200, 400 and 600 mm/min and pulse repetition rate values of 30, 50 and 70 kHz. Finally, although commonly the surface topography is evaluated based on the Ra and Rz values, in the current study the analysis of surface topography was done in terms of Sa and Sz, while statistical analysis was followed in order the obtained results to be interpreted.

Materials and Methods

The current series of experiments was carried out on a LASERTEC 40 laser machining center made by DMG MORI, which is equipped with a Nd:YAG pulsed laser that operates in 1064 nm wavelength, with 20W maximum nominal average power, nominal spot diameter of 30 μm and 100 ns pulse duration. A stainless steel SAE304 plate of 5 mm thickness was utilized as workpiece. Square pockets of 4x4 mm dimension were engraved by using unidirectional cross hatching

scanning strategy. The track distance T_d, i.e., the distance between two successive tracks was set equal to the hatching distance H_d, i.e., the distance between two subsequent pulses. The hatch distance is calculated based on Eq. 1 and the overlap between the pulses according to Eq. 2.

$$H_d = \frac{v_{scan}}{f} \tag{1}$$

$$overlap = 1 - \frac{H_d}{D} \tag{2}$$

with H_d the hatching distance in [mm], v_{scan} the laser beam scanning speed in [mm/s], D the nominal laser beam diameter and f the repetition rate in [Hz]. The scanning strategy and its main geometrical features are schematically depicted in Fig. 1.

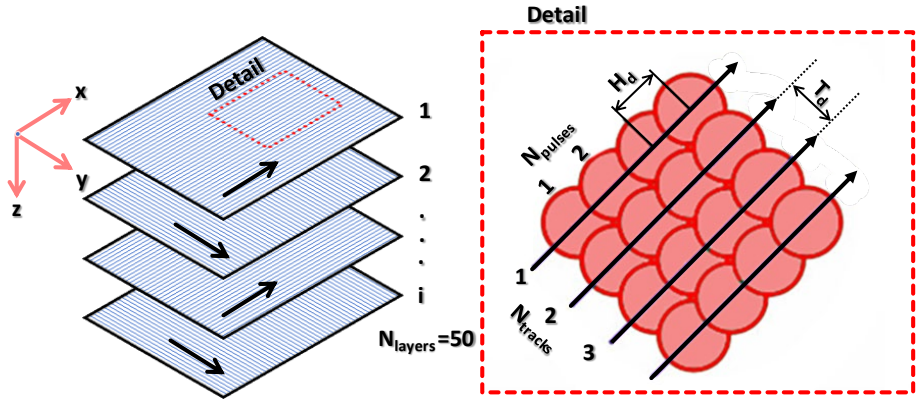

Fig. 1. Unidirectional cross hatching scanning strategy and its main geometrical features.

The DoE was based on Taguchi L9 orthogonal array with three factors at three levels each. Namely, the control parameters were the mean power P, the scanning speed v_{scan} and the repetition rate f. The mean power values were set between 8 and 16 W, the scanning speeds between 200 and 600 mm/s, while the repetition rate took values between 30 and 70 kHz. By utilizing the aforementioned machining parameters, the study covers a wide range of different power densities, hatching distances and track distances, thus, the impact and the significance of each parameter can be assessed. Moreover, in order the process to reach a steady state that will ensure representative and reliable results, each pocket was engraved by 50 successive layers. Finally, by using the touch probe measuring system of the laser machine, the laser beam was initially focused on the top surface of the plate. Thus, the standoff distance was initially zero for the first layer to be engraved, while, for the next layers, the standoff distance was increasing and was equal to the engraving depth. It is worth noting that the maximum applicable engraving depth is almost negligible in relation to the focal length. The machining parameters combinations based on the aforementioned DOE, along with the machining center features are listed in detail in Table 1.

Finally, the study of the surface topography was carried out in terms of Sa and Sz that were defined as:

$$\boldsymbol{Sa} = \frac{\mathbf{1}}{\boldsymbol{A}} \iint_{\boldsymbol{A}} |\boldsymbol{z}(\boldsymbol{x},\boldsymbol{y})|\, dxdy \tag{3}$$

where, A the definition area, and z (x,y) the height of the scale-limited surface at position (x,y) and **Sz** the sum of the largest peak height value and the largest pit height value within a definition area.

The surface roughness values were measured by utilizing the Focus Variation method in a Keyence VHX-7000 optical microscope equipped with specialized lenses. The measurements were

conducted by following the ISO 25178-2 standards, while, based on the obtained SR values, the cut off length was defined at 0.8 mm.

Results and Discussion

After the experiments were conducted, the surface topography was investigated by means of Focus Variation microscope. In Fig. 2a and b, the topography of two indicative surfaces produced by laser engraving under two different conditions, namely no.3 and 4, is depicted and in Table 2, the results regarding Sa and Sz are presented for all experiments. From these figures it can be seen that the surface includes various characteristic features, such as craters and peaks due to the intense thermal phenomena induced by the laser beam. Although different process conditions lead to different surface quality, as can be seen from the results of Table 2, this typical morphology is not considerably altered. It is worth noting that this type of surface is similar to the surface produced by other non-conventional processes which involve a high heat input, such as EDM. Although the surface quality is moderate-to-high, with Sa mostly varying between 0.57-1.75 μm, the high values of Sa and Sz observed for the experiments no.4 and 7 can be explained as a result of both high interaction time due to relatively lower value of scanning speed and considerably high overlap values.

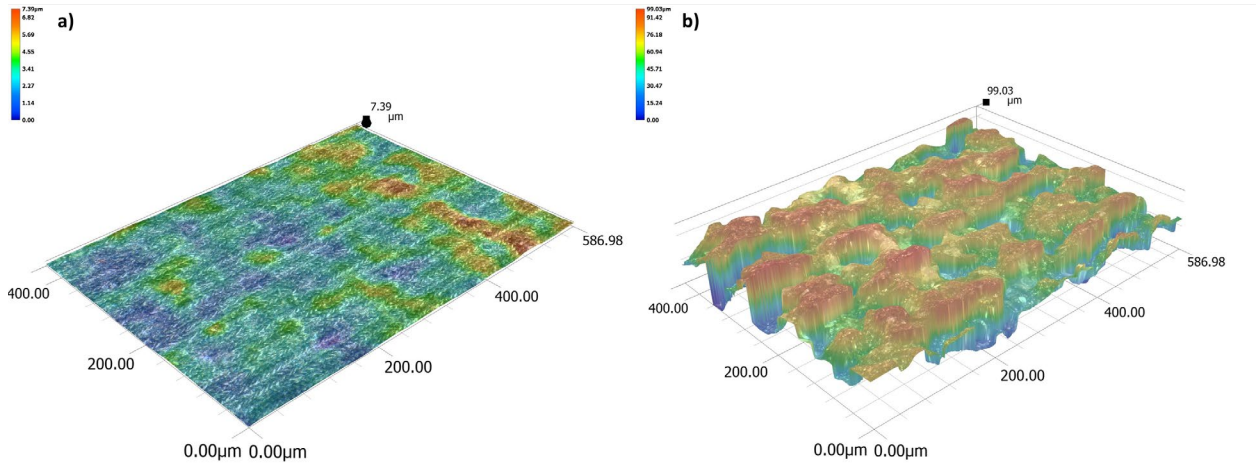

Fig. 2. Surface topography under different process conditions: a) 8 W / 600 mm/s / 70 kHz and b)12 W / 200 mm/s / 50 kHz.

Table 2. Experimental results.

#	Power [W]	Scanning Speed [mm/s]	Repetition Rate [kHz]	Hatching Distance [µm]	Overlap	Sa [µm]	Sz [µm]
1	8	200	30	6.67	0.778	1.75	16.37
2	8	400	50	8.00	0.733	0.84	6.28
3	8	600	70	8.57	0.714	0.57	5.34
4	12	200	50	4.00	0.867	11.57	87.35
5	12	400	70	5.71	0.809	1.50	15.28
6	12	600	30	20.00	0.333	0.76	6.64
7	16	200	70	2.86	0.905	10.81	110.75
8	16	400	30	13.33	0.555	1.03	9.92
9	16	600	50	12.00	0.600	0.67	6.52

Based on the experimental results of Table 2 it is deduced that there is a threshold of overlap beyond which the surface roughness rapidly increases. Namely, for overlap greater that 0.85 there is a significant increase in both Sa and Sz values. The parabolic increase trend of the surface roughness in respect to the overlap that it is depicted in Fig. 3, is in line with the respective literature [14].

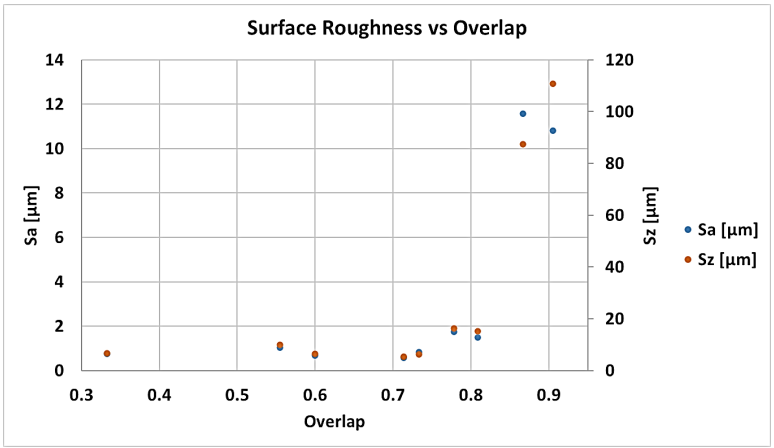

Fig. 3. Surface roughness values (Sa and Sz) in respect to the overlap.

In Fig. 4a and b, the main effects and interactions plots are depicted for Sa. At first, from the main effects plot it can be observed that although all parameters affect Sa, scanning speed causes the most significant variation of Sa values. More specifically, as the scanning speed increases, lower Sa is obtained, with the higher decrease of Sa values being noted between 200 and 400 mm/s. Thus, an appropriate selection of scanning speed values is crucial for achieving a high-quality surface during laser engraving process. Regarding the effect of mean power and pulse repetition frequency on Sa, it can be seen that they have a similar effect on Sa, as they both lead to an increase of average roughness up to a point and then the value of Sa remains almost constant.

Apart from the results presented in Fig. 4a, the interaction plots of Fig. 4b can also reveal more details about the combined effect of process parameters on Sa. Between mean power and scanning speed, a significant interaction is observed at the lowest value of scanning speed (200 mm/s), whereas for the other values of scanning speed, their interaction is negligible. However, the interaction of power and frequency is considerable for all levels of frequency, although a certain trend is not observed, as the correlation between power and frequency for each frequency level is different. Finally, the interaction between scanning speed and frequency is considerable only for the lowest value of frequency (30 kHz). Thus, it can be deduced that although power and frequency have a combined effect on the surface quality, the interaction between them and scanning speed is generally weak.

Various factors related to process parameters, such as the interaction time, overlap and energy per pulse contribute also to the creation of the surface topography. More specifically, if we consider the influence of scanning speed alone, with fixed values of mean power and pulse repetition frequency, due to the decrease of interaction time the heat-induced alterations of the surface are less intense, leading to improved surface roughness. As for mean power, when the other two parameters are fixed, the reason which leads to larger roughness is related to the larger thermal input to the workpiece, which leads to more intense thermal phenomena such as vaporization and remelting, which induce irregularities on the surface.

The effect of pulse repetition frequency, when scanning speed and power values are fixed, can be explained based on the interactions between various factors. More specifically, although the per pulse energy decreases, the hatching distance also decreases and the overlap increases. Thus, the higher number of repeated pulses, leading to a smaller overlap, creates a rougher surface with enlarged craters and other irregularities.

Finally, it can be deduced that, in order to avoid increased average roughness, lower power and frequency values should be used along with higher scanning speed values. However, these values should be selected taking also into consideration the effect of these parameters on the depth of produced pockets and the machining time, which are contradicting goals.

Afterwards, in order to be able to predict the roughness values in respect to process parameters for the specific material, an empirical relationship is established between process parameters and Sa. As a linear regression model was not able to describe the data with high correlation coefficient values, a power law model was adopted, as follows:

$$Sa = 151530 P^{0.354155} v_{scan}^{-2.70297} f^{0.920414} \quad (4)$$

The Mean Square Error (MSE) of the developed equation is 4.28060 μm^2 and the standard error of the regression (S) value is 2.06896 μm. The errors of the empirical equation can be attributed to the reduced number of experiments conducted when conducting the experiments with a DOE method like Taguchi method and some considerably high values occur. However, the choice of an established DOE method provided an excellent compromise between the cost of the experiments and the accuracy of the results.

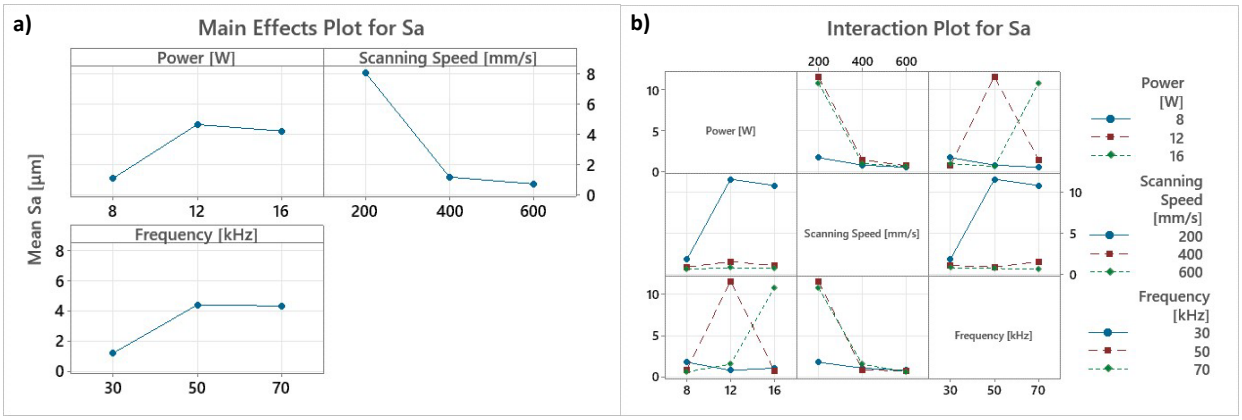

Fig. 4. (a) Main effects plot for Sa and (b) Interaction plot for Sa.

Regarding Sz values, the main effects plot of Figure 5a indicates that the three process parameters have a similar effect on Sz, as on Sa. Thus, it is shown that when laser scanning speed, which is again the most significant parameter, increases, the peak-to-valley height is considerably reduced for speed values up to 400 mm/s and then the decrease is slighter, whereas for both higher mean power and pulse repetition frequency, Sz increases more abruptly at first and then in a more gradual way. Moreover, the interactions plot of Figure 5b is also similar to that of Sa, indicating a higher degree of interaction between power and frequency, whereas the interaction between these parameters and scanning speed is weaker. An empirical relationship was also developed with a power law model with MSE value of 127.179 µm^2 and an S value of 11.2774 µm, in order to correlate the process parameters with Sz, as follows:

$$Sz = 197857 P^{0.818046} \upsilon_{scan}^{-2.52004} f^{0.859392} \quad (5)$$

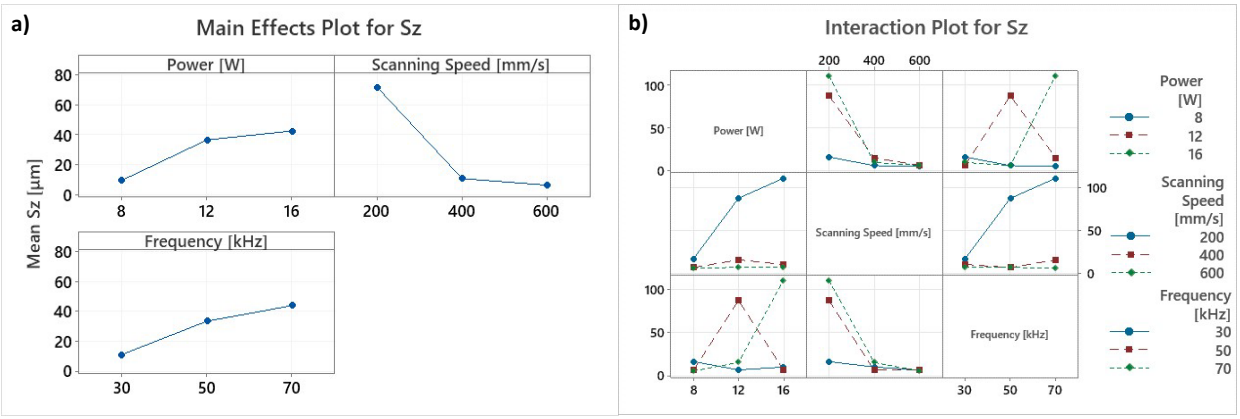

Fig. 5. (a) Main effects plot for Sz and (b) Interaction plot for Sz.

Summary

In this paper, the surface topography obtained during laser engraving of SAE304 is investigated by means of experimental work and statistical analysis. The experiment was designed based on Taguchi L9 orthogonal array for three levels of scanning speed, mean power and pulse repetition frequency in order to determine their effect on surface topography. After the results were analyzed, several conclusions were drawn:

Scanning speed considerably affects the surface topography, as indicated by the results of both Sa and Sz. For fixed mean power and pulse repetition rate, the decrease of interaction time between the laser beam and workpiece leads to lower heat input and less intense thermal phenomena, resulting in surfaces with higher quality and less irregular features.

Mean power and pulse repetition rate affect surface topography to a lower extent than scanning speed. As mean power increases, the heat input to the workpiece increases and a rougher surface is obtained as the more intense thermal phenomena lead to vaporization and remelting of the material and deeper microcraters are formed in the surface. Regarding pulse repetition rate, its increase leads to higher overlap and larger values of surface roughness. Thus, with regard to surface roughness, it is recommended that higher values of scanning speed and lower values of mean power and pulse repetition rate are desirable.

Abstract. Arc welding processes (AWPs) are performed by generating an electric arc between a metal electrode and the workpiece to be joined. Submerged arc welding, belonging to AWPs, is characterized by the peculiarity that the arc is not visible. Indeed, a granular fusible material flux is employed in the process to shield the parts to be processed, avoiding arc radiation and fumes and, at the same time, reducing the oxidation risks of the welded metals. The main process variables are current, voltage and welding speed. These variables have to be properly set to balance the specific heat in the weld pool for a proper process optimization.

Introduction

Fusion welding is a flexible technique characterized by high efficiency [1], widely employed in the mechanical industry to join conventional structural steels. To carry out the process, the materials are heated to a temperature below the melting point and a filler material allows the joint [2].

According to the filler material employed it is possible to distinguish several process variants. One of them is the Submerged Arc Welding (SAW), which the authors focused on. The process principle is based on the generation of an electric arc between the electrode and the base material. The arc is protected by a granular flow of flux from the atmospheric contaminants, in addition it is worth pointing out that the flux itself increases the conduction of the generated arc [3].

During the welding, the involved materials are subjected to heating and cooling phases, which occur very quickly affecting the microstructure creating a new metallurgical condition within the heat affected zone (HAZ) [4,5]. More in detail, the heat input depends on the current, voltage and welding speed, which are the main process parameters to set for carrying out the process. The welding current significantly affects the penetration while the voltage is responsible for the bead width and not greatly contributes to its penetration depth. Therefore, the input process parameters have to be set according to the joint typology and to the thickness of the metals to be joined [3]. The employed energy causes changes at its microstructure and, therefore, at the mechanical properties of the final joint.

The scientific literature reports studies which aim at understanding the influence of the process parameters on the joint. Jou [6] carried out experiments aiming at correlating the main process parameters to the weld bead by numerical investigations in order to predict its size. Numerical analyses and optimization techniques have been widely carried out to predict residual stresses and affected zones in different manufacturing processes [7,8]. These numerical techniques have been employed for analyzing thermal and mechanical behavior of welded components [9] as well as for predicting thermal cycles, residual stresses and deformations induced by this joining method [10]. Other authors reported the numerical simulation of the welding and cooling conditions and the subsequent investigation of the melted zone extension as well as of the HAZ and of the hardness profile [9].

The main focus of this work lies in the setting of a numerical model aiming at analyzing the effect of the variables on a multi-pass welding joint in terms of thermal properties, looking at the characteristics of the bead HAZ and of its distortions and residual stresses.

Material and Method

Material. The material investigated in this study is the medium carbon steel alloy ASTM A516 Grade 70, employed as base material and widely used in the construction of welded pressure vessels. The main requirement for its service is the high notch toughness. The EH14 copper coated wire, generally used in the construction of containers or boilers, was selected as filler material. The following tables (Table 1 and Table 2) report, respectively, the chemical composition and the mechanical properties of the employed materials.

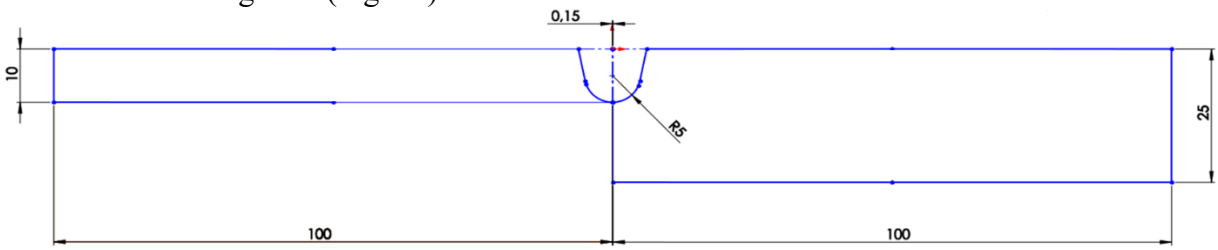
Table 1. Chemical composition of the base and filler material.

	Element [%]					
	C	***Mn***	***P***	***S***	***Si***	***Cu***
ASTM A516 Gr 70	0.31	1.2	0.035	0.035	0.45	-
EH-14	0.10	1.8	0.019	0.013	0.05	0.05

Table 2. Mechanical properties of the base and filler material.

	ASTM A516 Grade 70	**EH-14**
Tensile strength [MPa]	[485-620]	550
Yield strength, min [MPa]	[260]	470
Elongation in 8 in. [200 mm], min, %	17	30
Elongation in 2 in. [50 mm], min, %	21	-

The experimental test, performed to calibrate the heat source, was performed on plates characterized by different thicknesses (Fig. 1a), specifically dimensions of 100×400×10 mm^3 and 100×400×25 mm^3 were welded by SAW employing a specific clamping equipment designed to the aim of this investigation (Fig. 1b).



(a)

(b)

Fig. 1. a) Coupon geometry (mm) and b) experimental clamping system.

Method. A three-dimensional numerical model was developed by commercial ESI Sysweld software, which is one of the most widely used software for analyzing welding distortions and residual stresses through the finite element method. In fact, the software allows the welding process simulation providing the thermal analysis, which this work focuses on.

The numerical analysis starts with the calibration of the heat source, which characteristics affect the temperature distribution. The heat source moves along the weld path, for each pass taking into consideration specific experimental evidence. The double ellipsoid proposed by Goldak [11,12] was used to the aim of this study and modeled considering as parameters the arc efficiency η, half width of the fused zone a, its penetration depth b, its front length c_f and its back length c_b (Fig. 2).

The numerical model was built by using 80,500 elements and 87,771 nodes. The boundary conditions were defined to replicate the experimental state. This resulted in imposing constraints at a distance of 50 mm from the plates' extremity. Concerning the thermal boundary conditions, an ambient temperature of 20 °C and a heat transfer coefficient ranging from 0.040 to 0.032 W/mm-K, according to the thermal phases of the analyzed material, were set.

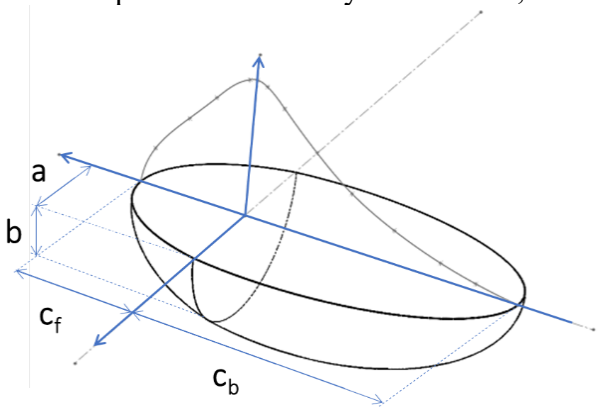


Fig. 2. Goldak's double-ellipsoid and parameters.

A multi-pass welding joint was executed. Specifically, the experimental procedure involves three welding steps. The first one (*Pass 1*) is performed on the bottom side of the plates to be joined and it is aimed at creating a sort of weld cup, while two second passes (*Pass 2*) and all the successive ones (*Pass 3+n*) are performed on the top side, moving on the left and on the right respect to the centerline of the weld bead, until the expected weld bead height is reached. Each pass typology is characterized by a different combination of process parameters and can start just as soon as the temperature measured on the plates is lower than 250°C.

The process parameters considered to the aim of this study are current (I), voltage (V) and welding speed (v). Table 3, below shown, reports the values set for the analyzed case study:

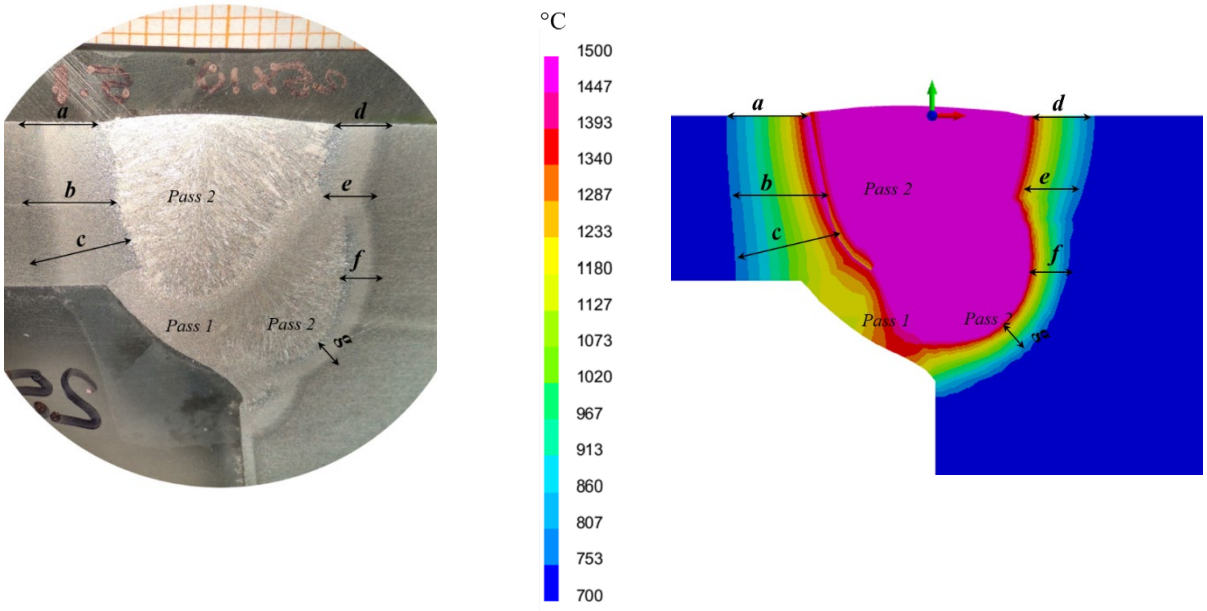
Table 3. Process parameters.

# Pass typology	I **[A]**	V **[V]**	v **[mm/min]**
Pass 1	440	27	320
Pass 2	540	25,4	384
Pass 3+n	675	34	768

Discussion of the Results

The multi-pass welding was investigated by dividing the analysis in two different steps. Specifically, *Pass 1*, being performed on the bottom side of the sheets, was not considered in the analysis. The numerical model starts setting and calibrating *Pass 2* performed in two steps. The first simulation was, therefore, run considering the weld beads obtained experimentally by

overlapping the first two *Pass 2,* hereafter named *Sample A.* To do that, specimens with dimension 70×35×25 mm^3 were firstly cross-sectioned from the center of the test plate and then the surface treated by grinding and polishing and finally etched. Looking at the macrograph (Fig. 4a), each *Pass 2*, and the respective deposit, is clearly visible as well as the HAZ. The geometry of each fused zone, coming from the macrograph, and the process parameters represent the input data for Sysweld. When the process was completely simulated, results were analyzed in terms of temperature distribution (Fig. 4b), comparing the numerical data with the experimental evidence.



(a) (b)

Fig. 4. HAZ measurement for Sample A: a) experimental test, b) numerical simulation.

In detail, the extension of the HAZ was measured both on the experimental macrograph (five different sections of the same sample were processed) and on the thermal histogram obtained from the simulation. According to that, the upper and lower limits of the temperature scale were set considering, respectively, the beginning of the transition zone in the austenitic field and the melting point of a low carbon steel. For estimating the zone affected by the process temperature, some points were selected and the length defined considering the perpendicular of the tangent to the point. Therefore, the segments a, b, c, d, e, f, g were measured and the values collected for both numerical analysis and experimental test. The comparison of gathered measurements, displayed in Fig. 5, demonstrates that the numerical model was calibrated properly, since the HAZ obtained in *Sample A* is actually equal to the one obtained experimentally.

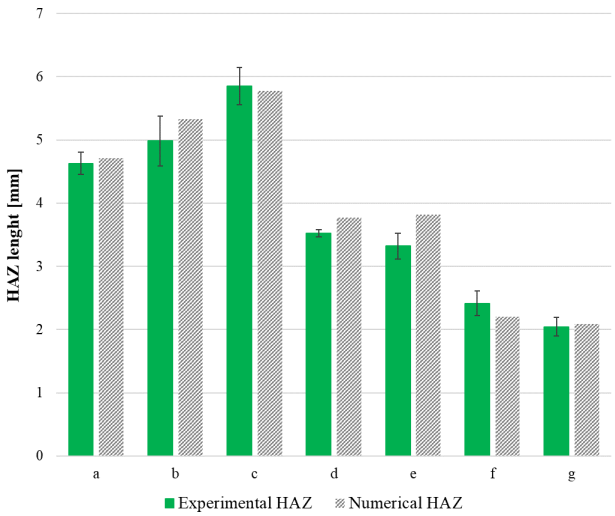


Fig. 5. Sample 1: Comparison of experimental and numerical HAZ lengths.

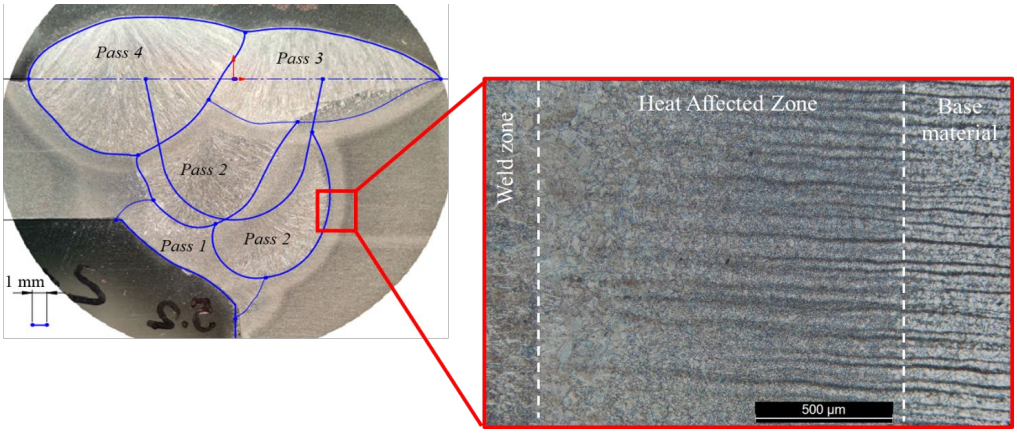
Once validated the *Pass 2* of the welding sequence, a second joint, hereafter named *Sample B*, was performed overlapping the subsequent *Pass 3+n,* depositing as much as material in order to complete the weld bead, as required by the welding procedure specifications. Two additional welding passes were required, named *Pass 3* and *Pass 4*.

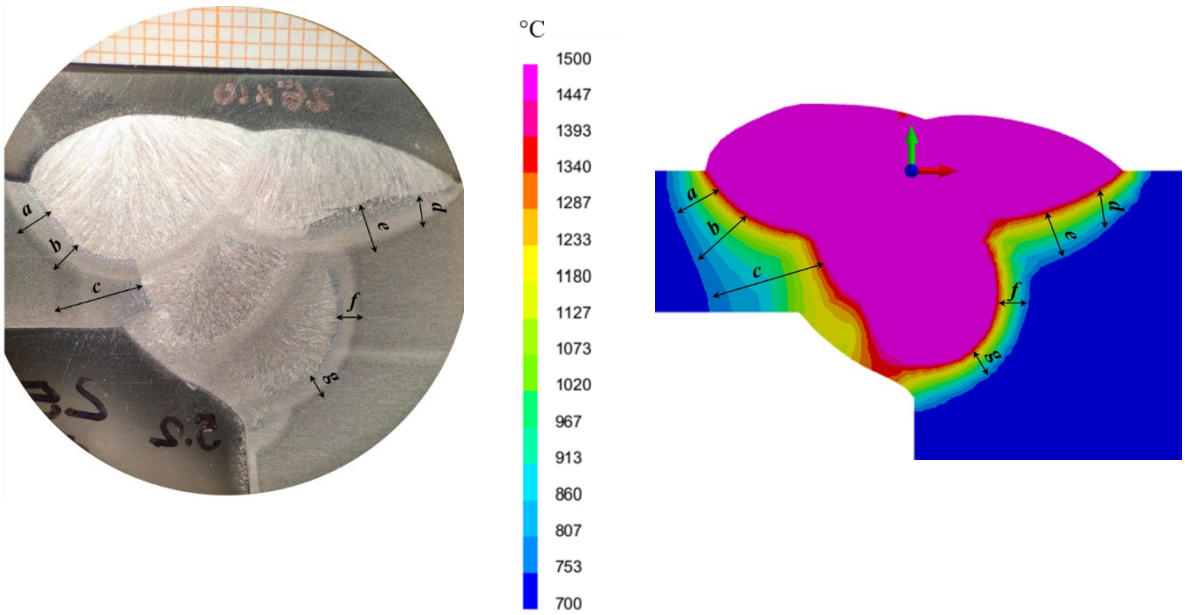
Fig. 6a displays the sectioned joint and each pass can be easily distinguished. It is interesting to look at the 5x enlargement, where the metallurgical transformation, due to the heat influence, of the weld zone, of the heat affected zone and of the base material is observable.



(a) (b)

Fig. 6. a) sectioned view of Sample B and b) its 5x enlargement.

The finite element model was then defined to simulate the welding process on *Sample B*. To be thorough, the measurement of the HAZ was detected as well (Fig. 7), and the comparison between numerical and experimental data, as previously performed for *Sample A*, are synthesized in Fig. 8.



(a) (b)

Fig. 7. Sample B HAZ measurement: a) experimental test, b) numerical simulation.

These further experimental measurements demonstrated the capability of the finite-element simulation in predicting the heat transfer, even if a multi-pass welding is analyzed. The numerical results agree with the experimental data, reasonably. Actually, differences on the left side of the welding bead, especially point *b*, can be detected. The experimental and simulated discrepancies could be attributed to errors related to a possible experimental variance along the length of the weld bead, considering also that the dimension of the samples is far from the usual industrial standards and, therefore, steady-state conditions could be just partially reached. Anyway, additional analyses are required to explain the highlighted inaccuracy, more clearly.

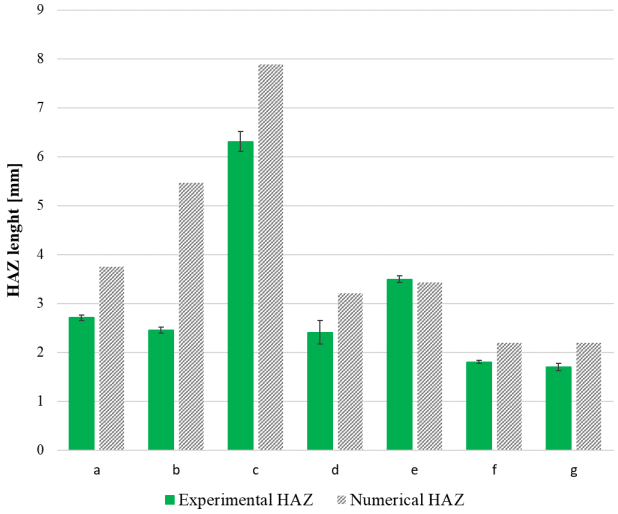


Fig. 8. Sample B: Comparison of experimental and numerical HAZ lengths.

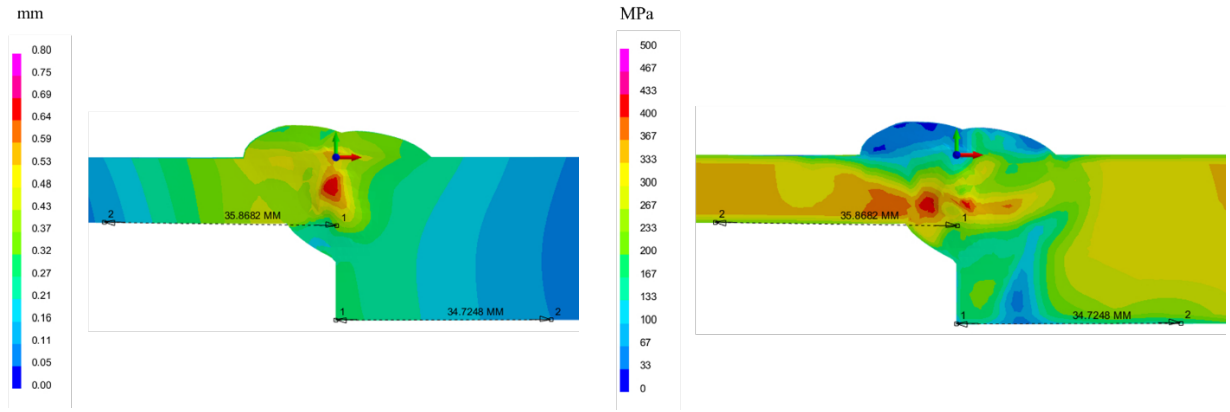
The experimental and numerical comparison proved the effectiveness of the numerical model therefore the potentiality of the obtainable results in improving the performance of jointed parts can be deduced by looking at displacements and residual stresses generated on the parts owing to

the multi-pass welding. Herein, for example, the dishomogeneity related to the different thicknesses of the sheets to be welded are observable, clearly (Fig. 9). Practically, this information can be useful to set a different clamping system and/or welding sequence to compensate for unbalanced stress and strain distributions, important for easier parts' assembly and for their fatigue life behavior.



(a) (b)

Fig. 9. a) Displacement and b) residual stress on Sample B at the end of the welding process.

Summary

In this work, the temperature distribution, the distortions and the residual stress within multi-pass welding of plates, characterized by different thickness, were investigated by a finite element simulation properly calibrated by experimental evidence. Specifically, the geometric parameters of the double Goldak's ellipsoid were set and applied on specific positions of the weld beads' geometry extracted by each experimental welding pass. The adjustments of heating source's shape, efficiency and position were performed to achieve a conformity between temperature distribution, obtained by the numerical analysis, and extension of the HAZ, extracted by micrographs of sectioned and prepared samples.

The obtained results showed a good overlap between the numerical and the experimental results, therefore, considering the good calibration of the model, preliminary results on distortions and residual stresses, difficult to analyse experimentally, where observed. Further analyses will be carried out by comparing, in terms of HAZ, distortions and residual stress, more samples processed by different process parameters, in order to speed the welding optimization up.

Keywords: Soundproofing, Polymeric Materials, 3D Printing, Research Equipment

Abstract. The soundproofing of certain spaces is necessary primarily to combat noise pollution generated by high-intensity noise sources. One of the ways to reduce the unwanted propagation of high-intensity sound waves is based on the use of panels made of polymeric materials. The expansion in recent decades of the manufacturing processes of parts by 3D printing has led, among other things, to the identification of ways to change the properties of the materials included in the parts manufactured by 3D printing and to modify, in this way, including the sound insulation properties of such materials. For the development of experimental research aimed at allowing the study of the sound insulation capacity of small panels made by 3D printing from polymeric materials, a relatively simple equipment was designed. Equipment includes an enclosure in which the sound source, the small panel, and the sensor of a device used to evaluate the characteristics of sounds. Experimental tests were carried out on panels made of polylactic acid. The experimental results were mathematically processed with the help of specialized software. An empirical mathematical power function model was determined. This empirical mathematical model highlights the intensity of the influence exerted by the thickness of the panel by the speed and volume of the sounds on the acoustic pressure level. It was found that the strongest influence is exerted by the volume of the sound wave.

Introduction

The sound corresponds to a mechanical vibration with a certain frequency and intensity transmitted through a gaseous, liquid, or solid acoustic medium. In principle, it is considered that the frequency of sound sensed by the human ear is between 20 and 20,000 Hertz. From the point of view of vibration frequency, near sounds are infrasound and ultrasound, respectively. When some sounds are appreciated by people as unpleasant, because of their frequency or because of too high intensity, they are called *noises*.

We can talk about *noise pollution* when the noise-producing source cannot be eliminated or removed. This pollution can adversely affect the health of people or other organisms. It is necessary to use solutions that diminish the intensity of the ultrasound transmission process to reduce the negative influence of noise pollution.

There is a wide range of solutions capable of reducing the intensity of the noise transmission process. One of these ways considers insulating materials from a sound point of view [1–4]. Plastic materials are sometimes used as soundproofing materials.

In principle, plastic materials are non-metallic materials with an amorphous structure obtained by melting together several constituents (resins, plasticizers, dyes, lubricants, fillers, and auxiliary materials). Plastic materials are easily shaped at temperatures usually in the range of 140-180 ° C. The technology of obtaining plastic materials by joining several molecules of the same type is called *polymerization*, and the results of its application are *polymers*. The parts made of polymeric

materials can be manufactured by different processes (by pressing, drawing, injection, thermoforming, etc.). Currently, a group of technologies in a remarkable expansion are the technologies based on adding materials, being *additive manufacturing technologies*. One of these technologies is *fused deposition modeling*, which involves the successive addition of layers obtained by advancing and depositing a polymer in a molten state.

For sound insulation, polymer panels manufactured through a fused deposition modeling process can be used in certain situations.

Therefore, it was normal for some researchers to turn their attention to the properties of polymeric materials manufactured by 3D printing processes that could reduce noise pollution. Thus, the problem of manufacturing by 3D printing some lattice structures capable of contributing to the reduction of noise intensity was addressed by Franklin et al. [3]. They used experimental tests, simulations of the studied processes, and appropriate methodologies to reveal the ability of the lattice structures to dampen vibrations with frequencies between 0 and 30,000 Hz.

Perrot and Hoang undertook research to improve the conditions for modeling the sound insulation properties of some structures made of cellular foams and the possibilities of manufacturing such structures [4]. They noted that 3D printing variants of cellular foams are still too expensive for widespread use.

Equipment for the study of sound insulation properties of some panels made of polymeric materials by 3D printing was presented in work [5].

The research, the results of which are presented in this paper, aimed to carry out experimental tests regarding the influence of the thickness of polymer panels, respectively the frequency and intensity of sounds, on the sound insulation capacity of polylactic acid panels manufactured by 3D printing.

Generation and Propagation of Sounds

Sounds can be generated by vibrating a solid body using different forms of energy. Thus, sounds are generated mechanically, electromechanically, hydraulically, pneumatically, etc. As mentioned, sounds can be transmitted through solid, liquid, and gaseous media. When sound passes from one medium to another, part of its energy can be reflected, a part is dissipated (absorbed) in the second medium, and another part passes through that medium (Fig. 1). The propagation of sounds takes place through successive contractions and elongations of some areas in the environment in which the sounds propagate.

If the flow corresponding to the incident energy is denoted by E_i, by E_a – the flow of absorbed energy, and by E_r – the flow of reflected energy, the sound absorption coefficient α at the level of the separation surface between two media can be calculated using relations of the form:

$$\alpha = \frac{E_a}{E_i} \tag{1}$$

or

$$\alpha = 1 - \frac{E_r}{E_i} \tag{2}$$

The different media traversed by the sound contribute to a gradual reduction in its intensity. In such conditions, *an acoustic impedance* can be defined as a quantity with the help of which the opposition of an environment to the propagation of acoustic waves is evaluated:

$$Z = \frac{p}{vS} \tag{3}$$

where p is the sound pressure, v is the velocity of the sound wave, and S - the surface through which the wave propagates.

Different sizes can be used to evaluate the intensity of sounds, one of which is the *sound pressure level* or sound intensity (expressed in decibels). Such a quantity represents the sound intensity level to a reference value.

The intensity of the sound wave absorption process depends not only on the properties of the material through which the sound wave passes, but also on some properties of the sound. Different materials exhibit distinct sound attenuation properties. Materials that absorb a greater amount of acoustic energy are considered soundproof materials.

Equipment for Evaluating the Sound Insulation Capacity of Some Panels Made of Polymeric Materials

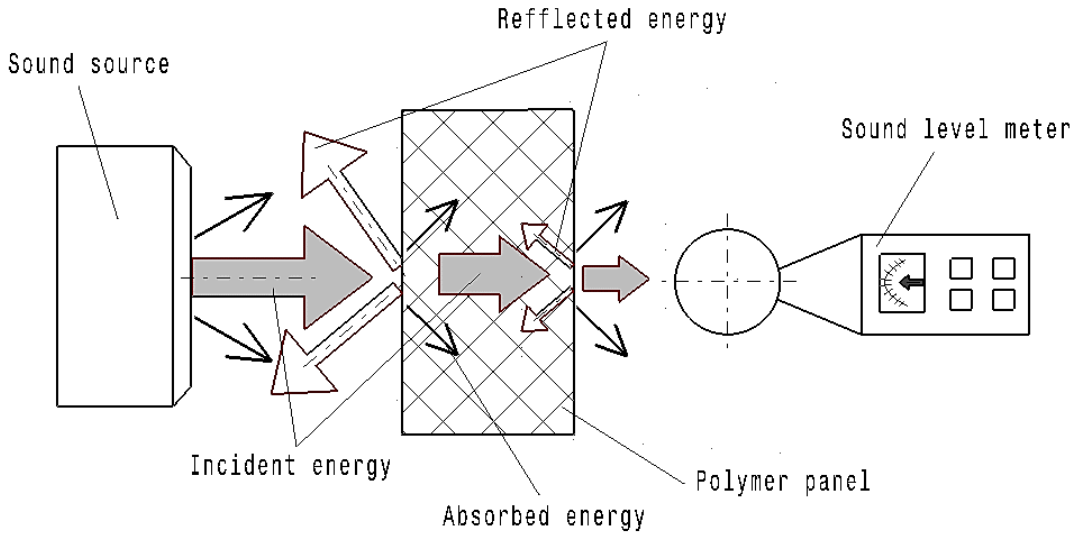

Fig. 1. Schematic representation corresponding to sound propagation from the source to the sound level meter, passing through the polymer panel.

One of the objectives pursued through the research, the results of which are presented in this paper, was to design equipment that would allow the evaluation of the sound insulation capacity of some panels made of polymeric materials.

It is known that for the evaluation of the sound insulation capacity of different materials, equipment incorporating the so-called Kundt tube can be used [6]. Since the accessible Kundt tubes allowed the use of relatively small test sample, the problem of designing and making specialized equipment for evaluating the sound insulation properties of the materials of polymer test samples with surfaces of 100x100 mm^2 and thicknesses of 1-6 mm was formulated.

The main requirements that such equipment had to fulfill were the following:

1. To allow the locating and clamping a test sample in the form of a panel of polymeric material, with an area of 100x100 mm^2 and with thicknesses of up to 6 mm;

2. To include a source of sounds whose characteristics (frequency, volume) can take values

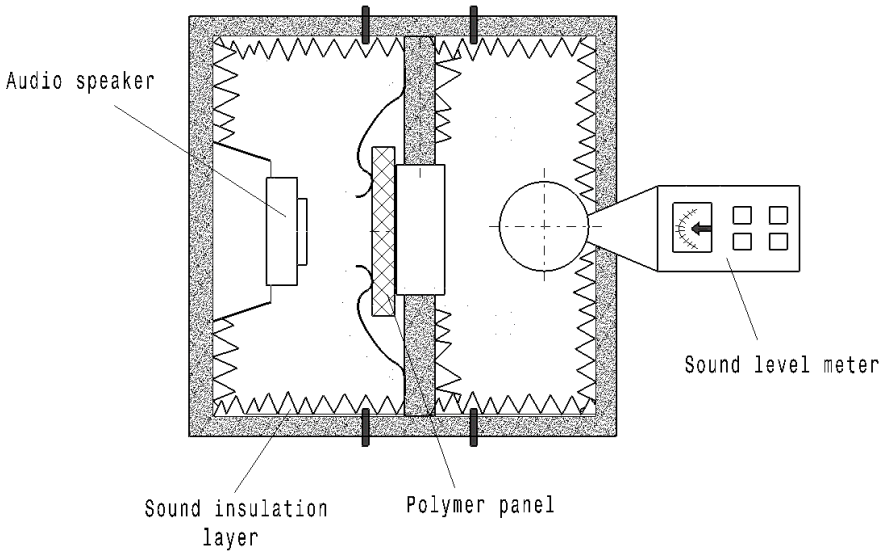

Fig. 2. Schematic representation of the equipment for investigating the sound insulation capacity of some polymer panels.

between certain limits;

3. To include a sound level meter;

4. The different components involved in the generation of sounds and, respectively, in their measurement can be located inside an enclosure to avoid disturbing the results by sounds from outside the equipment;

5. As far as possible, ensure conditions to avoid the sounds reflected by the walls of the enclosure affecting the results of the measurements.

The equipment represented schematically in Fig. 2 was designed to obtain information about the sound insulation capacity of some panels made of polymeric materials. In principle, the equipment includes three distinct compartments, which can be assembled with the help of hook fasteners. In the first compartment, a speaker will have to generate a sound commanded via Bluetooth through a program opened on a mobile phone or a computer. In the second compartment, a polymer sample having a certain thickness can be oriented and fixed. The sensor of a sound level meter (type HY1361 - China) enters the third compartment.

The walls of the three compartments were made of wood to ensure, as much as possible, an avoidance of the results being affected by the sounds existing outside the equipment. Also, to reduce the influence of the sounds possibly reflected by the walls of the compartments, the inner surfaces were covered with a layer of material also characterized by a high sound absorption capacity.

An image of the equipment can be seen in Fig. 3.

Materials Research Proceedings 28 (2023) 1719-1728 https://doi.org/10.21741/9781644902479-186

Fig. 3. Image of equipment used to study the influence exerted by some factors on the transmission of sound through small panels manufactured by 3D printing.

In Fig. 4, it can be observed how pockets were generated in the sample during its manufacture by 3D printing. This way of printing was done in the idea of having not only a 100% infill of the part so that the insulation can be better, but also in the idea of creating a resistance structure for the part considering the next usage of such a part in construction for example.

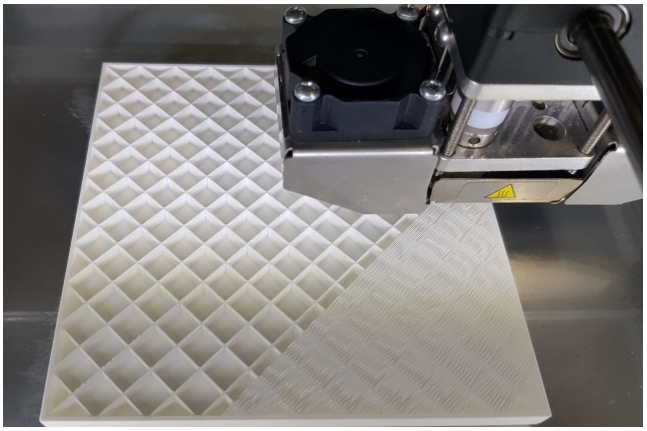

Fig. 4. Image taken during 3D printing of the 6mm thick panel with 10% grid infill.

Modeling Some Research Elements Using the Finite Element Method

A type of harmonic analysis was used to obtain a map of the sound pressure inside a closed enclosure. The 3D model assumes the existence of a speaker box in which there is a panel with a thickness of 1 mm manufactured by 3D printing. The design is similar to the one used in the experimental tests. A 100% cushion box enclosure was modeled (Fig. 5) because the surrounding acoustic environment serves as the domain in which the acoustic waves propagate. Therefore, a mesh of acoustic elements must surround the geometric body considered. In this way, the whole design distributes a certain topology to all elements to have a network control option available.

As excitation, it was necessary to choose between Mass Source, Surface Velocity, Diffuse Sound Field and other types. It was preferred Mass Source because it best suited the experimental setup. Excitation can be applied to vertices, edges or surfaces by introducing a pressure wave inside the system. The mass source is given by the Helmholtz equation (link) and if it is applied to a

surface, one can divide the mass flow by the area it is applied to. A plane wave was simulated in this way [link]. By suppressing the speaker and the test sample, the analysis mode treated the geometry as infinitely rigid, replacing it with voids that will act as sound reflectors. The maximum value of 15 kHz was set for the maximum range using a linear frequency. A far-field sound pressure level (SPL) plot was requested, assuming a 100mm sphere radius and 360o at the end of the theta angle, using the perfectly matched layers (PML) option to model the far-field radiation limit (Fig. 6).

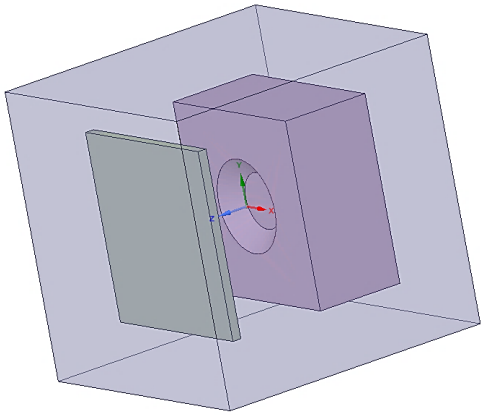

Fig. 5. Proposed 3D model design with 100% cushioned enclosure.

Air was the preferred propagation medium and we added a second enclosure designed to absorb the outgoing acoustic radiation without reflection coupled with PML elements. By adding a second coordinate system relative to the global one the orientation from the main axis (Y) was changed to be defined by the global Z and a construction surface was requested to be able to see the distribution of the results inside the enclosure.

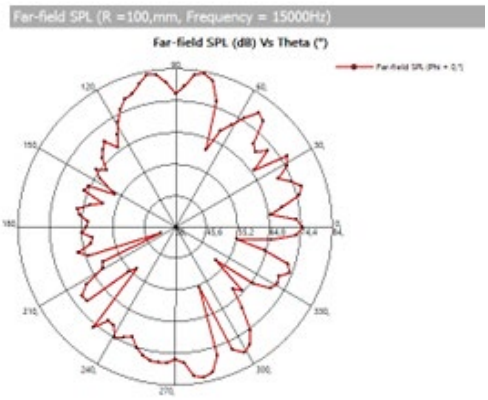

Fig. 6. Far-field sound pressure level at 360º distribution plot.

Fig. 7 highlights the pressure distribution that builds up inside the enclosure, reaching a value of 0.342652 MPa in the center of our panel.

Fig. 8 shows recordings of sound pressure levels recorded at 15 kHz with a peak amplitude of 108.67 dB in amplitude. It can be seen that the space between the speaker box and the panel is the most affected. The edges of the enclosure are all blue, which ensures that our setup works by trapping acoustic radiation without reflecting it.

The authors acknowledge that this analysis is based on an ideal setup and further refinement may be necessary before using the results in other areas of research.

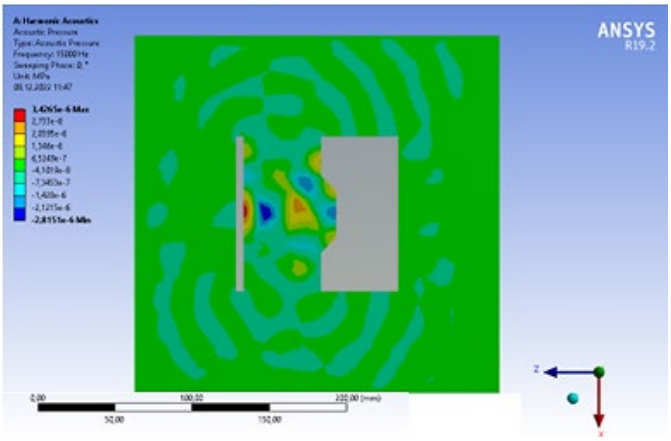

Fig. 7. Acoustic pressure accumulation at 15 kHz.

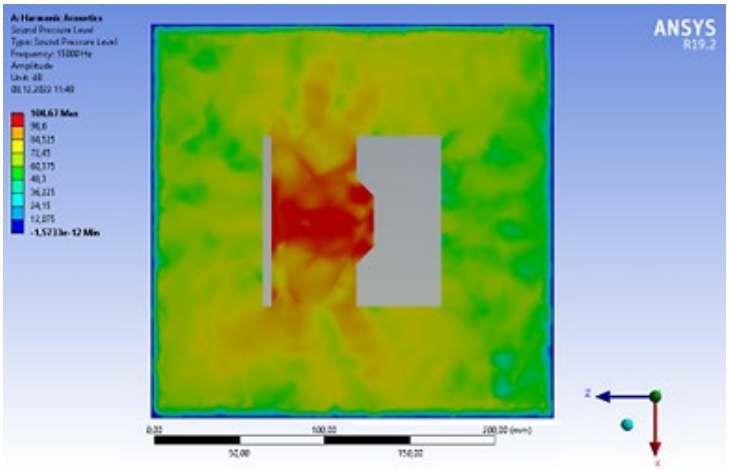

Fig. 8. Sound pressure level map at 15 kHz.

Experimentation of the Equipment for Evaluating the Sound Insulation Capacity of Some Polylactic Acid Panels

An experimental research plan was designed to highlight the influence of several factors on the sound insulation capacity of polylactic acid panels manufactured by 3D printing. These panels were manufactured under the working conditions recommended by the manufacturer of the printing equipment (Ultimaker 2 - Netherlands) with a 100% infill. As previously mentioned, the panels had an area of 100x100 mm^2 and thicknesses of 1 mm and 6 mm, respectively. The material used was PLA, polylactic acid as this is a usual material used in the printing process, but also being an organic material and the focus in the market and industry is on such materials.

Sound pressure level was used as the output parameter. This size was determined with the help of a sound level meter.

The input factors in the measurement process were the thickness t of the polylactic acid panel, the frequency f of the vibrations, and a size V relating to the sound volume. In this way, it was possible to plan the experimental trials according to the requirements of a full factorial experiment, type $L8$, with 3 independent variables at two levels of variation. Two-panel thicknesses (1 mm and

6 mm, respectively), two frequencies (500 Hz and 15,000 Hz, respectively), and two sound volume levels (10 % and 100 %) were used in this way. Generally speaking, the number of the independent variables can be bigger and more complex, but due to the usage of a Taguchi method for experimental research, there is possible to have like a concludent result with this L8 method type, minimizing a lot the number of the variables and the number of the trails for the experiments.

Both the values of the input factors and the results of the experimental tests can be seen in Table 1.

For a more appropriate interpretation of the experimental results, measurements were also performed without the polylactic acid panel, obtaining the following results: a) for V=10 % and f=500 Hz, I_s=95.2 dB; b) for V=100 % and f=15,000 Hz, I_s=95.0 dB; c) for V=100 and f=500 Hz, I_s=107.1 dB; d) for V=100 % and f=15,000 Hz, I_s=110 dB.

The experimental results were mathematically processed using specialized software based on the least squares method [7]. In this way, the following empirical mathematical power function model was obtained:

$$I_s = 123.027 t^{0.0216} f^{-0.0725} V^{0.0734} \quad (4)$$

Table 1. Experimental conditions and results.

Exp. no.	Input factors (coded value/real value)			Output parameter
	Panel thickness, t, mm	Sound frequency f, Hz	Sound volume level V, %	Sound intensity I_s, dB
1	-1/1	-1/500	-1/10	99.2
2	-1/1	-1/500	+1/100	110.1
3	-1/1	+1/15000	-1/10	68.7
4	-1/1	+1/15000	+1/100	84.8
5	+1/6	-1/500	-1/10	97.1
6	+1/6	-1/500	+1/100	109.1
7	+1/6	+1/15000	-1/10	62.7
8	+1/6	+1/15000	+1/100	80.1

By considering the empirical mathematical model constituted by equation (1), the diagram in figure 9 was developed.

The analysis of the determined mathematical model highlights that, among the three input factors considered, the strongest influence is exerted by the sound volume level V since, in relation (4), the exponent with the highest absolute value is attached to this factor. As expected, an increase in the sound volume level V results in an increase in the sound intensity I_s. Increasing the frequency f of the sounds leads to a decrease in the intensity I_s of the sound since the exponent attached to the factor f in equation (4) has a negative value.

Summary

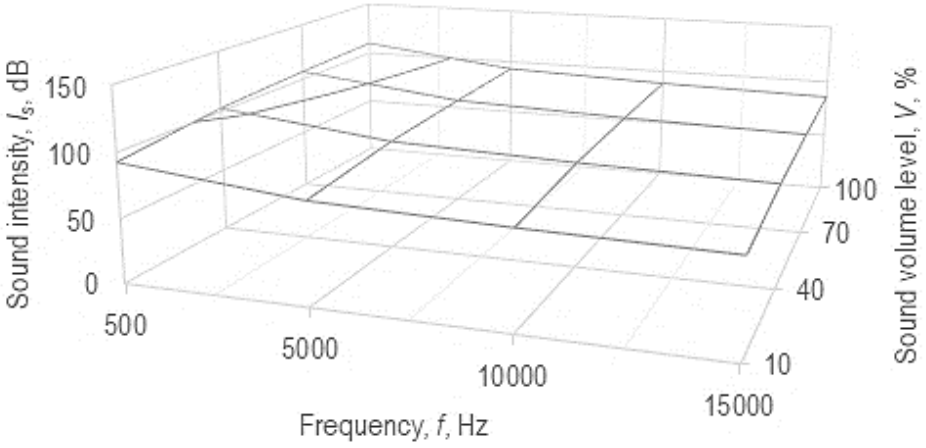

Fig. 9. The influence exerted by the frequency f and by the sound volume level V on the sound intensity I_s (t=1 mm).

The problem of evaluating the ability of some polymeric materials to contribute to the reduction of noise pollution is a current issue. For the experimental research of how different factors contribute to the variation of sound intensity after passing it through a polylactic acid panel, equipment was designed and made to provide conditions for the passage of sound through the polymer panel and the measurement of sound intensity with the help of a sound level meter. In the experimental tests, the panel thickness, frequency, and volume level of the sounds were considered input factors. An empirical mathematical model of the power function type was determined through the mathematical processing of the experimental results with the help of specialized software. It was found that the most significant influence on the intensity of sounds is exerted by the volume level of the sound passing through the panel. Increasing the frequency leads to a decrease in sound intensity after passing through the polylactic acid panel. In the future, it is intended to expand theoretical and experimental research on the influence of different factors on the variation of sound intensity after passing through panels made of different polymer materials or having different structural characteristics.

Abstract. Cold spray is a recently developed manufacturing technology for creating metallic layers on a variety of materials. Metallic particles are accelerated and strike the target surface using a pressurized gas flowing at supersonic speeds. In the last years, cold spray has gained increasing interest in different industrial scenarios, in particular, in the aerospace sector. Given the many fields of application, the need to understand how coated substrates behave when it is necessary to carry out machining operations arises. In this work, low-pressure cold spray equipment was employed to produce metal coatings on epoxy-based glass fibre-reinforced substrates optimized for cold spray deposition employing a layer of polypropylene on the composite surface. An automatic multi-purpose machine was used to drill 4mm diameter holes in the coated specimens considering the rotational speed fixed and varying the feed rate. The machined areas were then analyzed to assess the surface quality of the drilled holes and the burr morphology, considering different feed rate values and different entry surface of the drill-bit.

Introduction

In response to the growing demand for engineered materials capable of responding to the various requests arising during their applications, interest in composite materials such as Polymer Matrix Composites (PMCs), whose properties are completely tailorable due to their anisotropic structure, has increased [1]. Numerous engineering disciplines have been lured to the notion of producing lightweight, high-performance structures, resulting in a recent growth in the use of PMCs for high-end applications [2].

As examined in the literature [3], the metallization of PMCs has been recognized as one of the most promising approaches for further broadening their areas of usage and mitigating the challenges associated with their inherent inadequacies (such as their poor surface characteristics and high sensitivity to heat). In reality, surface metallization can enhance PMC erosion behaviour, boost thermal and electrical conductivity, and assure lightning protection, all of which are important considerations for the aerospace sector [4] .

The functionalization of polymer composite materials using standard processes such as plasma-enhanced chemical vapour deposition (PE-CVD), sputtering, laser ablation and evaporation, and liquid phase deposition is complex and costly, and the resultant coatings are difficult to modify. In reality, these technologies have the following disadvantages: high equipment and processing costs or work-piece size restrictions, low adhesive force, poor stability, lengthy production cycle, distortion of the substrate surface caused by molten particles, and high-temperature flames in thermal spraying (TS) [5].

Because of its capacity to generate thick coatings without compromising the substrate, cold spray (CS) technology has emerged as one of the approaches for metallizing PMC surfaces [6]. In

reality, CS employs kinetic energy to permit the deposition of micron-sized metallic particles (10-100 m in diameter) that do not melt and retain their original properties throughout the process [7].

Cold spray is a revolutionary powder deposition process that is increasingly being used to produce thick functional coatings from a variety of materials, including ceramics [8]. The name "cold deposition" refers to this method's ability to keep processed powder temperatures below the melting point of the particle's substance during the deposition process. As a result, the particles in the solid state strike the substrate at a relatively high velocity, distort, and bond together for coating creation and growth. As a result, CS may be sprayed on temperature-sensitive materials such as polymer matrix composites or plastics without causing considerable thermal degradation, surface deformation, oxide, vacancy development, or phase shift. Furthermore, these coatings reduce residual stress [9].

Cold spray offers resource efficiency benefits, which result in economic and environmental benefits that contribute to long-term sustainability [10]. Cold spray, for example, is a technique that may be described as a green manufacturing process since it releases no harmful emissions, has no discernible environmental impact, and is an important tool for sustainability in a variety of sectors. The heating source is electric and regulated at temperatures below the melting point of the substance being sprayed, thus there are no noxious fumes or other potentially harmful emissions. This prevents the melting of metal powder and the release of hazardous gases. In general, the benefits of cold spray for sustainable production fall into four categories: 1) the process has a minimal environmental effect; 2) repair rather than replacement; 3) better performance, which extends the useable life of components; and 4) an alternative to more polluting and/or less sustainable techniques [11].

Although cold spray has been extensively studied and optimized for the deposition of metal powders on metal substrates, little is known about the deposition of metals on composites, which is far more interesting because it would allow for completely tailored products from the core to the surface.

The majority of the investigations in the literature focus on CS deposition on thermoplastic-based substrates: because there is no other adhesion mechanism other than mechanical interlocking, deformation of the substrate and particles is required for adhesion to occur. This is only conceivable if the substrate is thermoplastic, as it is more ductile because of the weak links that exist between the polymeric chains. Thermosetting polymers, on the other hand, display brittle behaviour, with weakly adherent and inhomogeneous coatings.

However, thermosetting matrix composites are the most appealing in many industries (including automotive and aerospace) due to their high compatibility with fibres and strong mechanical properties. To address this issue, it was presented a unique method that may consist of putting a thermoplastic-based interlayer on the surface of a thermoset-based substrate to achieve excellent CS deposition [12].

However, the application of cold spray for additive, repairing, and coating manufacturing applications is still severely limited by the fact that, due to the poor control over the process, the products require post-processing procedures. Considering that the coatings obtained are substantially thicker than those created with typical coating processes, it is not viable to optimize the processing settings using literature data. In particular, since the drilling process of CS coating on composite involves layers of different materials, it is yet required to do in-depth research on the phenomena that take place during the process.

In this work, for the first time in the literature, a preliminary study on the drilling operations on metal coatings obtained by cold spray on thermoset-based composite substrates optimized for CS deposition is presented.

Materials and Methods

Substrate manufacturing.

By employing plain-woven glass textiles weighing 200 g/m2 and an epoxy infusion technique, square laminates of glass fibre-reinforced plastic measuring 100x100 mm were produced. A total of 16 0/90 cloth layers were piled to achieve a 5 mm thickness. A commercial epoxy resin optimised for infusion applications, with a glass temperature (Tg) onset of 85°C, was employed.

As was mentioned in the preceding paragraphs, several investigations have proven that it is challenging for the sprayed aluminium powder to adhere to the epoxy-based substrate [13]. The particle impact energy is what determines how well cold-sprayed metallic materials adhere to plastic (particle mass and velocity). Even with less impact energy, deformation of the particle is still necessary during the collision. Therefore, only a polymeric substrate that is softer and more ductile, like thermoplastic materials, can allow for the deposition of CS metal and the formation of coatings [12].

Therefore, a unique approach was here suggested based on Polypropylene (PP) film treatments carried out on the epoxy surface, therefore enhancing the metal anchoring, in order to build a metal coating on the composite substrates. Particularly, a heated plate press P 200 E was utilized to promote the PP-composite coupling and a commercial thermoplastic PP film with a thickness of 0.5mm was placed on the surface of each sample. The PP employed has a nominal Tg of -20°C and a melting temperature (Tm) of 170°C.

The dishes were heated to 200 °C, which is slightly higher than the temperature at which polypropylene melts, and then 5 bar of pressure was applied for approximately 5 minutes.

Cold Spray Deposition.

For the cold spray depositions, Dymet 423 low-pressure apparatus with nitrogen as a carrier gas was employed. In order to create the metallic coating on the PP layer, LPW South Europe provided micron-sized powders of the aluminium alloy AlSi10Mg (size range 15-45 μm).

Preliminary experimental results and literature findings served as the foundation for the method chosen for the coating production process [14,15]. Several coating tracks were first created by altering the process parameters in a wide range (inlet gas temperature: 150-600 °C, inlet gas pressure: 4-8 bar, stand-off distance (SoD): 10-80 mm). These coating tracks had a travel speed of the spraying gun equal to 8 mm/s. For the sake of brevity, this process was not described in this article. The optimal process parameters, employed for the deposition of the aluminium layer were determined according to the preliminary study (inlet gas temperature: 160°C, inlet gas pressure: 6 bar, SoD: 45 mm). During the deposition a K-type thermocouple was positioned on the substrate to assess the real process conditions.

To avoid degradation phenomena of the substrate and to ensure softening, the inlet gas temperature was specifically chosen by taking into account that the temperature of the gas flow on the target surface was below the melting point of the polymeric material and, at the same time, greater than the glass transition one. This was done to allow metallic particles to penetrate the polymeric surface. The proper gas pressure was chosen, taking into mind that the substrate will erode more quickly at higher pressures due to the significant shot-peening impact of the particles. Finally, in terms of stand-off distance, greater values of SoD result in particles rebounding, which results in a thin coating since the particles' velocity is reduced upon collision with the substrate. This finding was supported by the literature [16], which indicates that a denser coating forms when the particle momentum is higher.

A 60x60 mm coating was created on the composite substrate specimens' surface by spraying a single layer of Al-based particles. A PosiTest ATM was used to assess the adhesive strength of the coating obtained while complying to the ASTM D4541 standard. Using cyanoacrylate adhesive, aluminum dollies with 10 mm diameter were attached to the top of the cold-sprayed deposits. Using a drill bit, any extra glue or coating around the dolly was taken off. Dolly surfaces were

examined with an optical microscope to measure the quantity of removed coating in order to determine if the test was successful.

Machining of the specimens.

Drilling operations were performed using a 5-axis machining centre (C.B. Ferrari) with a 4mm twist drill bit. As indicated in Table 1, 16 holes were drilled while maintaining the rotational speed constant at 1000 rpm and varying the feed rate.

Table 1. Drilling process parameters employed in this research activity.

Hole	**Feed Rate [mm/min]**	**Hole**	**Feed Rate [mm/min]**
1	20	*9*	20
2	40	*10*	40
3	80	*11*	80
4	160	*12*	160
5	200	*13*	200
6	400	*14*	400
7	800	*15*	800
8	250 *(mean value)*	*16*	250 *(mean value)*

Drilling operations were performed perpendicular to the surface of the substrate. As illustrated in Fig.1, the first eight holes were drilled considering the uncoated composite side as the entry surface, whereas the holes from 9 to 16 were drilled with the coated one as the entry surface.

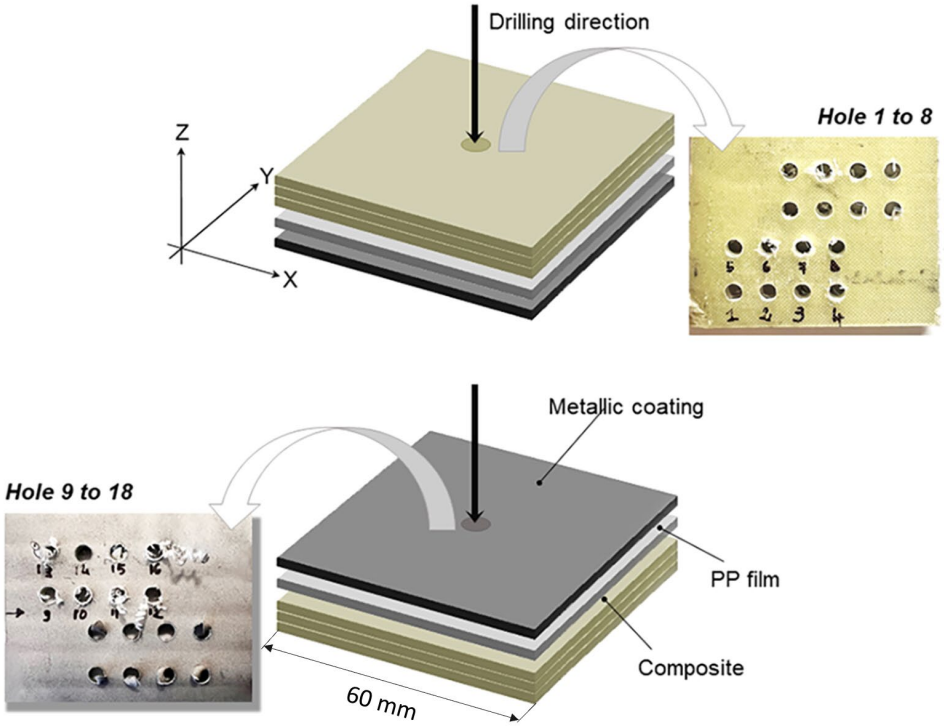

Fig. 1. Schematic illustration of drilling direction considered during the experimental tests.

Results and Discussion

As regards the holes obtained considering the epoxy-based composite as the entry surface the main results obtained by varying the feed rate are highlighted in Fig. 2. When the feed rate is increased it is possible to observe increasing delamination of the surface, defined as the inter-ply failure occurring during the drilling operation of the composite materials[17]. This phenomenon, as highlighted in Fig. 2, may be seen at the drilled-hole entry.

The plies separate from one another and form a peel-up delamination zone around the drilled-hole entry circumference when the drill penetrates the top surface of the laminate. This is caused by the contact between the composite material and the cutting edges of the drill, which creates a peeling force that acts in the Z direction through the slope of the drill [18]. In fact, when the thrust force is greater than the material's interlaminar bond strength, drilling-induced damage manifests as splitting between two adjacent layers.

Delamination is widely acknowledged as the primary mechanism of failure when drilling composite laminates and is regarded as a serious issue since it significantly lowers the material’s fatigue strength [19].

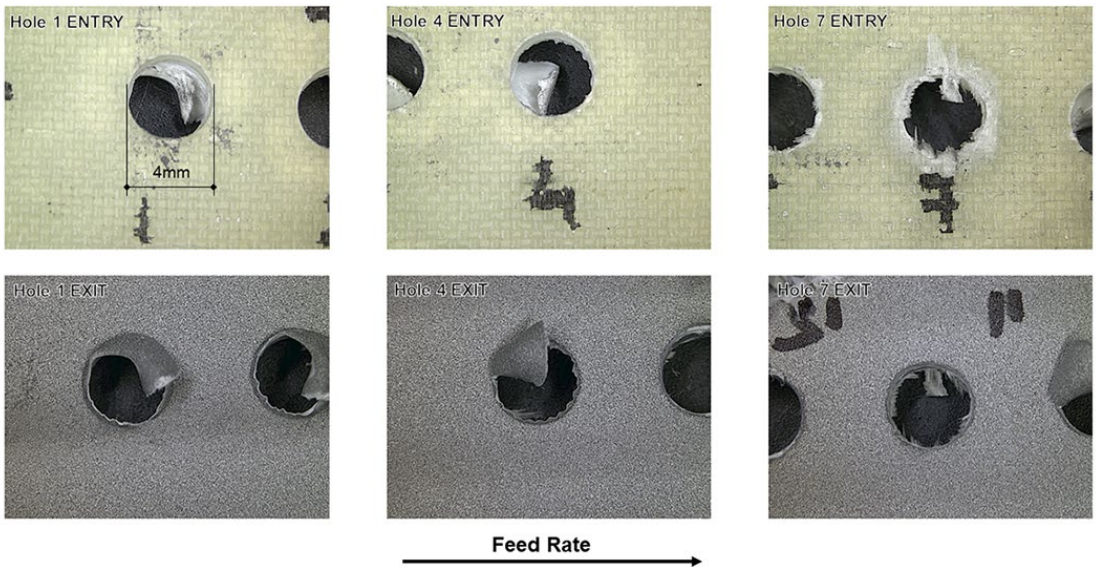

Fig. 2. Macrographs of the holes obtained considering the epoxy-based composite as the entry surface.

As the drill bit travels down the substrate's thickness, it will come into contact with PP film that has been cold-sprayed with aluminium powders. It is possible to observe the formation of burr, a push-out defect due to the deformation during the drilling process of the more ductile material compared to the epoxy-based composite . As the feed rate increases, this defect appears less evident. It is furtherly possible to observe, that the coating remains well adhered to the PP surface.

It, therefore, appears evident that the optimal feed rate value must take into account the opposing trend of delamination of the composite and push-down of the thermoplastic film.

As regards the holes obtained considering the coating as the input surface, the results obtained are portrayed in Fig. 3.

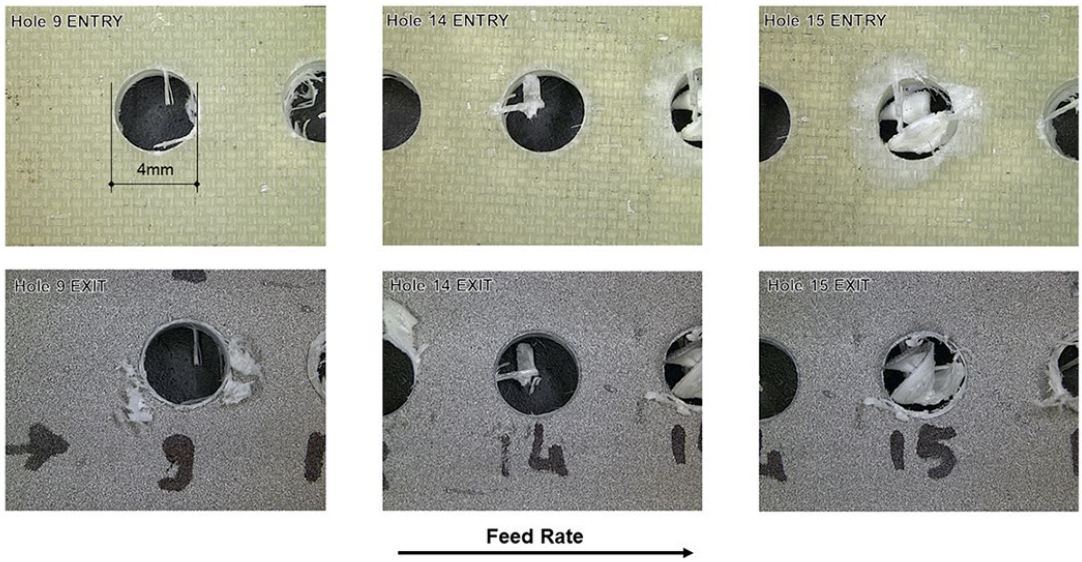

Fig. 3. Macrographs of the holes obtained considering the metallic CS coating as the entry surface.

Materials Research Proceedings 28 (2023) 1729-1738 https://doi.org/10.21741/9781644902479-187

Likewise the previous case, as the feed rate increases, the substrate might delaminate, in this case as a push-out delamination phenomenon. It should be noted that fiber breakage can be observed even at low feed rate values, as illustrated by observing hole 9.

However, in this scenario, we can notice the production of long continuous chips on the inlet surface, where the drilling bit penetrates the CS coating and the Polypropylene film, as shown in Fig. 4.

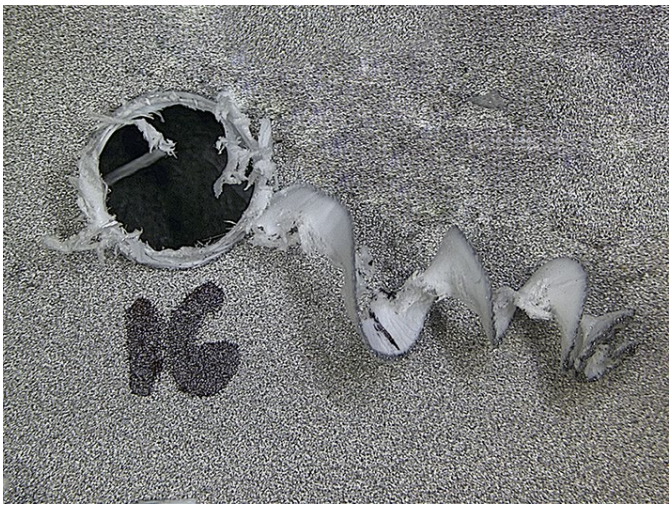

Fig. 4. Long continuous chip obtained with high values of the feed rate.

It is possible to assess that the feed rate strongly influences the length of the chips. Long continuous chips are undesirable as they could frequently tangle around the drilling tool and require hand removal, potentially affecting the operations [20]. In fact, low glass transition temperatures and low heat conductivity of the thermoplastic material are the main factors that contribute to tool clogging in thermoplastic composites. Due to friction, the tool temperature could rise above the glass transition temperature of the polymer during machining, causing the thermoplastic material to become rubbery and deposit on the tool's surface[21].

It is interesting to observe the presence of the CS coating on the surface of the chips created. In fact, the adhesion tests performed on the samples indicate that, despite the creation of the spiral chips, the coatings remain effectively adherent to the composite substrate. As depicted in the macrographic images of the dolly following the adhesion tests illustrated in Fig. 5, the coating is dense and homogenous. The measured average adhesion value is 5 MPa.

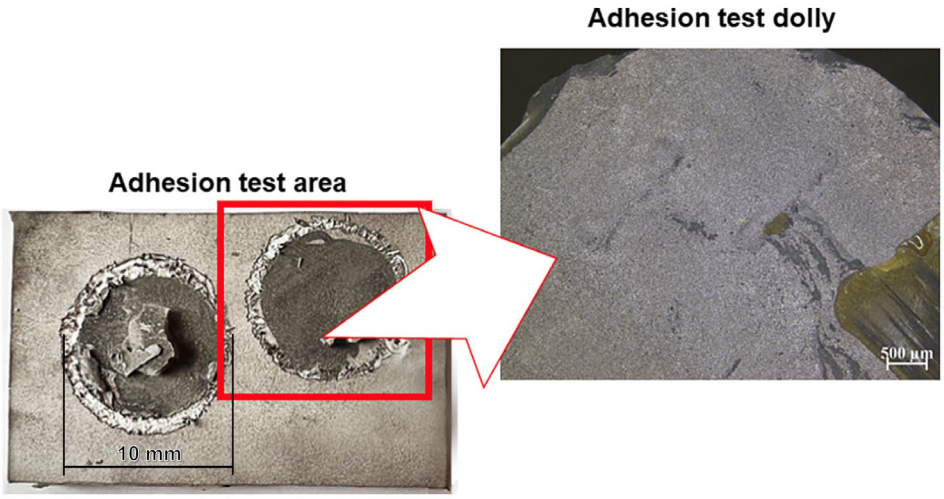

Fig. 5. Adhesion tests performed on the coated specimens. It is possible to observe the CS coating in the macrograph of the adhesion test dolly.

Confronting the results obtained by changing the entry surface of the drill, it is possible to assess that when the drilling operation starts from the composite laminate to the metal coating, no significant changes are observed in the composite to the coating/composite drilling sequence, when increasing the feed rate. However, the formation of long spiral metal/PP chips can be observed when the coating side is chosen as the entry surface, making further machining of the hole necessary and hindering the drilling operations.

Summary

The purpose of the work is to assess the influence of metal-based cold spray coatings on the quality of the holes and burr formation during drilling operations on composite laminates, optimized for CS deposition. The main findings of this work can be summarized as follow:

- the feasibility of drilling operations on cold spray coated samples was assessed
- the surface quality of the machined areas was analyzed by fixing the rotational speed and varying the feed rate
- The feed rate influences the delamination of the composite both at the drilled-hole entry (peel-up delamination) and exit (push-out delamination). Increasing the feed rate, the delamination effects worsen.
- it was shown that the machined-hole entry surface has a strong influence on the burr formation. In particular, long spiral chips are formed when the coating side is chosen as the entry surface.
- The coating remains well adhered to the surface during the drilling operations and remains adhered to the chips. This is further confirmed by adhesion tests performed on the coated surface.

Keywords: Constrained Friction Processing, Solid-State Processing, Mg Alloy, Fine Grains

Abstract. Constrained Friction Processing (CFP) is a novel solid-state technique suitable to produce rods especially from lightweight materials. The technology is particularly interesting to overcome the processing challenges associated with Mg due to its hexagonal close-packed (hcp) structure. The process is a variation of the refill friction stir spot welding (refill FSSW) technique, and is performed by plunging the rotating shoulder into the base material, which causes the material to be extruded into the cavity crated by the retraction of the rotating probe and, at the same time, being constrained by it. The complex shear and the heat generated during the process causes metallurgical transformations in the material, such as dynamic recrystallization, allowing for substantial grain refinement to micro- or even submicro- scale. In this study, real time data – torque, axial force and temperature – acquired from the process are analyzed in order to present, for the first time, a description of the CFP technique. Furthermore, the resultant features of the microstructure of a refined rod is explored.

Introduction

The demand for lightweight and environmental-friendly materials has increased over the years as the urge for reduction in greenhouse gas emissions scales [1]. In this scenario, the adoption of Mg and its alloys as structural materials is expected to increase due to their properties such as low density (1.74 g/cm³) and, thus, high strength-to-weight ratio. Nonetheless, the processing of these materials remains a challenge due to Mg's poor workability associated to the hcp crystal structure, which has a limited number of slip systems at room temperature [2].

Severe plastic deformation (SPD) techniques have been investigated for the processing of Mg alloys as means of microstructure tailoring aiming grain refinement and texture modification, which result in improvements on mechanical properties. Among those, Equal-Channel Angular Pressing (ECAP) was demonstrated to produce a refined microstructure on magnesium alloys after multiple passes, which is responsible to enhance the material ductility at moderate temperatures [3]. High-pressure Torsion (HPT) is reported to be capable of producing ultrafine microstructures Mg alloys, with an effect of doubling the strength of the base material [4].

While these techniques have been demonstrated to be able to produce fine-grained Mg and Mg alloy samples both for study of their fundamental properties and for potential applications, they may involve or even require multiple passes, considerable set up and processing times, besides potential dimensional limitations in the samples that can be produced. Most of these limitations

are alleviated or even overcome by using a newly developed technique called Constrained Friction Processing (CFP).

This friction-based technique is suitable for thermo-mechanical processing of lightweight alloys and is based on the fundamentals of the refill friction stir spot welding (refill FSSW) technique [5], but optimized for the production of extruded rods with fine or even ultrafine microstructures. CFP is performed using a 3-part toolset (a stationary clamping ring and the shoulder and probe as the rotating parts), and the processing steps are summarized in Fig. 1. Initially, the toolset reaches the surface of the plate for the clamping of the system using the set clamping force (a). Then, the rotating shoulder plunges into the base material, generating heat due to the friction and plasticizing the material. At the same time, the rotating probe is moved in the opposite direction in order to create a cavity to accommodate the plasticized material displaced by the shoulder and to constrain the material flow (b). Once the desired plunge depth is reached, the rotation of the tools stops and the shoulder is retracted to the level of the probe (c). Finally, the clamping of the plate is released and the tool system is removed, leaving a processed rod (d). The complete process time takes only few seconds depending on the plunge depth, what qualifies the CFP as a fast and simple way to obtain rods with refined microstructure.

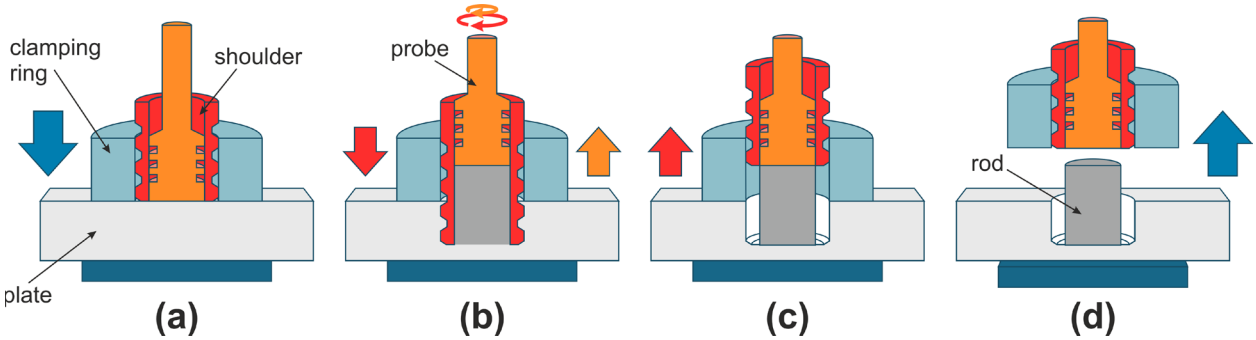

Fig. 1. Schematic representation of CFP: (a) clamping of the plate, (b) plunging, (c) shoulder retraction and (d) releasing steps.

The present study analyzes CFP characteristics in terms of torque, axial force and the temperature evolution in order to better understand the process and enable its further development. Typical CFP rods were processed using as-cast AM50 as base material, and information such as torque and axial force were recorded for each tool part, as well as the process temperature, which was measured using a thermocouple placed at the base of the processed rod. Finally, the microstructure of a typical rod is analyzed in order to demonstrate the potential of CFP on grain refinement.

Materials and Methods

The base material selected in this study is an as-cast AM50 magnesium alloy, obtained via permanent mold casting, as described by Elsayed et al. [6]. The as-cast material features a microstructure with typical dendritic grains (with grain sizes in terms of average diameter varying from 457 to 1023 μm), eutectic β-Mg17Al12 and secondary Al-Mn phases.

In this study, CFP rods were produced using a refill FSSW machine (RPS 200, Harms-Wende GmbH) operated in position control mode. Both axial and rotational movement of each tool part is actuated using individual transducers. The axial forces produced during the process on the rotating parts of the tool can be measured using four shear pancake load cells for each component. Furthermore, the torque produced by the probe and the shoulder is measured using a system consisting of a lever arm attached to the motor spindle that transmits the force to the load cell, also a shear pancake type. A schematic representation of the toolset is given in Fig. 2, which consists

of a molybdenum-vanadium alloyed hot-work tool-steel clamping ring (⌀17 mm) and probe (⌀6 mm), and a G40 tungsten carbide shoulder (⌀9 mm), resulting in an extrusion ratio of 2.25. For the experiment, a total of two samples were produced: one for the torque and axial force measurements, which was subsequently submitted to the microstructural, and one for the acquisition of the temperature evolution. In all cases, the rotation speed (RS) for both shoulder and probe was set as 1800 rpm, combined with a shoulder plunge speed (PS) of 1 mm/s at a constant clamping ring force of 12 kN. The plunge depth (PD) was set as 3.00 mm, resulting in a rod with a total length of 6.75 mm. The process parameters were selected based on preliminary experiments aiming the determination of the suitable processing window. The workpiece used for the CFP with dimensions of 100 x 25 x 6 mm³ was fixed to the stainless steel backing plate attached to the working table, ensuring the stability of the system during the process. No post-processing cooling was used in this study, whereby the produced rods were air cooled.

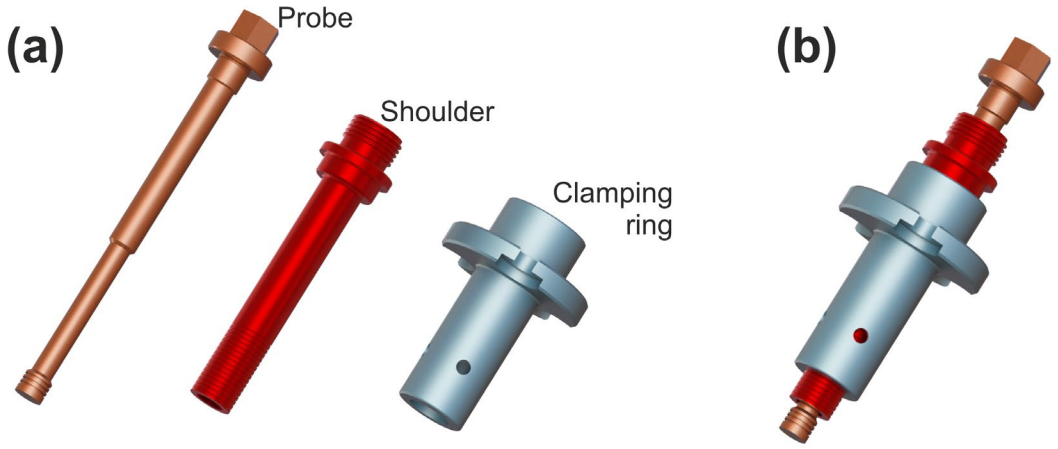

Fig. 2. Schematic representation of the toolset: (a) probe, shoulder and clamping ring, and (b) toolset assembly.

The temperature evolution during CFP was measured using a K-type thermocouple with an acquisition frequency of 50 Hz. The precision of the used thermocouple is ± 2.2 °C or ± 0.75% of the measured temperature, whichever is greater [7]. For this measurement, a 2.5 mm long, 0.6 mm diameter hole was drilled on the back of the workpiece, in a concentric position in relation to the tools. Therefore, the temperature was measured at a point 0.5 mm away from the root of the rod.

For the microstructural analysis, the rod was embedded in acrylic resin, grounded to #4000 Si C foil until the cross-section was reached, and mechanically polished to 0.2-µm water-free colloidal silica suspension. In order to reveal the rod's microstructure, the sample was etched by immersion for 15 s using an acetic-picric solution (180 mL ethanol, 20 mL distilled water, 7.5 mL acetic acid, 4 g picric acid). The metallographic analysis was performed using a VHX-6000 digital microscope. Micrographs were acquired using a Leica DMi8 microscope, where the grain size (d), i.e. average grain diameter, was measured according to ASTM E 112 (grain boundary intersection count method) [8] using the ImageJ 1.52a software [9].

Results and Discussion

Process Characteristics of CFP.

The position of the rotating tools (shoulder and probe) during CFP was recorded and is depicted in Fig. 3(a), along with the RS data. The process starts at t = 0 s, when the toolset just reached the surface of the plate, and the set clamping ring force was applied. In the plots, the tool plunge is indicated with positive values on the *y-axis*, while the retraction of the probe corresponds to negative values. With a set shoulder and probe RS of 1800 rpm, the shoulder starts to plunge the

Materials Research Proceedings 28 (2023) 1739-1746 https://doi.org/10.21741/9781644902479-188

material at a PS of 1.00 mm/s. For this processing route, the displacement of the rotating tools was set to follow a sine profile. The average volume of extruded material is 35.34 mm³/s. In order to constrain this volume of material without imposing any compression, the probe retraction speed is set as 1.25 mm/s, resulting in a total displacement of 3.75 mm at the end of the process.

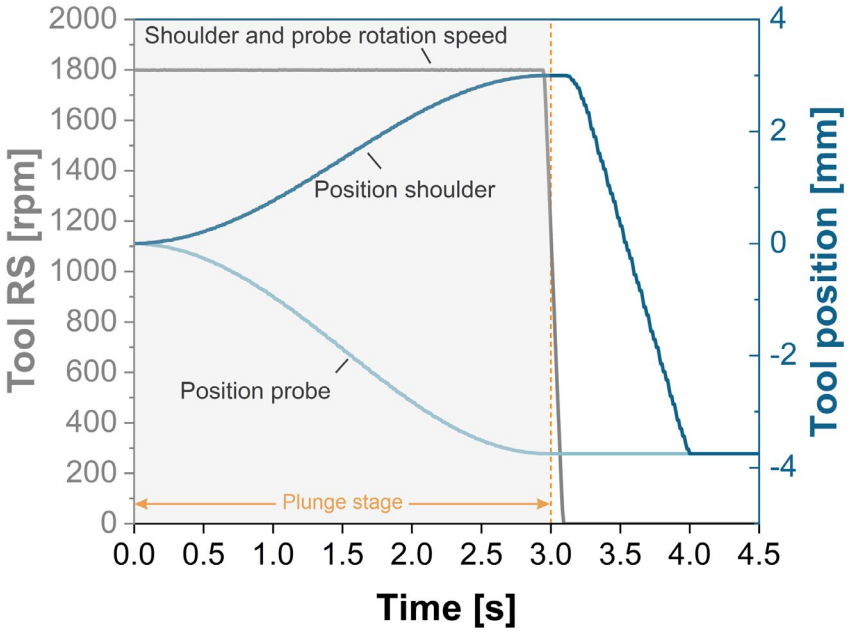

Fig. 3. Position and rotation speed (RS) data acquired for probe and shoulder during CFP.

The torque and axial forces for the probe and the shoulder are presented in Fig. 4. The axial forces correspond to the resistance of the material to the extrusion component of the CFP. For a better understanding of the mechanical efforts associated to the process, it is important to read the results of the actual CFP presented in Fig. 4 (a) along with the plots of the CFP performed without plunging into the workpiece, Fig. 4 (b), that represents the forces and torque related to the friction between the machine components and tool parts. In terms of axial forces, the effect of friction is negligible. The actual CFP axial forces measurement indicates a maximum force during the plunging of around 5.47 kN for the shoulder at t = 0.98 s. For the probe, the maximum axial force (1.66 kN) was measured at the beginning of the process. This likely corresponds to the reaction force to the material stuck between shoulder and probe remaining from the previous processing operation, since the material is not yet plasticized at this moment. Combined with the stuck material, this reaction force is also related to the displaced material produced on the probe due to the beginning of the shoulder plunge.

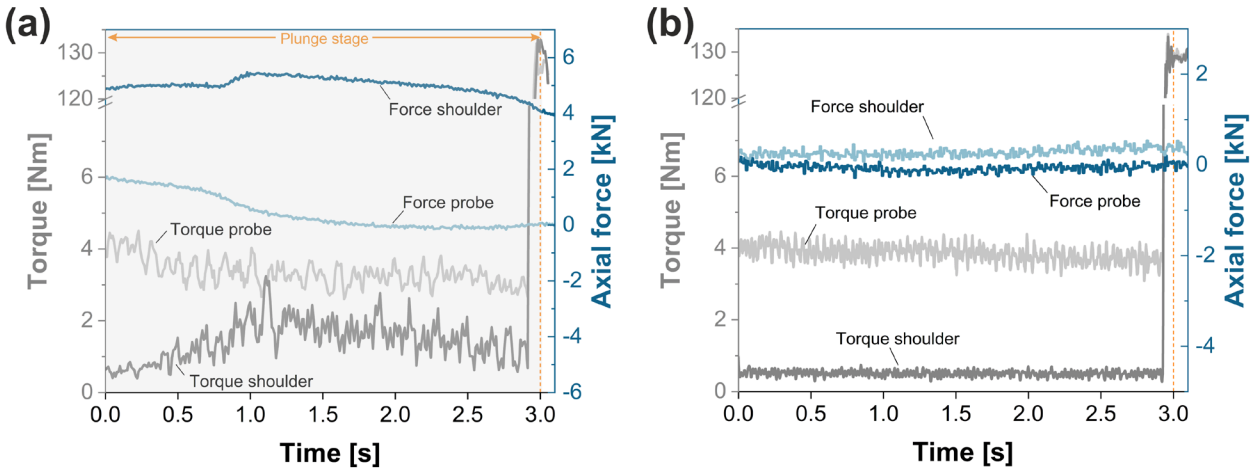

Fig. 4. Torque and axial force data acquired for probe and shoulder during CFP (a) on AM50 workpiece. (b) Measured torques and axial forces due to internal friction, without plunging into the workpiece.

The torque measurements during the CFP indicate the resistance of the material to be stirred due to the rotation of the tool, and are especially interesting for the shoulder. This is attributed to the negligible contribution of the probe to the torque, evidenced by Fig. 4, which shows an average of around 4 Nm. This is somehow expected, since the only contact between probe and material is on its lower surface and the shoulder and probe rotate at the same speed, generating a material flow that doesn't impose significant stresses at this surface. For the shoulder, the torque increases from the beginning of the process until it reaches its peak value of 3.20 Nm around t = 1.10 s. This is an indication of the obvious increase in the resistance of the material to the rotation movement as the shoulder plunging progressively increases. From this peak point on, the torque continuously decreases until the end of the process. It is interesting to point out that the peak values for torque and axial force are reached at the same time, indicating that at this point the material reaches the temperature and shearing conditions leading to plasticization.

As the shoulder approaches the set PD, the control system of the machine starts to drastically reduce the toolset RS to zero at t = 2.94 s for 0.15 s, resulting in a deceleration of 12032 rpm/s (Fig. 3). The deceleration of the tool results in a drastic increase of the torque up to 132 Nm for both probe and shoulder. The process then finishes with the shoulder moved upwards to the same position as the probe (y = -3.75), and releasing the clamping ring force, leaving the processed rod.

The analysis of the temperature measurements, depicted in Fig. 5, indicates that the peak values of torque and axial force for the shoulder occur at around 205°C (478 K). This corresponds to 52% of the AM50 melting temperature, according to differential scanning calorimetry (DSC) measurements reported by Kasprzak et al. [10], i.e. solidus and liquidus temperature of 434°C (707 K) and 640°C (913 K), respectively. Another aspect observed in Fig. 5 is that the peak temperature produced during the plunge stage of the process, Fig. 1(b), measured as 468°C (741 K), is 34°C above the solidus temperature of AM50 alloy and corresponds to 81% of the AM50 liquidus temperature.

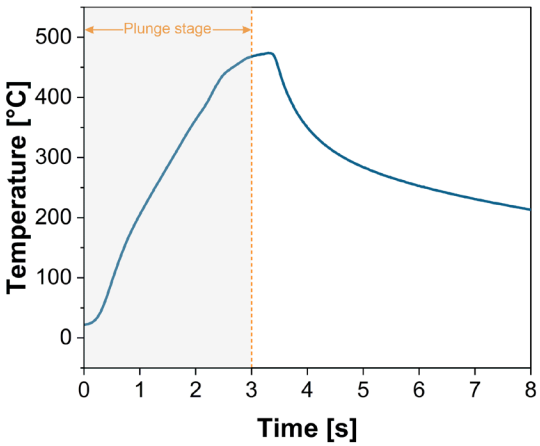

Fig. 5. Temperature evolution during CFP, measured via thermocouple placed at the rod's root.

Microstructure produced by CFP.

The microstructures of the base material and of the rod produced from the conditions presented are depicted in Fig. 6. The comparison of the rod with the surrounding base material indicates a strongly refined microstructure, with average *d* of around 7.7 ± 1.9 µm. This represents a reduction to around 1:96 in comparison to the base material.

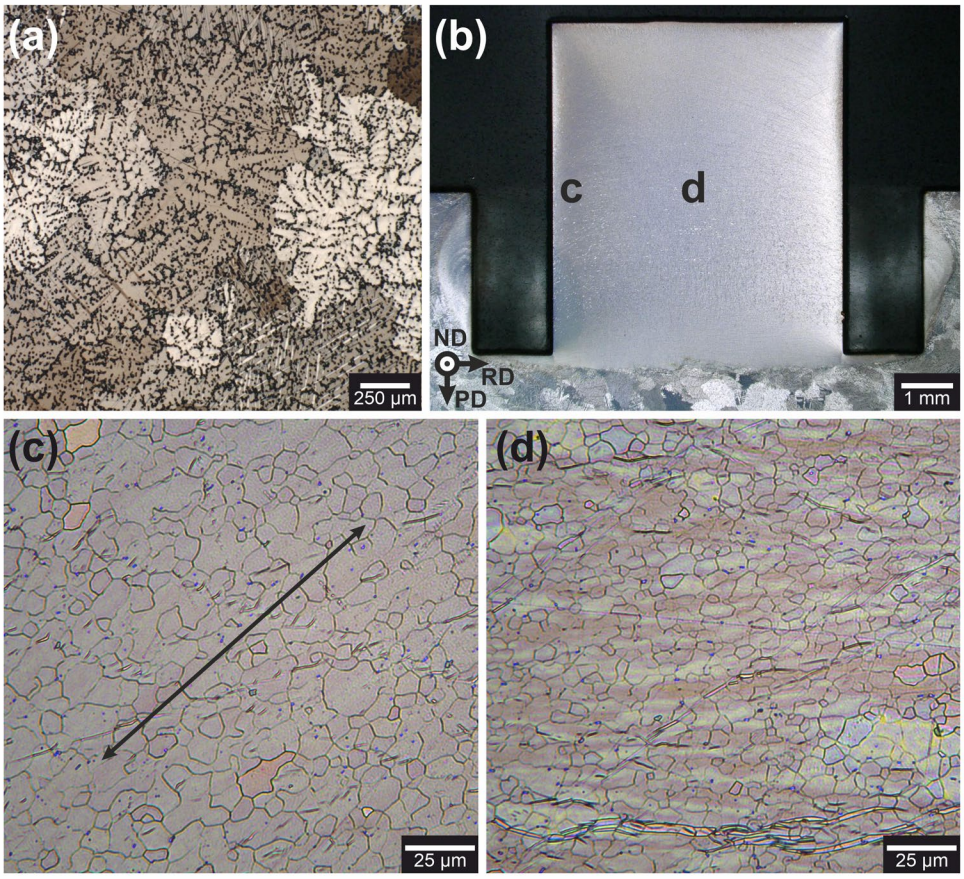

Fig. 6. Micrographs of (a) as-cast AM50 base material, (b) macrostructure of a rod produced by CFP and (c) and (d) micrographs of two selected regions of the rod.

The microstructure of a produced rod varies along the plunge direction (PD) as well as in the radial direction (RD). Two examples of microstructures are depicted in Fig. 6(c) and (d). Along the PD, it is possible to observe a refined and equiaxed microstructure with $d = 8.2 \pm 1.1$ µm. Although the grain structure along the PD is similar for every position, there is a variation in d due to the varying stirring conditions and distinct thermal histories as a function of the height. At the bottom of the rod, the average measured d is considerably smaller than the other positions of the rod, 5.4 ± 0.5 µm, while the average d at the top of the rod is 9.0 ± 0.7 µm.

Along the RD of the rod, less remarkable differences on d are observed, e.g., at the border (9.0 ± 1.8 µm) (c) and at the center (8.2 ± 1.1 µm) (d) of the rod. However, the examination of the grain structure at these two positions indicates some deformation of the grains along the direction of around 47° // PD. This may be attributed to the material flow conditions during CFP, described by Shen et al. [11] as a spiral curve similar to a conical compression spring, and developed layer by layer during the refilling stage of the refill FSSW, which is analogous to CFP.

Summary

In the present study, CFP was introduced and its characteristics were investigated in terms of torque, axial force and temperature evolution during the process. Furthermore, the microstructure of a typical AM50 rod produced via the novel CFP was analyzed. The main findings are summarized below:

- Although the probe plays an important role on the constraint of the material flow, the torque evolution during the process is negligible for this tool part. For the axial force, a peak value of 1.66 kN is found at the beginning of the process and is progressively reduced to roughly zero.
- The data acquired for the shoulder indicates peak values of torque of 3.2 Nm at t = 1.1 s and axial force of 5.47 kN at t = 0.98 s, i.e., roughly at the same moment. In this time interval, the temperature measured at the bottom of the rod reads around 200 °C, suggesting that the temperature of plasticization of AM50 during CFP is at least 52% of AM50's melting temperature.
- The produced microstructure has an average d of around 7.7 ± 1.9 µm, which represents a reduction of the initial as-cast base material of around 1:96. It is interesting to point out that this remarkable d reduction was obtained using a simple process setup in only 3 s of processing time, indicating suitable upscale potential of CFP.

Keywords: Electrical Discharge Drilling (EDD), Micro-Hole, Difficult-To-Cut Material

Abstract. The thermophysical properties of the electrodes material significantly impact performance of the electrical discharge machining (EDM). The aim of this article was to investigate the influence of thermophysical properties of selected materials on the EDM process. The effect of the thermophysical properties of these materials on process efficiency factors (material removal rate, linear tool wear) and hole geometry (aspect ratio, radial overcut) was analyzed. The results showed that selected thermophysical properties of the workpiece, such as thermal conductivity, melting point, have the most significant impact on the electro-erosion process. Optimal result parameters (material removal rate: 2.58 mm^3/min, linear tool wear: 4.95 mm, aspect ratio: 8.00, radial overcut: 0.046 mm) and no presence of "bottom cone" were obtained for EDM drilling in Inconel 718 and similarly for AISI 1045 steel. On the other end were high resistance alloys such as tungsten carbide and copper alloy.

Introduction

The electrical discharge machining (EDM) process is one of the unconventional methods of manufacturing. The process has been known since around 1943 [1]. However, efforts are still being made to improve its performance, parameters and the accuracy of the manufactured shapes. Experimental research is still being done to increase material removal rate (MRR), reduce tool wear (TW), and reduce surface roughness (SR) [2-4]. Additionally micro-holes requires high dimensional and shape accuracy without burrs and micro-cracks [5].

In the process of electrical discharge machining the workpiece material is removed as a result of phenomena accompanying electric discharges occurring in the inter-electrode gap area. The gap involves area between workpiece and working tool electrode. Energy transferred during the discharge in a form of spark melts and evaporates the metal. For the occurrence of electrical discharges, the electrodes are connected to the electric pulse generator. Space between the electrodes is filled with a working liquid. Also, the selection of parameters and material of the tool should ensure the removal of more material from the workpiece [6,7]. In addition, the EDM enables processing of electrically conductive materials, regardless of their hardness. This is the most important advantage of EDM process comparing to conventional machining methods. Thanks to that technique can be successfully used to produce parts from modern engineering materials in such industries as aviation, automotive and medical. In addition, due to the high accuracy of obtained geometry (approx. 5 μm), this process is also suitable for the production of micro-shapes, including micro-holes in the diameter range of 1-999 μm [6,8,9].

Currently, aviation, automotive and medical industries use engineering materials that are resistant to high temperature conditions, providing at the same time high strength, and high hardness. Within parts such as jet engines turbine blades are equipped with micro-holes which are made to increase their high temperature operational capabilities (up to 1,373 K). These micro-holes are called "cooling holes". When the jet engine is running, cool air flows through them, further reducing airfoil temperature [10]. However, due to the strength properties of the used materials, as well as the size of micro-holes (0.3 - 5 mm in diameter, depth to diameter ratio (40-600:1), the choice of technology for their production is limited. Currently, one of the most frequently chosen technologies for cooling holes manufacturing is electrical discharge drilling (EDD) [11,12].

In conducted research [13], Authors indicate that the thermophysical properties of the workpiece material and the working electrode affect the machinability the EDM process. At the same time also material of the working electrode have a strong impact on the EDM process. Calculated erosion resistance index shows how important it is to analyze such electrode material properties as thermal conductivity, specific heat and melting point. Similar research results are presented in the analysis of the impact of the thermophysical properties of the electrode material on the EDM process of such materials as AISI 304 stainless steel and Ti-6Al-4V alloy in [14]. The results indicated that the greater resistance of the material is (higher erosion resistance index, harder to EDM) lower overcut and lower taper rate are. According to this analysis, despite the low MRR value, good machining accuracy can be achieved. However, in [15], a significant impact of the thermophysical properties of the workpiece (in this case Inconel 718 superalloy) on the EDM process was demonstrated. In the analysis of the results, attention was paid to the change in the behavior of selected thermophysical properties of the superalloy under the influence of temperature. In this case, the thermal conductivity of the material increases with increasing material temperature. Also in [7], when analyzing the parameters of the post EDM surface layer, the high thermal conductivity of workpiece - steel HTCS was taken into account. The analysis of the results showed that the thickness of the white layer was in the range of 5-34.5 μm and depended mainly on the amount of thermal energy supplied to the workpiece. The amount of thermal energy that reaches the material and the speed of its propagation in the surface layer of the material depends on the thermal conductivity of the material.

The above examples of the analysis of the results of EDM process researchers indicate that the impact of the thermophysical properties of the electrodes material (workpiece material and tool electrode) significantly affect the selection of machining parameters and the efficiency of the process or the quality of the machined surface. Thus, the impact of these properties of the electrode material on stock removal, process efficiency or the quality of the treated layer is crucial to obtain effective machining.

The aim of this work is to investigate the influence of the thermophysical properties of five materials such as: tungsten carbide VHM, superalloy Inconel 718, carbon steel AISI 1045, copper alloy CuCr1Zr and aluminum alloy AW-2017A on the EDM process. The EDM process was performed using a brass tubular electrode with an outer diameter of 0.4 mm and a working fluid of deionized water. All tests were performed with same electrical pulse parameters such as gap voltage, current, cycle load (pulse on duration / pulse off duration). Moreover drilling process time was identical. The efficiency of the process was analyzed in terms of the material removal rate and linear wear of the working electrode as well as the geometric characteristics of the micro-holes (radial over cut, aspect ratio - the ratio of the hole length to its diameter). Finally, the results were linked to the thermophysical properties of the materials in which the micro-holes were drilled. The summary of test results in selected materials is also intended to show how strongly the thermophysical properties of the workpiece material affect the course of the process and performance factors.

Materials and methods

Material used for workpiece and tool.

Experimental EDM research was carried out in five selected materials:

- tungsten carbide VHM,
- Inconel 718 superalloy,
- AISI 1045 carbon steel,
- CuCr1Zr copper alloy,
- AW-2017A (AlCu4MgSi) aluminium alloy.

The selection of the materials was guided by their diverse thermophysical properties (see Table 1), as well as by their diverse chemical composition. Following scope of the article and the phenomena the EDM process, knowledge of selected thermophysical properties of the workpiece material is important. This is related to the impact of these properties on the EDM drilling process and on the efficiency of that process. For a more accurate analysis of the results, the chemical composition of each material was measured, which is shown in Table 2. The chemical composition was determined using an X-MET8000 X-ray spectrometer (Hitachi High-Tech, Tokyo, Japan).

Table 1. Thermophysical properties of the selected material.

Property (unit)	Workpiece Materials					Electrode Material

Brass tubular electrodes with external diameters of 0.4 mm and internal diameters of 0.215 mm were used for EDM drilling. Brass has good heat conductivity as well as low electrical resistance.

According to [24], brass is the best tool material for EDM machining. In addition, selected round electrodes are the best for micro-hole drilling [25].

Experimental details.

The micro-holes were made by electrical discharge machining on the custom made EDM machine. It is equipped with transistor controlled generator as well as NC controlled. In each type of workpiece 9 blind micro-holes were made. The drilling parameters in each material were the same and were selected in such a way as to ensure correct machining (minimize short circuits). The number of holes was chosen to reduce outliers from results evaluation. During the process, the tool electrode moved towards the workpiece with a feed rate controlled by gap voltage value and rotated at a constant rotational speed. The working fluid was fed with constant pressure through a channel in the electrode to the gap area between the electrode and the workpiece. The rotation of the working electrode and the continuous flow of working liquid under the narrow inter-electrode gap were intended to improve the stability of the process. These solutions improve the removal of erosion products (debris, air bubbles), reducing the possibility to occur short circuits or arc discharges. During the test, a new electrode was used in each of the tested materials in order to ensure the same working conditions for each workpiece material. To ensure electrical discharges to occur, both electrodes (tool and workpiece) were connected to an electrical pulse generator. Each hole was made with a fixed spindle displacement in the Z axis. Fig. 1 shows a diagram of the test stand.

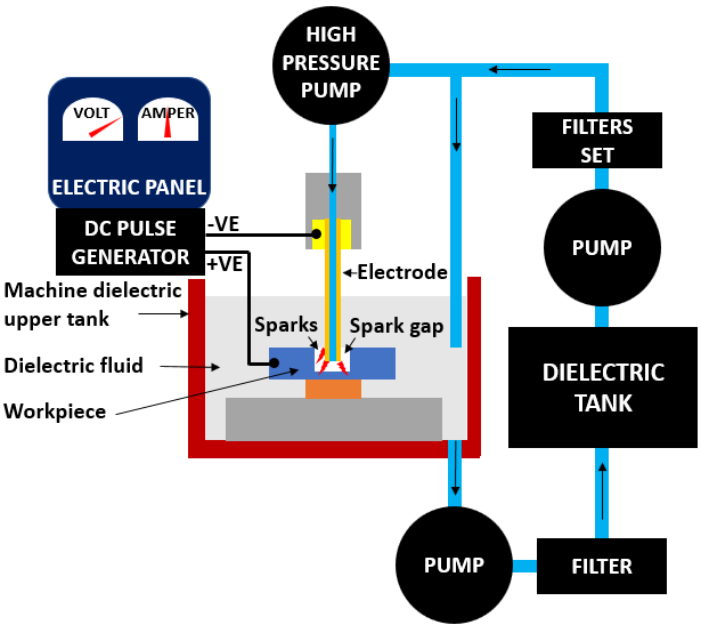

Fig. 1. Scheme of the EDM process test stand.

The drilling process was performed using the following conditions: current amplitude: 10 A, open voltage: 40 V, pulse on duration: 30 µs, pulse off duration: 30 µs, tool rotation speed: 500 rpm, capacitance: 1425 nF, working fluid: deionized water, working fluid temperature: 294 K, electrical conductivity of the working fluid: 10 µS/cm, working fluid pressure: 11 MPa, initial interelectrode gap: 100 V, the value of the spindle displacement in the Z axis: 8.9 mm, load cycle: 50%.
In this work below response parameters were analyzed:

- material removal rate (MRR), was calculated from the following equation:

$$MRR\ (mm^3/min) = V/t. \quad (1)$$

Where: V – volume of material removed, t – drilling time,

- linear tool wear (LTW, mm), determined as the shortening of the electrode along its length and measured after each hollow hole,
- the radial overcut (ROC), was calculated according to the below formula:

$$ROC\ [mm] = (D_{hole} - D_{electrode})/2. \quad (2)$$

where: D_{hole} – average input diameter, $D_{electrode}$ – outer diameter of the tool electrode, aspect ratio (AR), was calculated according to the formula:

$$AR = H_{depth}/D_{hole}. \quad (3)$$

where: H_{depth} – drill hole depth.
Diameter measurements were made using an Alicona C200 microscope (Alicona Imaging GmbH, Raaba/Graz, Austria). A dedicated lens with a high focal length was used for scanning. The vertical scanning resolution was 3 μm. The volume of material removed as well as holes geometry was measured using the GOM Inspect program (ZEISS, Oberkochen – Germany). The volume of the shallowest holes (< 1 mm deep) due to large on fluence of conicity on the volume of hole was directly measured using a volume measuring tool. In contrast, the volume of the deepest holes (> 1 mm deep) was measured as follows:

- a cylinder was created from the scanned hole, using the "best fit 3 sigma" method, which allowed the cylinder to be sufficiently matched to the scanned shape of the hole,
- cylinder diameter was measured,
- hole depth was measured,
- the volume of the hole (V_{hole}) was calculated using the formula:

$$V_{hole} = P_p \cdot H. \quad (4)$$

where: P_p [mm^2] – the surface area of the hole measured at depth 0.1 mm, H [mm] – hole depth.
In the case of holes made in aluminum alloy, due to their significant depth (H_{depth} > 6 mm), the holes had to be cut along the axis. This made it possible to measure accurately the depth of these holes.
The measurement results of the experimental studies are given in Table 3. Table 4 shows the calculated standard deviation for the determined result factors.

Table 3. Results of the experiments (average value).

Workpiece material	Results			
	V [mm^3]	t [s]	D_{hole} [mm]	H_{depth} [mm]
Tungsten carbide VHM	0.05	24	0.47	0.37
Inconel 718 superalloy	0.75	18	0.49	3.94
Carbon steel AISI 1045	0.53	19	0.50	2.67
Copper CuCr1Zr	0.11	47	0,48	0.67

Results and Discussions

Influence of the thermophysical properties of the electrode material on the efficiency of the process

In the EDM process, performance parameters such as material removal rate (MRR) and linear tool wear (LTW) play a key role [6]. Manufacturers are looking MRR increase options. At the same time tool wear generates about 50% of the crafting costs. Therefore TW reduction is expected. In addition, when producing micro-holes, electrode wear can be as high as 100%. As can be seen in the MRR result tables below, the process efficiency was different for each of the micro-holes analyzed. The highest material removal efficiency is observed for the AW-2017A aluminum alloy (about 6.5 mm^3/min) (Fig. 2a). Also, the other analyzed output factors turned out to have the highest values compared to the other materials (LTW - 2.25 mm, Fig. 2b, AR - 12.49, Fig. 2c). It is also worth mentioning that deep micro-holes production process, the material removal rate parameter is strongly related to the aspect ratio of the hole. This dependence is observed by analyzing the results in Fig. 2a and Fig. 2c.

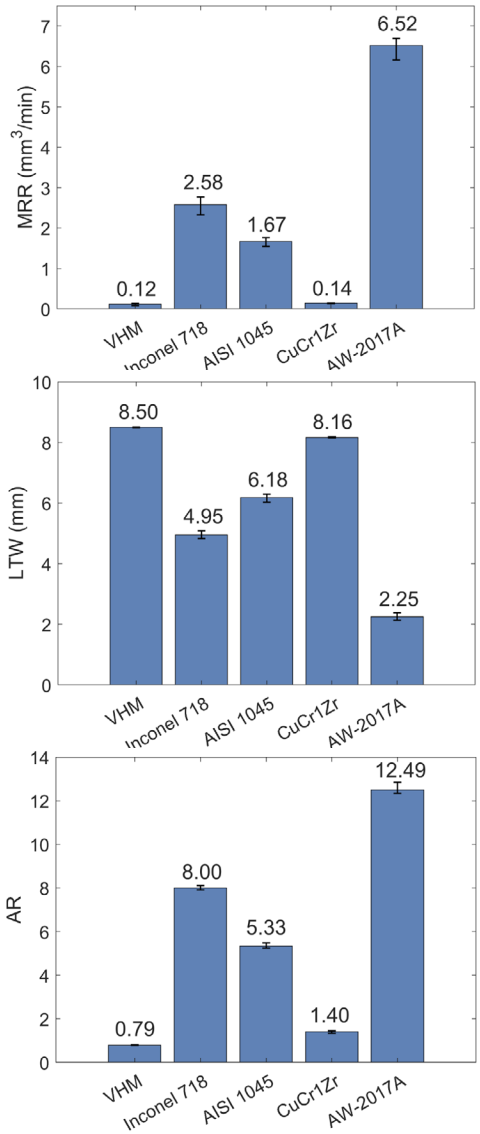

Fig. 2. The results of the EDM process factors: a) material removal rate (MRR), b) linear tool wear (LTW), c) aspect ratio (AR).

In the case of the electro-erosion process, one could conclude that the thermal conductivity of the workpiece material has the main influence on the material erosion process. This is related to the nature of the process. The nature of thermal phenomena that accompany electrical discharges and related extremely high temperature of the created plasma channel, approx. 4,000 – 8,000 K [26]. The consequence here is the non-stationary propagation of heat from the so-called surface sources, which are formed on the surfaces of the electrodes under the pressure of the plasma channel generated during the electro-erosive discharge. However, the analysis of the results shown in Fig. 2a for the MRR shows that it is the melting temperature that drives the performance of the EDM process. The highest MRR value (6.52 mm^3/min) was achieved for aluminum alloy. The thermal conductivity of this material (134 W/(m·K)) is similar to the thermal conductivity of tungsten carbide material (87.9 W/(m·K)). CuCrZr copper alloy, on the other hand, has an even better thermal conductivity than these materials (401 W/(m·K)). After analyzing the remaining thermophysical properties, the AW-2017A alloy has the lowest melting point (913 K) compared to the other analyzed materials (even lower than the melting point of the tool electrode material). This shows that the melting temperature of material is its property, which has a significant impact on the EDM process.

Further analysis of the results confirms the above statement. Analyzing the obtained results, VHM tungsten carbide also has good thermal conductivity (105 W/(m·K)). However, this material has a high melting point (approx. 2,273 K). The same applies to the CuCr1Zr chromium-circus alloy. This alloy also has good thermal conductivity (401 W/(m·K)), but has a high melting point (in the range of 1,338 - 1,356 K). A similar effect on the MRR of the thermal conductivity and melting point of materials can be observed for super alloy Inconel 718 and carbon steel AISI 1045 (thermal conductivity: 11.4 W/(m·K) and 48.1 W/(m·K), respectively, and melting point: 1,533-

1,609 K and 1,793 K, respectively). From the graph of Fig. 2a, it can be concluded that the material removal rate has similar values obtained for drilling in these materials.

Comparable conclusions were presented in [14], The authors indicate that material properties such as the melting point, the specific heat capacity and thermal conductivity affect the material removal rate during electro-erosion treatment of the material. The increase in these properties of the workpiece material cause its lower machinability by EDM, according to the index of resistance to the material erosion process given in [13]. In order to check how well selected materials can be machined by the EDM process, the erosion resistance index was calculated. The erosion resistance index (ER_{index}) calculations were made using the following formula (5) and are summarized in Table 5.

$$ER_{index} = \lambda \cdot c \cdot T^2. \tag{5}$$

where: λ – thermal conductivity (W/(m·K)), c – specific heat capacity (J(kg·K)), T – melting point (K). Calculated values of the erosion resistance index for individual materials presented in Table 5. The values of λ, c, T for the ER_{index} calculation were taken from Table 1 (in the case of a range of values, the maximum value in the range was considered). Equation (5) was used in accordance with the formula for calculating the machinability index by EDM presented in [13]. This formula shows that the square of the material's melting point has the greatest effect on the EDM's machinability of the material.

Table 5. Erosion resistance index of analyzed material (ER_{index}).

Tungsten carbide VHM	Inconel 718	Carbon steel AISI 1045	Copper CuCr1Zr	Aluminium alloy AW-2017A	Brass
Erosion resistance index ER_{index} [x 10^{10} $J^2/(m \cdot s \cdot kg)$]					
15.90	1.28	8.81	28.40	9.75	9.76

The calculated index of resistance to the EDM process confirms that its higher values for tungsten carbide VHM and CuCr1Zr alloy indicate that their EDM machinability is reduced. On the other hand, lower ER_{index} values for Inconel 718 superalloy, AISI 1045 carbon steel and AW-2017A aluminum alloy confirm the higher MRR value obtained. Also, according to the interpretation of the ERindex, a higher value indicates that a given material can be used as a tool electrode material. Certainly, the brass electrode is one of the most appropriate for the machining of Inconel 718 superalloy (the lowest ER_{index} obtained for Inconel 718, and the highest obtained ER_{index} for CuCr1Zr alloy). This is also confirmed by the obtained higher slenderness values (AR about 8) of the micro-holes hollowed out in this nickel-based superalloy.

In addition, the erosion resistance index informs how much wear of the working electrode can be expected when machining a given material. If the ER_{index} is higher, the material removal rate due to its poor EDM machinability will be lower. The working electrode will have to work longer and wear out more to remove the required amount of material.

It is also worth noting that the same drilling parameters and the same type of working electrode (with the same geometry, made of the same material) were used for the experimental research. The obtained results therefore show that the selected parameters and the type of working electrode are appropriate for drilling micro-holes in the AW-2017A alloy. This could also have influenced the most effective parameters for this material, such as MRR and LTW. The selected parameter values in this case ensured the stability of the process. In addition, the authors [14] also draw attention to the importance of thermal conductivity of the tool electrode material. The greater thermal conductivity of the working electrode material causes more heat to be dissipated in it. That turns in to the lower energy density of the electric discharge by that creating smaller craters on the

surface of the workpiece. Analyzing Fig. 2a, lower MRR values for Inconel 718 and carbon steel AISI 1045 can be associated with much lower thermal conductivity of these materials compared to the thermal conductivity of the working electrode material (λ lower by approx. 90% for Inconel 718 and approx. 70% for AISI 1045).

Influence of the thermophysical properties of the electrode material on the accuracy of micro-holes.

In the case of the analysis of micro-holes and their subsequent functionality in production parts, their high dimensional and shape accuracy is crucial. For this purpose, the radial overcut parameter of the micro-holes (ROC) was investigated (Fig. 4). The obtained results show that the ROC values are in the range of 0.03 - 0.06 mm. It can therefore be assumed that this parameter has similar values for analyzed materials. It can also be assumed that drilled holes are characterized by good dimensional accuracy.

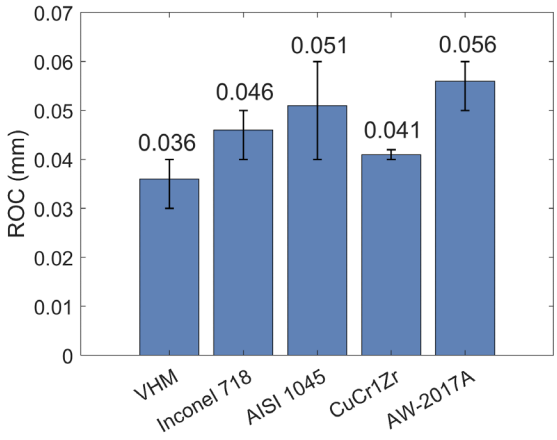

Fig. 4. The results of the geometric factor: radial overcut (ROC).

In addition, SEM images of the entrance of the wells showed the formation of a heat affected zone (HAZ) around the holes (Fig. 5). In case of VHM The HAZ layer includes also a material which has been melted but not fully removed and solidified at the edge of the hole. Such build-up material was not observed for neither Inconel 718 nor steel AISI 1045 which represent similar level of thermal conductivity. Large HAZ collar might result from heat being given off by a significant amount of re-solidified material formed at the edge of the hole drilled in the tungsten carbide. However, this certainly needs further investigation.

The SEM images for drilling in tungsten carbide and CuCr1Zr alloy show unremoved material at the bottom of the hole. In the literature, this phenomenon is called the “residual cylinder” [25] or “cone” [27].

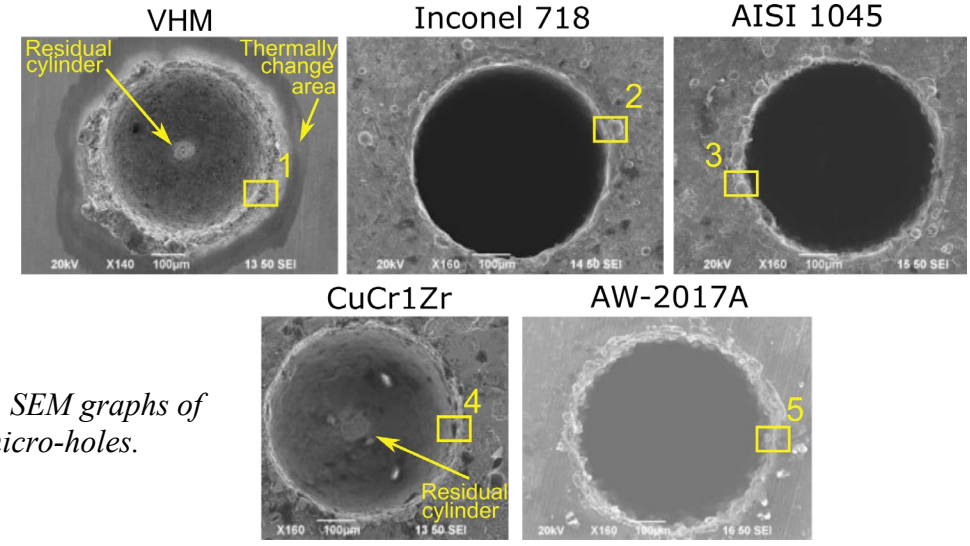

Fig. 5. SEM graphs of micro-holes.

Analysis of the hole entry shows clearly solidified material that has not been removed (Fig. 6). In addition, SEM photos and scans of the hole entry showed the so-called “residual cylinder” formed at the bottom of micro-holes drilled in tungsten carbide and copper alloy. This finding will be analyzed further in the article.

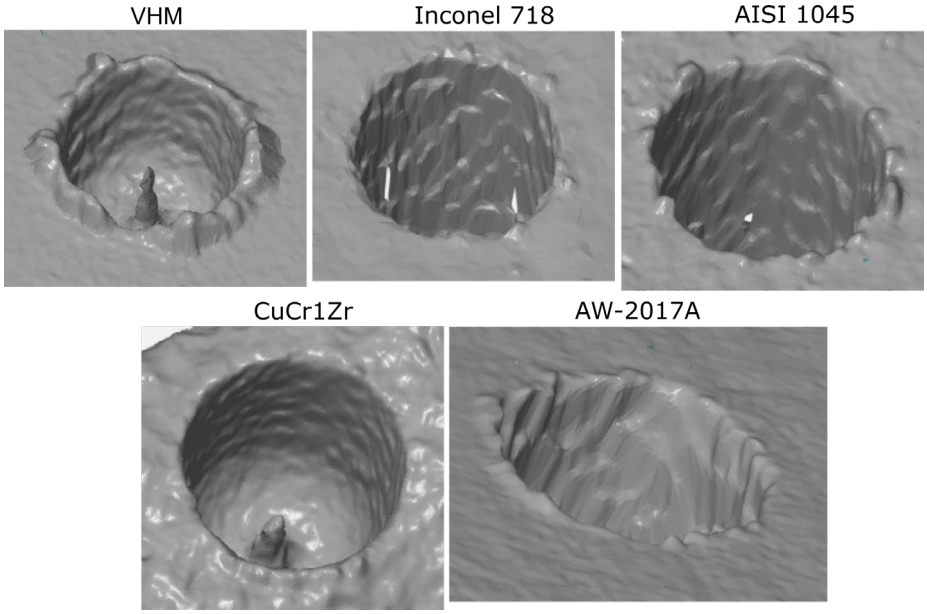

Fig. 6. Visualization of the entrance of micro-holes based on measurements.

Hole edge analysis (see in Fig. 7) showed that the smoothest edge was obtained for Inconel 718 superalloy and aluminum alloy. It is due to the good EDM machinability of these materials. Both have ER_{index} values lower or similar to brass. That is linked to the proper selection of the electrode material. On the other hand, on the edge of holes drilled in other materials, many defects such as microcracks and burrs. That is due to high ER_{index} and not optimized process parameters.

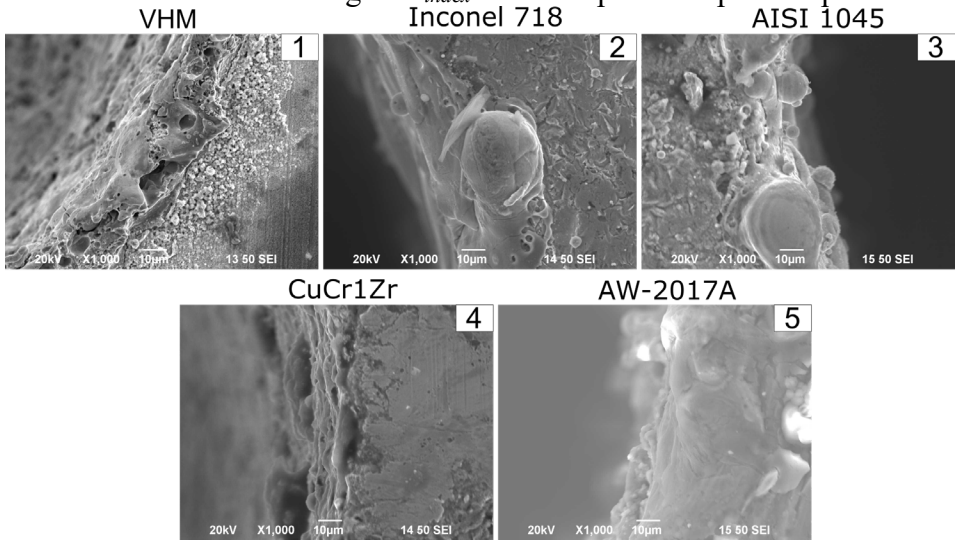

Fig. 7. Magnification of fragments marked as 1, 2, 3, 4, and 5, respectively, in Fig. 5.

In addition, VHM, CuCrZr and AW-2017A micro-holes cross-section reveals presence of residual cylinder located in the center of the hole bottom (Fig. 8). It represents not completely removed material. The measured height of the "residual cylinder" formed at the bottom of the holes drilled in the tungsten carbide, CuCr1Zr alloy and AW-2017A alloy was on average 0.30 mm,

0.17 mm and 0.25 mm, respectively.

The formation of the "residual cylinder" is influenced by the geometry of the working electrode - the tubular electrode, what has been explored in [25]. The front of the working electrode, due to the internal channel has a ring shape. Therefore, during the machining process, the heating of the material in the middle was lower comparing to material below the electrode “ring”. At the same time center of the hole receives more flushing what additionally cools that area. Thus, such conditions together with specific workpiece material properties prevented the effective removal of material in this area. In [27], it is explained that the "residual cylinder" is formed as result of the increased current density in the outside corner of the tool electrode tip. This increases the discharge frequency in the area of the bottom edge of the hole, and a lower frequency in the area on the bottom center. Uneven material removal together with higher flushing results in unremoved cone-shaped material. What interesting, remaining cylinder height increases together with the depth of the hole. In the analyzed test results, clearly visible that the cylinder remaining at the bottom in the holes has different shape or does not exist for different materials. Taking in to account that all holes were drilled with same material electrode and same parameters- all should present similar cone shaped bottom- assuming electric field is a main driver for that. Therefore it is suspected that “bottom cones” present in tungsten carbide and CuCr1Zr alloy results from the low machinability of these materials by EDM. When machining these materials, their thermophysical properties made stable machining much more difficult. What interesting, the aluminum alloy, in which the drilling was the fastest, the remaining cylinder at the bottom of the hole has comparable size to the one in carbide. That might be driven by high (the highest for selected materials) specific heat capacity. That parameter might prevent material removal similarly to high melting temperature of the VHM and high thermal conductivity of the copper alloy. Different properties produce similar result.

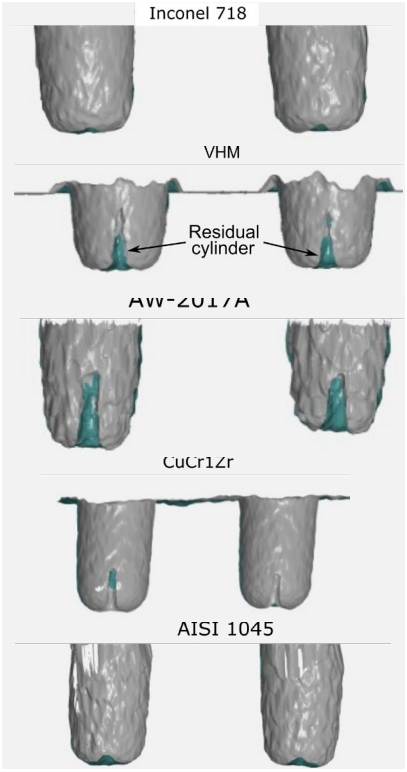

Fig. 8. Cross-sections of the bottom of the micro-holes.

Interestingly, both the Inconel 718 superalloy and AISI 1045 alloy present almost lack of a “residual cylinder” at the bottom of the holes drilled. This can be related to the lowest ER_{index} (for Inconel 718: ER_{index} = 1.28, for AISI 1045: ER_{index} = 8.81). At the same time ER_{index} of the working electrode material is higher brass ER_{index} = 9.75. This shows that in order to improve the accuracy of the bottom of the hole, the appropriate combination of electrodes is crucial. Despite the highest MRR value was obtained for aluminum alloy, the accuracy of the holes in this material requires improvement. On the other hand, the accuracy of holes drilled in Inconel 718 superalloy and AISI 1045 steel is acceptable, despite the lower efficiency of the EDM process.

Summary

The paper analyzes the impact of thermophysical properties of selected materials on the EDM performance. The analysis of the results showed that these material properties significantly affect the analyzed measures of the process such as MRR, LTW, AR. The greatest influence of properties such as melting point and thermal conductivity was observed on the EDM drilling process of micro-holes. The most important conclusions are as follows:

1. The best values were obtained for EDM drilling in aluminum alloy: MRR = 6.52 mm^3/min, LTW = 2.25 mm, and AR = 12.49. However, the accuracy of the geometry of micro-holes in this

material turned out to be unsatisfactory. Unremoved material in form ”residual cylinder” remained at the bottom of the hole.
2. Optimal values and high dimensional and shape accuracy (almost no “residual cylinder“ at the bottom of micro-holes) obtained for micro-holes drilled in Inconel 718 superalloy. Followed by: similar values and almost lack of „residual cylinder” presence in AISI 1045 steel.
3. Acceptable the EDM drilling process performance in Inconel 718 and AISI 1045 steel, was confirmed by the calculated erosion resistance index. The values of this index were the lowest for these workpiece materials (ER_{index} equal to 1.28 and 8.81, respectively for Inconel 718 and AISI 1045 steel), and were also lower than the value of this index for the working electrode material (ER_{index} = 9.76).
4. The results of the research carried out as part of this article show that other properties of modern engineering materials should also be taken into account during EDM process optimization.

Keywords: Electrochemical Machining, Effective Parameters, Material Modeling, Finite Element Method

Abstract. The process of electrochemical machining uses chemical reactions to dissolve material of the surface layer. This special kind of processing avoids undesired microstructural changes in the surface, such as the formation of dislocations. ECM is thus a very promising processing technique for high-strength materials. To model the complex chemical reactions in a computationally efficient manner, an inner variable is introduced, which describes the dissolution level of the material. The evolution of the inner variable is formulated based on Faraday's law of electrolysis. Furthermore, the use of an effective formulation of the necessary material parameters enables to consider this homogenized description of the dissolution process within an electrical finite element framework. Each effective material parameter is a result of classical mixture rules.

Introduction

Electrochemical machining (ECM) takes advantage of the anodic dissolution of metals, see exemplary in [1]. Due to the absence of mechanical loads during the ECM process, no undesired side effects, like formation of dislocations or residual stresses, occur. It is thus also possible to process even high-strength materials, see for instance [2-5].

The chemical reaction is driven by the electrochemical potential, whereby compared to electropolishing the electric part of the potential – and not the chemical one – is dominant. Fig. 1 schematically shows the idea of the process. The work piece and the tool serve as anode and cathode in the electrically loaded system. Due to the contact with the electrolyte and the already mentioned electrochemical potential the effect of the anodic dissolution takes place. This means that the metallic material depending on its valence dissolves into electrons, which go to the anode, and metal ions that are flushed away by the fluid. In reality – of course – the reactions are much more complicated, for instance due to a developing oxide layer, which would delay the dissolution process, as well as due to reactions at the cathode. The authors propose a new strategy [6], which is kept simple for the beginning and will be further extended step by step in future works. For the consideration of the oxide layer's influence on the dissolution of the work piece, a first approach is proposed in this article.

The next two sections deal with the generalized modeling concept using a smoother description of the dissolution as well as the related evolution equations. The idea has been already introduced in [6]. In the following, an introduced flow function enables to consider the influence of the already mentioned oxide layer. The article is completed by two simulations and conclusions in the later sections, respectively.

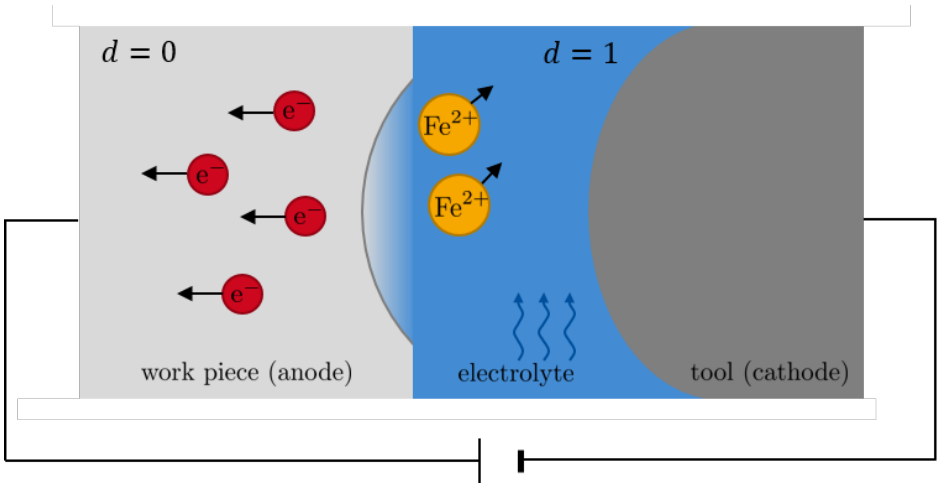

Fig. 1. Concept of the dissolution process with iron-based dissolution, see also [6,7]: dissolution variable $\boldsymbol{d}$ *varying between* $\boldsymbol{d = 0}$ *in the metal and* $\boldsymbol{d = 1}$ *in the electrolyte.*

The Concept of Effective Parameters Using the Dissolution Level as an Inner Variable

The inner variable d describes the state of the dissolution process. Hence, it is zero for the undissolved metal material and one for the completely dissolved material and thus for the electrolyte. At this point, for simplicity, the assumption is made, that the metal ions are permanently removed by the fluid flow. During the chemical reaction, d ranges between zero and one. Each material parameter at each material point within the simulation is then determined using a classical mixture rule. The resulting effective parameters are then marked by $\overline{(\cdot)}$. Depending on the choice of a series or parallel connection, they have one of the following forms

$$\overline{(\cdot)}_S = \left[(1-d)\frac{1}{(\cdot)^{ME}} + d\,\frac{1}{(\cdot)^{EL}}\right]^{-1} \tag{1}$$

$$\overline{(\cdot)}_P = (1-d)(\cdot)^{ME} + d\,(\cdot)^{EL} \tag{2}$$

respectively. Therein, $(\cdot)^{ME}$ and $(\cdot)^{EL}$ correspond to the individual material parameters of the metal and the electrolyte.

The conservation of electric charge that describes the electrical part of the observed multiphysical problem reads

$$\dot{\rho}_E + \mathrm{div}(\boldsymbol{j}) = 0 \tag{3}$$

wherein, the charge density ρ_E and the current density $\boldsymbol{j}$ depend on the field strength $\boldsymbol{E}$. They have the following forms

$$\rho_E = \mathrm{div}(\epsilon_0\,\bar{\epsilon}_r(d)\,\boldsymbol{E}) \tag{4}$$

$$\boldsymbol{j} = \bar{\kappa}_E(d)\,\boldsymbol{E} \tag{5}$$

with the material related and based on Eq. 1 or 2 effectively chosen relative permittivity $\bar{\epsilon}_r(d)$ and electric conductivity $\bar{\kappa}_E(d)$, the electric constant ϵ_0 as well as $\boldsymbol{E}$.

The primary unknown of the electrical problem is the electric potential v. Not yet obvious in the presented equations, its gradient is considered within the electric field strength via

$$\boldsymbol{E} = -\mathrm{grad}(v) \tag{6}$$

The original paper [6] additionally considers a thermally coupled system. There also a more detailed description of the effective parameter approach can be found, which is also later used for the consideration of a relocatable cathode in terms of a moving boundary value problem [7]. Due to simplicity, the additional thermal problem is skipped, here. More information on the finite element formulation and implementation can be found in [6,8].

Evolution of the Dissolution Level Based on Faraday

The anodic dissolution leads to the split of a metal atom into electrons and ions, see also Fig. 1. The temporal amount of the dissolution by this reaction can be described by Faraday's law of electrolysis. Motivated by [9] and introduced in [6,7], one can formulate the evolution equation of the inner variable d. The dissolution level of an incremental reference volume $\mathrm{d}V_{ref}$ reads

$$\dot{d}\ \mathrm{d}V_{ref} = v_{dis}\ \mathcal{A}\ \mathrm{d}I. \tag{7}$$

In Eq. 7, v_{dis} is a material parameter which is experimentally observed by our project partners of the *Werkzeugmaschinenlabor (WZL)* at RWTH Aachen University. It is thus not only related to Faraday's law but also to the efficiency of the performed experiment. The quantity $\mathrm{d}I$ describes the increment of the electric current. Furthermore, the dissolution only takes place if the material has contact to the electrolyte. To account for this constraint, the activation function $\mathcal{A}$ is introduced. The latter becomes one for contact with the electrolyte and is otherwise zero. This ensures that the anodic dissolution only takes place in material layers, which are at the surface.

Consideration of a Formed Oxide Layer and Its Damping Properties

The former sections deal with the state of the art of the new method to describe the ECM process. In the following, the modeling approach is extended to consider the oxide layer formation in dependency on $\boldsymbol{j}$. During the ECM process, one can observe the formation of such a layer on the anodic surface (see Fig. 2), which shows a diode-like influence on the electric problem and, thus, serves with the polarization voltage Δv_p as a barrier that has to be overcome before the dissolution process in the trans-passive regime can start.

The considered modeling strategy to methodologically describe the ECM process, was - due to our origin in mechanics - always driven by the idea of applying general solution schemes of mechanical problems to the electrochemical one. The presented work focuses on the more dominant trans-passive area and for simplicity neglects the removal at low current densities before the passivation of the material. Following the characteristics of a yield function in plasticity, a flow function ϕ^{OX} is introduced. As long as $\phi^{OX} \leq 0$, the oxide layer serves as an isolating barrier, preventing the electric flow. When $\phi^{OX} > 0$, the current flow over the surface as well as the dissolution process are initiated. A first assumption for a one-dimensional formulation of ϕ^{OX} reads:

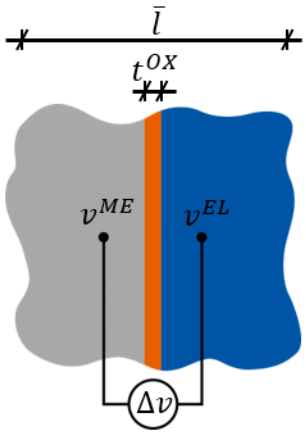

Fig. 2. Unit cell for the surface area with a characteristic length $\bar{\boldsymbol{l}}$: metal (grey) with potential $\boldsymbol{v^{ME}}$, oxide layer (orange) with thickness $\boldsymbol{t^{OX}}$ and electrolyte (blue) with potential $\boldsymbol{v^{EL}}$.

$$\phi^{OX} = |\boldsymbol{v}^{ME} - \boldsymbol{v}^{EL}| - \Delta v_p = \begin{cases} \leq 0 : \text{insulating} \\ > 0 : \text{conducting} \end{cases} \tag{8}$$

The choice of the flow function is based on experimental observations. The electric flow through the oxide layer and, thus, the material dissolution can start when the flow function is positive. Physically, this means that the potential difference

$$\Delta v = |v^{ME} - v^{EL}| \tag{9}$$

is higher than the polarization voltage Δv_p. For the three-dimensional case the formulation of a flow function is much more complicated. The reason for that is that one has to check the potential difference in each direction, especially for curved surfaces. But, this formulation is part of our future works.

Furthermore, the existence of the oxide layer also influences the effective material parameters. According to the chosen approaches in Eq. 1 and 2, they read

$$\overline{(\cdot)}_S = \left[(1-d)\frac{1}{(\cdot)^{ME}} + \frac{t^{OX}}{\bar{l}}\frac{1}{(\cdot)^{OX}} + d\frac{1}{(\cdot)^{EL}}\right]^{-1} \tag{10}$$

$$\overline{(\cdot)}_P = (1-d)(\cdot)^{ME} + \frac{t^{OX}}{\bar{l}}(\cdot)^{OX} + d\,(\cdot)^{EL} \tag{11}$$

Therein, $(\cdot)^{OX}$ corresponds to the parameters of the oxide layer, which are weighted by its thickness t^{OX} in relation to the effective length $\bar{l}$ of the examined unit cell.

Finally, the introduction of a modified current density $\boldsymbol{j}_{mod}$ enables to take into account the insulating character of the oxide layer. It has the form:

$$\boldsymbol{j}_{mod} = \begin{cases} \boldsymbol{0}, & \phi^{OX} \leq 0 \\ \boldsymbol{j} - j_0\boldsymbol{n}, & \phi^{OX} > 0 \end{cases} \tag{12}$$

with the normal $\boldsymbol{n}$ on the metal surface and a reduction term

$$j_0 = \kappa_E^{OX}\left(-\frac{\Delta v_p}{t^{OX}}\right) \tag{13}$$

Numerical Results

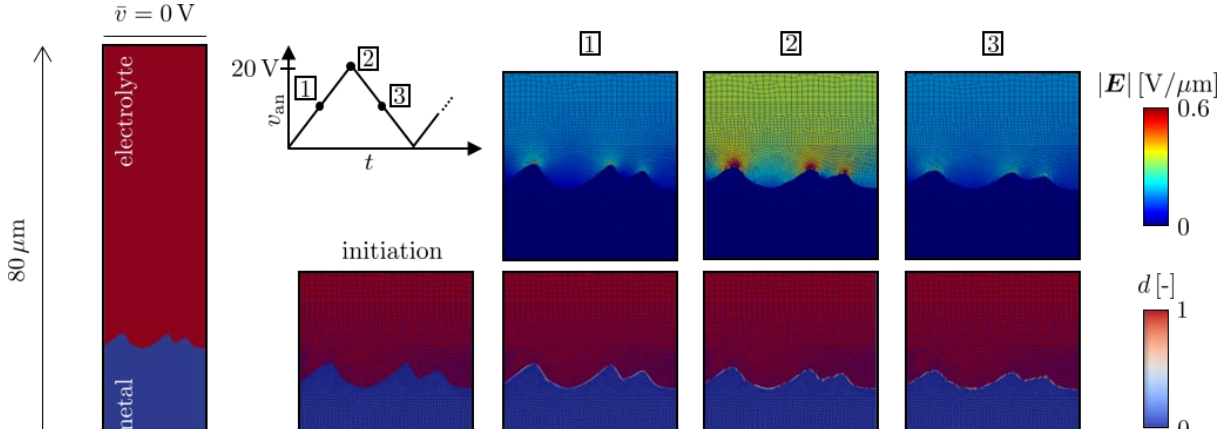

Fig. 3. Pulsed electrochemical machining with initial non-uniform roughness and without consideration of the oxide layer: boundary value problem (left) as well as norm of the electric field strength $\boldsymbol{E}$ and dissolution level $\boldsymbol{d}$ for different load steps during the first cycle (right).

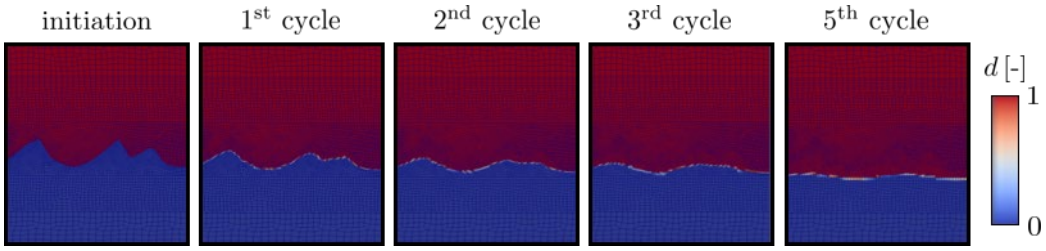

Fig. 4. Pulsed electrochemical machining with initial non-uniform roughness and without consideration of the oxide layer: dissolution level $\boldsymbol{d}$ *after individual load cycles.*

Within this chapter, two simulations are presented. The used material parameters are given in [6]. The first example shows the simulation of a pulsed electrochemical processing of a material surface with an initial non-uniform roughness and without considering the influence of the oxide layer. Fig. 3 (*left*) shows the boundary value problem. The electric potential is prescribed at the anode and linearly varied between 0 V and 20 V. It is zero at the cathode. On the right part of Fig. 3, the norm of the electric field strength and the dissolution level for different time steps of the first pulse are presented: The electric field strength is highest at the peaks of the structure and results in a faster dissolution, there. The flattening of the surface roughness is also presented in Fig. 4. It shows the dissolution level before the first, after the first, second, third and fifth cycle. Similar simulations with a different initial roughness are also given in [6] and [10].

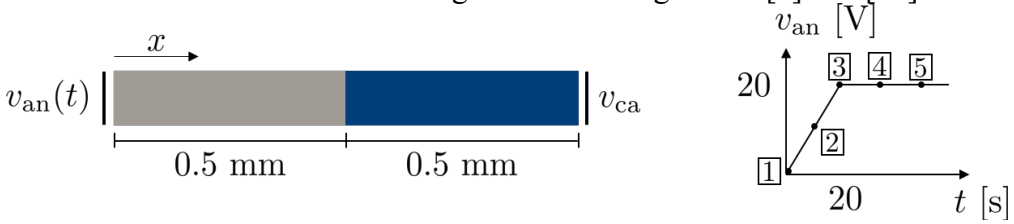

Fig. 5. Electrochemical machining with consideration of the oxide layer: boundary value problem (left) and prescribed electric potential at the anode with marked load steps (right).

In the second example, a one-dimensional academic problem is assumed as presented in Fig. 5. The electric potential at the cathode is prescribed with zero. At the anode the potential is linearly increased to a maximum value of 20 V and then kept constant. The assumed polarization voltage reads $\Delta v_p = 1.5$ V. Fig. 6 shows the resulting dissolution level and the electric potential for some chosen times steps, which are marked in Fig. 5. The results for this first simulation considering the oxide layer show that before the difference between the electric potential in the metal and the electrolyte reaches the critical value of the polarization voltage no material dissolution takes place. After that, the chemical reaction is initiated and the dissolution begins.

Summary

The presented model contributes to the field of modeling the anodic dissolution during electrochemical machining. The formulation is based on the use of effective material parameters.

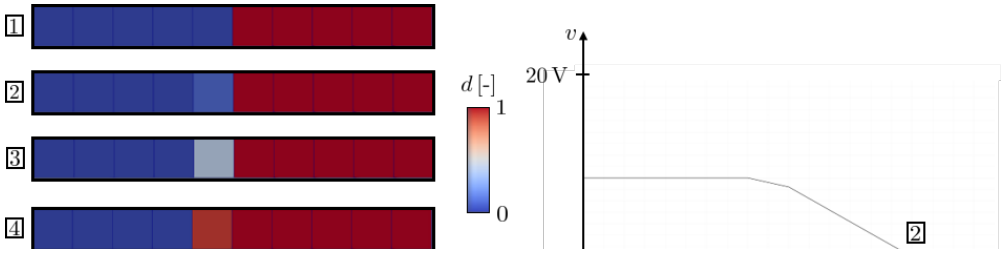

Fig. 6. Electrochemical machining with consideration of the oxide layer: dissolution level $\boldsymbol{d}$ *(left) and electric potential* $\boldsymbol{v}$ *plotted over* $\boldsymbol{x}$ *(right) at marked load steps, see Fig. 5.*

Compared to our earlier works, an idea is proposed how the influence of a formed oxide layer can be taken into account and which thus refers to the trans-passive area of the electrochemical process. The presented numerical results reveal the complex mechanism.

The earlier described material model already accounts for the iron-based dissolution based on Faraday's law of electrolysis. Now, the model also accounts for a polarization voltage which has to be overcome within the trans-passive area, before the removal can start. But, of course, it is still a simplification of the complex and coupled chemical reactions. Besides further three dimensional simulations of the ECM process – also in combination with the removal before passivation – in future works, the modelling approach must be able to consider the full electrochemical potential to describe the material dissolution of the individual alloying elements at the anode. Additionally, a polycrystalline structure and different phases of the metal will be included, which influence the resulting surface roughness. Once the reactions at the anode will be described in more detail, the focus of further works will lie on the reactions at the cathode and the fluid structure interaction. The presented model neglects these local effects on the dissolution process and assumes, so far, that developed heat, gases and ions are permanently transported away by the electrolyte.

Keywords: Sinking Electrical Discharge Machining, Cemented Carbide, Coefficient of Friction

Abstract. Cemented carbides possess properties that predestine them as a durable tool. However, these properties hinder conventional machining, which is why Electrical Discharge Machining (EDM) is a promising alternative. Three different EDMed cemented carbides were compared with a ground surface in a pin-on-disk test setup. They were evaluated under dry and lubricated conditions with two distinct antibody materials. The tests did not reveal a correlation between the surface roughness of the cemented carbide pins and the coefficient of friction. However, some test sets yielded very different results, which is why particular considerations should be made with new sliding compositions.

Introduction

The requirements for tools used in forming processes are subject to a continuous increase [1]. On the one hand, higher strength materials are used as workpiece material in forming in order to implement lightweight design. On the other hand, the tolerances become narrower to allow net-shape production, reducing subsequent machining steps and increasing material efficiency. Both developments result in higher tool loads and thus shorter tool life time [2,3]. Therefore, it is part of current research to investigate the properties and applicability of new tool materials such as cemented carbides [4,5]. Cemented carbides can resist high compressive stresses and are significantly harder than conventional tool materials. This makes cemented carbides substantially more resistant to wear [6]. However, these properties hinder conventional machining simultaneously. Grinding is only possible in the case of certain geometries and milling proves to be very challenging [7]. One alternative applied to machine forming tools from cemented carbides is electrical discharge machining (EDM) [8]. Due to its thermal working principle, EDM is able to machine workpieces independently from their mechanical properties [9]. EDM employs several thousand discharges per second, which are temporally and spatially very confined. These discharges consist of plasma, which melts and evaporates the adjacent material. On the one hand, not all material that is molten is also removed from the discharge location and thus leads to the formation of a recast layer, also known as white layer due to its appearance in cross sections. On the other hand, not all heat that is transferred from the plasma to the workpiece is involved in melting or evaporating the material. Some of the heat is transported further below the surface but only heats the material up to a certain temperature. In some cases it can reach the corresponding phase transformation temperature. Because the amount of heat is very little for each single discharge, it is quickly dissipated into the periphery. This leads to rapid cooling and in some cases a freeze of the material in the current phase and geometry [10]. The tensions resulting from this process can lead to residual stresses and cracks. Especially cemented carbides are prone to these effects, because they consist of two or more different phases with different thermophysical

properties. One way to reduce the impact on the workpiece is the application of a sequence of different machining steps each subsequent one with lower heat input. This sequence allows for productive machining whilst keeping the effect on the rim zone as small as possible. For cemented carbides, it has been proposed [11] to use needle type discharges in order to optimise production with both objectives in mind. It has been shown that this approach can be applied successfully for fine and ultra-fine grained cobalt cemented tungsten carbides [12]. It could also be seen that the surface roughness changed from one machining step to the other. Therefore, the objective of this research is to identify the influence three different surface topographies of two different cemented carbide grades have on the sliding behavior with two different antibodies and tested in two different lubrication conditions. Several authors have published research regarding the tribological behaviour of cemented carbides [13,14], because of their properties that destine them for the use as forming tools. Another aspect that is regularly researched is the tribological performance of surfaces produced by EDM. It has been shown, that the craters can serve as reservoirs for the lubricant or to reduce particles in the contact zone [15,16]. Additionally, Sari et al. [17] compared the load carrying capacity of wire EDMed gears to those manufactured with profile grinding and found that the characteristic surface structure resulting from the EDM process leads to beneficial tribological conditions in rolling contact. They attributed this to the statistical and non-directional crater structure resulting from EDM, which allows the roughness to get flattened instead of resisting the load and thus reducing the peak stresses in the material. However, it must be expected that the effects are different in this case because the investigated material was hardened 16MnCr5 instead of the present cemented carbide, which will most likely not be reshaped by the counterbody. In contrast, Bergs et al. [18] did not get the same results in a disk-on-disk test comparing wire electrical discharge turning (WEDT) to grinding. In their case, the flattening of the WEDTed surfaced did not yield the same surface roughness as the ground specimen. However, it has to be noted that the WEDT processes is more challenging than WEDM because of an increased punctiform heat input and the need for a precise runout in combination with the moving wire. The present paper aims to combine both elements and investigate the tribological behavior of cemented carbides machined by EDM.

Experimental Setup

The experimental setup was chosen according to previous investigations, however, some alterations have been made. The process of specimen preparation was the same as previously [19]. The only difference lies in the geometry of the tested pin. For the present investigations, the specimens had a convex contact area and the body of the pin was 10 mm by 10 mm. The radius of the convex area was 20 mm. As depicted in Fig. 1 on the left, the cemented carbide pins were cut from blocks via wire electrical discharge machining (WEDM) with an oversize on the top of the pin of 1 mm. This oversize was then removed via sinking electrical discharge machining (SEDM). The oversize and the machining technology of SEDM were chosen in order to make the material experience the roughing steps of the technology whilst still reaching the best available surface finish of Ra = 0.2 µm. The technology was applied three times in a different way. The first pins were created whilst only applying the first machining step. This machining step is called roughing. The second set of pins was created using the first machining step and all steps necessary to reach a surface roughness of Ra = 1 µm. This machining operation is called finishing. The third set of pins was created using all the previous machining steps and all additional machining steps in order to reach a surface roughness of Ra = 0.2 µm. This machining operation is called super-finishing. Both GFMS EDM machines used hydrocarbon oils as dielectric. While the Cut 2000 X Oil Tech used IonoFil 100, the Form 2000 VHP used Ionoplus IME-MH, both by the company oelheld. The tool materials were 0.2 mm brass wire for WEDM and copper tungsten (WCu) with 80 wt% for SEDM. The materials of the pins were CTF30 and UMG01 by Ceratizit [20]. CTF30 consists of 15 wt% cobalt and tungsten carbide grains with a size of 0.8 - 1.3 µm, whereas UMG01 does not

contain a significant amount of binder material and consists of tungsten carbide grains with a size of 0.2 µm. The friction test was conducted according to previous investigations [19, 21]. The setup can be seen in Fig. 1 on the right hand side. The cylindrical antibody was mounted on a lathe and rotated with a constant angular velocity of $\omega = 312.5\ min^{-1}$ resulting in a surface velocity relative to the pin of $v = 6.25\ m \cdot min^{-1}$. Two different antibody materials were used in this investigation: 42CrMo4 and 16MnCr5. The radii of the cylinders were r = 20 mm each. The pins were pressed on the rotating cylinder with a force of $F_n = 5000$ N. The force F_n was controlled with a 9011A force sensor and the resulting force F_t with a 9257B dynamometer, both by Kistler. In order to evaluate the effect the eroded surface has on the transport of lubricant, the tests were conducted with and without minimal quantity lubrication. In the case of lubrication, the Lubrimat L60 by Steidle was used to apply single drops of lubricant every few seconds.

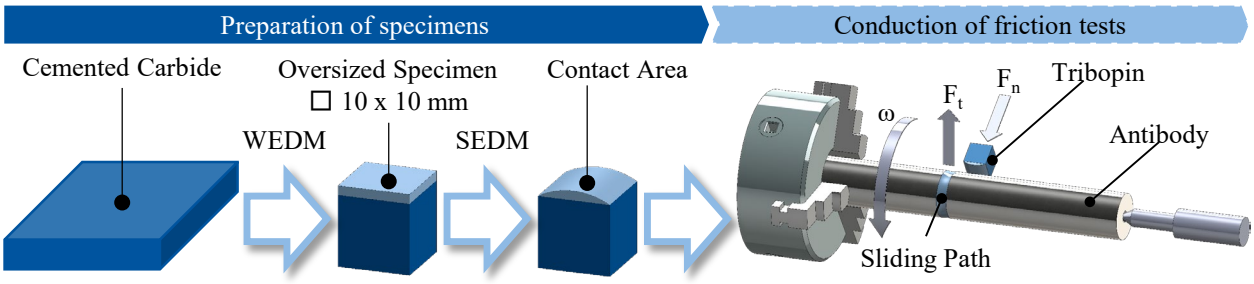

Fig. 1. Process of preparation of specimen and test setup according to [21].

Three different outputs from the tests were evaluated. Firstly, the tangential force F_t resulting from the applied force F_n and the rotation ω were measured. An arrow indicating this force F_t can be seen in Fig. 1 on the right. However, because of the difficulties described in a previous publication [19], where the investigations were conducted according to the setup schematically depicted in Fig. 2, top left was changed. There, the theoretical contact between the specimen and the antibody was a line. Because material was quickly sticking to the surface of the specimen and the antibody was reshaped during the test procedure, the stick-slip effect occurred. This caused strong vibrations and increased the overall level of the detected tangential force, which can be seen in Fig. 2, left bottom. In order to prevent the stick-slip effect and the resulting vibration, the test setup was revised according to the schematic drawing in Fig. 2, right top. Here two cylinders can be seen that are placed orthogonally to each other. The actual pins were only a cuboid cutout of the rear cylinder, which does not affect the contact area. Both cylindrical surfaces have the same radii of r = 20 mm. This setup theoretically causes a point contact, which reduces the risk of vibration. It can be seen in the graphs comparing the two setups that the revised setup is able to measure the force without vibrations or deviations. The subsequent evaluation of the measurements is a lot more stable and reliable since the section to be evaluated does not have to be chosen manually.

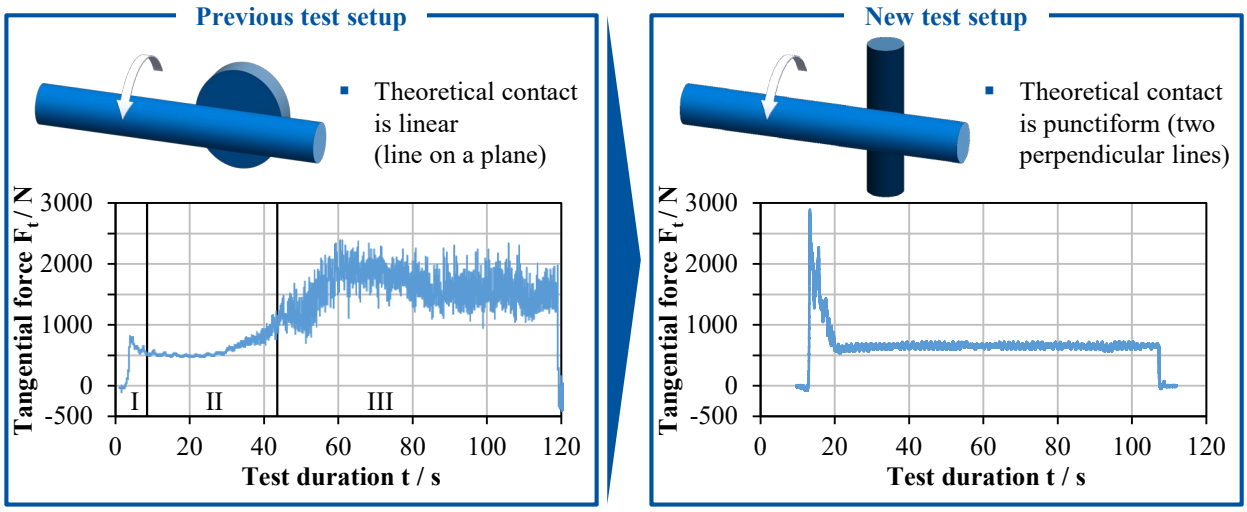

Fig. 2. Comparison of previous and revised test setup [19].

The second and third output from the investigation are the surfaces of the specimen and the antibody. Both were investigated using the optical microscope Smartzoom 5 by Zeiss. For comparison, some cemented carbide pins were ground to the desired shape with a diamond grinding wheel bound with artificial resin. Since each experiment was conducted thrice, the according number of pins had to be created from the corresponding materials. This totaled in a number of 96 pins, 48 from each cemented carbide grade and 12 of each surface finish.

Results

In order to give an idea of the surfaces that were created with the different machining operations described in the experimental setup, Fig. 3, left depicts the average surface roughnesses of all pins used in this investigation. For statistical reasons, all pins were tactilely measured three times with a Waveline 800 by Jenoptik. The colours of the columns indicate the material, with dark blue being CTF30 and light blue being UMG01. As expected, it can be seen that the surface roughness decreases with the increased number of machining steps. However, a clear difference between the two materials can be perceived as well. The surface roughness of UMG01, the small grained and binderfree material is significantly smaller for all compared surface conditions. As described by Bergs et al. [22], this difference cannot entirely be attributed to the smaller grain size. For the roughed specimen, the white layer, which consists of molten and resolidified material, is significantly larger than the largest protruding WC grains.

On the right hand side of Fig. 3 the average coefficient of friction is depicted. The coefficient of friction μ is the quotient of the two forces F_t and F_n as shown in Eq. 1. Because the applied force F_n varied slightly from test to test, both forces were measured and averaged over the same duration as denoted in Fig. 2, right bottom.

$$\mu = \frac{F_t}{F_n} \tag{1}$$

In this part of the investigation, the averages are calculated over all surface conditions of the pins. The purpose of this diagram is to highlight the difference between the two antibody materials. However, the differences are marginal. For both antibody materials, the average coefficient of friction (COF) appears to be the same with respect to the lubrication condition. It can be noted that the coefficients of friction (COFs) with dry 42CrMo4 are slightly larger than those with 16MnCr5, while the deviation is a little larger as well. In the lubricated condition, this result is turned around and the COFs with 42CrMo4 are slightly smaller than those with 16MnCr5. From the present

results it can be presaged that the described effects are a little more dominant with CTF30 than with UMG01, while there is no difference detectable within the cemented carbide pins with 16MnCr5. Regarding this evaluation it can be stated that the antibody materials do not seem to have a strong effect on the COF.

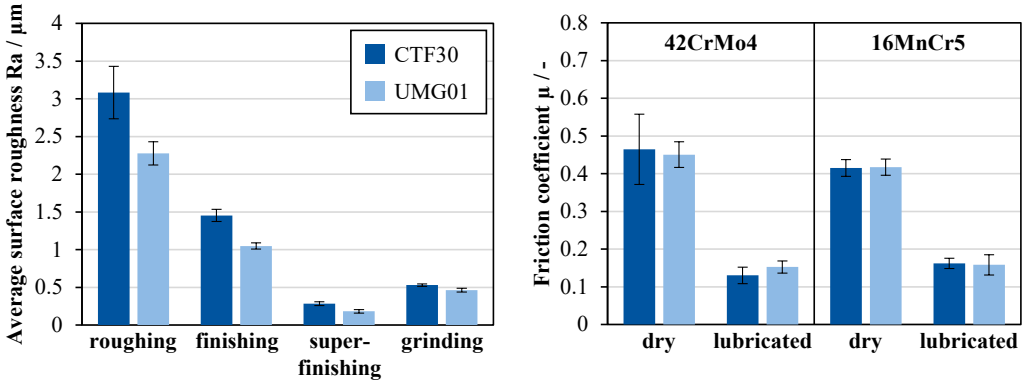

Fig. 3. Average surface roughness of the cemented carbide pins and the average coefficient of friction for both antibody materials and both lubrication conditions.

A more detailed analysis of the COFs is depicted in Fig. 4. Here both cemented carbides and all surface and lubrication conditions are separately displayed for the antibody material 42CrMo4. On the left hand side, the COF is shown as it appeared without any lubrication and on the right hand side it is shown as it appeared with the application of lubricant. Regarding the dry condition, a large deviation can be seen for the ground CTF30 specimens. Here one ground pin yielded a COF of 0.75, which was much higher than all the other results. In general, there is no correlation between the surface roughness and the COF. For CTF30, the worst COF of the eroded specimen resulted from the finished pins. The roughed and super-finished surface conditions resulted in the lowest COFs. For the eroded UMG01 pins, no significant difference between the COFs can be recognized and it should be noted that these results have very little deviations. Only the ground UMG01 pins have significantly lower COF of around 0.4.

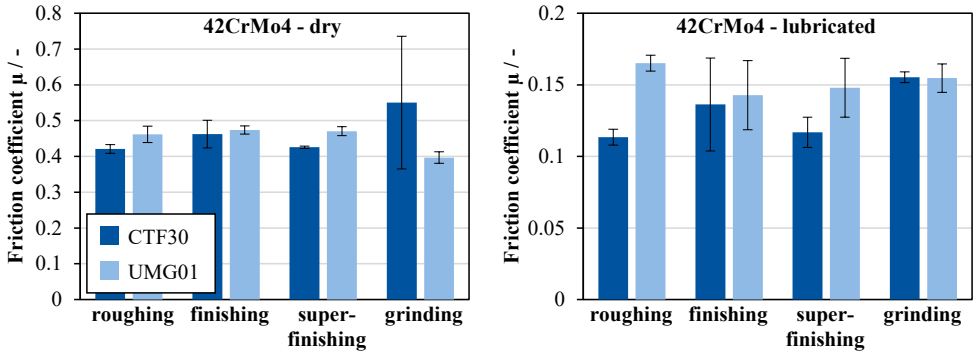

Fig. 4. Coefficients of friction for 42CrMo4, all surface conditions of the cemented carbide pins and for both lubrication conditions.

The deviations appearing in the diagram on the right hand side of Fig. 4 appear to be significantly larger than those from the unlubricated surface condition on the left hand side. However, it needs to be emphasized that the scale is different and the largest deviations on the right are slightly smaller than those of the finished CTF30 pins on the left, which is the largest

without considering the ground CTF30 pins. The lubricated CTF30 pins show a very similar appearance to the unlubricated ones. The finished CTF30 pins result in the largest COF for the eroded pins and the roughed and super-finished pins result in very similar COFs. All eroded CTF30 pins result in a lower COF than the ground pins. This might be caused by an effect suggested by Sari et al. [17]. They described the capability of the discharge craters to transport a lubricating medium into the contact area. They found that the durability of gears machined by EDM can be higher because of this effect and in contrast to the doubts created by the harmful effect EDM has on the surface integrity. However, the same effect cannot be seen for the pins made of UMG01, even though the ground pin has almost exactly the same COF as the one made from CTF30. The finished and super-finished UMG01 pins have a slightly lower average COF, but the deviations are large enough to range them on the same level as the ground pin. Furthermore, in contrast to CTF30, the roughed UMG01 pins have the highest overall COF for this lubrication condition and antibody material. Especially, when comparing the two results for the roughed pins, which both have a very little standard deviation, it becomes apparent that there must be a difference resulting from the material of the specimens.

The second antibody material investigated was 16MnCr5. The resulting COFs are displayed in Fig. 5, where the non-lubricated condition is shown on the left and the lubricated condition is shown on the right. For the dry condition, no successful tests could be conducted for the roughed and the ground UMG01 specimen. The specimen broke or the force was quickly overreaching the measurement scale, indicating an upcoming breakage. This happened for all the specimen of the corresponding test series even though the tests were conducted in a randomized order, which reduces the chances that this result is solely caused by an outlier. All other tests on this antibody material have worked in the same way as on 42CrMo4 and have shown the same force pattern as seen in Fig. 2. The remaining COFs from the dry constellation show very little variance. Neither the material of the specimen nor the applied surface finish seems to have a significant influence. In comparison to the antibody material 42CrMo4, which has an average COF for the dry condition of 0.46, the average COF is slightly lower with a value of 0.42. The lubricated condition displays a very different result. Here, the COFs vary throughout both investigated parameters. For CTF30, the differences are only slight, but it can been seen that the COF shrinks with a decreased surface roughness for the eroded specimens. The ground specimens however, yielded the highest COF, albeit not having the highest surface roughness. All results for CTF30 are within a smaller range than the results of UMG01. Especially, between the roughed and the finished specimens there is a large difference, with the prior having the smallest COF on this antibody material and the latter having the highest COF for all tests conducted under the lubricated condition. The super-finished and the ground UMG01 specimens have a very similar average COF, however, the deviation was larger for the super-finished specimens. When comparing the two antibody materials for the lubricated condition, it becomes apparent that 42CrMo4 yielded a lower average of 0.14 but the deviations in the test were significantly larger. In contrast, the average COF for the lubricated 16MnCr5 was 0.16 with a relatively small deviation. Additionally, the comparison of the cemented carbide pins for the lubricated tests also reveals an interesting difference. For 42CrMo4, UMG01 does not appear to be affected by its surface condition. In contrast, for 16MnCr5, UMG01 yielded different results for different surface conditions. The results for CTF30 can be read vice versa.

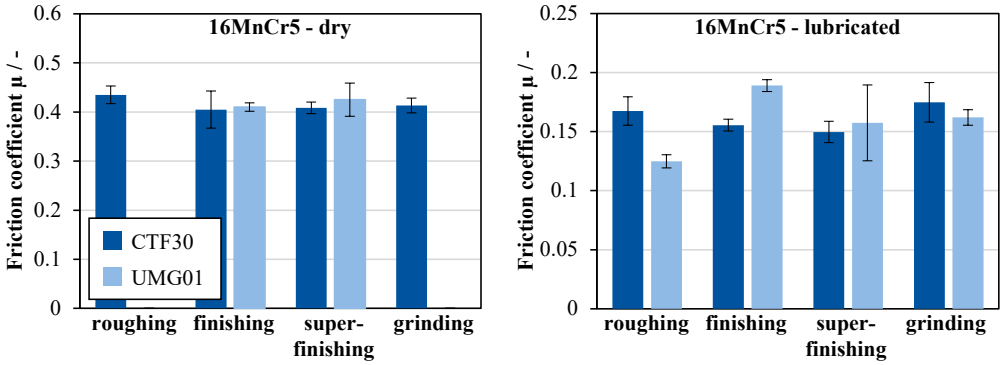

Fig. 5. Coefficients of friction for 16MnCr5, all surface conditions of the cemented carbide pins and for both lubrication conditions.

The results for the COF contrast the results presented by Llanes et al. [23], who found that the COF correlates with the surface roughness. However, they used a scratch test setup, where the indenter was a spherical tip diamond with a radius of 50 µm and the antibody was the EDMed cemented carbide. In general, the results are in good agreement with literature regarding tests conducted in dry conditions [14,24] and are only slightly higher in the lubricated condition than the laser textured specimen tested by Fang et al. [13].

In Fig. 6 and Fig. 7, the surfaces of the cemented carbide pins can be seen after the tests. In Fig. 6, the pins tested with 42CrMo4 as antibody material are depicted and in Fig. 7 the pins tested with 16MnCr5 are shown. In both figures, several broken pins are displayed. However, most of them broke when the test setup was disassembled. In Fig. 6, only the super-finished UMG01 pin number 3 broke during the test. For Fig. 7, all the super-finished and the first roughed UMG01

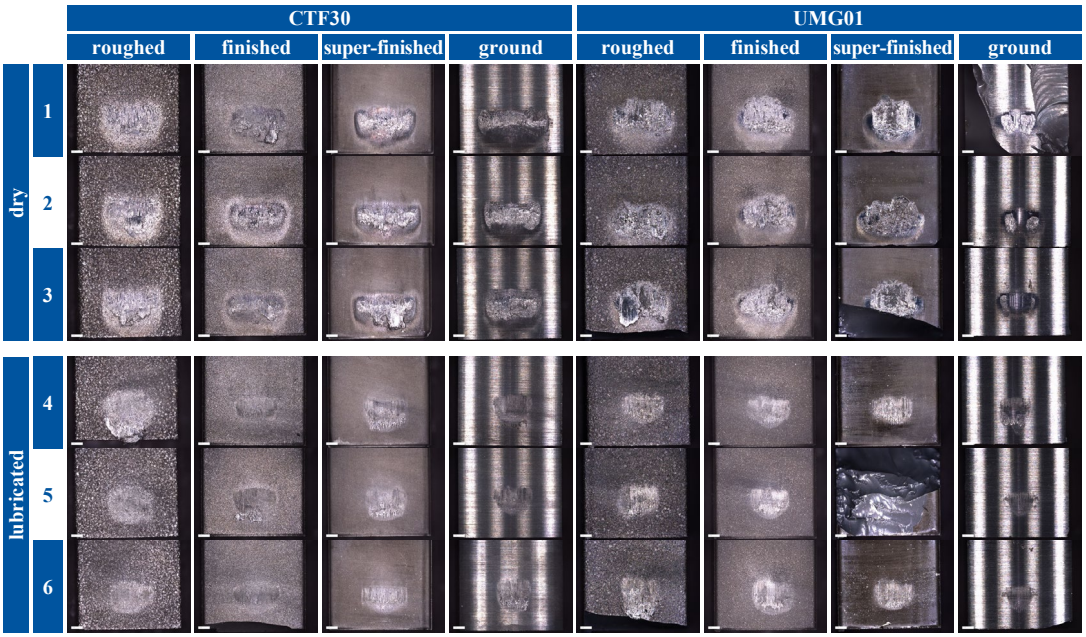

Fig. 6. Microscopic images of the surfaces of all pins tested on 42CrMo4.

pins broke in the test without lubrication. The remaining two roughed UMG01 pins were causing an overload in the measurement system and were therefore stopped. All the pins that broke first caused an overload, which is why these pins were accounted for as broken.

For both antibody materials, different regions are present on most cemented carbide pins. On the one hand, there are regions which appear to be flattened and on the other hand there are regions that have accumulated material. Even though the tested cemented carbides are significantly harder than the tested shafts, profilometry revealed that the tips of the profile have been flattened. An energy dispersive X-ray spectroscopy (EDX) has been conducted to reveal that all the material that appears to be bulged has in fact migrated from the test shafts and is not rearranged material from the cemented carbide pin.

When comparing the microscopic images from Fig. 6 and Fig. 7, a difference in the size of the imprint can be observed. For the antibody material 42CrMo4, the imprint appears significantly smaller than for the antibody material 16MnCr5. Similarly, the imprints on the shafts are larger on 16MnCr5 than on 42CrMo4.

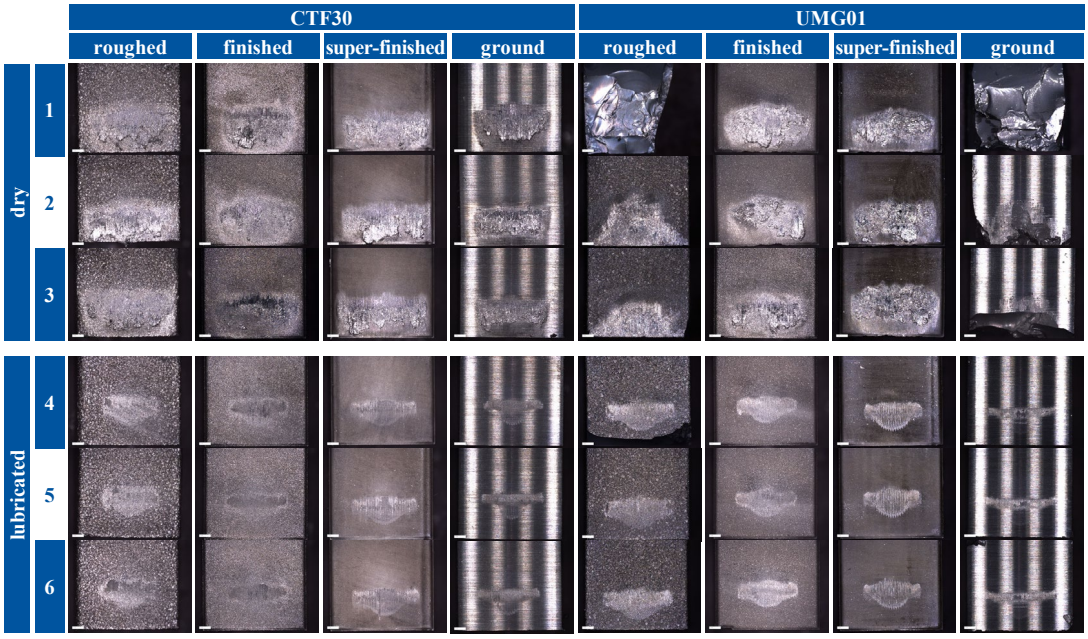

Fig. 7. Microscopic images of the surfaces of all pins tested on 16MnCr5.

Summary

The coefficient of friction of two distinct cemented carbides in contact with two different antibody materials was investigated in a dry and a lubricated setup. The cemented carbide pins were machined through sinking EDM to three different surface finishes and one set of pins was manufactured by grinding as a reference. Even though the surface roughnesses differed from one machining strategy to the other, no general correlations between the surface roughness and the COF could be found. Likewise, both antibody materials yielded similar results in the respective tests. Some test configurations, however, did show significant differences, which indicate the necessity to evaluate each configuration of materials and surface properties independently. This is especially obvious with the broken specimens from the series 16MnCr5, dry, roughed and ground. The friction reducing effect of the craters presumably present in the lubricated setup could not be identified with the same extend as it is in literature, which is attributed to the smaller dimensions of the craters found on cemented carbide surfaces.

Funding

The authors thank the German Research Foundation (DFG) for funding the DFG project BE 2542/42-2: “Analysis of discharge-dependent surface integrity of cemented carbide forming

dies machined by sinking EDM and its influence on the tribological characteristics and the resulting fatigue behaviour"(project number 290130034).

Keywords: Ultrasonic Burnishing, Surface Quality, Carbon Coated Tool

Abstract. Ultrasonic burnishing is a relatively new and effective method for improving the surface finish of metal parts. Burnishing strongly affects the surface quality, improving surface properties such as, surface hardness and surface roughness. Previous studied have observed that changing some burnishing parameters significantly affects the burnished surface quality. In this research, using a carbon-coated burnishing tool, tangential misalignment angles were varied on a corrosion resistant tool steel that has not been previously investigated. Two different burnishing tools were used to study their effect on surface quality and surface hardness. The results revealed that coated tungsten carbide tool has produced superior surface finish compare to non-coated burnishing tool which is the new finding. It is rather surprising that surface roughness has not increased as it typically happens during burnishing but a clear surface roughness enhancement was observed. The results showed a clear improvement in surface roughness (80-86%), whereas surface hardness did not change significantly.

Introduction

Ball burnishing and other forms of burnishing methods have gained popularity in recent years, as they not only affect the workpiece surface but also improve both the physical and mechanical properties of turned parts [1]. The goal of all burnishing methods is to create surface layers of high quality to improve the surface properties of mechanical components, such as surface roughness, hardness residual stress, and microstructure in different applications that require an excellent surface finish and dimensional accuracy [2,3]. Such methods are mainly used on rotating components with high-quality requirements, such as automotive axles, bearing parts, or crankshafts [4].

In manufacturing industries, the burnishing process has proven to be an easy and economical surface enhancement technique in secondary operations like grinding, honing, and lapping [5]. The burnishing process leads to the plastic deformation of the work surface when it comes in contact with a highly polished and hardened tool known as a burnishing tool [5].

Ultrasonic burnishing is less well known than the roller, ball, or diamond methods. This modern method is used for finishing metal surfaces by forging at very high frequency. Forging is performed with a ball-shaped finishing head at extremely high ultrasonic frequency while the workpiece rotates along a fixed axis, as depicted by the schematic in Fig.1. A constant spring load is applied to the burnishing tool to keep it in contact with workpiece surface. The process removes no material from the workpiece. Instead, it causes plastic deformations on the part surface, thereby creating residual stresses and improving surface quality [6].

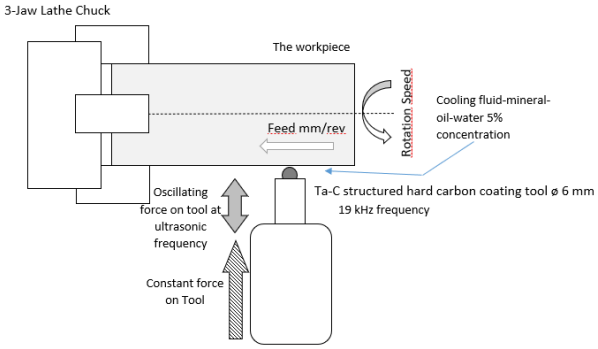

Fig.1. Schematic of the ultrasonic burnishing process.

Raza et al. recently published an extensive overview of past research on surface integrity in different burnishing processes, including ball burnishing, roller burnishing, and low plasticity burnishing (LPB) [5]. The authors found that carbon chromium, TiN coated EN31, tungsten carbide, high carbon and chromium steel, and HSS steel were all common roller materials reported in past research work. The burnishing process is mostly used to improve hardness, surface roughness, fatigue strength, corrosion resistance, wear resistance and microstructure properties, and to generate compressive residual stresses [5]. A ball burnishing tool consists of a hard ball constructed from hard materials. According to Raza et al., most researchers have used carbide material for the ball because of its high modulus of elasticity and high density. However other ball burnishing tool material is also used including alumina carbide, cemented carbide, silicon carbide, silicon nitride, ceramics, and carbon steel [5,6]. Moreover, as Prasad et al. state, most researchers have studied and optimized the burnishing process parameters on the surface roughness and surface hardness of ferrous and nonferrous metals, such as brass and aluminium alloys [5,6].

Little research work has been conducted on tangential misalignment or carbon-coated tools in ultrasonic burnishing, although many authors have examined burnishing methods, such as the ball, roller, or slide effect on material integrity [7-12]. Moreover, to our knowledge, no study has investigated the effect of ultrasonic burnishing on the surface quality of cylindrical stainless-steel workpieces with different tangential alignments a carbon-coated tool. Furthermore, based on our literature review, no researchers have used ultrasonic burnishing to finish Corrax material. The material is used in the mold industry and in different engineering parts [13]. For this reason, there is a clear need to evaluate the effect of ultrasonic burnishing on the surface finish in this context.

Methodology

HIQUSA ultrasonic burnishing equipment was used to burnish a workpiece manufactured from a corrosion resistant-tool steel with an initial hardness of 385 HV. As shown in Fig.2, ultrasonic burnishing was performed on the stainless steel, commercially available as Corrax. The workpiece was pre-machined from a diameter of 90 mm to 88 mm, with a length of 500 mm. The designations and typical compositions of the test material used are shown in Table 1. The test material is well-suited for mould-making parts and it exhibits excellent resistance to corrosion [13].

Table 1: The chemical compositions (wt%) of the tested work material.

Corrax						
C	**Si**	**Mn**	**Cr**	**Ni**	**Mo**	**Al**
0.03	**0.3**	**0.3**	**12.0**	**9.2**	**1.4**	**1.6**

Fig. 2, below, depicts both the HIQUSA ultra burnishing equipment used to undertake the burnishing process and the Tangential Misalignment Angle (TMA), kappa (κ). TMA is defined as

the angle formed between the burnishing tool axis and axis of the shaft. For the tool oriented 90° to the shaft, TMA is considered as 0 and it can increase on either side - hence positive and negative TMA are possible. It is important to study TMAs, since in burnishing process, one semi-spherical (burnishing tool) and a cylindrical surface get in contact with each other and double curved surfaces [2] could form. Beside the possible effect on cylindricity, surface roughness can be vary significantly [2].

In our previous work [2], burnishing was performed on Stavax stainless steel using a wolfram carbide ball with a finishing head 6 mm in diameter. The Ta-C structured hard-carbon coated-tool used in this research is known commercially as BALINIT® MILUBIA [15]. Burnishing in this case was limited to a TMA range of 0°-45°. The burnishing parameters are shown in table 2. The ultrasonic burnishing parameters were 80 rpm for the spindle speed and 0.05 mm/rev for the feed, while forging was performed at a frequency of 19 kHz. The spring preload was 1.5 mm for the workpiece. A cutting fluid (filtered 5% oil-water emulsion) was used to cool the tool in the process.

Table 2. Burnishing process parameters.

Burnishing parameters	Ultrasonic burnishing
Force P	5.40 N
Frequency	19 kHz
Preload on the spring	1.5 mm
Feed	0.05 mm/rev
Speed	80 rpm

However, in the present work, the burnishing parameters were changed to 500 RPM and a ø 6 mm carbon-coated tool was used. The tool feed and burnishing frequency of the tool head were kept constant, as in Fig.1 [2]. With this configuration, burnishing was only possible at 0° TMA, while a higher TMA resulted in deteriorated surfaces.

Surface Roughness

MarSurf PS 10 apparatus was used to measure the surface roughness of the burnished bands along a cylindrical shaft. This equipment uses a stylus measuring probe and the cut-off length value is selected as 2.5 mm. The device was used to measure the roughness of both the pre-machined and burnished surfaces.

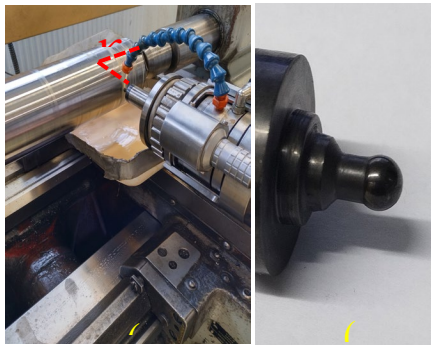

Fig. 2. Burnishing equipment: (a) tangential misalignment angle (TMA) κ, (b) carbon coated tool head.

Surface Hardness

Brickers-220 equipment was used to measure the surface hardness of the burnished bands along the circumference of the shaft. Each burnished band was approx. 5 mm in length. Hardness was measured five times at each location, which corresponded to a different tangential misalignment angle.

Results and Discussion

The test material surface after burnishing is shown in Fig. 3. The surface finish differences between the burnished surfaces produces by the Ta-C hard carbon coated tool (green) and the wolfram carbide tool (red) can be easily distinguished. This demonstrates that tool material and coating significantly affects the surface finish.

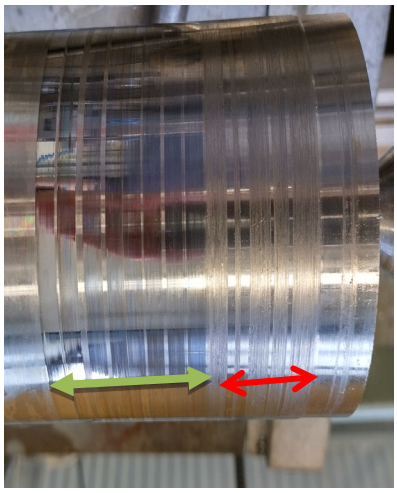

Fig. 3. Surface with carbon coated tool head (green arrow) and a wolfram tungsten carbide (red arrow).

Surface hardness.

The hardness of the machined (after the turning operation) shaft prior to burnishing was measured as 385 on the HV10 scale ± 15. The same value is 41 on the Rockwell C scale (HRC), which is comparable to the as-supplied hardness value provided by the manufacturer of Corrax [13].

The use of coated tools during burnishing, resulted in a rather uniform surface hardness with both positive and negative tangential misalignment angles (TMAs), implying that TMAs has exert no effect on surface hardness (Fig 4). This finding contrasts with the results for Stavax (a stainless steel with a different composition from Corrax) where surface hardness increased (1.5-3.6%) compared to a machined but unburnished surface. This effect could be associated with material behaviour or the use of coated tools and therefore must be further investigated. However, ultrasonic burnishing has been found increase surface hardness by 6.8 % for 34CrNiMo4 steel [14].

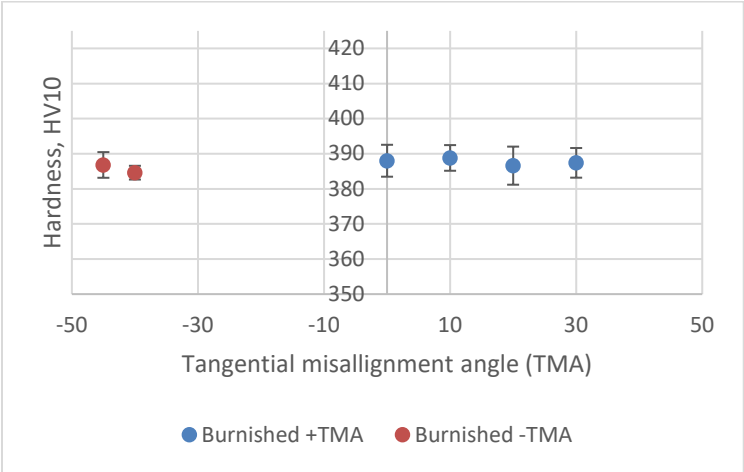

Fig. 4. Surface hardness measured on the Rockwell HRC scale for various test-material tangential misalignment angles.

Surface roughness.

For purposes of comparison, the surface roughness of an unburnished and machined (turning only) surface was measured as 1.6 µm. Surface roughness appeared to be affected by changing TMAs, where 0 degrees yielded a rough surface compared to higher TMAs. The increase in surface roughness compared to the machined surface was a minimum of 80% and maximum of 86%, which is an extremely positive influence. Overall, surface roughness, which reflects superior surface quality, improved significantly compared to the machined surface. This result is comparable to the burnishing of Stavax [2]. Fig 5 demonstrates the significant improvement in surface roughness achieved by using the coated tool. These findings are also in accordance those reported in the literature on the effect of burnishing on surface quality [2,7].

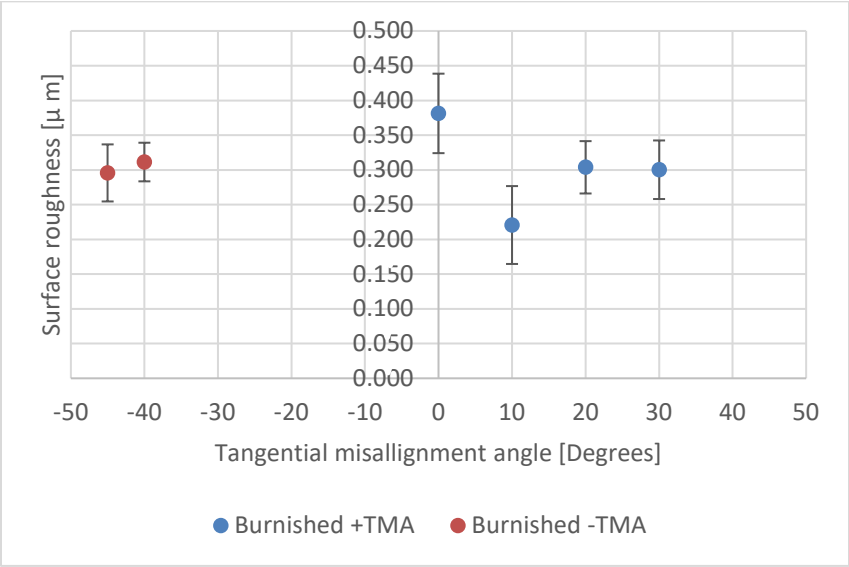

Fig. 5. Surface roughness of Corrax material (Ra).

Summary

Ultrasonic burnishing is a finishing process which imparts beneficial compressive residual stresses and enhanced surface properties. The method is especially suited for shafts and mechanical parts but can be implemented on flat-face surfaces as well. In this study, ultrasonic burnishing was applied to Corrax (a stainless-steel material) using coated tools. The study analysed the effects of changing the tangential misalignment angle (TMA) on surface hardness and on surface roughness. The following conclusions can be drawn:

- For the specific case of Corrax, ultrasonic burnishing exerted very little effect on surface hardness, which is an unusual burnishing behaviour that requires further investigation.
- Coated burnishing tools enhanced surface roughness by 80-86% which is comparable with previous results.
- Performing the ultrasonic burnishing operation with the Ta-C structured hard-carbon coated-tool 6 mm diameter and 19 kHz frequency, the Corrax material is a suitable combination for the application of the process in terms of surface quality enhancement.
- Ultrasonic burnishing treatment process with tungsten carbide (Ta-C) structured hard carbon coated tool has resulted much superior surface quality compared to non-coated burnishing tool.

Influences in deep hole sinking (EDM, ECM) that make it difficult to analyze the process status

SCHULZE Hans-Peter[1,a *], HERZIG Mathias[1,b] and KRÖNING Oliver[1,c]

Keywords: EDM, ECM, Hybrid Processes, Process Analysis

Abstract. A particular problem of deep hole sinking is the correct process analysis during the sinking process. It is important to know the primary technological objectives and to design the process regulation accordingly. Due to the objectives high removal rate, minimum roughness of the inner surface, high dimensional accuracy, etc., the analysis criteria are clearly changed and must be made available to process regulation. Another influencing parameter is the structure of the process energy source (PES).

Introduction

When sinking deep holes, it is of particular importance that the current process status of the machining process is precisely analyzed in order to give the process controller the correct signals to continue machining. In the following article, the two basic methods ECM and EDM will first be discussed, with the special features in the areas of the frontal, the lateral and the transition gap being considered. Differences in these areas occur particularly when the feed rate deviates greatly from the current removal rate. Another machining case is when the inner surface of the countersink is to be designed in a defined manner.

When using a hybrid processing method between EDM and ECM, the current and voltage curves analysis becomes even more complex because transient pulses also occur. It must also be noted that the ED parts of the machining take place in an electrolyte and are only local, while the EC removal always takes place over a large area. This raises the question of whether the pulse analysis can be used to regulate the feed rate or not. Finally, the topic of the applied process energy source (PES) is discussed.

Process Analysis ECM

In its process analysis, the ECM must distinguish whether it is used to sink a specified profile into an undefined surface, to rework a profile, or to sink deep holes, whereby aspects greater than 10 are assumed. EC milling is excluded from further considerations.

In the case of maximizing productivity and no special requirements for the inner surfaces of the holes, solutions are possible, as shown in Fig. 1 [1]. In the case of the insulation of the cathode surface, Fig. 1,II, it can be assumed that the current-voltage analyzes relate entirely to the front gap. As a result, this analysis can be used for feed regulation. The size of the lateral gap will depend on the insulation configuration at the edges of the lateral gap. It must be noted that if the lateral gap is too small, the flushing of the frontal gap will be negatively affected.

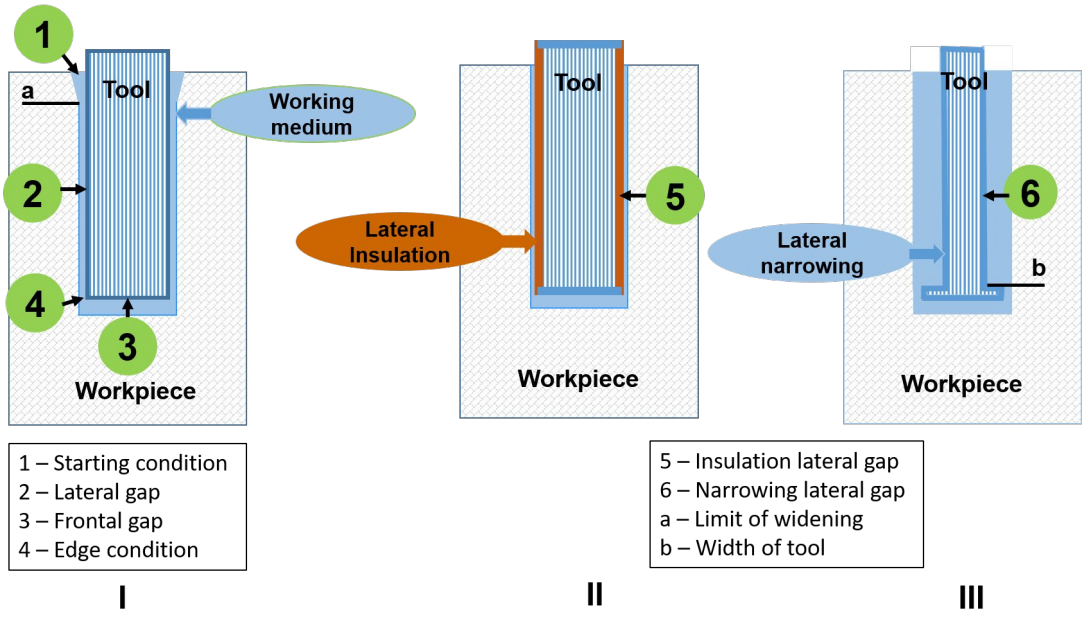

Fig. 1. Different conditions by ECM and EDM.

Fig. 1,I shows the areas of interest for analysis. In area 1, the starting conditions are at the surface. Due to larger stray fields, a larger area is removed than later in the hole area. The frontal erosion is reduced due to the areal removal with ECM. Area 1 can be minimized if the frontal area of the tool electrode is designed as a cone. In area 2, the side gap is widened by the fixed arrangement (a) until the current density no longer allows removal. Therefore, the side gap is usually slightly conical. In contrast to the arrangement in Fig. 1,II, where removal can no longer take place due to the lateral insulation (5), in Fig. 1,III, the active side gap is achieved by narrowing the tool electrode. This intensifies the rinsing effect (6), and which lateral gap is created depending on the front height of the tool electrode (b). The working gap on the front side depends on the ratio of the removal on the front side to the feed rate. It would be ideal if both were the same size, then, there would be a constant front gap. However, the current and voltage recordings only show us the overall picture of the individual ablation areas. It is sufficient for the critical process states such as soft short circuits or discharge since the machining process has to be interrupted or the rinsing has to be improved to achieve the desired surface quality.

Process Analysis EDM in the Electrolyte

If the EDM process is considered in the conventional sense, then we have a dielectric as the working medium and a cathodic polarity for the workpiece [2]. The discharge conditions are determined by the electrical field conditions and the degree of contamination in the working gap. In contrast to the ECM, a small area is removed locally but with a high frequency and constantly changing location. It can be assumed that the electrical discharge binds the entire energy through its plasma channel and that the removal ratios at the anode and cathode can be calculated from this.

Referring to Fig. 1, area 1 is mostly more frayed, while area 2 shows less taper. There is also a rounding in the corner area 4, but not as homogeneously as with the ECM. The primary removal area is the front gap, because there the gap is constantly regulated to a specified gap by the feed rate. Flushing in the side gap reduces the dielectric strength, so isolated discharges also occur there. These discharges determine the roughness of the hole wall. Even with the EDM, we cannot assign the current and voltage curves to the areas defined in Fig. 1, but only look at the effect afterward [3].

If hybrid-machining processes are to be analyzed, then some conditions from the conventional EDM conditions no longer apply [2,3,4].

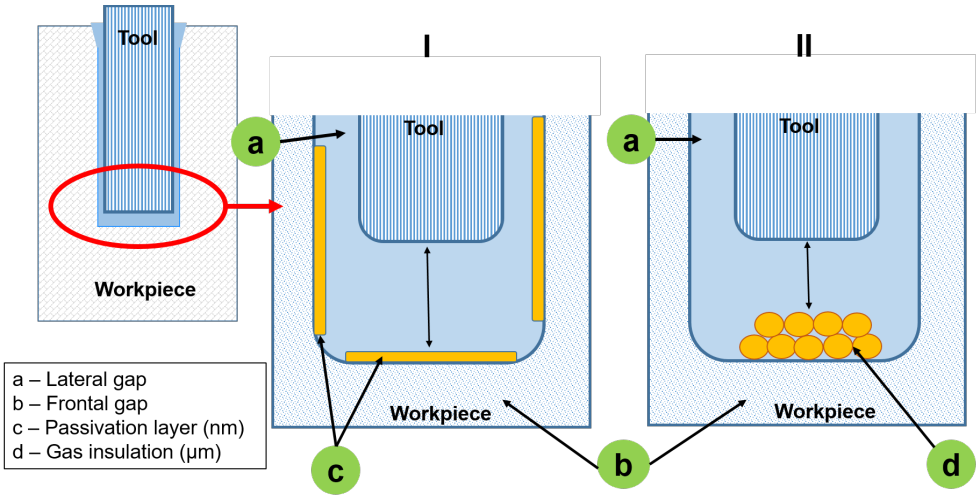

Fig. 2. Changed ED conditions in the hybrid ED-EC process.

In Fig. 2, it can be seen that the electrical breakdowns are not determined by the working medium, but by passivated layers (Fig. 2,c) and/or gaseous deposits (Fig. 2,d**)**. The breakdown takes place in these phases, while the formation of the discharge channel (plasma, gas volume) primarily takes place in the electrolyte. Since in hybrid applications, there is almost exclusively an anodic polarization of the workpiece, the sparks are removed over a larger area than with the original EDM. Passivation in the lateral gap prevents further erosion from a certain lateral gap width and is, therefore, decisive for the surface quality of the inner wall surfaces of the bore. For electrical breakdown, the condition I in Fig. 2, hence electrical breakdown in very thin solid layers, must be considered.

In the case of passivation layers in the nanometer range, a field breakdown occurs because even a small voltage drop across the passive layer leads to high electrical field strength. Assuming a layer thickness of 10 nm and a voltage drop of 1 V, the electric field strength would be 10^8 V/m. At these field strengths, altered effects of electrical conductivity (tunneling, hopping) take place in a dielectric solid. If the insulating effect is eliminated, a combined heat/field breakdown can occur via the remaining front gap. In the electrolyte, the discharge channel spreads out more, depending on the electrical conductivity of the electrolyte, than would be the case in a dielectric. As a result, energy is withdrawn from the discharge base, and the crater formations become smaller and larger.

Fig. 3 shows where one can speak of hybrid machining methods and which basic removal processes cause the main removal.

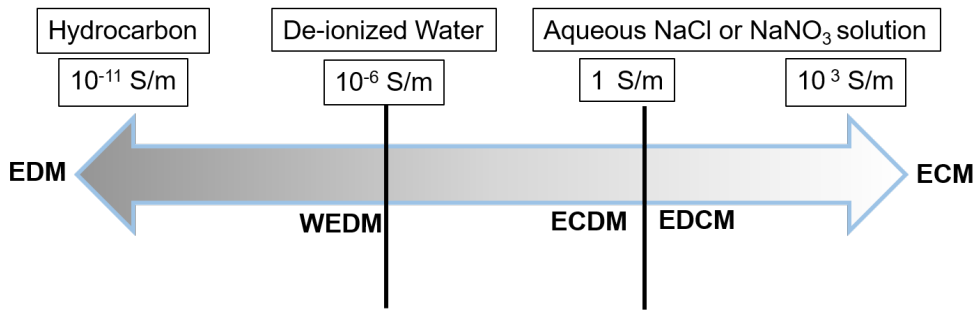

Fig. 3. Dependence of the hybrid ED-EC process on the electrical conductivity of the working medium [5].

A contrast to this is in Fig. 2II where the dielectric layer is a gas layer. The gas accumulations are usually thicker than the passive layers and more mobile in their formation, so the breakdown conditions can change quickly. The tool's rotation or the working gap's flushing can cause these changes, for example. Another special feature can be that the gas layer is accumulated as gas bubbles or as a homogeneous gas layer. In the latter case, the discharge can be described according to the EDM models based on gas discharges. With the accumulation of gas bubbles, a small EC removal can still have an effect, which leads to a heating breakdown due to the extremely reduced working surface with a very high current density.

Fig. 3 shows that the ECD erosion by the discharges is at electrical conductivities below 1 S/m, while the EC-dominant EDC erosion is at electrical conductivities above 1 S/m.

Process Analysis of the Hybrid EDM-ECM Process

For process analysis, two applications are available for comparison, which were intensively examined in two studies. In the first study, a wire EDM system [3] was analyzed in terms of its current and voltage curves, while in the second study, EDC sinking of smaller holes was considered. The primary objective was to assign the current-voltage pairs to a fundamental erosion or disturbance condition and internal surfaces with minimal roughness.

With sinking, the current and voltage curves shown in Fig.4 are typically related to the basic processes. The output data of the process energy source (PES) [6] are 30 A and 50 V, with a reduced EC current resulting from the impedance conditions (Eq. 1–4) of the test arrangement. By increasing the electrical conductivity of the working medium, the EC current could be increased accordingly.

In the case of the short circuit, the full PES current appeared and the voltage drops to almost zero volts. In the EC processing (Fig. 4), it was reduced to approx. 7 A here. The pulse in Fig. 4,B is an exception, which is determined by the characteristics of the PES. The number of partial overshoots (Fig. 4,C) increases with increasing immersion depth, which suggests very short partial discharges due to contamination of the working gap. An ED discharge (D) and an arc discharge (E) can then be seen in the right-hand diagram of Fig. 4. With a pulsing of 5 µs pulse-on and 5 µs pulse-off, these two discharges show a strong negative overshoot in the switch-off range, which can be attributed to the capacitive components (capacitor discharge) of the passive residual layer.

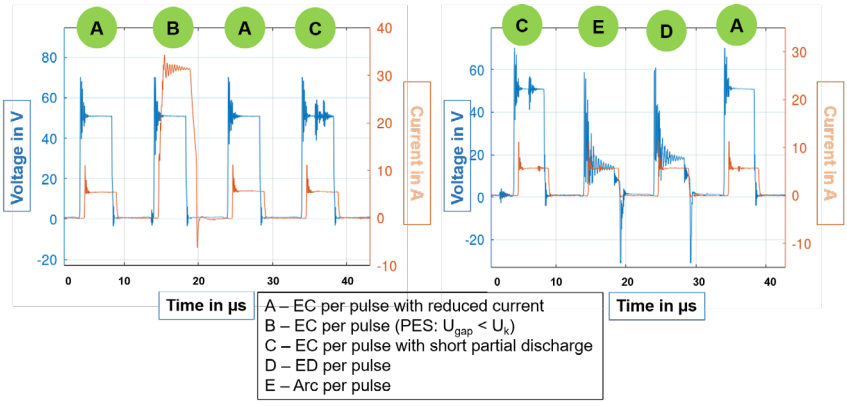

Fig. 4. Basic processes in hybrid hole sinking EDCM [7].

In Table 1, the pulses that occur after the current and voltage curves are selected must be differentiated according to the basic pulses, the pulses with transitions between basic erosion and the pulses that are specifically given by the characteristics of the PES. From the percentage number

of pulse types per time unit, it can be concluded whether the lowering process is ideal or needs to be corrected by the process regulation.

Table 1. Categorization of the pulses according to base, transition, and PES-dependent pulses.

Index	Conditions	Comments	Typ
a	$U_{max} = U_{PES}$ and $I_{gap} = I_{EC}$	EC-Pulse	Basic
b	$U = U_{spark}$ and $I_{gap} = I_{ED}$	ED-Pulse	Basic
c	$U < U_{spark}$ and $I_{gap} = I_{arc}$	Arc-Pulse	Basic
d	U = 0V (very close) and $I = I_{PES}$	Short circuit	Basic
e	U falls below the spark burning voltage	ED-Pulse → Arc-Pulse	Transition
f	U increases to U_{max}	ED-Pulse → EC-Pulse	Transition
g	U_{max} falls to U_{spark}	EC-Pulse → ED-Pulse	Transition
h	U_{max} falls to U_{arc}	EC-Pulse → Arc-Pulse	Transition
i	Solution of the Passivation via ECM		PES
k	Dynamics of the gas layer loosens the insulation		Flushing
l	Collapsing voltage U_k of the PES gives security of processing		PES

In Fig. 5, the pulse transitions are visible, which are defined in Table 1 under the indices e to h. The position in Fig. 5,A corresponds to the transition from the EC phase with an intermediate plateau to the ED phase. The intermediate plateau may be because the final ED erosion arose from thermal breakdown. In Fig. 5,B,C EC ablations can be seen, which are determined by the characteristics of the PES used, which is explained in more detail in the next section. Finally, Fig.5,D shows the transition from the ED phase to the EC phase.
These findings were also found largely in the WEDM investigation [3], which was used to work with a static PES.

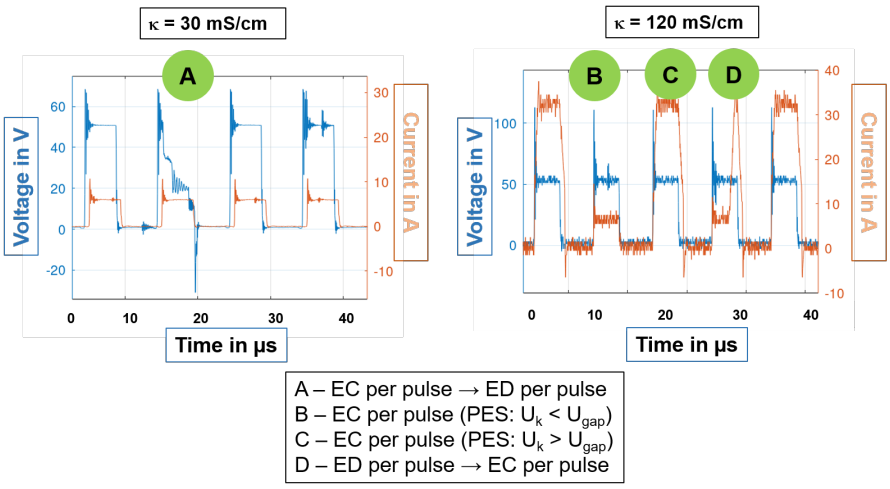

Fig. 5. Pulses with process transitions in ED hole sinking [7].

Influences of PES

A special process energy source (PES) was used for the hole sinking, the characteristics of which are shown in Fig. 6. Up to the break voltage U_k, it acts as a current source. It determines the pulse energy of the ED discharge and the arc discharge with its set current IPES. The operating point of the ECM is then determined by the load characteristic of the working gap. The working point ECM 2 is present when the working voltage is close to the maximum voltage U_{max}. As the electrical

conductivity of the working-gap resistance increases, the voltage drop across the gap decreases compared to the total impedance of the PES load, i.e. smaller currents automatically appear in the working gap.

The total impedance of the PES load is Z_{PES} Eq. 1 and is made up of the components of the contact Z_{ko}, the leads Z_{Li} and the working gap Z_{el}. If the electrolyte has high electrical conductivity, the remaining impedance components must also be small so that the PES voltage drops completely across the working gap. In the case of a current source, however, the same current would always be impressed, which would be important for the ECM. With a voltage source, a desired current can be achieved by changing the voltage, leading to ED discharges in the side gap for a long time. The voltage difference ΔU in Fig. 6 determines how quickly the current falls after exceeding U_k and depends on the structure of the PES.

According to Eq. 2, only the impedance of the working medium Z_{wm} is decisive for EC machining, which depends on the working gap a_x, the machining area A_x and the electrical conductivity κ of the working medium. Due to the passivation (Eq. 3, Z_{pass}) or the formation of gas bubble layers (Eq. 4, Z_{bub}), the impedance changes in that these layers have their impedance, with the capacitive components also playing a role. Furthermore, the impedance of the remaining working gap fluid remains (Eq. 3, Z_{fl1} and Eq. 4, Z_{fl2}). Only the layer impedances are then of interest for the breakdown conditions.

The advantage of the PES used is that it has a self-regulating effect, which means that process regulation can be significantly reduced.

$$\underline{Z}_{PES} = \underline{Z}_{ko} + \underline{Z}_{Li} + \underline{Z}_{el} \tag{1}$$

$$\underline{Z}_{el} = \underline{Z}_{wm} \quad \text{for ECM} \tag{2}$$

$$\underline{Z}_{el} = \underline{Z}_{pass} + \underline{Z}_{fl1} \quad \text{before EDM} \tag{3}$$

$$\underline{Z}_{el} = \underline{Z}_{bub} + \underline{Z}_{fl2} \quad \text{before EDM} \tag{4}$$

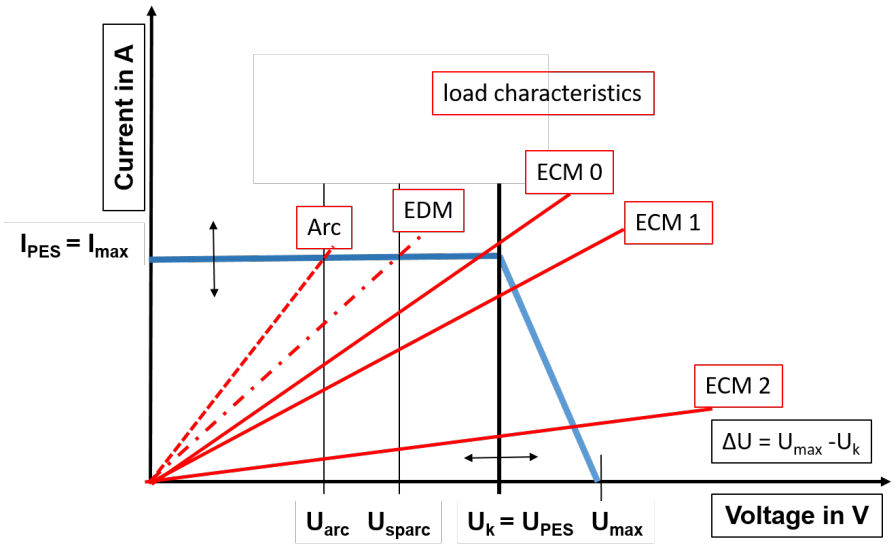

Fig. 6. Characteristic of the PES with different load curves.

Simplifications of the Process Analysis in the Hybrid Process Under Defined Technological Target Parameters

The machining process can be evaluated using pulse analysis for its process regulation but also for the technological objective. The technological objectives can be minimizing the machining time, the quality of the inner surface of the hole or the accuracy of the countersunk hole. In Fig. 7, a processing example is used to show how specific process states and a sequence of process states appear in the voltage-current characteristic [8, 9]. What is not apparent are the transition pulses. In the example, the frequency of the basic processes can be seen, with ED and EC pulses taking place in roughly the same number, while soft short circuits represent around 10% of the processing cases.

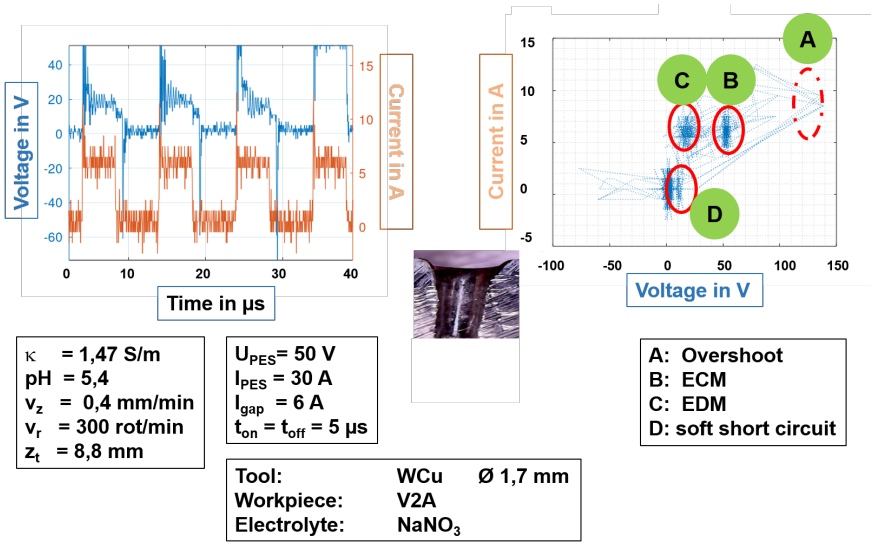

Fig. 7. Voltage – Current curve for 100 pulses in sinking deep of 8.8 mm [7].

If a more precise statement is to be made about the process states for regulation, then the sequence of pulses defined in Tabelle 1 must be made. The current and voltage limit values required for this are known from the literature or can be determined from a test run. With a smooth, shiny inner surface of the holes, the proportion of ED discharges in the side gap should be minimal. From the sequence of the pulse phases, there is a higher probability of isolated ED phases occurring in the side gap, since ED phases in the frontal gap only expose small areas for ECM.

Summary

To predict the processing result with pulsed hybrid EDM-ECM methods, assigning the individual pulses to a specific basic processing or a transitional behavior is necessary. It is difficult to find out where the effects of the removal take place. They are primarily to be found in the front gap because here, the size of the working gap is continuously tracked by the feed rate. In the lateral gap, on the other hand, static behavior can be assumed, which means that no further removal or application mechanisms are effective after the lateral gap has reached a certain size.

In the hole sinking study, a special process energy source was used, which acts as a current source up to a voltage U_k, after which it acts as a voltage source. The advantage of this PES is that it protects itself against working currents that are too high and causes a kind of self-regulation for the critical processing pulses.

The process regulation via the feed regulation can take place through targeted analysis of the pulse processes in terms of their phases and sequence. This makes it possible to achieve smooth, shiny surfaces even for deeper countersinks.

Abstract. Carbon fiber reinforced (CFR) composite rings with and without interlaminar carbon nanotubes (I-CNTs) were manufactured starting from high performance prepregs used in aeronautics. Nano-particles deposition was obtained by an innovative easily scalable procedure which does not affect composite processability. A CNTs-solvent solution was sonicated for an established time to reduce bulk CNTs agglomerates. The solution was poured on prepreg stripes and left at room temperature for solvent evacuation. The prepreg stripes were wrapped on steel pipe to obtain the annular configuration and manufactured by an out-of-autoclave (OOA) process. The consolidation pressure was applied through a thermo-shrinkable tube and curing occurred in oven. Stereomicroscopy and mechanical tests were performed on CFR and I-CNTs/CFR rings. A good adhesion among the plies was observed as well as the positive effects of CNTs deposition; an increase of 34%, 15% and 17% was obtained for the stiffness, the peak load and the fracture energy of the functionalized rings, respectively.

Introduction

The extensive use of carbon fiber reinforced polymer (CFRP) composites in highly-valued fields such as Automotive, Aeronautics and Aerospace is mainly due to their high structural performances and light weight if compared to alloys. Currently, the real challenge in these fields requires the development of new qualified materials and new production technologies that are more scalable at industrial level.

Generally, composite stiffness and in-plane strength are governed by reinforcing fibers, whereas matrix and matrix/fibers adhesion are responsible for creep, peeling strength and interlaminar shear strength (ILSS) resistance. Adding fillers in the polymer matrix before fiber impregnation can lead to property improvements, achieving even higher performances. For this reason, more attention must be paid to resin processability which can be negatively affected by changes in its formulation, with detrimental consequences for the final composite. Carbon nanotubes (CNTs) can interact with the matrix at a microscopic level enhancing its rigidity and strength. The CNTs insertion affects the resin mobility with a reduction in all the stages of the curing process. Consequently, the increase of the resin viscosity is responsible for lower reactivity and worse fiber impregnation during manufacturing of composites structures.

In the last decades, many researches discussed the positive effect of CNTs insertion in the resin matrix. All the studies are focused on the definition of an easily implementable and repeatable technique for spreading nanoparticles on dry or wet carbon fibers. Different solutions have been investigated. The most adopted strategies deal with the modification of the polymeric matrix before impregnation (massive mixing), using a massive interlayer between prepreg plies and the use of dispersed nano-reinforcements (interlaminar deposition).

Positive effects arising from mixing nanoparticles with the matrix before wet lamination of CFR fabrics were demonstrated by Leão et al. [1]. In particular, the positive effect was evaluated on the mechanical performances of carbon/epoxy composites with an increase of the ultimate tensile strength and the toughness of about 18% and 62%, respectively. Tefera et al. [2] demonstrated an increase in flexural strength of laminates manufactured by resin transfer molding with CNTs treated and non-treated with nitric acid to obtain carboxylic functional group. These solutions mixed with epoxy resin formed the matrix in 24 h – 96 h. Increments of about 17.4% and 15.3% for manufactured samples were measured for treated CNTs and for the lowest mixing time (24 h). Massive mixing not always ensures benefits to molded composites; in fact, matrix properties can be severely affected as well as the resin processability. For this reason, in industries other solutions are preferred, being the resin of the matrix already qualified for specific applications and changes in its properties are generally undesirable.

Interlaminar deposition of nano-reinforcements is another possible strategy that has a small influence on the resin processability. The insertion, as interlayers of hierarchical short carbon fibers synthetized with CNTs was proposed by Zhou et al. [3] who obtained increase of 125% in the fracture energy of nano-reinforced CFR epoxy laminates. Following this approach, Zheng et al. [4] manufactured CBT/polysulfone nanofiber paper by vacuum filtration, to be used as interleaf. Enhancements in interlaminar toughness both in mode I and mode II were obtained. The former is related to pre-cracked laminate failure governed by peel forces and the latter to the crack propagation by shear stresses. Moreover, interleave thickness greatly affects the interlaminar properties. Ou et al. [5] demonstrated that the interlaminar fracture toughness in mode I increase up to 76% for an interleaf thickness of 10 μm whereas it decreases to 36% by increasing thickness interleaf up to 15 μm. On the other side, mode II fracture toughness increases continuously when increasing the interleaf thickness up to 15 μm. Another important aspect was demonstrated by Nasirmanesh et al. [6] who inserted a CNTs interleaf in the midplane of an 8-ply laminate. In this case, impact tests revealed that crack initiation and propagation is confined around the CNT interleaf whereas it spreads all over the thickness for the base laminate. Moreover, flexural tensile failure is the predominant fracture mechanism on CNTs sheet base laminates compared to interlaminar shear breakage. Static tests revealed that tensile strength is the same whereas residual tensile strength and corresponding strain to failure was higher for CNT based laminates. Superior mechanical performances can be obtained by an aligned CNT configuration over composite plies. This effect is exalted by the use of thin plies as demonstrated by Cohen et al. [7]. In particular, an increase in the ILSS up to 10% compared to traditional laminates were obtained. Kaynan et al. [8] produced thin CNT reinforced adhesive interlayers used to mold interlayered CFR laminates. On one hand, the use of massive interlayers allows to increase the composite mechanical properties, on the other it leads to a lower manufacturability. Drawbacks come from both deposition strategies. Yourdkhani et al. [9] demonstrated that re-agglomeration and filtration of CNTs during liquid processing affect CNTs dispersion in the resin matrix. At first, they evaluated the degradation of CNT dispersion and the results underlined that laminates with interlaminar nano-reinforcements exhibited values slightly greater for compressive strength and electrical conductivity than traditional neat laminates. To date, the most viable solution is integrating CNTs in composites by using functionalized interlayers even if a more complex manufacturing procedure is necesary. This trend is confirmed by Li et al. [10] who inserted CNT buckypaper in the mid-plane of glass fibre reinforced laminates.

In previous works, the authors developed an innovative procedure easily scalable on an industrial level. The process allows CNTs deposition during the lamination sequence without adding intermediate step and thus avoiding to negatively affect the processability of the matrix. Specifically, multiwalled carbon nanotubes (MWCNTs) are mixed with a solvent and sonicated for an established time to exfoliate the bulk agglomerates. After, the mixture is poured on one

surface of the uncured CF prepreg plies and left at room temperature for solvent evacuation before lamination. Finally, increase in peeling and bending strength were obtained compared to neat laminates, when commercial automotive prepreg were used [11], as well as a better bending strength was achieved for aeronautical autoclave-molded prepregs [12].

In this study, MWCNTs were deposited as interlaminar reinforcements (I-CNTs) on a commercial aerospace fabric prepreg with the same procedure described above and developed by the authors. In this case, the laminated prepregs were molded in a tube shape with and without I-CNTs. Specifically, an out-of-autoclave process was used for the molding step as already done previously by authors for thermoplastic composites [13]. Observations with stereomicroscope and compression tests up to failure were carried out to evaluate both the soundness of the manufacturing process and the mechanical performances.

Materials and Methods

Tube shaped composite samples with and without 1wt% I-CNTs were manufactured by an out-of-autoclave (OOA) process. A 1 wt% of I-CNTs was chosen thanks to authors' previous studies [10, 11] that had established a good interaction of MWCNTs with the resin matrix with this percentage. Higher percentages caused an excess of CNTs which worsen the interaction with the resin matrix. Conversely, lower percentages cause less detectability of matrix interaction effects. Commercially epoxy matrix prepregs (40%) CYCOM® 977-2 by Solvay, commonly used in aeronautics, were used in the experimentation as well as commercial MWCNTs. The whole manufacturing process is shown in Fig. 1.

MWCNTs had a length of 10-30 μm, minimum outer diameter of 8 nm, purity higher than 95 wt%, ash lower than 1.5 wt%. Exfoliation of MWCNTs occurred in order to minimize the presence of bulk aggregates, and subsequently interlaminar deposition was performed. A MWCNTs-isopropanol solution was mechanically mixed through a magnetic stirrer for 1h and sonicated for 1h. In this way, a good level of nanoparticles exfoliation was achieved and agglomerates were not visible at naked eye. The solution was poured on prepreg stripes 960 mm in length and left at room temperature for 1 day to allow solvent evacuation. From now on, neat samples have been named CFR while the ones with interlaminar carbon nanotubes have been called I-CNTs/CFR. Prepreg stripes were wrapped around a steel pipe, being the mold, of 50 mm as nominal outer diameter and of 220 mm in height, and about 6 windings were obtained. The assembly was placed inside a thermo-shrinkable tube made of crosslinked polyethylene (PEX) by ELCON. A release film of fluorinated-ethylene-propylene (FEP) was placed on the rings-mold and at rings-PEX interfaces to favor the tube extraction. When heated, the thermo-shrinkable tube reduces its initial non-equilibrium diameter (85 mm) to a smaller equilibrium-diameter (25 mm), exerting a circumferential pressure on the tube surface. Curing was carried out in oven (by Nabertherm) at 180 °C for 1 h, and after cooling at room temperature, the workpieces were extracted. Four rings with and without I-CNTs were produced.

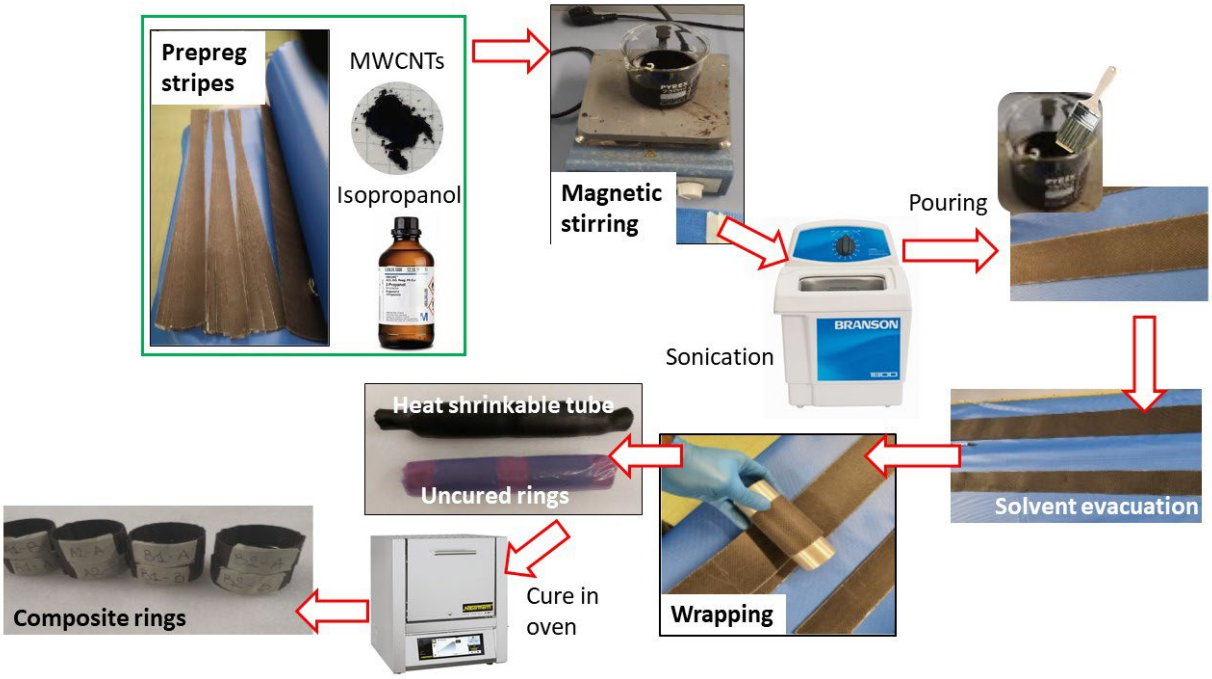

Fig. 1. Procedure of I-CNTs deposition and rings molding by the out-of-autoclave process.

Physical dimensions were measured and densities were evaluated through a hydrostatic scale to reduce the effects of manufacturing defects. Optical observations through a stereomicroscope Leica S9i were made to investigate plies adhesion and compaction. Compression tests up to failure were performed on an MTS Alliance RT/50 Universal testing machine to investigate the effect of I-CNTs on the macroscopic behavior of the composite rings. Transverse compression setup configuration, where the axis of-the movable machine crosshead is perpendicular to the longitudinal axis of the rings was used. A test speed of 1 mm/min and an acquisition frequency of 10 Hz were set.

Results and Discussions

Reduction of the molecular mobility in composites laminates is the key factor to understand the positive effect of the nanoparticles with the polymer matrix. The strongest effect is obtained when interpenetrating structures are placed in the interlaminar region. Also, the resin processability in thermosetting-based composites should be affected as little as possible, and molecular mobility is the main parameter to take into account. Fiber impregnation and diffusion, responsible of high polymerization degrees, are enhanced by low resin viscosity. In light of this, the positive effect of CNTs integration is a compromise between the improvements in the structural behavior and the minimum influences on the resin processability. This aspect represents the main goal of all the new developed technologies.

The proposed manufacturing procedure of interlaminar nanoparticles deposition does not alter the resin composition, minimally affecting its processability. Moreover, the use of additional layers either in the form of interleaves or adhesives is avoided. This procedure only adds a technological step consisting in sonicating the resultant isopropanol-MWCNTs solution to debundle and exfoliate CNTs and to reduce the presence of bulk agglomerates. Also, the solvent is used only to obtain a uniform distribution over the prepreg surfaces and its ease of evacuation allows to leave only the interlaminar nanoparticles. The use of commercially available prepreg, already optimized for industrial applications, requires a good experimental setup for interlaminar nano-reinforcements deposition, in order to enhance the structural behavior of functionalized laminates.

The proposed out-of-autoclave molding process guarantees good compaction among composite layers, after winding. The stereoscope observations, shown in Fig. 2, clearly highlight the six windings obtained after wrapping. Bleeding occurred during curing and a good level of adhesion was reached; fibers interpenetration among the layers was not observed. Defects related to the manufacturing procedure were observed in some areas since the mold was not optimized at this stage of the experimentation. The external surfaces un-homogeneities are due to asperities of the inner surfaces of the PEX tube and these irregularities can be easily overcome optimizing the molding assembly. However, the main objective in the study is to verify the feasibility of the process and this has been confirmed.

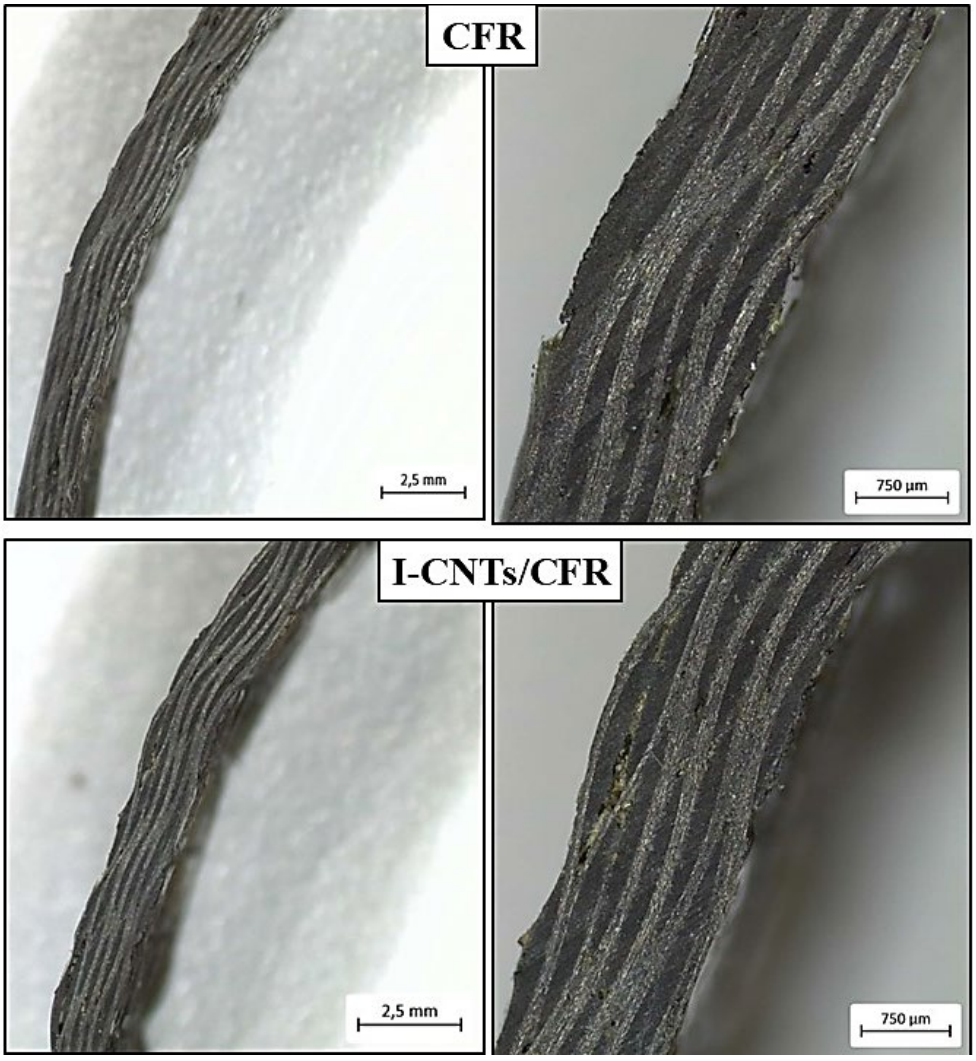

Fig. 2. Stereoscope images of CFR and I-CNTs/CFR ring samples.

CFR and I-CNTs/CFR rings had similar thickness of 2.1±0.2 mm and 2.0±0.3 mm respectively, nearly 0.3 mm for each ply. In Fig. 3 the evolution of thickness for rings with and without CNTs is shown in polar coordinates, that is, ring thickness was measured at a different angular position. Densities of CFR and I-CNTs/CFR rings were 1.37 g/cm^3 and 1.34 g/cm^3 on average. They were measured through a hydrostatic scale because of the irregularities on the rings surface. Lower densities of functionalized composites are due to the presence of interlaminar reinforcements which slightly increase the distance among prepreg plies.

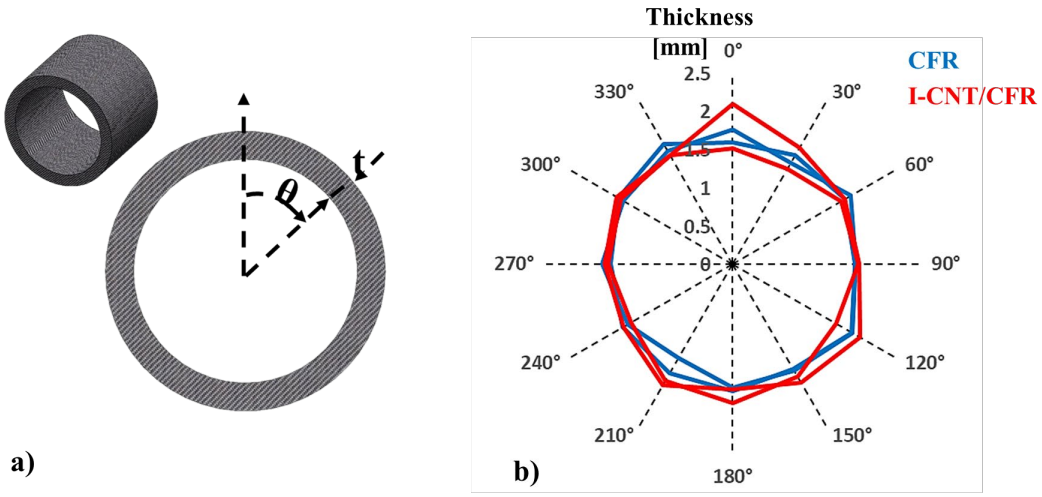

Fig. 3. Evolution of thickness for CFR rings and I-CNTs/CFR rings in polar coordinates.

Improvements by the addition of MWCNTs can be seen at room temperature as a consequence of the molecular mobility reduction mechanism. Compression tests were performed in transverse configuration and results are shown in Fig. 4 as load-displacement curves.

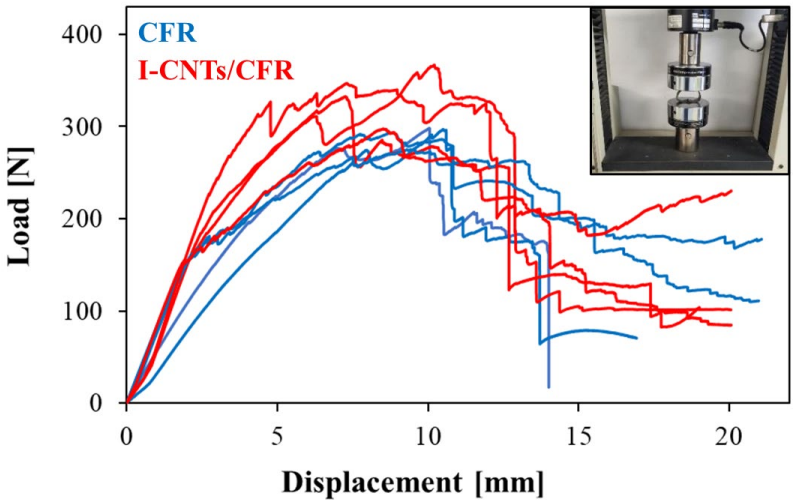

Fig. 4. Compression curves of composite rings.

Table 1. Stiffness, load peak and fracture energy values calculated from the curves.

	Stiffness	Peak Load	Fracture Energy
	N/mm	N	J
CFR	65 ± 20	291 ± 11	3.5 ± 0.7
I-CNT/CFR	86 ± 7	336 ± 34	4.1 ± 0.6

The non-homogeneous nature of the composite rings is responsible for some oscillations in the load-displacement curve, which do not affect the interpretation of the interlaminar CNTs effect. Stiffness, peak load and fracture energy are summarized in Table 1. Despite the lab scale OOA

procedure, stiffness, peak load and fracture energy increase of 32%, 15% and 17%, respectively, for I-CNTs composites compared to traditional ones. In particular, also considering only the better responses for CFR without I-CNTs (e.g. 83 N/mm for stiffness, 283 N for peak load and 4.1 J for fracture energy), the ameliorative effect of the CNTs would be in any case confirmed. The manufacturing process does not affect the positive role of CNTs at all. This preliminary experimentation, aims to highlight the effectiveness of interlaminar CNTs on the global mechanical behavior of I-CNTs composites. The increased structural performances aimed by CNTs insertion confirms what found also by literature review about this topic [9,10].

Summary

The use of commercial materials is the best solution for high-valued engineering applications in which material qualification and certification has strict restrictions. Commercial material innovation is strictly related to the improvement of already high performances which should be enhanced through simple and easily scalable processes. In this light, any proposed improvements in laminate manufacturing should minimally affect the initial structure and composition of the materials. This, in order to avoid the re-designing of the structure or the change of the processing strategies. All these needs have been matched by the proposed manufacturing procedure consisting of interlaminar deposition of CNTs on CFR prepregs by CNTs-solvent solution dispersion. In particular, the proposed additional step for composite functionalization does not alter the commercial material processability. CFR and I-CNTs/CFR composite rings were manufactured by a non-conventional out-of-autoclave process which guarantees plies compaction and repeatable structure quality even if further optimization in the molding setup are needed. The effects of CNTs deposition were demonstrated by the slight density reduction of I-CNTs composite rings with an increase of distance between the plies. Moreover, the compression tests showed a positive effect with an increase in the stiffness and in the peak load of I-CNTs/CFR composite rings. Further analysis could be performed to understand the effects of CNTs insertion on molecular mobility at higher temperature. Moreover, the ideal CNTs' content as function of the adopted manufacturing process is another big issue as well as the investigation on delamination mechanisms.

Keywords: Carbon Fiber Composites, Engineering Plastics, Gears, Powder Metallurgy, Green Compaction, Sinter-Forging, Die Technology

Abstract. Carbon fiber reinforced engineering plastic (CFREP) small-sized parts were fabricated by PM (Powder Metallurgy)-oriented forging process. This manufacturing procedure consisted of the green compaction and sinter-forging steps. In the first step, the CFREP powders were consolidated to a green compact with high density. This preform was further sinter-forged into a final product by hot stamping with the use of the induction heating unit. Hardness distribution was measured to describe the consolidation behavior with increasing the compression load, and to optimize the sinter-forging conditions for solidifying the green compact to the sintered product. X-ray tomography was utilized for non-destructive diagnosis on the residual pores and defects. The eight-teeth gear model was fabricated to demonstrate that two step procedure wrought well to yield the dense and defect-free gear with sufficient strength and integrity.

Introduction

The composite materials have been used to improve its mechanical and functional properties by combining the secondary phase materials and the matrix [1]. In particular, CFRP (Carbon Fiber Reinforced Plastics) and CFRTP (Carbon Fiber Reinforced Thermo-Plastics) have been widely used to produce the light-weight and high strength structural parts and members [2,3]. In those composite materials, their intrinsic properties are controlled not only by the fiber orientation and density in reinforcement but also by the selection of matrix plastics [3,4]. The normal CFRP is made from the epoxy-resin matrix and the carbon long-fibers; the CFRP ply and woven cloth are also used as a staring material for near-net shaping of parts and members. Most of those CFRP parts and members have been fabricated by using the autoclave processing [5] and the hot/warm stamping [6] with the finishing step. In particular, the small-sized parts and structural members are often yielded by hot stamping the laminated ply sheets [7]. The carbon short-fiber reinforced plastics are injection molded into various small- to medium-sized products from the pelletized feedstock [8]. Those processes work well when the composite matrix is made from relatively low glass transition temperature plastics such as epoxy. Most of engineering plastics (EP) have much higher glass transition temperature than normal matrix plastics; they are difficult to be molded or compressed into products. In addition, their feedstock is usually made of powders and particles; a new manufacturing process is necessary to fabricate the small sized EP and CFREP parts from this feedstock.

The mechanical gears are a typical element to transfer the applied load from input to output, to reduce the rotational speed in reducer, and to construct the mechanism of movement [9]. As reported in [10], the light-weight gears with high stiffness play an important role in the reducer at the robot arms and joints and in the automatic mechanics for electric vehicles. In addition, the gears with high radiation resistance are also needed in the robotics working in decommissioning

operations [11]. Most of engineering plastics have sufficient radiation resistance and high specific strength to provide a solution to those demands.

In the present study, the carbon fiver reinforced engineering plastic (CFREP) powders are selected as a feedstock to fabricate the CFREP gears with sufficient hardness and integrity. Two-step powder metallurgy oriented procedure is developed for this fabrication. First, the CFREP powders are poured into a die cavity to consolidate them into the green compact with relatively high density. This green compact is further sinter-forged to an eight-teeth gear-model product. The hardness distribution is measured to describe the green compaction behavior and to investigate the effect of holding temperature and applied load on the sinter-forging process. The X-ray tomography is also employed to make non-destructive evaluation on the defects and porosities left in the green compact and sinter-forged gear. Three dimensional profilometer is used to measure the dimension of gear teeth with reference to the CAD (Computer Aided Design) data.

Methods and Materials

Two-step PM (Powder Metallurgy) oriented method is stated in details on the green compaction step for cold forging the CFREP powders to a green compact and on the sinter-forging step to consolidate the green preform to the final product. How to characterize the green compact and sinter-forged gear product, is also explained in the following.

Two-Step PM-Oriented Procedure.

Two-step PM-procedure to fabricate the CFREP product consists of the green compaction step in cold and dry and the sinter-forging step in hot. As illustrated in Fig. 1, the feedstock powders were poured into a die cavity in the die set. In the green compaction step, the load was applied to the punch to consolidate them into a green compact with the specified density in cold and dry. The incremental compression mode was utilized to deliver the powders to every branch of cavity for uniform consolidation. This green preform was fixed into the other die set to sinter-forge this preform into a sintered product at the elevated temperature. The indirect heating method was employed to preserve the hot forging condition by using the high-frequency induction heating (HF-IH) system (YS-Electrical Industry, Co., Ltd.; Kofu, Japan). In both steps, the CNC (Computer Numerical Control) system (Precise Stamping Laboratory, llc.; Tokyo, Japan) was commonly utilized.

The solid lubrication was utilized to reduce the friction on the contact interface between the punch/core surfaces and the work in these two-step processes. The h-BN sprayed film was formed onto the punch and die surfaces before each operation. After green compaction, the punch is first released and the core-die was reloaded to move down for ejection of formed compact. In nearly the same manner, the sintered work was also ejected from the die-set.

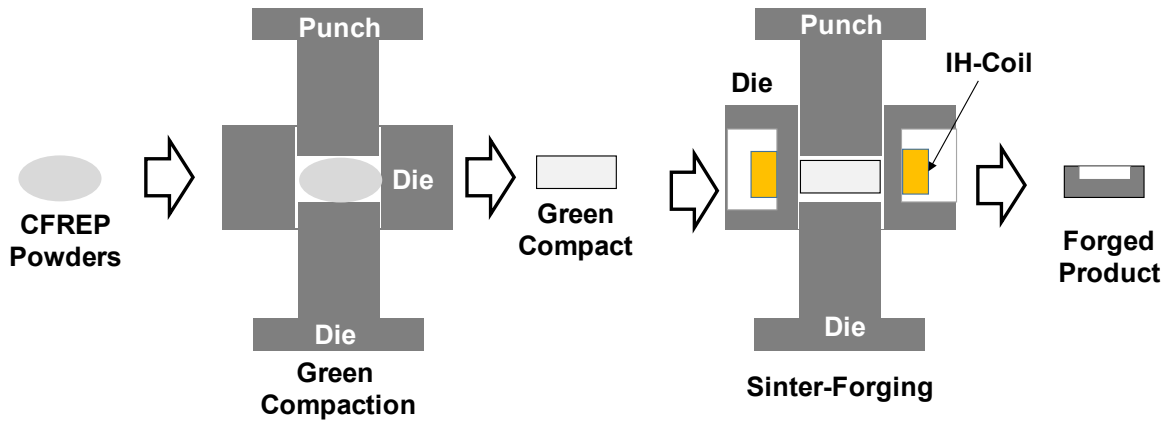

Fig. 1. A schematic view on the two-step PM-oriented procedure from the feedstock powders to the product. a) Green compaction step, and b) sinter-forging step.

Green compaction.

Among several materials, the CFREP powders (Aurum-PD450; Mitsui chemicals, Co., Ltd.) were selected as a feedstock for fabrication of gear models by the two-step procedure. This Aurum-PD450 was a thermoplastic polyimide with Tg (Glass transition temperature) of 518 K (or 245°C) and Tm (Melting temperature) of 661 K (or 388°C). When using the injection molding, the mold temperature could be higher than 673 K; this PD450 must be difficult to be shaped into products by using the injection molding. Table 1 summarized the mechanical properties of this Aurum-PD450. Compared to normal thermoplastic polymers such as PP (polypropylene) and PC (polycarbonate), higher strength and modulus characterizes this feedstock.

Table 1. Mechanical properties of Aurum-PD450.

Item	Typical data	Testing method
Tensile strength	90 MPa	ASTM D 638
Ultimate elongation	90 %	ASTM D638
Bending strength	140 MPa	ASTM D 790
Bending modulus	3 GPa	ASTM D790
Izod impact strength	90 J/m	ASTM D256

Fig. 2 depicts the CFREP powders as an initial material for green compaction. The carbon short-fibers were included into each powder at the preparation of powder feedstock.

Fig. 2. CFREP powders as a feedstock for consolidation via the cold, dry stamping to a green compact.

In the normal powder metallurgy (PM) processes, the original powder feedstock was poured into a die cavity and consolidated by stamping in cold. As stated in [12], the metal and alloyed powders with lubricants were mixed and compressed in the die to build up the green compact. This green compact was further processed to degrease the lubricants from the green compact before sintering and sinter-forging processes. In the present two-step PM procedure, no lubricating oils and waxes were utilized in green compaction and sinter-forging steps to minimize the contamination.

Materials Research Proceedings 28 (2023) 1799-1808 https://doi.org/10.21741/9781644902479-195

In this consolidation process, the relative density of green compact is controlled by varying the applied load. As stated in [12], this relative density of green compact has significant influence on the homogeneity and uniformity of products in the sinter-forging step. Hence, the hardness of green compact is measured by varying the applied load. Figure 3 shows an experimental setup for consolidation of CFREP powders to a green compact, corresponding to its schematic view in Fig. 1a. The load cell was embedded into the lower die. Owing to the programmable loading sequence in the CNC stamping system, the stoke schedule of upper die set was controlled to densify the green compact through the incremental loading sequence.

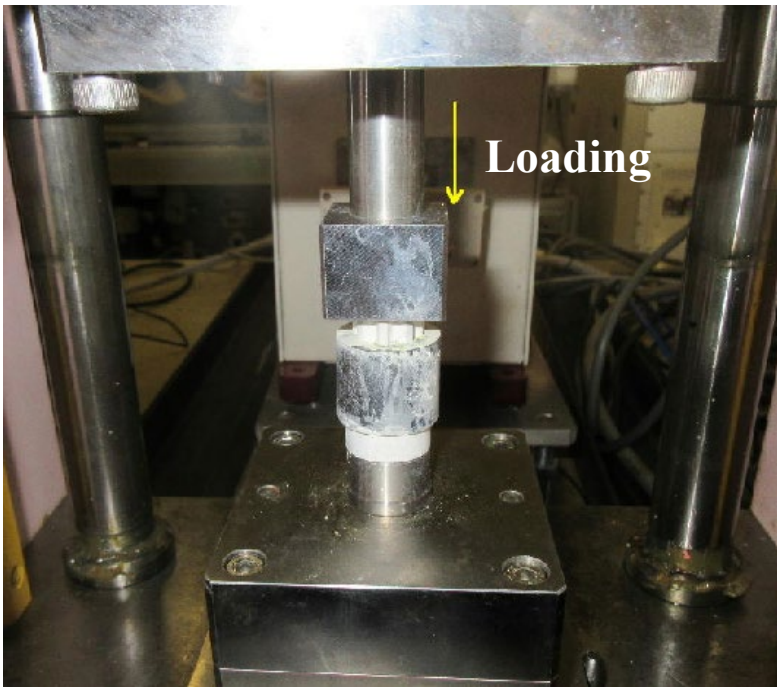

Fig. 3. Experimental setup for consolidation of CFREP powders to green compact in correspondence to its schematic view in Fig. 1a.

Sinter-Forging.

The green compact preform was fixed into the die-set for sinter-forging, as shown in Fig. 4. The HF-IH coil was placed to surround the die set with the designated clearance to optimize the spatial impedance between the dies and the coil. The load was first applied to 2 kN before heating the die set. The load was increased to the holding load at the specified temperature. The holding duration was constant by 600 s. In the following experiment, the holding temperature and applied load were varied to optimize the sinter-forging conditions by measuring the surface hardness. The sprayed h-BN film was also used for solid lubrication on the die surface.

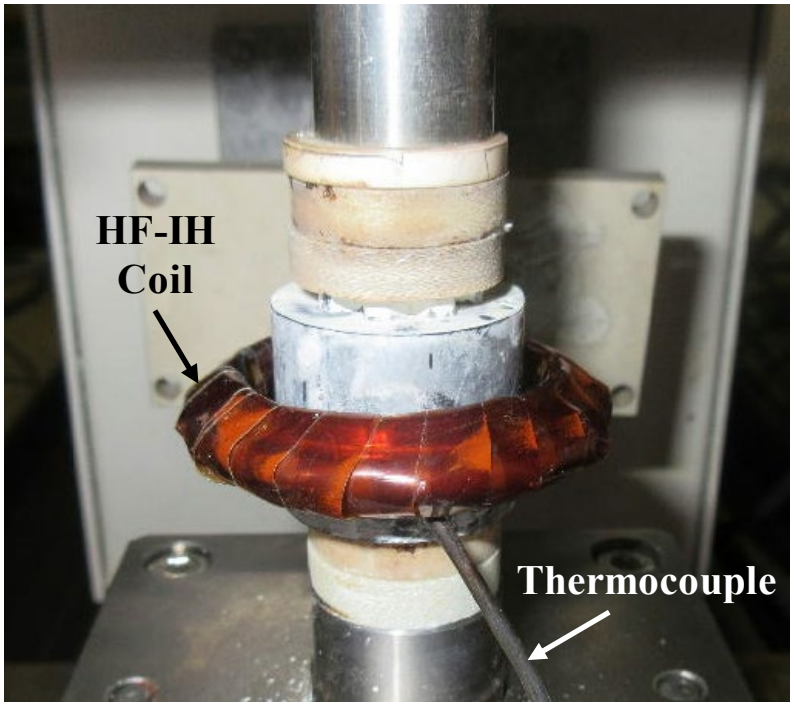

Fig. 4. Experimental setup for sinter-forging of the green compact to the forged gear product in correspondence to the schematic view in Fig. 1b.

Characterization.

A table-top X-ray tomography apparatus (X-1; Ueda, Japan) was employed to make non-destructive evaluation on the residual pored and defects in the green compact as well as the sinter-forged products. The intrinsic spatial resolution is 50 – 100 μm; however, the X-ray penetration capacity must be optimized to improve the spatial resolution in practice. Otherwise, no X-ray images are obtained when the applied power is too much or too low. Through the learning step, the optimal conditions were fixed and used in the following diagnosis. Three dimensional profilometer was also used to measure the part dimension of each tooth in the sintered gear with reference to the original CAD data and to discuss the dimensional accuracy of sintered CFREP gears.

Results

The cold and dry consolidation process is described by measurement of the average and maximum hardness in the teeth of green preforms in each loading condition. The sinter-forging behavior is also described by hardness measurement to search for the optimal processing conditions. The X-ray tomography is utilized to validate the dense green compacts and sinter-forged products. Three dimensional profilometer is utilized to measure the tooth profile and configuration for practical usage as a gear with reference to the standard.

Green compaction behavior.

The CFREP powders were consolidated in cold and dry to green compact preforms, the hardness of which was measured in each green compaction conditions to determine the appropriate load. A typical green compact was depicted in Fig. 5a when the applied load was 3.2 kN. The X-ray tomography was utilized for non-destructive evaluation on the density distribution in the inside of preform. As shown in Fig. 5b, no pores and defects were detected by this diagnosis. Three cross-section X-ray tomographic images proved that the preform had homogeneous density distribution.

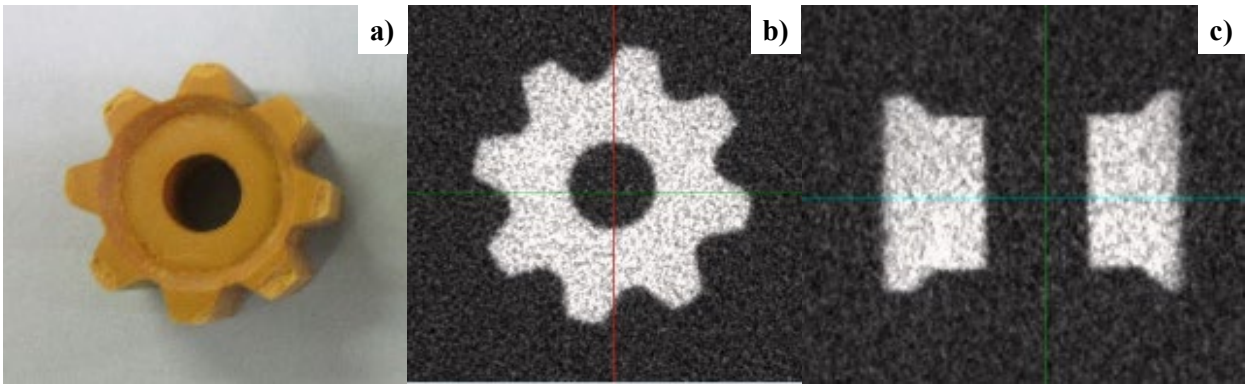

Fig. 5. A green compact after cold, dry stamping by applying the load of 3.2 kN. a) Overview of the green compact, b) X-ray tomographic image on the green compact from the top view, and c) X-ray tomographic image on the green compact from the side view.

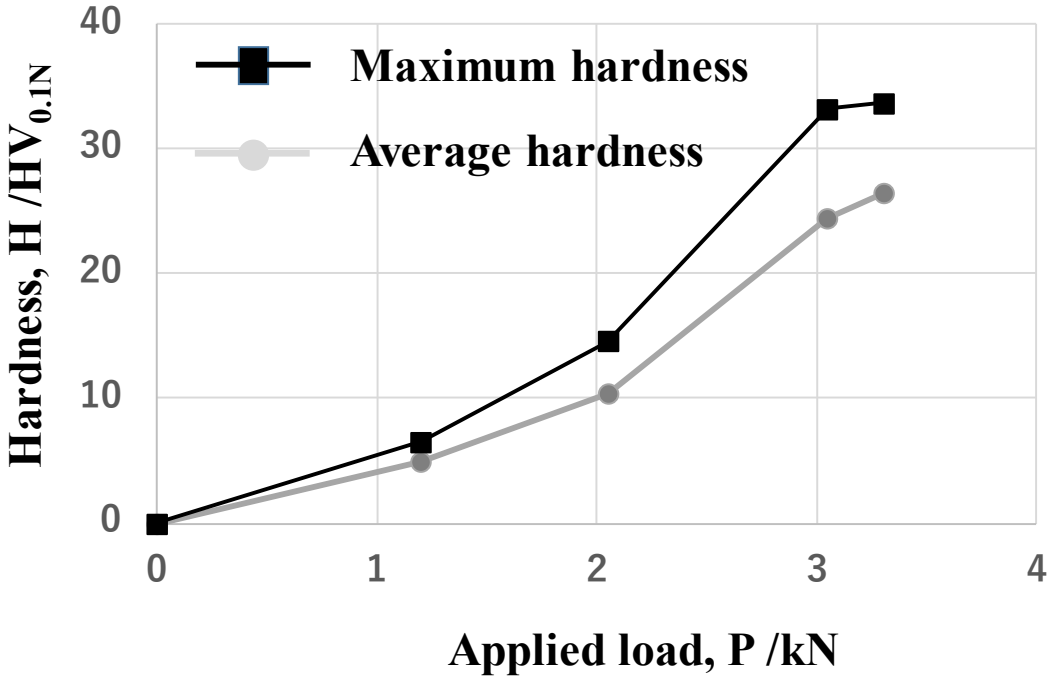

Fig. 6. Variation of the average and maximum hardness with increasing the applied load in the green compaction.

The average and maximum hardness were measured at each tooth of eight-teeth green compact preform. The applied load and duration were constant by 0.1 N (or 10 gf) and 10 s, respectively. As shown in Fig. 6, both hardness increased monotonously with increasing the applied load (P) up to P = 3 kN. This reveals that densification of CFREP powders advances with increasing the applied load during this consolidation process. The deviation of the maximum hardness from the average one increased with increasing P. This might be because of the friction on the surface of dies. When P > 3 kN, both hardness turned to be nearly constant; the green compact is near-fully consolidated in dry and cold. Several green preforms were fabricated by applying the load of 3.2 kN to investigate the hardness distribution among teeth of gear preforms.

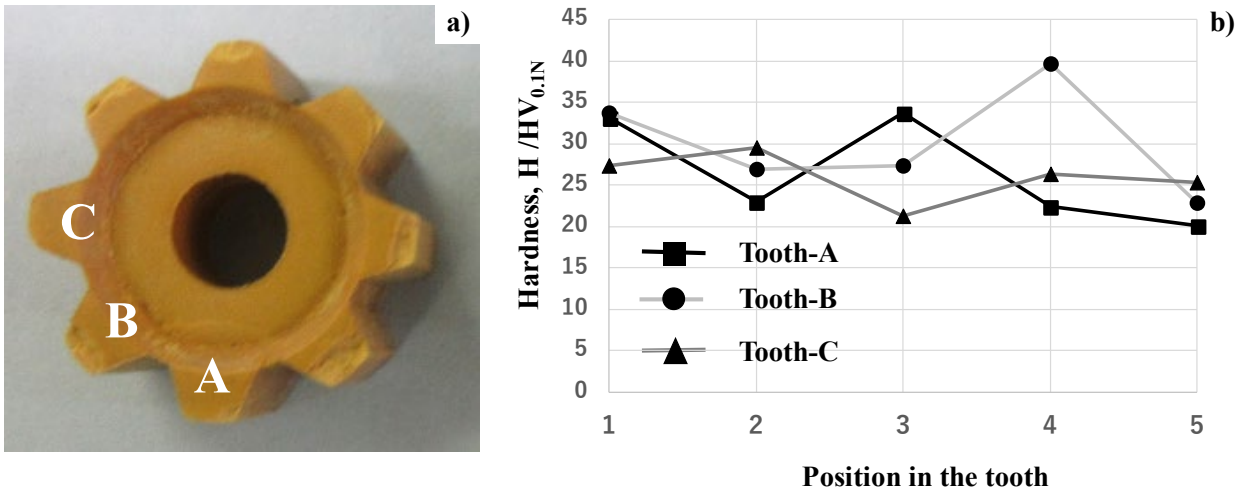

Fig. 7. Deviation of the surface hardness among the teeth of green preform gear when applying the load by 3.2 kN. a) Selected three teeth for measurement in the gear preform, and b) deviation of surface hardness among five positions in each tooth.

Three teeth (A, B, C) of green compact were selected to measure the hardness at the five positions in each tooth as depicted in Fig. 7a. The center point of tooth was denoted by No. 2. No. 1 and No.3 points were located away from this center point in the upper and lower directions by 0.075 mm, respectively. No. 4 and No. 5 points were also located away from No. 2 in the right and left sides by 0.075 mm, respectively.

Fig. 7b shows the hardness distribution in each tooth for A, B and C teeth. Since the average hardness is 27 $HV_{0.1N}$ in Figure 6, the deviation in each tooth ranges from 21 $HV_{0.1N}$ to 34 $HV_{0.1N}$ excluding the extraordinary high hardness. That is, the feasible hardness of green compact is estimated to be 27 $HV_{0.1\,N} \pm 7$ $HV_{0.1N}$; the statistical deviation is controlled to be less than a single standard deviation from the average hardness.

Most of this dimensional deviation comes from the powder flow and deformation behavior under compression. After [13], the rearrangement of CFREP powders by powder flow has more influence on the density of green compact than the deformation of CFREP powders. The incremental compression mode might be necessary to make more uniform densification in the green compact.

Sinter forging behavior.

The green compact specimens were fixed into the die cavity for sinter-forging. The specimen was first compressed and held by 2.0 kN during induction heating as shown in Fig. 4. The die temperature was inline monitored by using the thermocouple, which was embedded into the die. The holding temperature (T_H), the loading sequence, and the holding duration (τ) work as a main parameter in this sinter-forging process. T_H must be higher than Tg; T_H could exceed Tm since the actual specimen temperature might be less than Tm due to the thermal conductivity through die wall and the gap conductance between the specimen and die surface.

At first, the parameters were fixed at T_H = 668 K (or 395°C) and τ = 600 s, the sinter-forged preform was fabricated as shown in Fig. 8a. The X-ray tomography was also employed to investigate the sintering behavior; the X-ray irradiation intensity was lowered to distinguish the pores and defects left after sintering. Figure 8b shows the cross-sectional view of sinter-forged specimen. No pores and defects were seen in the inside of preform.

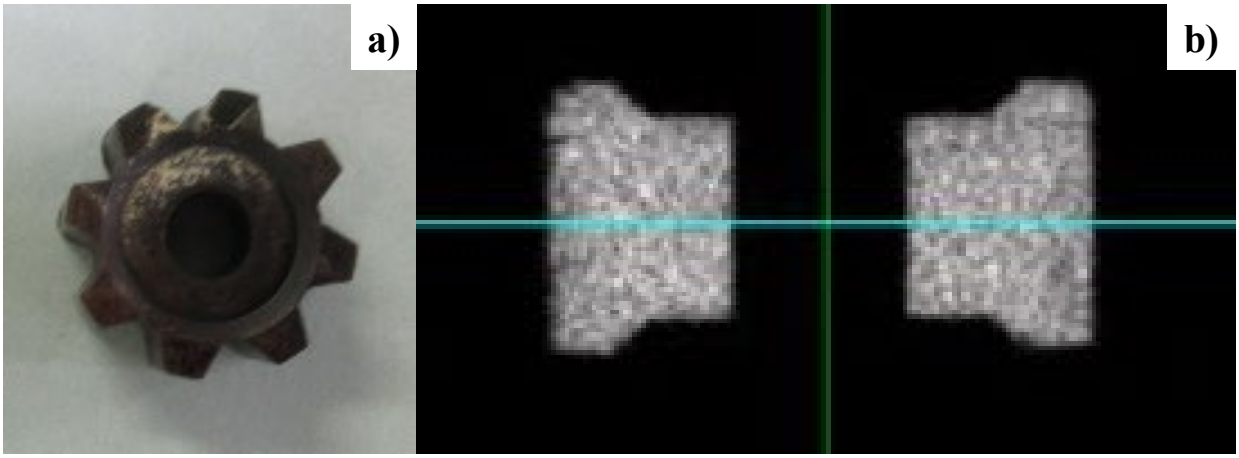

Fig. 8. A sintered gear after hot forging at 668 K for 600 s by 2 kN. a) Overview of the sinter-forged product, and b) X-tomographic image on the sinter-forged product in Fig. 5a with three cross-sectional images.

Table 2. Variation of the maximum hardness by varying the holding temperature just below Tm and the applied load in the sinter-forging.

Specimen	Holding Temperature (T_H) ℃	Applied load (P) kN	Hardness (HV0.1N)
#1	381	2.5	41
#2	387	3.0	38
#3	389	4.0	47

Let us investigate the effect of T_H and applied load (P) on the sintering behavior. T_H was varied below T_m of polyimide matrix. Table 2 summarizes the variation of measured maximum hardness by varying T_H and P. Compared to the hardness distribution of green compact in Fig. 7b, higher hardness was attained by sinter-forging. Different from the sinter-forging of electrically conductive metallic powders [14], the loading schedule must be controlled and optimized to attain much higher hardness at the sinter-forged gear-teeth of non-conductive CFERP.

Table 3. Dimensional measurement of sinter-forged CFREP gear by three dimensional profilometer.

Item	D_c (mm)	D_{cic} (mm)	D_{coc} (mm)
Sinter-forged CFREP gear	4.963	15.969	11.981
Die for sinter-forging	5.02	16.06	12.04

Quantitative evaluation on the CFREP gear.

Three dimensional profilometer in the projector-type (CALYPSO) was utilized to measure the center hole diameter (D_c), the diameter of circumscribing inner and outer circles (D_{cic} and D_{coc}) were measured for the sinter-forged CFREP gear at T_H = 450 ℃, by P = 3 kN and for 300s. Table 2 compares the measured data and original dimensions of die. In every dimension of gears, a negative deviation of 0.5 % is commonly measured in the sinter-forged CFREP gear. This deviation can be improved by optimization the sinter-forging conditions.

Discussion

As stated in [15], most of engineering plastic gears are made from polyacetal (POM) and MC Nylon, which is essentially polyamid resin, U-PE (Ultra High Molecular Weight Polyethylene), and PEEK (Poly-Ether-Ether-Ketone). Although they are characterized by the lightweight, the non-rusting, the quiet operating, and the injection molding enabling low cost, they suffer from the low strength, the tendency to hold heat, and the large dimensional change. In particular, the thermal distortion by relatively large coefficient of thermal expansion influences on the gear performance working in operation, in addition to the geometric distortions by the resist temperature change, the moisture absorption rate and the resistance to chemicals. The present CFREP gear has higher strength, chemical and thermal stability than those normal engineering plastic gears. Especially, this gear is free from the thermal distortion and dimensional change. To be noticed, those normal engineering plastic gears have no ways in hardening and strengthening. This CFERP gear is made from high strength polyimide matrix and carbon short fibers. This high strength composite design reflects on the high hardness even for the green compact.

Let us discuss the radiation resistance of CFREP gears. As discussed in [16], the CFRP has a risk of microstructural damage without CNT modification; this damage might come from the interfaces between the carbon fiber and epoxy matrix. The carbon fiber – poly imide interface is enough strong to reduce the risk of microstructural damage even under γ-irradiation conditions. This superiority in the radiation resistance is attractive to the gear box in reducer and in mechanical control unit of robots working in decommissioning operations.

The PM processing has been utilized to make mass production of small-sized and middle sized automotive parts. Its merits for fabrication of CFREP gears by the two-step PM processing, are as follows: 1) easiness to yield the complex shaped gears as a spur-gear, milter and bevel gears, screw gears and warm gears, 2) adaptivity to join the two gear units into a single working gear by sintering under compression, and 3) strengthening of gear teeth by homogeneous distribution of CFREP powders including the short carbon fibers.

In the present study, the green compaction and sinter-forging is performed in the uniaxial compression mode so that this two-step procedure has no ways to control the short-fiber orientation in the consolidation and forging. The CFREP powder flow control as well as the incremental loading in sinter-forging must be effective to make fiber-orientation control around the tooth part of CFREP gears.

Summary

Two step powder-metallurgy manufacturing procedure is proposed to fabricate the carbon reinforced engineering plastic gears from the powder feedstock. Through the green compaction step, the original powders are consolidated in cold to a solid gear-preform with relatively high density without significant pores and defects. This preform is sinter-forged at the holding temperature below the melting point for 600 s under the applied load to fabricate the CFREP gear with dimensional accuracy. In the further optimization of the processing parameters, the dimensional accuracy is improved with sufficient tolerance within the requirement of highly qualified gears.

Abstract. This work focuses on the design and fabrication of a continuous filament made of flax yarn and bio-based thermoplastic polymer. For this purpose, the sheath-core process has been explored by using an extrusion laboratory line equipped with a wire coating die to manufacture a flax core coated with PLA. The polymer properties were investigated (thermal transition, mechanical properties, melt viscosity) to link the polymer properties, the process and the properties of the resulting filament. The filament diameter decreases and surface defects appear when the pulling speed increases. The mechanical characterization of flax/PLA filaments demonstrates a higher elastic modulus, higher stress at break and lower strain at break as compared with pure PLA filaments. Such PLA coated flax filaments are a relevant option to widespread the use of biobased composites.

Introduction

Generalities about biocomposites.

Working with eco-friendly materials, recycling, and reusing are key challenges to face the demand for renewable resources. According to this statement, biocomposites are a great attraction, as they are produced from biofibers and biopolymers, and can present the required properties and functionalities at a reasonable cost [1]. The biocomposites market forecast report has estimated that the market size is likely to attain $10.89 billion by 2024, and the fabrication of materials from biobased feedstock is likely to raise from 5% in 2004 to 18% in 2020, and ~25% in 2030 [2]. Vegetal fibers such as flax and hemp have attracted significant focus as a potential alternative to synthetic fibers like carbon and glass [3], and biocomposites have been largely employed for several secondary applications in aerospace, automotive, packaging, electronics, and building sectors. It is thus important to keep developing new processes to widen the application panel of these renewable materials.

The choice of reinforcement largely relies upon the inherent chemical and physical characteristics of the fibres. Right from the cultivation to processing phases, various factors such as environmental conditions, processing methods or fiber age, influence the properties of plant fiber. Some of these features also have a direct effect on several biocomposite responses such as fiber-matrix bonding, thermal stability, or moisture sensitivity [4]. On the other hand, considerable research works are being performed in developing fully biodegradable materials (green composites) by combining biodegradable polymer matrix with biofiber [5]. The manufacturing of natural fibre-reinforced biocomposites is based, in general, on the technologies used for conventional synthetic short fibre composites, such as extrusion, injection moulding or compression moulding. Nevertheless, suitable processing methods and conditions must be chosen to manufacture fibre-reinforced biocomposites. To obtain biocomposites with suitable properties,

it is crucial to control their thermal stability, interfacial adhesion, fiber distribution, type and content [6].

Flax fibres.

In this work, flax has been chosen among all vegetal fibres for its good mechanical properties and its availability at industrial level and local scale. After extraction from the flax straw (woody core), fibres are organised in bundles, linked by a middle lamella, which cements the cell walls of adjacent cells together. It is mainly composed of pectic polysaccharides, lignin, and a small amount of proteins [7]. Many industrial processes aim to remove this natural matrix, to improve the separation of elementary fibres and the composite matrix/flax adhesion. However, these processes also bring undesirable side effects such as deterioration of the fibre and loss of mechanical performance [8].

Sheath-core flax/PLA.

Nowadays, flax is often found in composite materials under the form of unidirectional ply, woven, or short fibres, but an emerging technique is the use of long fibres for 3D printed composites. Material extrusion is defined as an additive manufacturing process in which material is selectively dispensed through a nozzle. Additive manufacturing process creates complex 3D parts through directionally orientated extrusion. The simplicity and relatively low price make of material extrusion make it widely used in many research works [9]. Two main options exist to print composites with continuous natural fibres: (i) in-nozzle impregnation in which the yarn and the molten matrix arrive simultaneously inside the noozle, and (ii) pre-impregnated filament printing in which the core yarn is trapped into a matrix sheath. Simultaneous impregnation of thermoset resin and continuous fibre in the extrusion head leads to several process issues, such as fibre content and feed, deposition rate and path [9]. Also, passing fibre and thermoplastic filament through a single nozzle limits control over fibre and can lead to poor overall surface finish and increased voids [10].

In this work, a novel process will be explored to improve the quality of a sheath-core filament, made of flax yarn coated by a PLA (polylactic acid) matrix. PLA is a bio-based polymer which uses have been drastically widen these last years, as it is renewable and biodegradable, and it is obtained from agricultural crops like sugar beet or corn. It demonstrates good mechanical strength, stiffness and can be processed with conventional polymer processing techniques. In addition, when looking at its life cycle, it appears that PLA requires nearly one tenth of the fossil energy when compared to synthetic polymers [11]. These factors make PLA an ideal choice to experiment biodegradable composites. In this research work, material intrinsic parameters were explored such as fibre properties, PLA thermal transitions and melt viscosity. Then, several filaments were manufactured with a wire coating die equipment while varying the pulling speed. Then, the structure and the properties of the resulting filaments were investigated to correlate the PLA properties with mechanical behaviour of the filaments.

Materials and Methods

Flax yarn.

The first test batch was carried out on flax sliver, which is a product originally manufactured for garment-textile fabrication. In order to design a very thin and soft yarn, this flax material has been prepared for wet spinning process: firstly, the fibres have undergone a chemical degumming process with low concentration caustic soda. This step is crucial to separate cellulose and non-cellulose parts and to get rid of all the pectins and sticking agents present on the fibres to keep their cohesion. Also, this process turns the flax from hydrophobic to hydrophilic, which is a major requirement for the wet spinning process. After degumming, fibres were bleached with peroxide to prepare them for further transformation and finishing, such as dyeing. Flax sliver was turned to yarn on a Linimpionti BMR1 wet spinning machine, presented in Fig. 1a. Machine speed was 15m.min^{-1}, with a drawing of 4, and a torsion of 450 revolution.min^{-1}. Final yarn has a count of 66

± 3 Tex. For flax yarn characterisation, the tensile tests are carried out on a Tenso-Lab 4 v. (Mesdan Lab, Italy) apparatus, according to standard NF EN ISO 2062 [12] over a length of 250 mm, with a speed of 250 mm.min^{-1} and a preload of 0.50 cN.Tex^{-1}.

PLA 3 grades.

PLA is a linear thermoplastic aliphatic polyester obtained from lactic acid. As shown in Fig. 1b, lactic acid has two enantiomer form L-Lactic and D-Lactic acid due to its chiral geometry. It results in dimers with three enantiomer forms: L-lactid, D-Lactid and DL-Lactid [13]. In this work, two different grades of PLA are studied from NaturePlast: PLE005 and PLE005-A (called respectively in this work PLA-A and PLA-B). PLE005 (PLA-A) is a homopolymer of L-lactid (>99%) with high crystallisation potential and PLE005-A (PLA-B) is a copolymer of L-Lactid (>95%) and D-Lactid (<5%) with slower crystallisation kinetics due to the presence of D-Lactid [14]. PLA pellets were systematically dried in an oven at 60°C for few hours before any experiment. Indeed, the presence of water in PLA while processing can affect its property by hydrolysis phenomenon and plasticising of the crystalline phase [15].

Extruder and wire coating die.

The wire coating die is presented in the scheme in Fig. 1c. The die is a commercial equipment provided to fit a single screw Rheomex extruder on a Polylab OS system by ThermoFisher. The flax fiber enters through the top and exits at the bottom of the scheme. The molten polymer enters at the left side and it flows into a tube up to join the fiber to coat it. The screw is L/D= 25 and its rotating speed is kept constant at 5 rpm. The temperatures are 180°C for the screw, 170°C inside the die. Then, the fiber coated with the molten PLA exits the die at the bottom of the scheme. The coated fiber is pulled out the die with a system equipped with 2 rollers. The pulling speed has been varied between 0.003 and 0.2 m.s^{-1}. The flow is considered as steady, incompressible and isothermal, the flowing profile is a Poiseuille-type, with a maximum fluid velocity ($V_{r=R}=V_{max}$) at the vicinity of the fiber and a sticking condition at the die wall ($V_{r=0} = 0$). A modular part can be changed to vary the thickness of the polymer coating, the nozzle dimensions chosen in this study are 2 and 4 mm. The maximum shear rate just before exiting the die $\dot{\gamma}$ is calculated by V_m/e, with e the width of the channel where the polymer flows. The maximum shear rate is 200 s^{-1} for a 2 mm diameter filament.

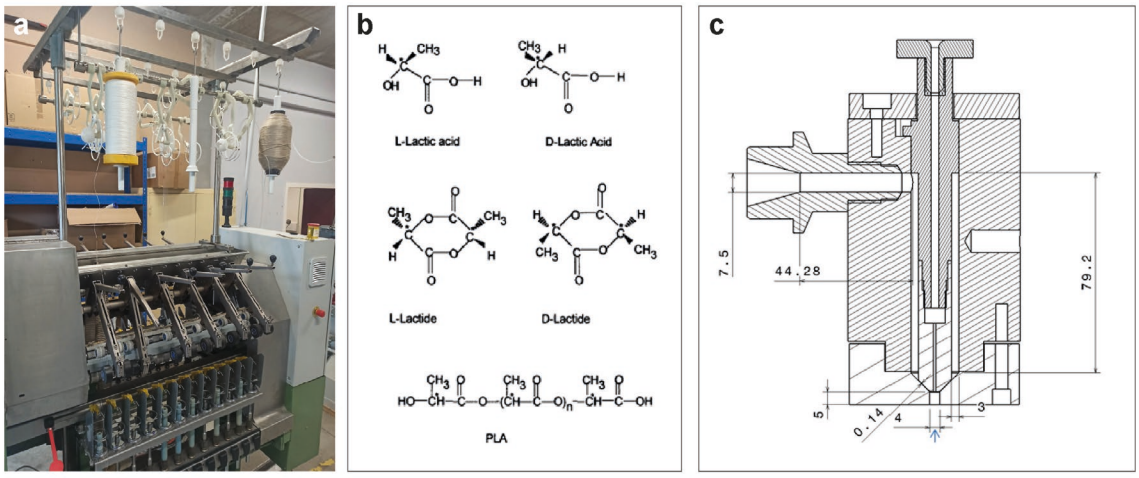

Fig. 1. Wet spinning machine (a), structures of lactic acid, lactid and PLA [15] (b), wire coating dye (c).

Rheological behavior.

The polymer coating thickness could be predicted by considering the process parameters and the polymer rheological properties. For that, we measured the complex viscosity of the two grades of PLA in an oscillatory rheometer MCR501 by Anton Paar, applying the Cox-Merz equivalence.

The experiments were carried out using a 25 mm diameter parallel-plate configuration with a 1 mm gap. Initially, dynamic strain sweeps were performed to determine the linear viscoelastic regime (LVR). Time sweeps were performed to check the thermal stability of the polymer along the experiment duration. Frequency sweeps were performed to measure G' and G'' between 200 and 230°C with 10°C steps, from 100 to 0.1 rad.s^{-1}. Since the angular frequency is limited to 100 rad.s^{-1}, we applied TTS at the reference temperature of 200°C to extend the shear rate range to attain the 200 s^{-1} involved in the process.

DSC.

The thermal transitions and enthalpy were determined using a Mettler Toledo DSC1 under a nitrogen flow rate of 50 mL.min^{-1}. After heating at 210°C to cancel the thermomechanical history, a cooling rate at 10°C.min^{-1} was applied followed by a second heating ramp at 10 °C.min^{-1}.

Mechanical characterisation.

For pure PLA, specimens were injected on a Proxima H120 (Billion, France) at 190°C to 175° from nozzle to rear barrel with mould regulated at 40°C to achieve a low crystallinity. The tensile tests were carried out on a 33R4204 (Instron, United State) testing machine, equipped with a mechanical extensometer 2620-604 (Instron, United State) and a load cell 2525-805 of 5kN (Instron, United State) according to standard NF EN ISO 527 with a speed of 3mm.min^{-1}. In this study, five specimens were tested for each grade of PLA.

Optical observations. A microcutting machine Mecatome T202 (PRESI, France) was used for sample preparation with an ultra-thin wheel UTW-R200U (PRESI, France). Samples were directly observed on their cross-sections with a binocular Leica Wild M420 at magnification of x40. The surfaces of PLA filaments were inspected through a high-resolution microscope Keyence VHX-6000S (Bois-Colombes, France) in a reflection and transmission mode with a magnification of x100.

Results

Mechanical characterization of PLA.

The tensile behaviour of both PLA is shown in Fig. 2. PLA-A and PLA-B show an elastic domain in their first percent of elongation indicating no modification in their microstructure. Then, PLA display a plastic domain where modifications in the microstructure appear, mainly chains' conformation and crystalline slip, until specimens breaking.

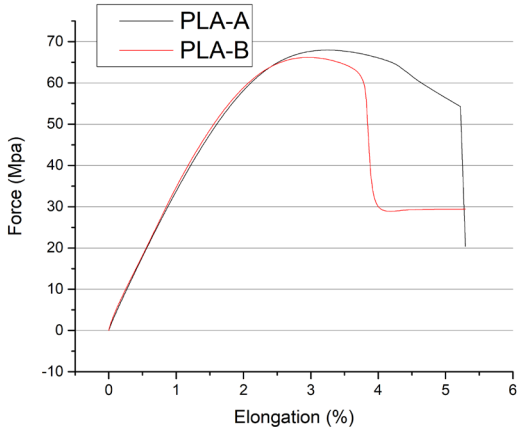

Fig. 2. Tensile curve of PLA-A and PLA-B.

The tensile properties of PLA-A and PLA-B are shown in Table 1. PLA-A, despite its low crystallinity due to high cooling rate during injection molding, has a slightly higher rigidity and strain at yield point than PLA-B. Previous studies have shown that a higher crystallinity of homopolymer of PLLA improves its rigidity and resilience [16]. PLA-B accepts longer elongation

before breaking than PLA-A because of less crystallinity resulting in higher macromolecular mobility.

Table 1. Mechanical properties of PLE005 and PLE005-A

	Young Modulus	**Stress at yield point**	**Elongation at yield point**	**Elongation at break**
	(Mpa)	(MPa)	(%)	(%)
PLA-A	3700	67.6	3.17	4.10
PLA-B	3500	65.2	3.08	>15

Thermal transitions of PLA.

Thermal transitions of PLA upon heating are shown in Fig. 3a. Glass transitions of PLA-A and PLA-B are 66°C and 60°C respectively. Their melting point are 178°C for PLA-A and 155°C for PLA-B. Those temperatures depend of the initial composition of PLA and its molecular weight. Also, the crystalline phase has stronger intermolecular interaction and lower flexibility [17], increasing the melting temperature. As expected, PLA-A reaches a higher crystallinity than PLA-B due to its higher concentration of L-Lactide. In Fig. 3b, DSC thermogram shows that PLA-A starts to crystalize at 117°C when cooling from a molten state. The crystallisation kinetics depends on its concentration of L-Lactid and molecular weight. At a cooling rate of 3°C.min^{-1}, PLA-B does not undergo crystallisation when cooling from a molten state due to presence of D-Lactid. Variation of D-Lactid concentration affects the crystallisation kinetics of PLA, at concentration higher of 15%, its crystallisation is not possible. Authors have shown that the crystallisation of PLA is 60 times faster from a concentration of 6.6% to 0.6% of D-Lactid [13].

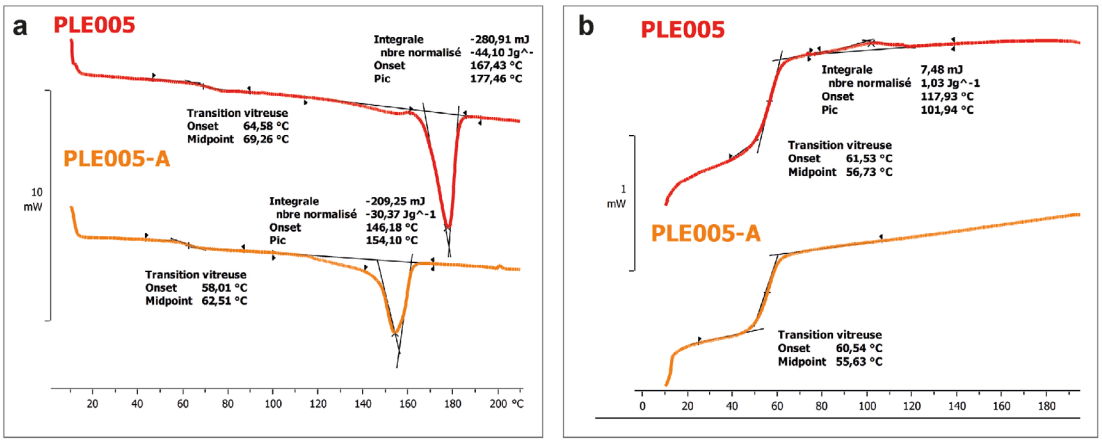

Fig. 3. DSC thermograms of PLA, heating ramp (a) cooling ramp (b).

Viscosity of PLA.

TTS was applied to frequency sweeps at 200, 210 and 220°C to obtain master curves shown in Fig. 4. The curves do not follow the rheological behavior expected for molten polymers, indicating a structural evolution with time. However, the slopes of G' and G'' are closed to the ω^1 and ω^2 dependency. This complex flowing behavior is mentionned in the literature: Lactic acid exists in two enantiomeric forms, L-lactic acid and D-lactic acid, whose co-crystallization forms a stereocomplex with a melting point about 50 °C higher than PLA homocrystals [18]. Neat PLLA demonstrates a Newtonian plateau at low frequencies, typical of polymer melts, while such

behavior is not observed when PLLA is blended with 5% PDLA. In the presence of PDLA, significant deviation of complex viscosity at low frequencies can be associated to the interaction between chains caused by stereocomplex formation [19]. This agrees with our findings, the master curve deviate from the expected trend for PLA-B which contain <5% of PDLA according to the manufacturer. Also, the complex viscosity of PLA- B is higher than those of PLA-A, likely due to the presence of a small concentration of stereocomplex in the PLLA melt. Moreover, measurement of the melt rheological properties of PLA is complicated by degradation effects resulting in chain breakage. Master curves of dynamic viscosity constructed using time-temperature superposition show significant dispersion for unstabilized PLA [20]. Finally, the complex viscosity of PLA-A and PLA-B is about 100 and 250 Pa.s respectively, at the Newtonian plateau.

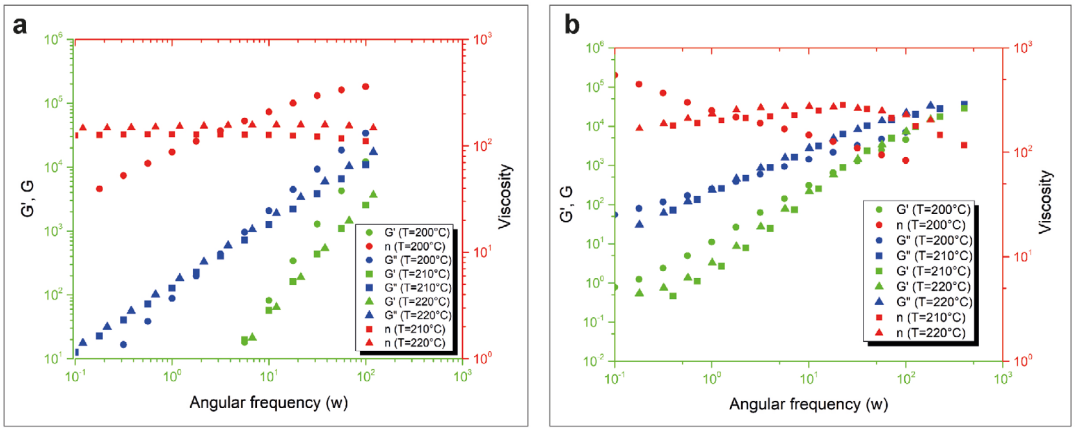

Fig. 4. Viscosity curves of PLA-A (a) and PLA-B (b).

Extrusion rates are often limited by the surface defects that appears at the die exit when the shear stress is too high [21]. At the die exit, the velocity profile goes from a parabolic shape to a plug one, resulting in tensile stresses that can crack the surface of the extrudate. This is known as the shark skin effect. In our cases, this defect is more likely to appear for PLA-B whose viscosity is higher, for the same shear rate, hereby related to the pulling speed. Such surface defects are seen in Fig 5 for both PLA. At low pulling speed, the filament surface of PLA-A is smooth Fig. 5a, whereas air bubbles Fig. 5b and shark skin effect Fig. 5c are visible for higher pulling speed. As expected, no shark skin effect was noticed for PLA-A due to a lower viscosity as seen in Fig. 4. Since PLA and flax fiber were thoroughly dried before processing, these bubbles could not stem from residual water. Another explaination could be associated with the design of the die in which the molten polymer could trap air where it meets the fiber.

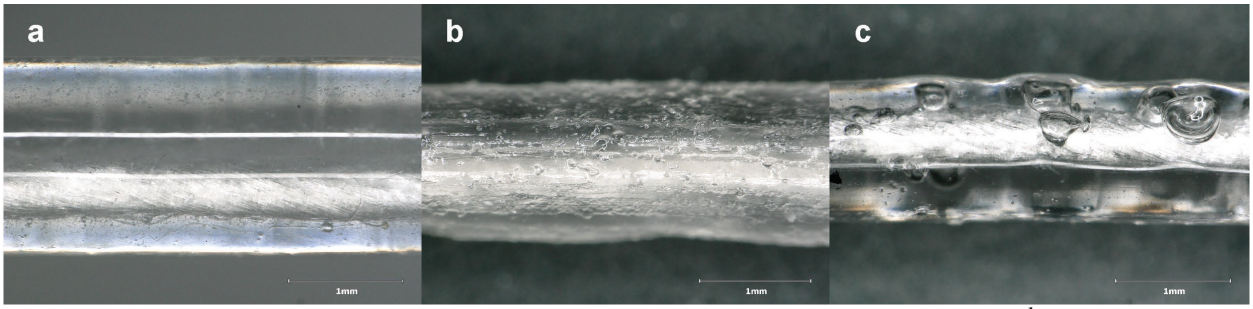

Fig. 5. Optical micrographs of PLA filament surfaces of PLA-A at 0.014 m.s^{-1} (a), PLA-A at 0.040 m.s^{-1} (b), PLA-B at 0.040 m.s^{-1} (c).

Microscopic observations of PLA injected with flax yarn.

Table 2 presents the longitudinal section of PLA extruded with flax yarn. Cross-sections show a clear irregularity in the location of the flax yarn: it tends to go to the side of the filament instead of its centre.

Table 2. Transversal section of the filaments, depending of the pulling speed and grade (PLA-A and PLA-B).

Pulling speed	PLA-A	PLA-B
0,008 $m.s^{-1}$		0,014 $m.s^{-1}$		
0,040 $m.s^{-1}$		
0,065 $m.s^{-1}$		

Mechanical properties of PLA injected with flax yarn.

Fig. 6a shows the filament diameters for the two grades of PLA. As expected, when the pulling speed increases, the PLA coating thickness around the flax fibre get thinner. No effect of the viscosity is seen, since the diameters are similar for both grades Fig. 6b shows the impact of pulling speed on the stress strain curve of the two PLA/flax (PLA-A and PLA-B) filaments pulled at 0.008,

0.014, 0.040 and 0.065 $m.s^{-1}$. It appears that the highest is the shear rate, the lowest is the strength at break: a fast-pulling speed creates a thinner polymer layer onto the flax yarn.

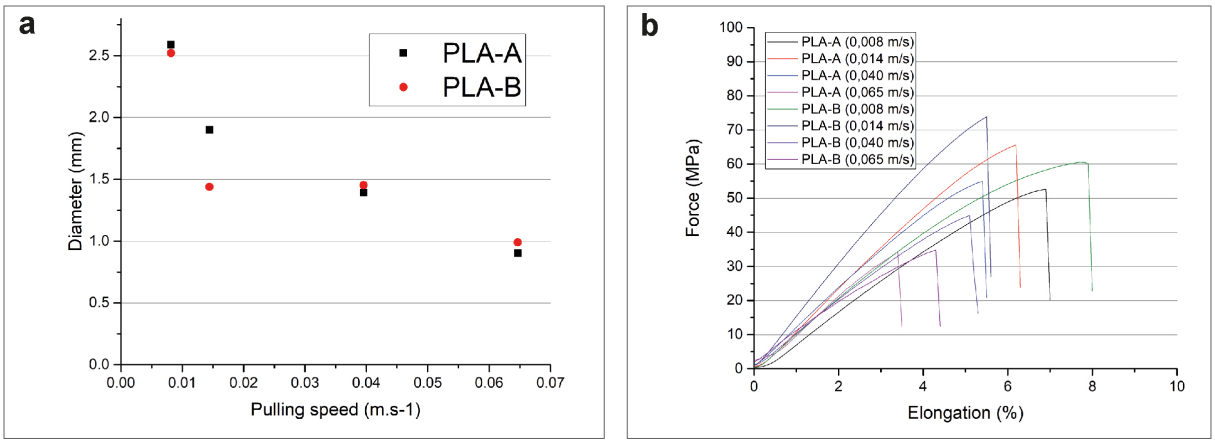

Fig. 6. Evolution of the diameter with the pulling speed (a), Stress strain curve of PLA-A and PLA-B for 4 pulling speed (b).

Fig. 7a presents the stress strain curve of flax yarn, pure PLA filaments and PLA coated flax filaments (referred as PLA injected). It is clear that adding flax yarn, which has naturally a higher stiffness, increases the filament rigidity and decreases the elongation at break compared to pure PLA filaments. The impact of PLA grade and pulling speed is less obvious. Fig. 7b presents the elastic modulus of pure PLA-A and PLA-B for the 4 pulling speed, along with PLA-A and PLA-B coated flax at one speed. The elastic modulus is higher for filaments containing flax. When increasing the pulling speed, the elastic modulus decreases. This could be attributed to the surface defects appearing at high shear rates as seen in Fig 5.

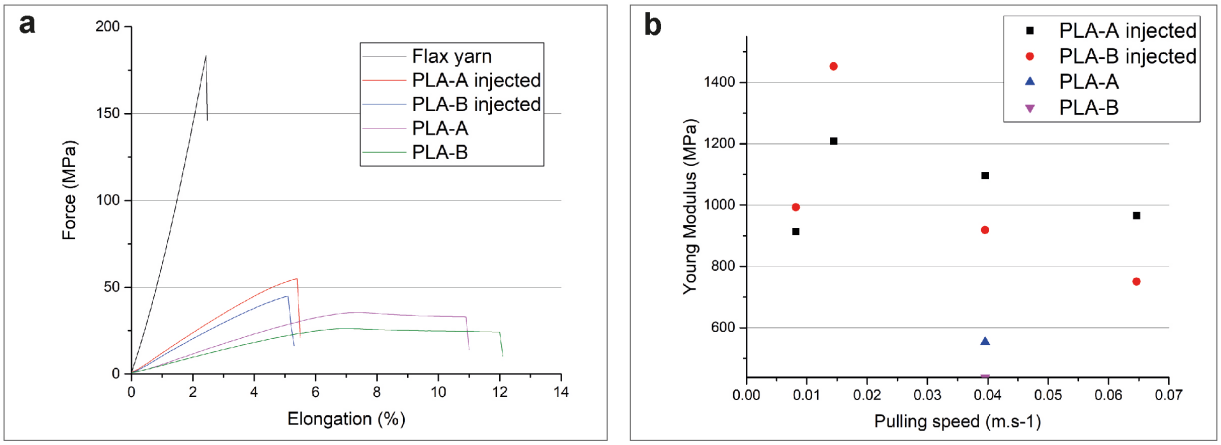

Fig. 7. Stress strain curve (a) and Young's modulus (b) of flax yarn, PLA coated flax and pure PLA filaments.

Summary

In the present work, a wire-coating die was used to manufacture novel filament of flax yarn with a PLA coating. The material properties were assessed to check whether the polymer properties are suitable with the extrusion process.

The main conclusions of this research work are as follows:

- The two grades of PLA are suitable to be extruded in a wire-coating die. A range of filaments with various diameters was successfully achieved.
- The filament diameter decreases when the pulling speed increases
- The tensile properties of the PLA coated flax and better than pure PLA filaments.

This work demonstrates the ability to obtain flax/PLA filaments. Further work will focus on printing composite parts with such filaments. Also, it might be relevant to study the interfacial adhesion between the flax yarn and the PLA matrix to enhance the mechanical properties of the composites obtained by 3D printing.

Keywords: Thermal Diffusion, Shear Strength, Energy Director, Composites, Ultrasonic Welding

Abstract. Thermoplastic composites offer new possibilities for the aerospace industry. Large and thin structural parts can be processed rapidly and more cost-effectively than thermoset composites since the latter need to undergo lengthy curing reactions. An additional advantage is the possibility of being assembled by welding processes. However, joining thermoplastic composites remains challenging due to the lack of knowledge of the impact of process parameters (time, pressure, temperature) on the welded joints. A polymer film named energy director (ED) is usually set up at the interface to enhance the weld resistance. A combined experimental-numerical approach was carried out to estimate the influence of ED thickness on the thermal diffusion within the assemblies and the mechanical resistance of welds in the ultrasonic welding (USW) process. The studied materials are unidirectional carbon fibre-reinforced polyetheretherketone (CF/PEEK) and 50 µm and 250 µm polyetherimide (PEI) films as ED. Thermocouples (TCs) are inserted into the PEI layer to measure the temperature evolution during USW. Besides, the thermal profile is obtained based on the simulation of conduction phenomena through the thickness of the material using the finite element method (FEM). The effect of the ED through-thickness model points out the evolution of the temperature profile with time during the USW process for different PEI thicknesses. For both ED thicknesses, the temperature reached is above the PEI glass transition (220 °C) allowing macromolecular interdiffusion. According to our results, only the first ply reaches the melting temperature of PEEK, showing that the composite parts are not thermally affected during USW. Because of the high conductivity of unidirectional CF/PEEK composites, a thinner ED leads to a too-short heating time at the interface. Associated with too high power in a short time, a lower weld resistance of APC-2 parts is obtained by single lap shear for 50 µm PEI layer, 12 MPa, compared to 43 MPa obtained for 250 µm. A higher PEI thickness at the interface slows down the cooling step, resulting in a deeper interdiffusion of PEI and so, a stronger weld.

Introduction

Ultrasonic welding is a process that makes it possible to obtain good-quality welds quickly and affordably [1,2]. In USW, the heat is generated at the interface by friction between the two parts through high-frequency vibrations. Indeed, the process can be easily implemented at an industrial scale and the cycle times are in the order of seconds. Ultrasonic welding does not need any specific material property [3]. No additional device is necessary to generate heat in the welding area compared to induction and resistance welding for which, susceptor and resistor are required, respectively. The development of an industrially viable solution for ultrasonic welding of CF/PEEK would give this family of composite materials an undeniable advantage over thermosetting composites.

Many parameters affect the ultrasonic welding quality, such as welding time, pressure, amplitude and type of energy director [4,5]. Monitoring the thermal diffusion is crucial to relate process parameters to welds' performance. Nevertheless, measuring the temperature during welding processes is challenging and the works related are rare [3]. Non-invasive techniques do not exist yet to assess the temperature profile at the interface during welding. Due to the closed contact between the two composite parts with an integrated PEI layer, it is difficult to measure the temperature and almost impossible to control it. Moreover, the very short cycle times during USW reduce the means available to measure the temperature. Any device placed between the two specimens would alter friction phenomena, thus, changing heat generation [6,7]. Besides, some works report thermal profiles during USW obtained by simulation of thermal transfer [8,9], but none of them focuses on ED thickness.

In this work, the thermal analysis conducted on CF/PEEK composites using different thicknesses of PEI are displayed. The micro-thermocouples were chosen to minimize their influence during welding. The experimental section presents quasi-non-intrusive temperature measurements where temperature profiles are analyzed through the influence of USW parameters. The mechanical resistance of welding joints and process parameters for two PEI thicknesses on CF/PEEK are correlated to the thermal profiles. The thermal diffusion through the sample thickness from the interface is investigated from a FEM analysis in the numerical section.

Materials and Methods

Experimental methods.

Continuous carbon fibre-reinforced polyetheretherketone composite, named APC-2 from Cytec Industries and polyetherimide, named Ultem 1000 from Sabic, have been used.

The composite plates were produced by compression with Pinette Emidecau Industries Lab800 thermo-compression device. Two types of plates are manufactured: (1) APC-2 plates and (2) APC-2 with a 250 µm or 50 µm PEI layer on top plates. A stack of 14 unidirectional plies of APC-2 was made to obtain a mirror symmetry lay-up $[0/90]_7$. The PEI film was integrated on the APC-2 plates.

The thermocouples were 80 µm diameter K-type from Omega. Chromel and Alumel threads were supplied separately and welded using the air arc welding technique. TCs are inserted according to the procedure described by Bonmatin et al. [10]. The TCs were deposited and covered with a metal mass of 5 kg on the composite containing the PEI film to insert them into the polymer layer. The assembly was then placed in an oven for 40 min at 290 °C. Then, the TCs were extended to connect them to a Logger GL980 midi data recorder from Graphtec Corporation.

Omega 4X ultrasonic welder from Mecasonic was used for the experiments. It is welding equipment with a working frequency of 20 kHz and a maximum load of 3000 N. The displacement amplitude of the waves generated by the generator is amplified by a factor of 1.7 by the booster and by a factor of 1.7 by the sonotrode.

The quality of the assemblies was assessed by lap shear strength (LSS). The assemblies tested were made following ASTM D1002, with samples of 100 x 25 mm^2 corresponding to length and width respectively, and an overlapping area of 10 x 25 mm^2. The Single Lap Shear (SLS) tests were performed on the Instron Universal 33R4204 tensile machine equipped with a 100 kN load cell with a crosshead speed of 2800 $N.min^{-1}$. The value of LSS [MPa] was calculated with Eq. 1.

$$LSS = \frac{F_{max}}{l_0 \cdot w} \quad (1)$$

In the SLS test, the strength of a weld depends on the load at the breaking point F_{max} [N], the length of the weld zone l_0 [mm] and the width w [mm].

Numerical methods.

To carry out the simulation, the FEM has been chosen. It consisted of the simplification of differential equations for numerical use. These methods, introduced for many years, are still widely used for the resolution of thermal problems [11,12]. The configuration applied for the simulation was a simple one-dimensional (1D) thermal conduction model in which the in-depth heat diffusion throughout the material part, especially in the first layers of composites was considered. Abaqus software from Dassault System was used for the numerical analysis of heat transfer. The model considered the thermal and physical properties of the polymer changing with temperature and melting heat. In this case, the heat source term was considered to be null because no volumetric internal energy was generated. A non-stationary thermal model was developed, where the software used the local heat equation (Eq. 2).

$$div\left(k\vec{\nabla}T\right) = \rho C_p \frac{\partial T}{\partial t} \quad (2)$$

where k is the thermal conductivity [W.(m.°C)$^{-1}$], T is the temperature [°C], ρ is the material density [kg.m^{-3}] and C_p is the heat capacity [J.(kg.°C)$^{-1}$]. The left-hand term corresponds to diffusion whereas the right-hand term corresponds to the transient heat state.

Results and Discussion

Experimental analysis.

During the welding process, the power [W] and displacement of sonotrode [mm] were recorded over time [s] by the machine, and they were plotted to identify different stages of USW according to Villegas's work. The welding machine can work in different modes, mostly the welding is controlled by time or displacement of the sonotrode. The time-controlled welding allows finding the optimum displacement of the sonotrode where the process is stopped in the stage before degradation of the material [13]. The temperature measurements were taken by thermocouple integrated into the PEI film during welding for every 1 µs. The three curves of power [%], displacement [%], and temperature [°C] are presented as a function of time [s] in Fig. 1. The maximum power of the machine considered for the calculation is 3000 W and the maximum displacement represents the thickness of two PEI layers, 0.5 mm and 0.1 mm.

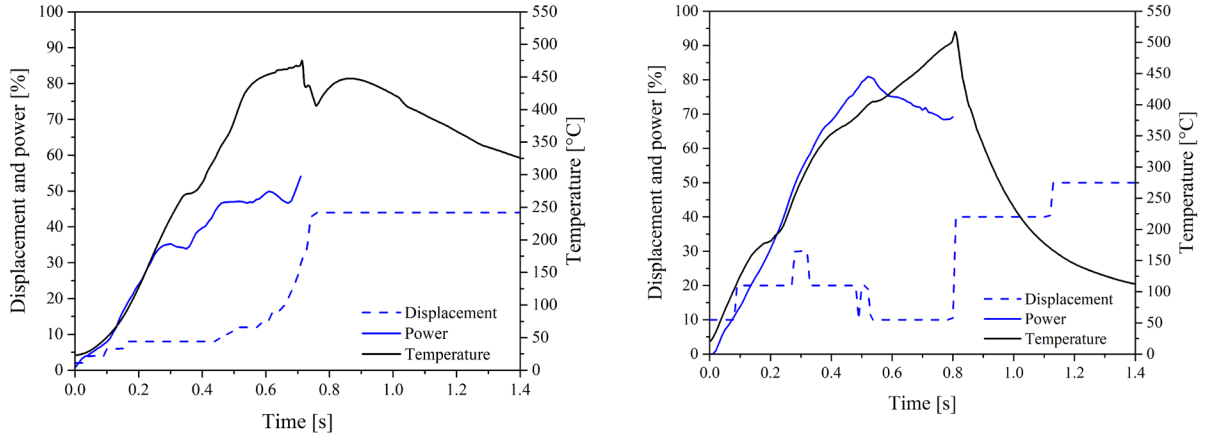

Fig. 1. Temperature monitoring with thermocouples during USW of APC-2 composites with integrated (a) 250 µm PEI for an amplitude of 68 µm, a load of 2.5 bar and a displacement of 30 % (b) 50 µm PEI for an amplitude of 68 µm, a load of 2.5 bar and a time of 0.8 s.

For the assembly of CF/PEEK with 250 µm PEI, the optimized displacement-controlled mode was applied at 30 %, Fig. 1.a, to melt the first plies of adherents. Regarding the welding of CF/PEEK with 50 µm PEI, the displacement-controlled mode at 40 % was not enough to weld the assembly while at 50 % high degradation of material was observed, so the time-controlled mode with optimized 0.8 s has been applied, Fig. 1.b. The same trend on the temperature curves during the welding step from room temperature to the maximum one can be observed. The latter reached 475 °C at 0.714 s and 517 °C at 0.807 s with a heating ramp towards 800 $K.s^{-1}$. Then, very rapid cooling is observed with a ramp towards 600 $K.s^{-1}$ and 1600 $K.s^{-1}$. ED with smaller thickness causes higher power of welding around 80 % with only two stages. At first, heating of the ED at the interface occurs due to the phenomenon of friction. The sonotrode does not move significantly because the materials involved in this step are still rigid and have not yet undergone a change of state. Then, the PEI continues to warm up. It begins to flow as a result of nucleation (viscoelastic heating mechanism controlled by surface friction heating) and the growth of hot spots at various places in the area of overlapped composite parts. The flowing of the energy director after reaching its glass transition causes a decrease in power and a displacement of the sonotrode. It can be assumed that the ED is not completely molten (lack of the third stage) and it seems that the first plies of composites do not reach the melting temperature of PEEK. So, there is no risk of degradation or delamination of PEEK composite parts during USW with these parameters. Displacement of the sonotrode until the end of welding achieves 50 %, which means that the thermocouples were in contact with the composites which explains the fast cooling rate. Due to high conductivity, carbon fibres contribute to very efficient heat diffusion.

After temperature monitoring, the mechanical strength was calculated. LSS are 43 ± 5 MPa and 12 ± 2 MPa for CF/PEEK with PEI of 250 µm and 50 µm, respectively.

Numerical conditions.

The transient thermal model was applied to the same welding configuration as the previous section, i.e. two layers of PEI, as seen in Fig. 2. The composite parts are 2 mm thick, and each PEI layer was 0.25 mm or 0.05 mm thick. A narrow transverse slice corresponding to the stacking of the three materials was designed in two dimensions (2D) by Abaqus. Therefore, a conduction model was performed, allowing to obtain the through-thickness thermal fields. To create this model, the following assumptions were used:

1) The interfaces between PEI and CF/PEEK were not perfect and thermal contact resistance was taken into account,
2) The studied materials were only PEI and CF/PEEK and the material properties varied with the concentration of each one, a mix of both materials was not considered,
3) Taking into account the thermal anisotropy of the composite, only the through-thickness properties of materials were considered,
4) The thermal behaviour of the sonotrode, steel plates or other tools was not considered,
5) Finally, only conduction was considered (neither convection nor radiation).

With these hypotheses, the conduction model gave an approximate thermal evolution at any point of the thickness and the evolution of temperature gradients over time.

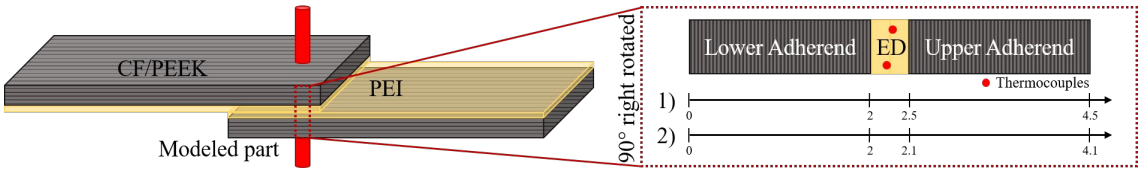

Fig. 2. Through-thickness model of the welding configuration, the distance through the thickness (mm).

The model is concentrated on the thermal properties of the CF/PEEK because such properties evolve much with temperature when PEEK changes from a glassy state to a flow state or a molten state. These properties are presented in Table 1. Those of PEI are presented in Table 2.

Table 1. Thermal properties of APC-2 [14].

Temperature [°C]	Thermal conductivity [W.(m.°C)$^{-1}$]	Specific heat [J.(kg.°C)$^{-1}$]	Density [kg.m^{-3}]
0	0.42	800	1601
50	0.52	930	1598
100	0.60	1040	1593
150	0.70	1260	1586
200	0.70	1300	1575
250	0.70	1400	1563
300	0.75	1550	1551
350	0.68	1650	1537
400	0.65	1700	1524

Table 2. Thermal properties of PEI [15].

Temperature [°C]	Thermal conductivity [W.(m.°C)$^{-1}$]	Specific heat [J.(kg.°C)$^{-1}$]	Density [kg.m^{-3}]
0 - 400	0.22	1248	1270

To consider the interface of CF/PEEK and PEI, the thermal conductance used for the model is presented in Table 3.

Table 3. Thermal conductance between CF/PEEK and PEI.

Temperature [°C]	Thermal conductance [W.(°C)$^{-1}$]
0 - 400	1000

Elements used for the model are four-node linear heat transfer quadrilateral elements, called DC2D4 in Abaqus software. The mesh is composed of two elements across the width of the studied area, as seen in Fig. 3. Two layers of 250 µm PEI have been meshed with 20 elements of 12.5 µm thick while for 50 µm PEI they have been meshed with 5 elements of 10 µm thick. The APC-2 layer is single bias meshed with an element size varying from 12.5 µm to 0.1 mm, and the mesh is increasingly finer near the PEI layer.

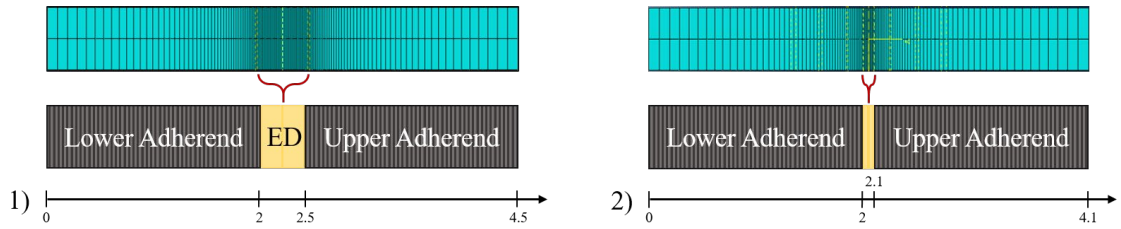

Fig. 3. Mesh elements of the out-of-plane model, the distance through the thickness (mm).

As recorded experimentally, the initial temperature of the specimen was considered to be at 23°C for 250 µm PEI and 20°C for 50 µm PEI. Therefore, this initial temperature was applied to the whole model. Adiabatic boundary conditions were used on the lateral sides, as well as on the upper and lower external surfaces of the composites.

The recorded temperature profile, shown in Fig. 1, was applied to the PEI layer presented in Fig. 3. At $t_0 = 0$ s, the temperature corresponds to the initial temperature. Then, the experimental temperature ramp was applied up to the value of 475°C at 0.714 s for 250 µm PEI and 517°C at 0.807 s for 50 µm PEI. This thermal profile was applied at the interface between the two integrated PEI layers.

Transient heat transfer analysis was used for this model and only the nodal temperature (NT) was computed as output data to understand the time and spatial evolution of the temperature field along the thickness of the assembly. This model contains two steps corresponding to the heating phase and the cooling phase. The heating phase lasts 0.714 s for 250 µm PEI and 0.807 s for 50 µm PEI as measured experimentally and the cooling phase lasts 15 s.

Simulation analysis.

Nodal temperatures were computed and their temporal evolution was compared, during the cooling phase, with the experimental thermogram (black line) recorded and plotted in Fig. 4. Three of the four curves correspond to different locations of the numerical model, showing respectively the interface between two integrated PEI layers (blue dashed line), the interface between APC-2 and the integrated PEI layer (green dashed line) and the interface between first and second composite ply (red dashed line).

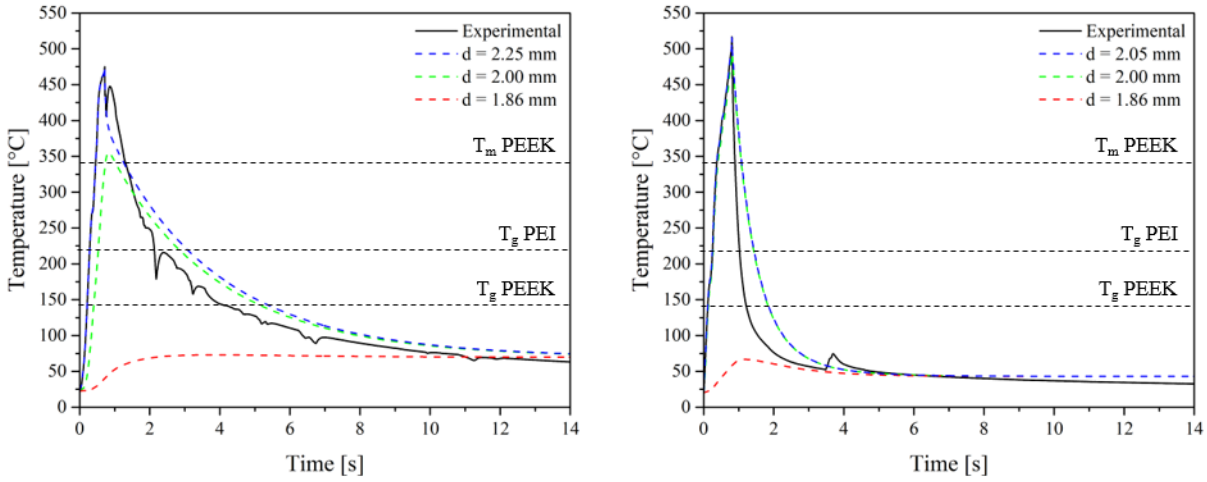

Fig. 4. Experimental and numerical thermograms during UW (a) for 250 µm PEI (b) for 50 µm PEI.

Comparing the experimental value to the numerical thermogram at the interface between the integrated PEI layers (d = 2.25 / 2.05 mm), where the TC are located, a slight difference can be highlighted. The cooling ramp is slower in the model, exhibiting either a too-high numerical contact conductance or a gradient of thermal properties in the interphase zone, which is not considered in the model and the numerical temperature starts to get closer to fit the experimental one. One hypothesis is that input material data from the literature do not fit the studied material. Moreover, the model does not take into account some heat exchanges like convection or exchanges with the jaws (adiabatic upper and lower surfaces boundary conditions). Regarding the material,

the composite is made of unidirectional PEEK thermoplastic with carbon fibre. The thermal conductivity of CF/PEEK is higher than the one of the PEEK and so, when the heat moves to APC-2, it is mostly evacuated by the fibres. Moreover, in the case of CF/PEEK with 50 µm PEI, the TC significantly affects the diffusion of heat. The small thickness of ED and displacement during USW causes contact between TC and carbon fibre. The through-thickness modelisation also does not take into account transverse material properties and only propagates the heat through the thickness. Thus, every simulated temperature could be considered slightly overestimated.

Regarding the curve at the interface between APC-2 and the integrated PEI layer (d = 2.00 mm), the maximum reached temperature is 355°C for 250 µm PEI and 494°C for 50 µm PEI. The APC-2 composite reaches its melting (T_m) during welding in this configuration. It means that PEEK melting occurs within the first ply.

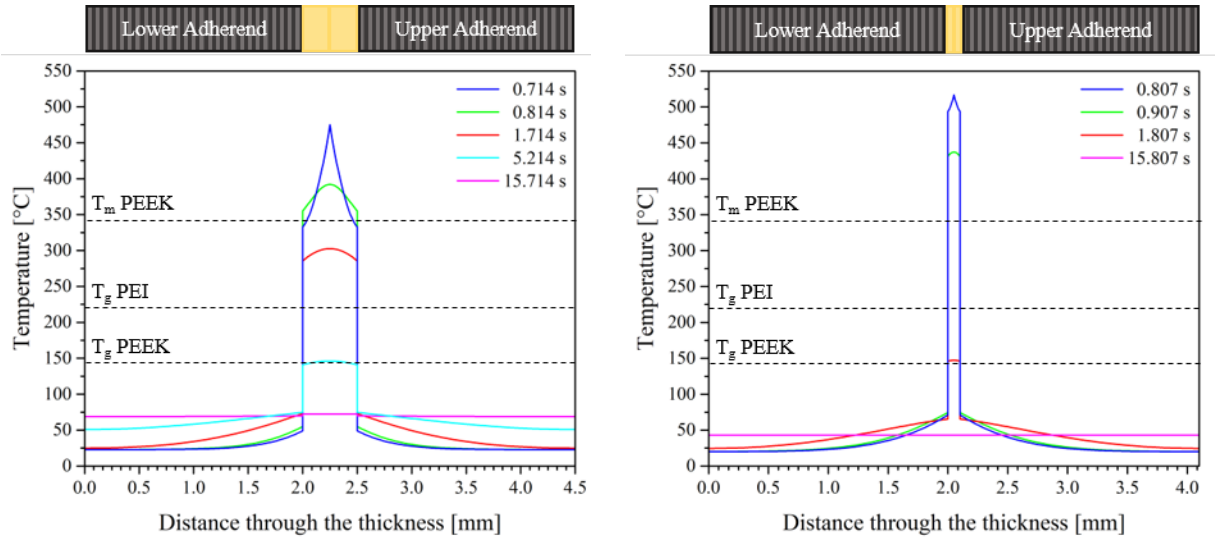

Fig. 5. Temperature profiles through the assembly right after the end of the vibration step with different welding times (a) for 250 µm PEI (b) for 50 µm PEI.

The spatial evolution of the temperature, right after the ultrasonic welding process and during the cooling step, is plotted along the thickness in Fig. 5. The true distance along the path with a reference value between the integrated PEI layers is plotted against the temperature. Different welding times are shown from t_c = 0.714 / 0.807 s (end of vibration step) to t = t_c + 15 s (end of the cooling step). It can be noticed that the profile is symmetrical from the middle of the integrated ED and, as expected, it is due to the symmetry of the stacking sequence of the model (geometry, material and section), loading and boundary conditions. Also, the curves present breaking points at a distance of 2.00 mm (PEI/PEEK interface), 2.25 /2.05 mm (PEI/PEI interface) and 2.50 / 2.10 mm (PEI/PEEK interface). As the thermal contact resistance was taken into account for the non-perfect interface between PEI and PEEK, a drastic drop in temperature is observed after 4.5 s for 250 µm PEI and 1.0 s and 50 µm PEI.

At the temperature t_c as the thermal loading is applied between two integrated PEI layers, the temperature in the middle of ED shows its peak at a value of 475 / 517°C. It is above the T_g of PEI, measured at 220°C, which implies that all the PEI is flowing. Moving to the interface between PEI and the composite layer, it appears that the temperature decreases to reach 355 / 494°C. This thermal evolution highlights the fact that ED, right after the ultrasonic loading, is partially flowing. The flowing material is located at the interface between PEI layers and allows interdiffusion

between those two PEI layers, it is the condition to get a strong weld. Concerning composite parts, the maximum temperature reached during heating is above T_m of PEEK, measured at 340°C, which contributes to interdiffusion of the first plies. The time t_c is the starting point for the transfer of heat from the ED to the composite.

At $t = t_c + 0.1$ s, the heat flux has already started to be transferred from the two integrated PEI layers to CF/PEEK composites. The breaking point is no longer visible because the contact between integrated PEI layers is considered to be perfect. The ED temperature decreases and its maximum temperature is 392 / 437°C in the middle of the ED. The heat moves from the middle to the exterior, i.e. from the highest one to the lowest temperature. Regarding the composite layer, its maximum temperature is 355 / 435°C at the interface and still above its T_m giving mobility to the amorphous phase of the PEEK. At $t = t_c + 1$ s, in the case of thicker ED, the temperature is still above T_g of PEI while for the smaller thickness of ED, the temperature is already below. The same temperature for thicker ED is obtained after 5.214 s.

For the rest of the cooling process, the temperature at the centre of the ED decreases while it increases at the end of the assembly reaching the quasi-thermal equilibrium at the end of the cooling step, $t = t_c + 15$ s.

To conclude, in the studied configuration with a welding time of 714 / 807 ms, the temperature is above the T_g of PEI in almost the entire thickness of ED. This indicates that interdiffusion is possible between the PEI layers. Concerning APC-2, the maximum temperature reached is 355 / 494°C. It can be assumed that the PEEK matrix is thermally affected during welding allowing interdiffusion in the first ply, the second ply remains not affected. However, in the case of 50 µm PEI, the time to create a strong weld between ED and composite was too short causing low mechanical resistance. LSS results agree with the thermal scenario described above: 43 ± 5 MPa and 12 ± 2 MPa for CF/PEEK with PEI of 250 µm and 50 µm, respectively.

Summary

This study focused on the temperature profiles during welding for different thicknesses of ED. CF/PEEK parts with 250 µm and 50 µm thick PEI layers were assembled by USW. A non-intrusive experimental procedure was carried out to measure the temperature at the welding interface. It was observed that the thermocouples must be inserted entirely inside the layer, otherwise, they can alter the temperature measurement.

The curves of power and displacement of the sonotrode over time have shown that different stages and specific points can be identified (heating, flowing of PEI, final flowing and cooling) in comparison with the temperature profiles. As the interface is a closed contact during welding, measuring the temperature at the interface is difficult. However, welding power and displacement have been shown to have a strong connection with thermal history. Too high power during welding distorts the composite.

To evaluate the thermal diffusion from the interfaces between CF/PEEK and PEI layers, a FEM was developed. Considering the input parameters for the model, it is important to mention that thermal contact resistance has a significant impact on thermal diffusion. For both thicknesses, the PEI reaches its T_g, allowing macromolecular interdiffusion between the two parts, the condition to get a strong weld. Besides, the model predicts that only the first ply of the composite parts is thermally affected, in which the temperature within the PEEK matrix exceeds its T_m. Such local heating at the interface prevents composite degradation and deconsolidation. However, in the case of the smallest ED thickness, a too-high power in a short time leads to poor welding of APC-2 parts. It has been confirmed with the mechanical characterization of welds, 12 MPa was obtained for the 50 µm PEI layer, compared to 43 MPa obtained for 250 µm. A higher PEI thickness at the interface slows down the cooling step of highly conductive unidirectional CF/PEEK composites, resulting in a deeper interdiffusion of PEI and so, a stronger weld. These results contribute to a better understanding of the thermal transfer phenomena during USW. By varying the ED thickness,

we demonstrated the possibility to assemble composite parts by USW without affecting the whole composite parts, thus preventing composite degradation and deconsolidation.

Further work will focus on PEEK and other polyaryletherketones (PAEK) as energy directors, to assess the effect of crystallinity at the interface on mechanical strength.

Keywords: Laser Welding, Thermoplastics, Optical Properties, Single Lap Shear Test

Abstract. Laser transmission welding (LTW) is a suitable process for assembling thermoplastic materials. This joining process is used to assemble most thermoplastics, but high-performance thermoplastics, such as polyetherketoneketone (PEKK), have received less attention until now. The present work deals with joining PEKK parts by LTW in amorphous over semi-crystalline state configuration. The optical properties of amorphous and semi-crystalline states were measured. The effect of the upper part thickness (2 or 4 mm) and those of the laser power reaching the interface was assessed through the determination of the heat affected zone (HAZ) dimensions and the mechanical resistance of the bonds. Single lap shear (SLS) tests were conducted to investigate the influence of the process parameters on the interfacial strength and to validate the weld quality. The highest LSS is obtained around 60 MPa. When increasing the laser power, the dimensions of the HAZ increase, and the mechanical strength decreases.

Introduction

Laser transmission welding (LTW) is an assembly process used for joining thermoplastic materials with a near-infrared (NIR) laser. Parts to be joined are overlapped and clamped together for welding. The laser beam faces the upper part and irradiates the assembly interface. Here, the laser energy is absorbed and converted into heat. This allows the polymers to melt at the interface and, by molecular interdiffusion, a weld seam is created during cooling.

For laser irradiation to reach the interface, the upper substrate needs to be transparent to the laser wavelength. To achieve the absorption at the interface, two techniques can be applied: use an absorbing medium at the joint interface; or assuring that the bottom substrate is absorbent at the wavelength of interest. For the first method, special NIR-absorbent dyes or pigments are applied at the joint interface, like ClearWeld® technology [1].

For the second one, a laser-absorbent part serves as lower substrate to achieve the energy absorption at the interface. However, most thermoplastics are transparent to the NIR laser radiation in their natural state. Although, the bottom substrate can be rendered absorbent by different methods. The first one is filling the polymer with an absorbing additive, like colorants [2,3] or reinforcements [4,5]. And the other and much less studied option is to increase the degree of crystallinity of the lower substrate to modify its optical properties. Indeed, the crystalline structure of semi-crystalline polymers limits the light transmission [6], and increases the light travel path,

leading to higher absorption [5,7], whereas an amorphous polymer is transparent in NIR. Despite its potential, this approach was rarely studied to weld thermoplastics.

High-performance thermoplastics such as Poly-Ether Ether Ketone (PEEK) and Poly-Ether Ketone Ketone (PEKK), can be processed into amorphous and crystalline states, depending on the processing conditions. Few works have studied LTW of PEEK and PEKK without additives. Amanat et al. studied the joining of PEEK films with ClearWeld® at the interface [8]. In their work, semi-crystalline PEKK assemblies showed a higher weld strength than amorphous PEEK joints, for all the laser speeds and power considered. Villar et al. welded PEKK thermo-compressed samples using an 808 nm NIR laser device [9]. They control the degree of crystallinity of PEKK to obtain quasi-amorphous and semi-crystalline samples, to be used as upper-transparent and lower-absorbent substrates, respectively. However, the results of mechanical strength of these welds are scarce in the literature, and none focus on PEKK welds.

In addition to the optical properties of the substrates, the process parameters can influence the bond quality in LTW: laser power, welding speed, laser beam size and, clamping pressure.

In this work, we study the joining process of amorphous and semi-crystalline PEKK by LTW. The optical properties and process parameters are correlated with the size and shape of the weld, as well as its mechanical strength. The originality is to keep constant the laser power reaching the interface while varying the thickness of the upper-substrate.

Materials and Methods

Kepstan® PEKK grade 7002 was supplied by Arkema France in pellets. PEKK 7002 is a semi-crystalline thermoplastic with tunable crystallinity due to its crystallization kinetics.

After drying the pellets at 120°C for 30 hours, specimens were manufactured by an injection molding press Proxima 50 from Billion. Two crystalline morphologies of unfiled PEKK were obtained: amorphous form (PEKK-A) and semi-crystalline form (PEKK-SC). Samples molded were plates of 95 × 95 mm² with 2 and 4 mm thick for amorphous form (PEKK-A2 and PEKK-A4 respectively), and 2 mm thick for PEKK-SC.

The molded plates were cut into 25 ± 3 mm width rectangular samples, then dried at 120°C for more than 24h and kept into a desiccator before welding. Acetone was used to clean the samples surfaces.

Differential Scanning Calorimetry (DSC) scans were carried out in a DSC 1 Stare System Mettler Toledo. Ramps of 10 $K \cdot min^{-1}$ were used for heating from 25°C to 380°C, and cooling from 380ºC to 25ºC. Glass transition temperature (Tg), melting temperature (Tm), cold crystallization temperature (Tcc) and degree of crystallinity (Xc) were obtained at heating. Cooling was used to obtain the crystallization temperature from melt (Tcm) and the maximum crystallinity (Xc-max).

The optical properties were measured using a FTIR spectrophotometer Bruker Vertex 70. Transmission (T) and reflection (R) factors were measured using an integration sphere with an Infragold Lambertian coating. Characterization was made at room temperature for the wavelength range of 0.9 to 2 µm. Absorption factors (A) are obtained using Eq. 1.

$$T + R + A = 1 \quad (1)$$

Transmissivity of clamping glass was experimentally measured using a power-meter Gentec Pronto-500, by comparing the output power measured before and after going through the glass.

Lap-joint configuration (Fig. 1) was used for welding, with an overlap of 12.5 mm, as indicated on ISO 4587:2003. The amorphous substrate was positioned over the semi-crystalline one.

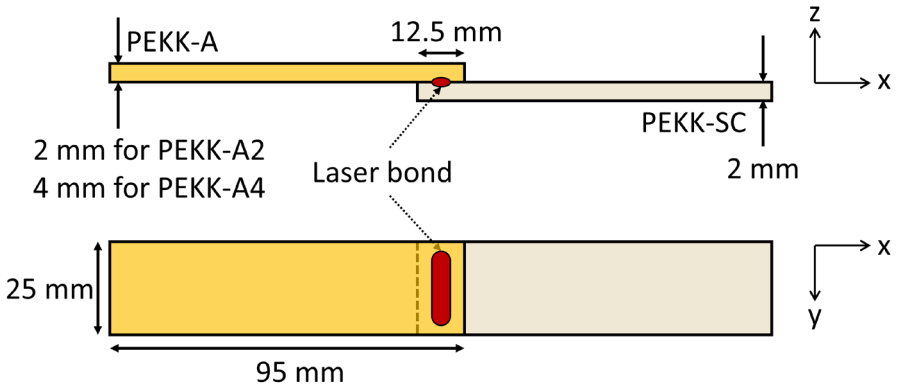

Fig. 1. Schematic diagram of lap-joint configuration used for welding PEKK-A/PEKK-SC (not to scale).

The assembly configuration is kept fixed on the welding machine platform. A support is placed under the amorphous sample to keep the interface parallel to the platform. A 15 mm thick semi-transparent glass plate is positioned over the assembly to apply the clamping pressure necessary to ensure intimate contact at the joint interface. The weld is created at the center of the overlap area using a moving laser. Thus, the interface is heated as the laser beam moves over the samples, following a predefined welding path. This LTW technique is known as *contour welding*.

Samples are welded using an ES weld 200 welding machine from ES Laser with a Diode laser of 975 nm. Output laser power can be set from 0 to 220 W with a resolution of ± 3 W. A circular shape laser beam is used with a beam diameter of 5 mm, obtained at maximum laser defocus. Clamping pressure is constantly applied at 3.8 MPa thanks to the glass plate. The welding path is a straight line: the laser beam moves from its initial position (L0) until the indicated weld length (Lw) of 20 mm, as shown in Fig. 2.

When a constant speed is used to irradiate the interface from L0 to Lw, an ovoidal weld bond is created instead of a thick line, as shown in Fig. 3A. To obtain a more homogeneous weld bond along the line laser path, like in Fig. 3B, a procedure combining static and dynamic irradiation is applied. The procedure starts by statically irradiating the interface for 2 seconds at L0. Then, the laser moves to irradiate at the given speed, from L0 to Lw. Finally, the laser statically irradiates the interface for 1 second at Lw. That allows to melt the interface all along the welding path in a more homogeneous shape of the weld bond (Fig. 3B).

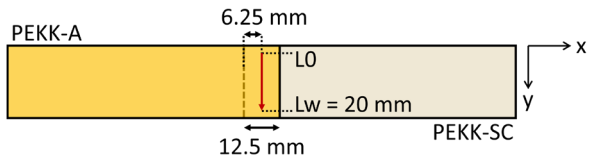

Fig. 2. Schematic diagram indicating the welding path position, direction and dimensions on the PEKK-A/PEKK-SC assembly.

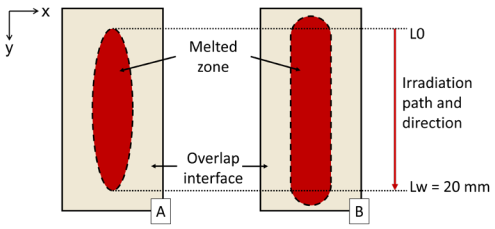

Fig. 3. Schematic diagram of the melted zone's shape created at the interface when irradiating with (A) dynamic condition, (B) static and dynamic condition.

The optimum welding speed to achieve the melting at the interface, regardless of the laser power, is 60 mm/min, as determined by previous tests. Thus, welding speed is kept constant for all welds. After irradiation, clamping pressure is maintained for 120 seconds while cooling.

Two process parameters are varied for this study: the transparent substrate thickness (2 and 4 mm) to obtain PEKK-A2/PEKK-SC and PEKK-A4/PEKK-SC assemblies, and the laser intensity. For the laser power, the preliminary welding tests indicated that the power-range needed at the interface to melt it without burning it is between 75 and 95 W. Thus, four power intensities were selected: 75, 85, 88, and 95 W. That provided eight configurations for the study (Table 1).

Table 1. Assembly configurations.

	75 W	**85 W**	**88 W**	**95 W**
PEKK-A2/PEKK-SC	A2/SC-P1	A2/SC-P2	A2/SC-P3	A2/SC-P4
PEKK-A4/PEKK-SC	A4/SC-P1	A4/SC-P2	A4/SC-P3	A4/SC-P4

Single lap shear (SLS) tests were carried out to characterize the lap-joint welded samples strength. An INSTRON 550R tensile machine was used with a load cell of 50kN and a cross head load rate of 2800 $N \cdot mm^{-1}$. Each sample was tested until failure. The load at failure F_f [N] was recorded and the type of failure mode was identified. Also, the normalized lap-shear strength LSS [MPa] was obtained by dividing the force at failure by the contact area Ac [mm^2]. This area was measured by microscopy for the samples that failed at the interface.

Visual inspection of the welds was carried out with a numerical optical microscopy VHX-6000S from Keyence. Post-failure bond interfaces were characterized to obtain the shape and dimensions of each weld. The weld cross-sections of post-welding bonds were visualized to characterize the HAZ along the weld path.

Results

Thermal transitions.

Fig. 4A shows a typical DSC thermogram of PEKK 7002 amorphous specimens. Tg is 158 ± 2°C and Tm is measured at 317 ± 2°C. Crystallization temperatures are around 202 ± 1°C for Tcc, and 295 ± 1°C for Tcm.

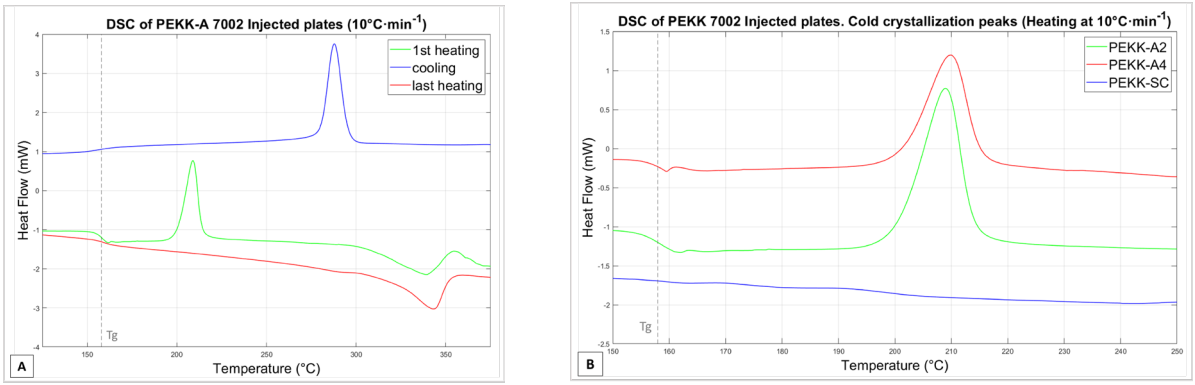

Fig. 4. (A) DSC scans of PEKK 7002 amorphous molded plates. (B) cold crystallization peaks of molded samples obtained on the first heating DSC scan.

In Fig. 4B, an exothermic peak is observed around 200°C for amorphous samples (green and red curves), after glass transition. This indicates cold crystallization, occurring when the sample is not fully crystallized. Indeed, right after Tg, the macromolecules have gained enough mobility to self-organize into crystalline structures. For PEKK-SC, no peak is observed because the sample is

already fully crystallized. To assess the degree of crystallinity, the enthalpy of this peak (ΔHcc) is subtracted from the melting enthalpy of the first heating (ΔHm), then the result is divided by the enthalpy of 100 % crystallized polymer ($\Delta H_{100\%}$), considered as same as PEEK (130 $J \cdot g^{-1}$) [10]. A degree of crystallinity of 4 ± 2% was found for PEKK-A and 20 ± 2% for PEKK-SC.

Optical properties.

The laser irradiation that strokes the samples' surface can be transmitted, reflected and/or absorbed. For that, transmission, reflection and absorption factors of the samples need to be determined. The transmission factor (T) characterizes the quantity of incident laser irradiation that will be able to go through its thickness. The reflection factor (R) indicates the portion of the irradiation that will be reflected by the material surface. Finally, absorption factor (A) will provide the fraction of the incident irradiation that will be absorbed by the material, either at the surface or in the volume. These three factors are related between them by Eq. 1 and they can be expressed in percentage for the desired wavelength.

In the visible light spectral range, PEKK-A has a natural yellow translucent coloration, whereas PEKK-SC samples are opaque with a natural beige color. Their optical properties are necessary to verify their compatibility with LTW at 975 nm. The results are gathered in Table 2.

Table 2. Transmission, reflection and absorption factors of PEKK molded samples.

Substrate	T [%]	R [%]	A [%]
PEKK-A2	75 ± 1.5	13 ± 0.1	12 ± 0.1
PEKK-A4	62 ± 0.7	13 ± 0.1	25 ± 0.1
PEKK-SC	20 ± 0.02	48 ± 1.7	32 ± 1.7

The transmission spectrum of PEKK samples is seen in Fig. 5. At 975 nm, PEKK-A samples have a transmission factor higher than PEKK-SC ones: 75 % for PEKK-A2 and 62 % for PEKK-A4, against 20 % for PEKK-SC. Also, increasing the thickness of PEKK-A decreases the transmission factor by more than 17 %. Based on previous works of LTW on PEKK [9] a transmission factor of 60% is suitable to achieve melting at the interface. Consequently, 2 and 4 mm thick PEKK-A samples seem adequate to be used as transparent upper substrate for LTW.

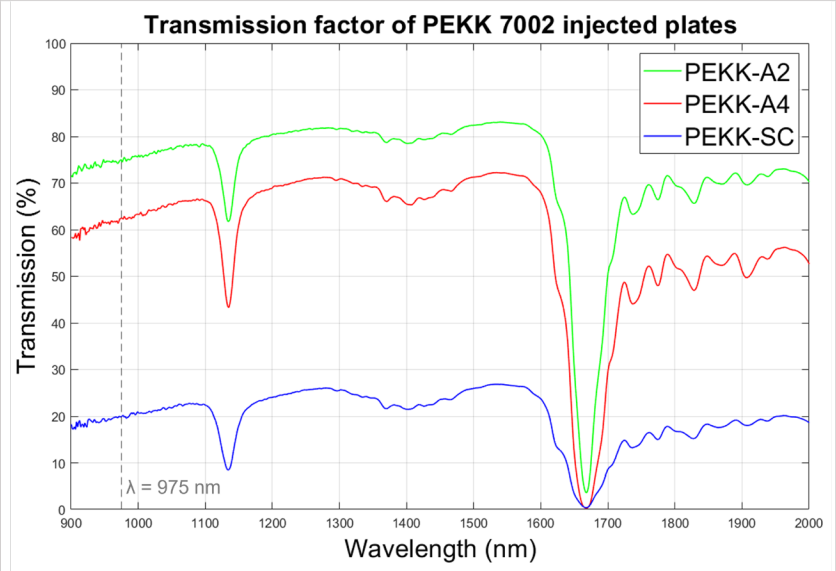

Fig. 5. Transmission spectrums of PEKK 7002 molded samples.

Table 2 pointed out that the sample with the highest absorption factor is the semi-crystalline one. Even if its absorption is low (32 %), it is higher than its transmission factor (20 %). This validates the suitability of PEKK-SC as absorbent substrate for LTW.

To irradiate the assembly interface, the output laser irradiation (Po) will first go through the clamping glass and then through the transparent substrate. Therefore, the output laser power value will decrease after going through each layer, according to the transmission factor of each layer. Hence, the power reaching the assembly interface will be the percentage of output power that the glass and the transparent substrate will allow to transmit. At our laser wavelength, the clamping glass has a transmissivity of 0.82, as evaluated with the power-meter. Then, the transmission factor of the transparent-upper substrate depends on its thickness: 0.75 for PEKK-A2, and 0.62 for PEKK-A4. Thus, the power at the interface (Pint) can be calculated using Eq.2 and Eq.3 for PEKK-A2/PEKK-SC and PEKK-A4/PEKK-SC, respectively.

$$P_{int(A2)} = P_0 \times 0.82 \times 0.75 \quad (2)$$

$$P_{int(A4)} = P_0 \times 0.82 \times 0.62 \quad (3)$$

The power at the interface is set between 75 and 95 W. Table 3 indicates the output laser power used for each type of assembly to obtain the desired power at the interface for each targeted power.

Table 3. Laser power used for LTW.

	P_0 [W]		P_{int} [W]
	for A2/SC	**for A4/SC**	**For both**
P1	123	148	75
P2	139	168	85
P3	144	175	88
P4	154	188	95

Weld characterization.

The cross-section of the weld bond along the weld path is observed to characterize its heat affected zone (HAZ). Fig. 6 shows a micrograph of the assembly cross-section before and after welding for A4/SC-P2. Before welding, we can easily identify the interface line between the overlapped substrates (inside the red dashed rectangle in Fig. 6A). After welding, the HAZ appears as an oval shape replacing the interface line (inside the red dashed contour in Fig. 6B). The color change from yellow to white within the HAZ demonstrates a modification of the crystallinity. All the weld bonds characterized showed this same shape and aspect on their HAZ.

The PEKK-SC shows a yellow coloration within the HAZ: the substrate became amorphous on cooling. This means that PEKK-SC absorbed enough laser power to melt at the interface and that the cooling ramp was faster than the crystallization kinetics. Also, in PEKK-SC, the HAZ is so deep that it almost reaches the bottom of the substrate. It indicates that the laser irradiation penetrated the sample, as stands by Jones et al. [1], and was absorbed on the volume and not only at the interface. The average depth for both types of assemblies is 1.4 ± 0.2 mm. With these parameters, it would not be possible to weld lower parts thinner than 1.4 mm.

In PEKK-A substrate, the HAZ colors go from yellow to white. The melting zone is mainly located at the interface. The white color indicates that PEKK-A sample undergoes cold crystallization. Tcc was measured at 202°C in Fig.4. Following laser absorption at the interface, this temperature was achieved by heat conduction from the lower part. Moreover, the shape and colors of HAZ indicates that the samples really merged at the interface to create a strong bond.

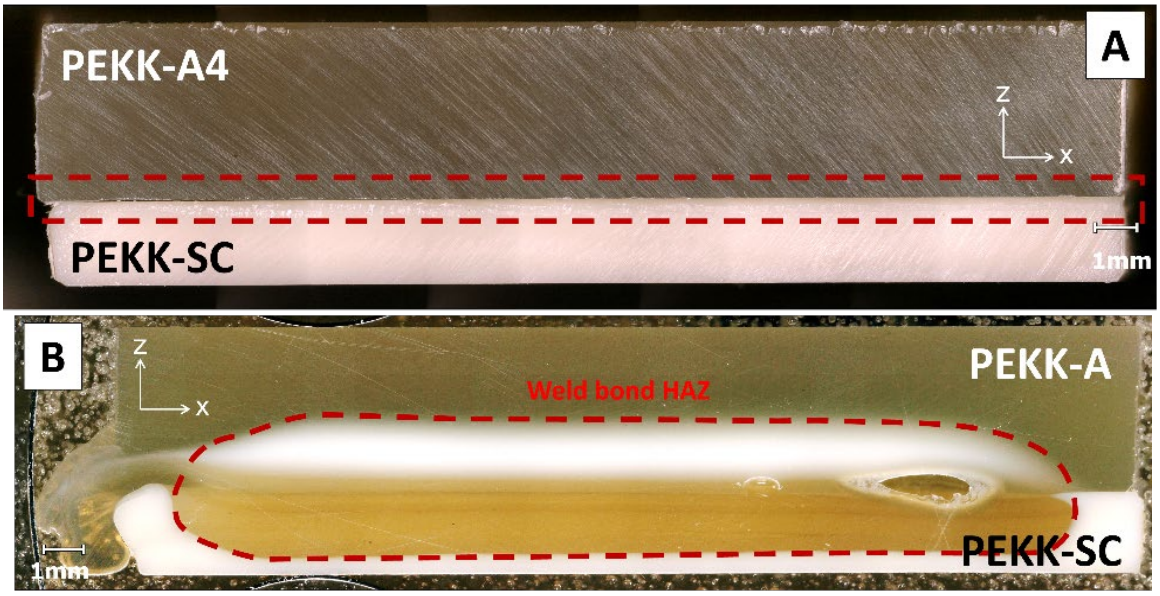

Fig. 6. A4/SC-P2 assembly cross-section along the welding path (A) before and (B) after welding.

HAZ dimensions were measured for each assembly configuration. Its height (along the X axis) and length (along the Z axis) were plotted against the power used for welding in Fig. 7. A notorious increment on the HAZ dimensions with the power is noticed. This increase is almost linear for three of the four intensities (75, 85 and 95 W). The HAZ dimensions obtained at 88 W do not follow the regular trend. A possible explanation is related to the uncertainty of the power. Indeed, the values of power are defined with ± 3%. Thus, the data obtained for 85 and 88 W are expected to be close to each other.

For the HAZ height, almost 1 mm of difference is found from lowest to highest power, for both types of assemblies (A2/SC and A4/SC). Concerning the length of the HAZ, it is quite the same on A4/SC, with only 0.3 mm of difference from the lowest to the highest power. For A2/SC, this length improves considerably with laser intensity, with a gap of 1.6 mm. Moreover, this HAZ length is higher than the welding path used for welding (20 mm) in all the configurations. That indicates that the irradiation procedure used, combining static and dynamic irradiation, had a positive impact on the melting at the interface. This increment of the HAZ dimensions with laser power can be explained by the fact that increasing the laser power maximizes the heat input which leads to a greater volume of melted material at the interface, resulting in a higher welded zone.

The HAZ dimensions also increase with the increase of the transparent substrate thickness for each laser power. This can be caused by the scattering of the laser irradiation through the samples. Thus, PEKK-A4 seems to scatter more the light than PEKK-A2, which increases the distribution of the energy over a larger area.

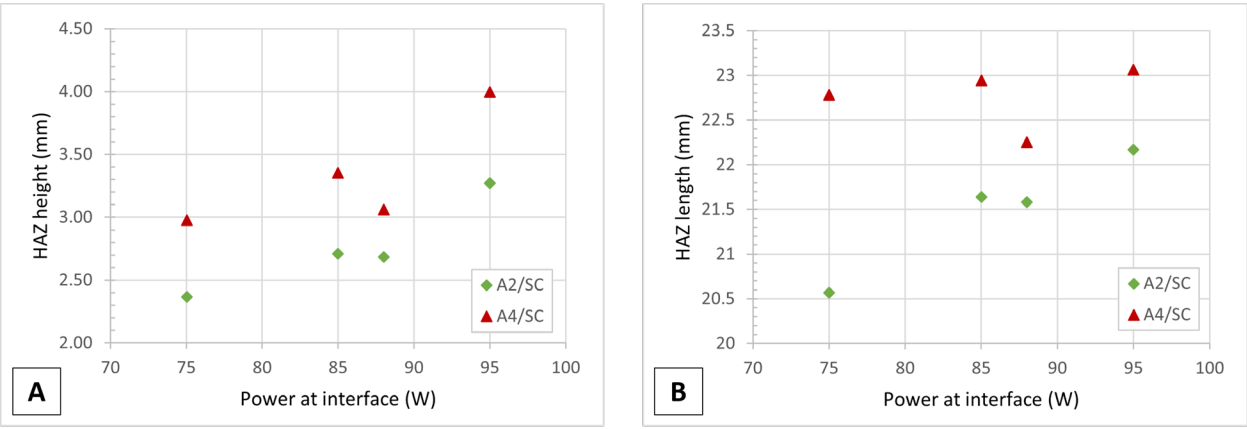

Fig. 7. HAZ dimensions (A) height and (B) length, plotted against the laser power used at the interface.

Different mechanical tests are carried out to quantify the resistance of welded samples by LTW: DCB [2,11], wedge [12], and SLS tests [8,11,13-16]. SLS is the easiest and most used test.
When tested in SLS, lap-joint welded samples failed in different modes. To identify their failure type, four failure modes are defined (Table 4) inspired by the classification proposed by Amanat et al. [8] for LTW on PEEK. Two types of failure were obtained within our assemblies:

- *Cohesive failure*: this indicates that the bond broke and was separated as if it was ripped off. The samples actually fused at the interface, creating a strong weld.
- *Substrate near joint*: one or both substrates broke near the weld bond, but the bond was fully or mostly intact, proving that the bond strength is superior to the substrate strength.

Table 4. Failure modes for LTW samples tested by SLS.

Failure mode	Appearance	Inference	Description
Interfacial		Bond strength << substrate strength	Assembly fails at the interface because no real material cohesion was created at the irradiated interface. Most undesired result.
Cohesive		Bond strength ~ substrate strength	Assembly fails at the interface within the weld bond created.
Substrate near joint		Bond strength > substrate strength	Failure within the substrate but near the interfacial region and weld bond intact (or mostly).
Bulk substrate		Bond strength >> substrate strength	Bulk substrate results in tensile yield and brakes far from the weld bond. Most desired result.

Even though two failure modes were obtained, only the samples that failed in cohesive mode are analyzed in this paper. The overlap interface is visible so the real contact area can be measured to obtain the LSS value for each cohesively failed assembly. 1 or 3 samples over 5 failed cohesively for each configuration. A hypothesis steaming from this high dispersion is related to the irradiated surface that can vary locally due to heterogeneities of the samples: different macromolecular organization, and micro-voids or particles inside them. These heterogeneities can lead to the scattering of the laser path in the upper substrate, and to an inhomogeneous absorption of the laser irradiation in the bottom substrate. The LSS obtained are plotted with the power for both type of assembly in Fig. 8.

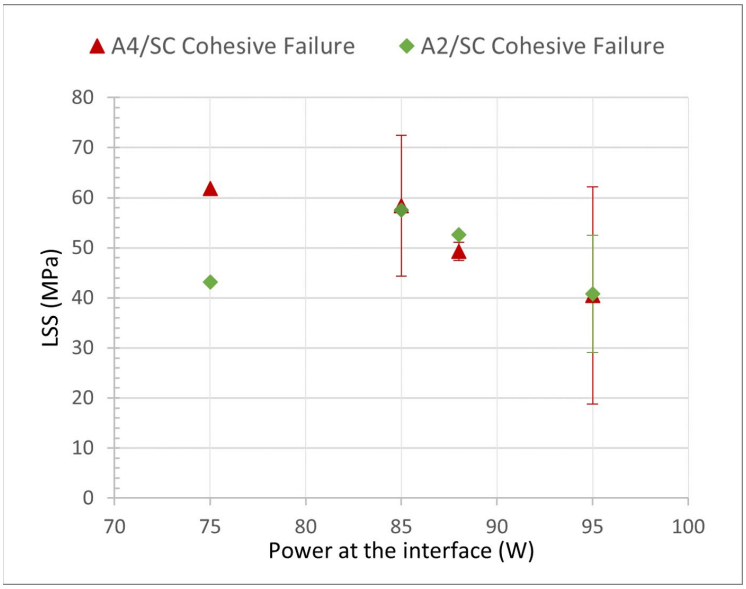

Fig. 8. LSS (MPa) of LTW samples failed cohesively. Bars indicate the measuring range.

The strength obtained at one laser power is the same for both types of assemblies except for the first laser power of 75 W. However, the strength decreases with laser power from 85 W. This drop in weld strength can be caused by different crystalline morphology at the interface. Indeed, the crystallinity of PAEK is strongly impacted by its thermal history. A higher power reaching the interface would result in a higher temperature and slower cooling ramp. As proved on PEEK [17], the refinement of the primary lattice takes place when the temperature is higher than or equal to the previous crystallization temperature. An evolution of the lattice sizes could result in lower ultimate tensile strength. Further studies are needed to clarify this point. Overall, the strength of our assemblies is higher than those achieved by Potente et al. when welding PEEK T-joint specimens with similar thicknesses for the transparent substrate [18]. They achieved a maximum strength of 40 MPa, while our minimum is of the same value for both types of assemblies.

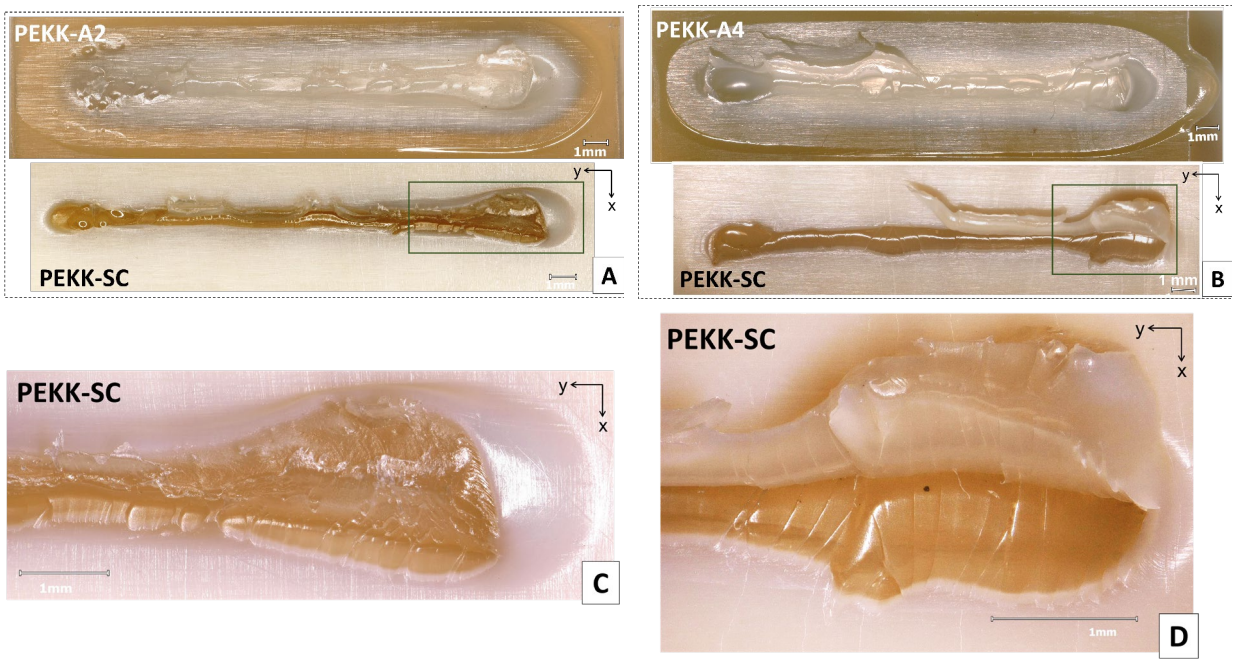

Fig. 9. Weld bond of assemblies failed with cohesive mode. The opened overlapped interfaces allow to visualize the weld bond on each substrate of the assembly for (A) A2/SC-P2 and (B) A4/SC-P2. (C) Magnified view of inset show in (A). (D) Magnified view of inset shown in (B).

The cohesively failed weld bonds were characterized by optical microscopy. Fig. 9 shows the micrograph of the opened overlap of cohesively failed assemblies in the PEKK-A and PEKK-SC substrates. The weld bonds show signs of sheared material on each substrate. That indicates that the samples were melted and fused together at the irradiated zone and that the bonds were shared during mechanical test.

Summary

PEKK 7002 grade is suitable to be welded with amorphous over semi-crystalline sample configuration. The following conclusions are outlined:

- The optical properties of the substrates were measured in injection molded plates:
  - A transmission factor of 40 % is measured on amorphous plates at the wavelength of interest, even with 4 mm thick. Thus, the amorphous state is transparent enough to allow LTW.
  - Increasing the thickness of the amorphous substrate from 2 to 4 mm decreases the IR transmission factor by 17 %.
  - The absorption properties of the semi-crystalline state of PEKK 7002 make it suitable for LTW.
- We targeted to define the process parameters according to the material properties to get a strong and reliable weld.
  - The output laser power was varied to obtain the same laser intensity radiation at the interface considering the transmission factor of the transparent substrate.
  - The welding speed and irradiation procedure were established to allow the materials to melt at the interface all along the welding path.
- Relationships between the process parameters, the material properties and the dimensions of the HAZ, and the mechanical resistance of the welds were determined. The highest LSS

is 60 MPa, demonstrating the ability of LTW in achieving strong welds in amorphous over semi-crystalline PEKK.

Further work will focus on extending the study to other process parameters. A thorough characterization of the HAZ will be carried out to link the crystalline morphology to the thermal history undergone within the HAZ.

Keywords: Ultrasonic Welding, Composites, Roughness, Shear Strength

Abstract. In this work on ultrasonic welding of CF/PEEK composites, it was established that the surface roughness of the substrates has an influence on the interfacial strength of a joint. The joint resistance is lower when the roughness increases. Interestingly, a new characteristic time was found, named the healing plateau time (t_{HP}), which is determined by the displacement versus time curves during ultrasonic welding. This time seems to be related to the shear strength of the joint. This is a major finding, because it appears as a non-destructive way of predicting the quality of welds. Besides, DNS test on CF/PEEK unidirectional composite pointed out 40% higher shear strength compared with SLS, performed on CF/PEEK substrates assembled with a 250 µm PEI integrated energy director. Ultrasonic welding was optimized to reach a performance close to the shear strength of bulk.

List of abbreviations

CF	*Carbon fiber*	$QDNSS_{max}$	*Quasi double-notched shear strength maximum value*
D_h	*Healing degree*		
D_{IC}	*Intimate contact degree*	Ra	*Profile's arithmetic mean deviation*
DNS	*Double-notch shear*		
G_{IC}	*Mode I energy release rate*	Rz	*Average profile height*
$G_{IC(\infty)}$	*Bulk material resistance*	SDB	*Sandblasted*
G_{IIC}	*Mode II energy release rate*	SLS	*Single lap shear*
HP	*Healing plateau*	SS	*Shear strength*
LSS	*Lap shear strength*	SS_{bulk}	*Bulk material shear strength*
LSS_{max}	*Lap shear strength maximum value*	STB	*Shotblasted*
$\lambda_{cut\text{-}off}$	*boundary wavelength between roughness and waviness*	STD	*Standard*
		t_h	*Healing time*
PEEK	*Polyetheretherketone*	t_{HP}	*Healing plateau time*
PEI	*Polyetherimid*	t_{ic}	*Intimate contact time*
QDNSS	*Quasi double-notched shear Strength*	t_{rep}	*Reptation time*

Introduction

Composites in aeronautics are currently dominated by thermosets, but the development of high-performance thermoplastic composites is booming. These materials open the way towards new forming and assembling processes. *Ultrasonic welding* (USW) is a joining method that uses ultrasonic vibrations and pressure over time to generate heat at the contact surfaces. Joining is achieved by the formation of a molten interphase which consolidates on cooling under pressure. The use of an energy director, a pure polymer film between both surfaces to be welded, facilitates the surface wetting to achieve intimate contact. *Polyetherimide* (PEI) is often used as energy director for joining *Polyetheretherketone* (PEEK) matrix composites, as both polymers are miscible. Moreover, PEI has the advantage of flowing at a lower temperature than PEEK, which facilitates the mobility of its macromolecular chains through PEEK.

The weld quality in USW depends on several process parameters and material properties, but geometric parameters must also be considered. Besides, interface healing and intimate contact between both surfaces to be welded are still not fully understood. According to Voyutskii [1], surface wetting is not sufficient to develop interfacial strength in polymer welding, the chains must be able to diffuse from one surface to another. Before the polymer chains diffuse from one side to the other one, intimate contact is established by the flow of asperities onto the surface of polymeric materials. Then, healing is generated by the chains diffusing across the interface and their random rearrangement. The highest welding strength is achieved when healing is completed and the interface disappears completely. Intimate contact describes the evolution of physical contact between both materials to be welded. It represents the true contact surface, formed by the asperities in contact, in opposition to the apparent contact surface. Initially, a perfect contact is impossible because of the surface roughness. It is assumed that roughness improves the frictional effect in USW and increases the temperature at the interface. But on the other hand, the imperfections must be flattened under pressure to generate intimate contact. Indeed, the intimate contact is the necessary condition for the polymeric chains to diffuse across the interface. The effect of roughness on weld strength is rarely considered and to date, no experimental study of roughness in USW is available. Usually, the specimens to be welded are prepared from plane plates without considering their roughness. However, various surface qualities are obtained when parts are manufactured in industrial conditions. Therefore, a deeper knowledge is needed to weld despite imperfect geometry or unusual roughness. Some analytical approaches were developed to handle this topic. In the most advanced existing models, the *intimate contact degree* (D_{IC}) has been established by considering the roughness as a set of rectangular asperities [2,3], far from realistic geometry. However, this model may be sufficient to predict the influence of roughness on the joint quality, by linking the roughness parameters to pressure, viscosity and welding time. Further refinement of models may be interesting to fit the realistic roughness parameters. Anyway, such models must be validated with experimental data, which are the purpose of this article.

This work aims to contribute to the prediction of the weld resistance in USW according to the initial part roughness. Thus, the influence of roughness on the interfacial strength is investigated by combining mechanical characterization and analytical approach. Most studies choose the *mode I energy release rate* (G_{IC}) to evaluate the adhesion of an assembly composed of 2 bulk materials [4,5,6]. This energy release rate could be considered as the resistance of welds. It can be compared to the $G_{IC(\infty)}$ corresponding to the bulk material resistance. This energy release rate, attributed to a multiplicative combination of interfacial and bulk effects depends on the adhesion time [7]. Eq. 1 relates it directly to the polymer *reptation time* (t_{rep}). t_{rep} mainly depends on the temperature and the polymer chain hindrance (Eq.2). It defines the average time needed for a polymer chain to completely leave its initial position. The latter is represented in the reptation theory by a tube from which the macromolecule escapes at the extremities.

$$\frac{G_{IC}(t)}{G_{IC\infty}} \approx \left(\frac{t}{t_{rep}}\right)^{\frac{1}{4}} \quad (1)$$

$$t_{rep} = \frac{N^3 lo^3 \mu_M}{N_e k_B T} \quad (2)$$

With: N number of monomers, lo segment length of an ideal chain, μ_M dynamic viscosity, N_e number of monomers between entanglements, k_B Boltzmann constant

In the aerospace industry, it is customary to consider the shear strength of joints instead of energy release rate. It was therefore decided to implement a new approach based on the mode II resistance and to discuss its validity while quantifying the influence of roughness.

Materials and Methods

USW was performed in displacement mode using a Mecasonic Omega 4x pneumatic welding machine. The input parameters were the applied pressure, the amplitude and the sonotrode displacement. Time, displacement, and energy dissipation were recorded by the device during welding. Fig. 1 shows the general layout of the welding system.

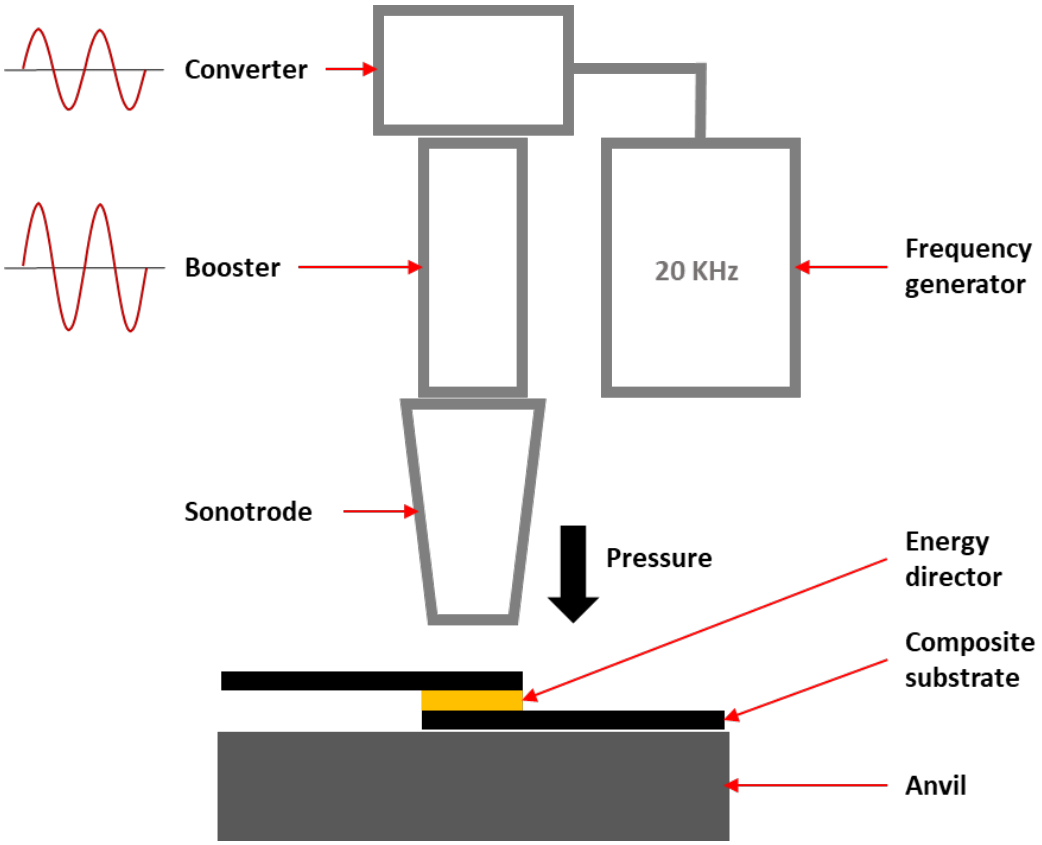

Fig. 1. Layout of the ultrasonic welding device.

Composite plates were manufactured with a Pinette Emidecau Industries Lab800 thermo-compression device. The substrates were made of APC-2 prepreg supplied by Solvay, which is composed of unidirectional *carbon fibers with polyetheretherketone matrix* (CF/PEEK). Composite plates underwent an additional step to integrate a 0.25 mm thick pure polymer film of Ultem 1000 PEI as energy director under compression. To vary the surface finish of these composite plates, steel backplates of different roughness were used. Several surface conditions were tested to obtain different types and values of roughness.

The composite plates were then cut in 100 x 25 x 2 mm substrates. Before welding, their roughness was measured using a Mahr MarSurf PS1 roughness meter, by averaging 5 measurements spread over the area to be welded, in the longitudinal direction on each sample. A comparison between the *profile's arithmetic mean deviation* (Ra) (Eq. 3) and the *average profile height* (Rz) was carried out but did not show a significant difference. Therefore, Ra was chosen as the default measurement parameter. In accordance with roughness tables, the *boundary wavelength between roughness and waviness* ($\lambda_{cut\text{-}off}$) was chosen to be 0.8 mm for roughness below 2 µm, and 2.5 mm for roughness above 2 µm. The limited size of the specimens welded area made it inadequate to take higher values of $\lambda_{cut\text{-}off}$.

$$\mathrm{Ra} = \frac{1}{n}\sum_{i=1}^{n} |Yi| \tag{3}$$

With:Yi deviations of the evaluation profile from the surface mean line.

Two types of mechanical tests are carried out for this study: The specimens were prepared according to, *Double-Notch Shear* (DNS) testing from ASTM D-3846 and *Single Lap Shear* (SLS) testing from ASTM D-1002.

DNS testing specimens measuring 79.50 x 12.70 x 4.05 mm were cut from a plate with all unidirectional fibers oriented in the direction of the compressive load. The specimens were then double-notched. The tests were conducted on a special compression device as shown in Fig. 2A, which allows the specimen to be held vertically without buckling. A micro-torque spanner was required to tighten the equipment's nuts up to 0.1 N.m. In addition, welded specimens were cut to DNS dimensions to characterize assemblies. To compensate the offset, a counterpart of the same material, with same thickness, was glued to each side of the assembled specimen.

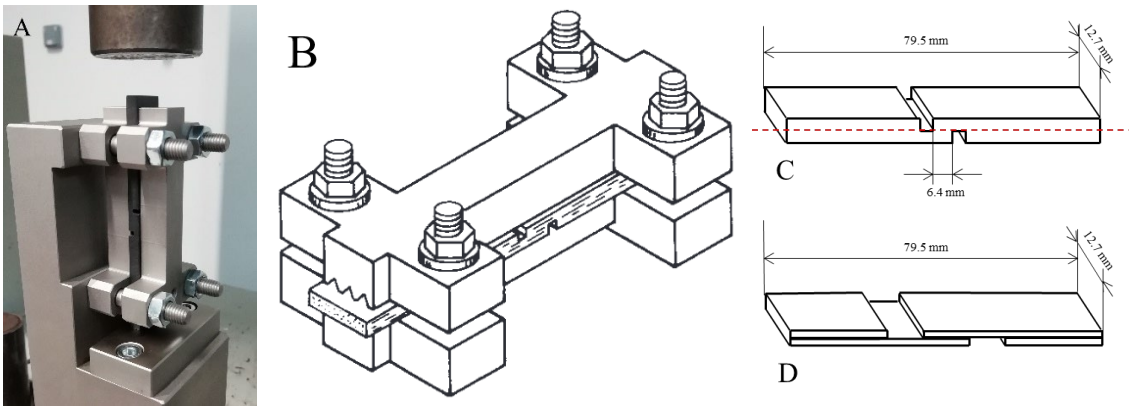

Fig. 2. (A) DNS testing equipment on CF/PEEK composite, (B) scheme of the DNS equipment according to ASTM D-3846, (C) Standard DNS specimen, (D) Quasi-DNS welded specimen.

Then, SLS testing were performed on welded specimens as shown in Fig. 3. An Instron 33R4204 tensile machine with a 100kN cell and adjustable jaws were used. Specimen shear resistances were evaluated, and the fractured surfaces were examined.

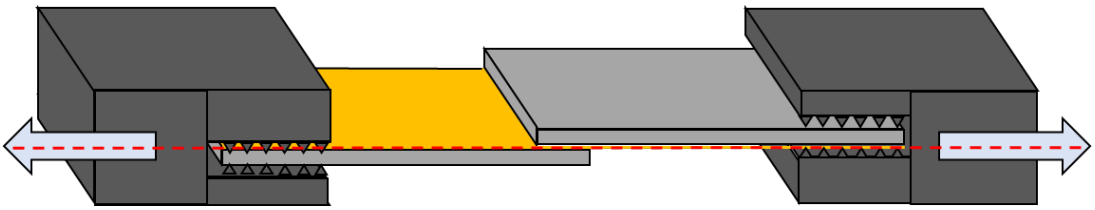

Fig. 3. Principle of the SLS test performed on a CF/PEEK composite with PEI energy director integrated on each welding surface.

Results and Discussion

Rather than establishing a *mode II energy release rate* (G_{IIC}) based on Eq. 1, we chose to compare the *shear strength* (SS) of a joint to the *shear strength of the bulk material* (SS_{bulk}) which is considered to be the maximum shear strength reachable. This ratio could be considered as the *healing degree* (D_h) of the joint and it can be related to the reptation time of the polymer (Eq. 4).

$$\frac{G_{IIC}(t)}{G_{IIC\infty}} \approx \frac{SS(t)}{SS_{bulk}} \approx \left(\frac{t}{t_{rep}}\right)^{\frac{1}{4}} = D_h \quad (4)$$

DNS tests gave a SS_{bulk} value of 73 ± 5 MPa, which is the shear strength value of the bulk material. It is assumed that the strength of assemblies could not reach those of the bulk, due to different entanglement rate in the interface vicinity. It does not mean the quality of assemblies is poor. The welds obtained with optimized welding parameters were characterized. The strength of the bulk was compared with our best assembly configuration by SLS and by a quasi-DNS method, where the assemblies were adapted to fit into the DNS tooling provided. For this comparison, only joints that led to composite fracture were considered. The DNS and SLS tests were performed on a set of 5 specimens, a smaller number for the quasi-DNS test, as several samples were rejected due to failure in the energy director. The advantage of the quasi-DNS test is that the assembly is placed in a pure shear configuration. For the rest of the study, shear strength obtained by SLS test are called Lap Shear Strength (LSS) while strength obtained by quasi-DNS are called Quasi Double Notched Shear Strength (QDNSS). The mean and maximum values for these tests are given in Table 1. The results obtained for both tests are different, +40 % for $QDNSS_{max}$ compared to LSS_{max}, confirming that SLS test does not only imply Mode II fracture. This difference suggests that DNS testing is a more reliable method for the determination of mode II strength than SLS.

The healing degree determined by the QDNSS/SSB ratio is D_h = 93.7 %, which means that the welding parameters were fully optimized. This healing degree should be studied further to see whether it is suitable to define the quality of a joint. Similarly, it would be possible to set a performance ratio for the SLS test. LSS/SS_{bulk} ratio is close to 60 %. Consequently, reaching this value in SLS tests could mean a very good performance is achieved for such assembly. Thereafter, it should be difficult to go beyond this LSS_{max} in SLS testing with the same materials.

Table 1. Shear strength values of CF/PEEK composite assemblies with PEI energy director. LSS is obtained by SLS testing and QDNSS is obtained by quasi-DNS testing method. LSS_{max} and $QDNSS_{max}$ are the maximum values of the corresponding tests.

SSB [MPa]	LSS [MPa]	LSS_{max} [MPa]	QDNSS [MPa]	$QDNSS_{max}$ [MPa]
73 ± 5	43 ± 4	50	68 ± 2	70

Quasi-DNS testing could therefore be a substitute for SLS testing. In addition to a better assessment of the mode II loading, this can lead to cost saving due to smaller specimen sizes and cheaper equipment.

To study the influence of roughness on UW, two surface conditions were tested on the PEI side of the plates. One was generated by thermocompression in contact with a sandblasted backplate (SDB), and the other one with a shotblasted one (STB). The roughness of each specimen was measured before welding. The range is quite large on these specimens: between 9 and 32 µm. The substrates were classified to have pairs of equivalent values. The reference specimens were standard ones (STD), meaning they had a relatively smooth PEI energy director. Their arithmetic roughness was measured between 0.2 and 0.4 µm. The optimized welding parameters for the standard specimens were kept for the rough ones. After welding, the joints were tested in SLS. The results shown in Fig. 4A demonstrate that the higher the roughness, the lower the apparent LSS. Moreover, a high deviation in the results is pointed out. After visual inspection of the fractured surfaces of most joints fractured below 20 MPa, it appears that these welds are incomplete, which means that some portions of the welding area are still intact, and the fracture is located within the energy director. To obtain the true LSS of assemblies, image processing in ImageJ software gives access to the true welded area. The latter is then reported to the true LSS value and plotted versus the roughness in Fig. 4B. A plateau at around 22 ± 4 MPa is identified, which corresponds to the minimum lap shear strength of the weld for these materials, regardless their roughness. Nevertheless, when comparing STB and SDB backplates specimens with STD ones, there is a real gap in roughness, respectively with a minimum value of around 10 µm for rough specimen, and a maximum value of 0.4 µm for smooth ones. Thus, a roughness threshold shall exist between both values, and the fluctuation from 0.4 µm to this threshold should be interesting to study. Unfortunately, no intermediate data are available for this study.

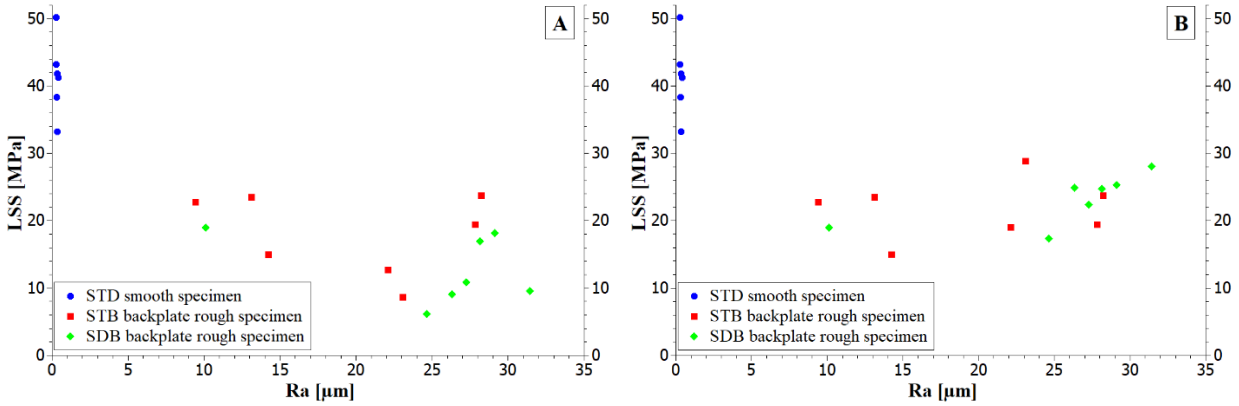

Fig. 4. (A) LSS of CF/PEEK assemblies as a function of PEI energy director roughness. (B) The same results obtained by using the true welded areas in the strength calculation.

To go deeper towards understanding such results, the welding curves are closely examined and compared with the obtained roughness and LSS values. Fig. 5 shows typical welding curves, which highlight the sonotrode displacement over time and the dissipated power during welding. The curves show the main characteristic stages of ultrasonic welding as described by Villegas [8] with slight variations due to different tooling and welding configuration, namely, stage 1) heating of the energy director, stage 2) after a first peak of dissipated power, energy director starts to melt, stage 3) the entire energy director is in a molten state and the sonotrode begins its main displacement, stage 4) includes a second power peak, the matrix at the contact of the energy director starts to melt locally, and stage 5) the matrix at the interphase is completely molten and the degradation begins due to overheating, while the dissipated power starts decreasing.

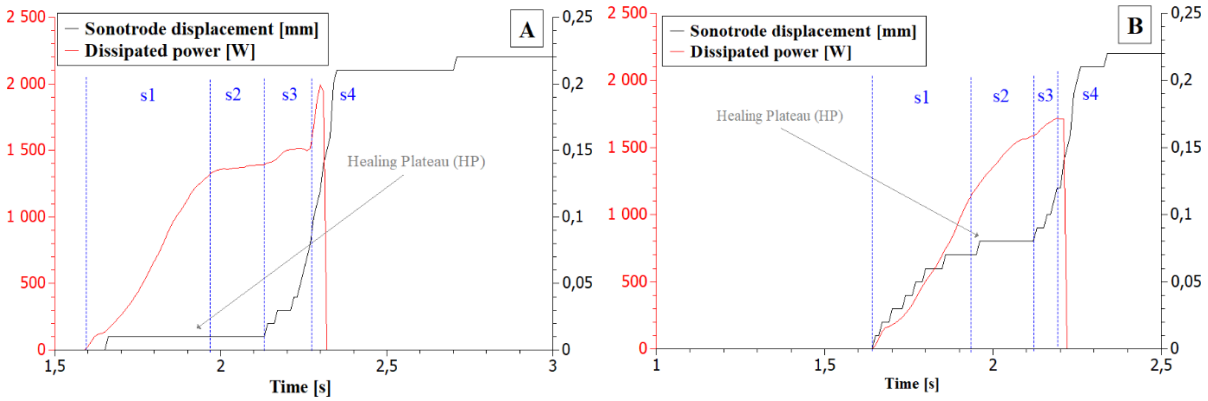

Fig. 5. Welding curves showing sonotrode displacement and dissipated power versus time. Typical curves for (A) standard specimens, (B) rough specimens.

The reference specimens led to the best results by reaching the middle or end of stage 4, which usually involves the joint fracture located within the composite plies. For the rough ones, the welding process more frequently stops during stage 3 or at the very beginning of step 4, and the break often takes place inside the energy director. However, significant differences appear between these graphs' displacement curves. The welding of rough specimens revealed a clearly visible plateau on the displacement curve during stage 1 and 2, which is obvious for all specimens. To date, this phenomenon has never been mentioned in the literature, probably because no study has focused on assembling rough surfaces until now, but smooth specimens. It is similar to fluctuations surrounding the initial point of displacement. However, the sonotrode displacement in stage 1 indicates that this plateau is representative of the beginning of the intimate contact between the welded surfaces. In the following, it will be called *Healing Plateau* (HP). *Intimate contact time* (t_{ic}) is identified as the time required to reach this plateau. Fig. 5b shows a significant power requirement to heat the substrate interfaces and flatten the surface asperities. In this case, rather than getting a first power peak, the change in slope seems to match with the stage 2 transition, which occurs during the HP. In the examples shown, the HP of rough specimens lasts slightly less than half as long as for smooth specimens (here, t_{HP}smooth = 0.53 s and t_{HP}rough = 0.24 s).

There is another important point to consider. In displacement mode in USW, the requested final height arrives too quickly, this is why stage 4 is scarcely reached. The sonotrode travelled distance to reach the plateau is a loss which prevents from achieving the requested displacement and thus, obtain an efficient joining. The roughness could help predicting the height of HP and t_{ic}, as shown in Fig. 6. There seems to be a trend for all roughnesses, but with significant variability for the lowest ones. Therefore, it should be possible to adjust the welding distance depending on the roughness, in order to reach the desired height in displacement mode. For LSS values below 10 MPa, identifying the HP is not obvious.

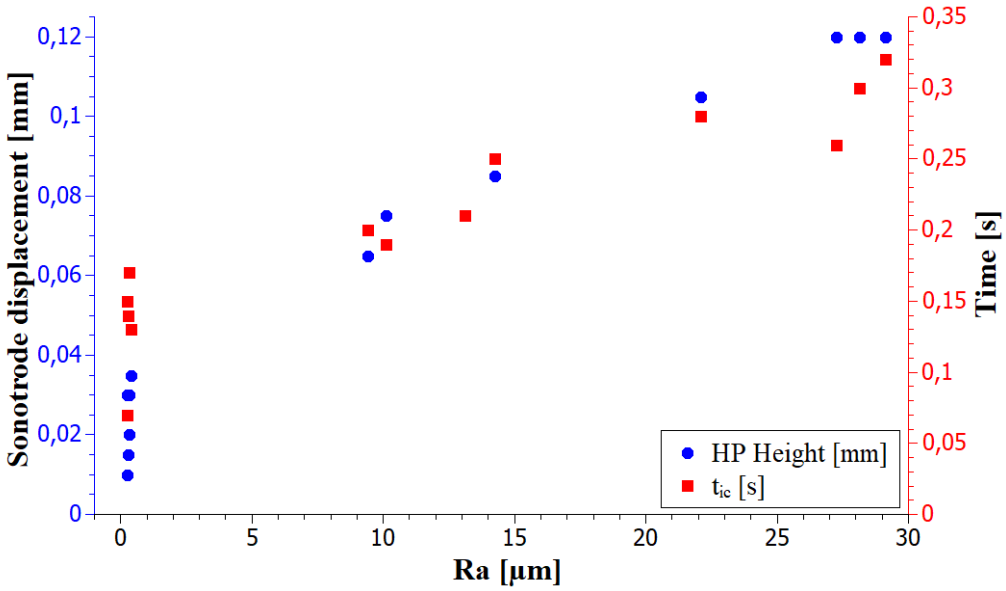

Fig. 6. Healing plateau height position (rounds) and experimental intimate contact time (squares), defined from the welding curves during sonotrode displacement for assemblies with LSS > 10 MPa.

The *healing plateau duration* (t_{HP}), which is finally a characteristic heating time of the interphase, could therefore be responsible for the strength of the assemblies. All plateau durations were measured on the welding curves, using a first-order derivative function to highlight the displacement variations. These results were scaled to the weld area and compared to each joint resistance in Fig. 7. A proportionality appears between t_{HP} and the LSS values. This trend seems to imply that t_{HP} should be maximized to obtain the best welding results. This finding, if confirmed by further studies, could be a simple and non-destructive way of assessing the quality of an ultrasonically welded joint.

To go further in the analysis, the *healing time* (t_h) and t_{HP} are highlighted. It is expected these two values are related. Assuming t_{rep} is considered unitary, and the shear stress of the bulk in SLS is fixed to our maximum value LSS_{max}, the shear stress and time ratios were calculated and plotted in Fig. 8 according to Eq. 4. The resulting trend looks like a line that does not pass through the origin, suggesting t_{HP} is different from t_h.

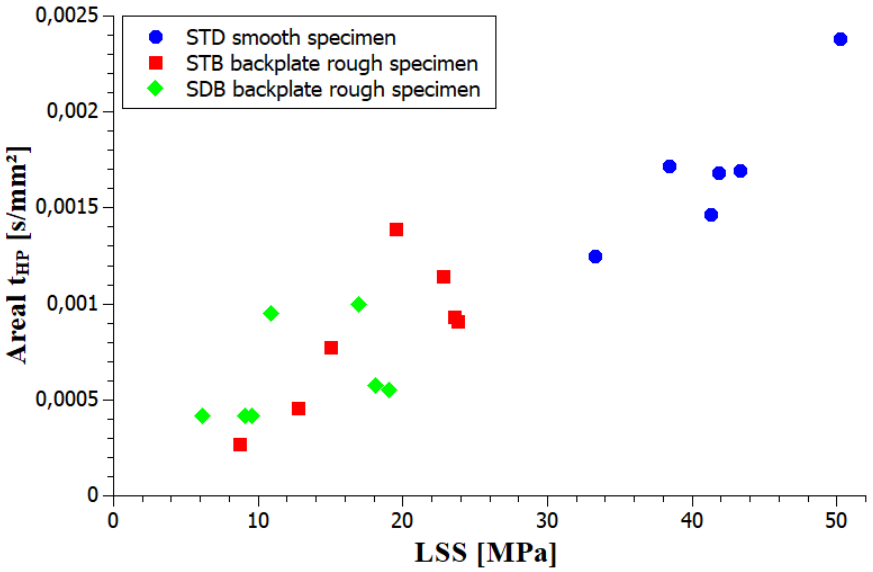

Fig. 7. Link between the healing plateau duration and the shear strength of welded assemblies.

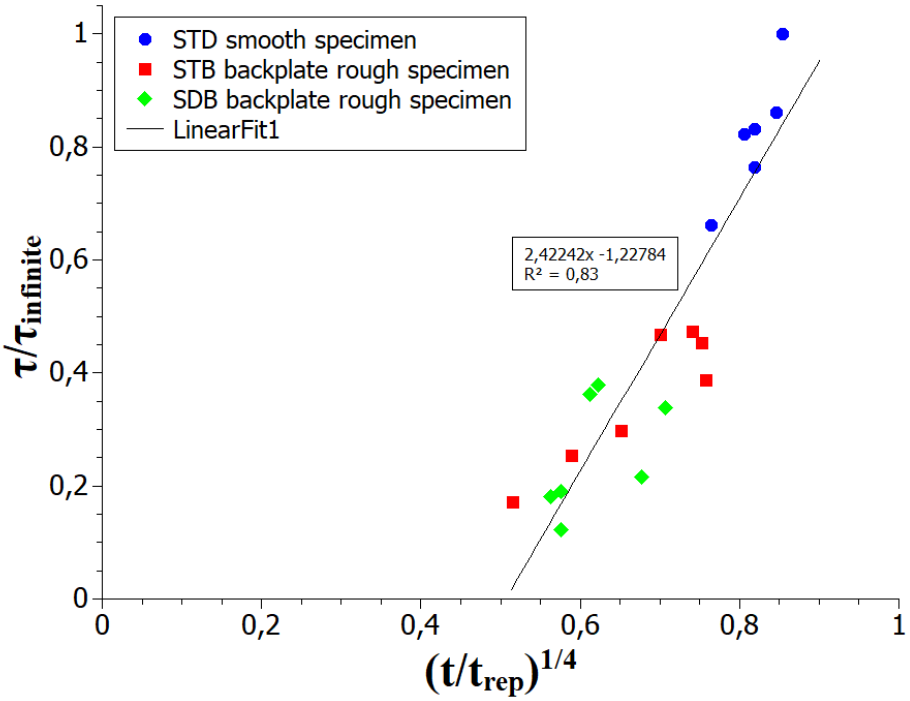

Fig. 8. Healing degree obtained by plotting shear stresses versus time ratios.

Summary

The influence of roughness when assembling composite plates by ultrasonic welding was studied. For that, composite specimens were manufactured with various roughness. For the first time, the intimate contact time was identified experimentally through the power and displacement welding curves. The displacement curves revealed a characteristic plateau duration, particularly evident on rough surfaces, which appears to be directly related to the joint shear strength. Exploiting this knowledge is a first step towards non-destructive examination of assemblies. It was established that this characteristic time is not the healing time of the interface during welding, but the link

between them seems obvious. A high roughness seems to have a negative effect on the strength of a joint welded in displacement mode by USW.

Finally, DNS test as a method of assessing Mode II strength has proven to be more reliable than SLS test, in addition to being less costly in terms of equipment and materials. Nevertheless, it can be established that an SLS test resulting in an LSS/SS_{bulk} ratio of 60% or more demonstrates the high quality of an assembly.

Keywords: Nanocomposites, Damping, Ultrasonic Welding, Graphite Nanoplatelets

Abstract. The selection of an adequate coupling film for welding thermoset composites (TSC) is primary for improving the degree of automation in the composite industry. Ultrasonic welding (UW) is a well-established technique for joining composites and has recently been utilized in the aerospace and automotive industries. To achieve an efficient joining, the use of a polymer-based material placed at the welding interface called an energy director (ED) is required. The choice of the coupling layer material is linked to several requirements, such as processing temperature, high adhesion to the TSC adherend and mechanical strength of the resulting welded joints. Most importantly, the viscoelastic dissipation of the ED influences the heating mechanism and the joint behaviour since the hysteresis loops generated during welding are dissipated into viscoelastic heat. In this work, the authors investigated the possibility of using Poly-vinyl-butyral (PVB) reinforced with graphite nanoplatelets (GNPs) as a coupling layer in UW of TSC adherents, showing that an improvement of lap shear strength (LSS) of 80% with respect to neat PVB.

Introduction

Joining of TSCs has been limited to mechanical fastening and adhesive bonding, or a combination of the two [1]. In the first case, the drilling of holes results in stress concentrations and weakening of the thin composite structure, also significantly reducing its lightweight potential [2]. In contrast, adhesive bonding, although not requiring holes, needs rigorous surface preparation, high curing temperatures and pressures and long curing times to preserve the long-term durability of bonded composite joints [3].

Thus, the development of novel joining techniques able to overcome these drawbacks is required. Welding is a highly efficient process for joining composites, being capable of producing joints in relatively short cycle times, characterized by equivalent or better performance than adhesively bonded or mechanically fastened joints. Specifically, ultrasonic welding (UW) is a well-established technique for joining composites and has recently been utilized in the aerospace and automotive industries [4,5]. However, it requires the melting or softening ability of the polymer with increasing temperature, being applicable only in joining fibre-reinforced thermoplastic composites (TPC). To weld TSC, the use of polymer-based films placed at the welding interface is required to promote frictional and viscoelastic heating [6]. These coupling films, called energy director (ED), must satisfy various requirements such as processing temperature, high adhesion to the TSC adherend and mechanical and environmental performance of the resulting welded joint [7].

In contrast to other welding processes, in the UW, heat is generated by the internal damping of an applied ultrasonic vibration. During ultrasonic welding, the parts are subjected to a longitudinal mechanical vibration with a high frequency (typically 10-40 kHz). The mechanical vibration causes a standing wave in the welding parts in the form of heat [8]. The mechanism of heat

generation is via viscoelastic dissipation due to the cyclic deformation of the plastic. In a purely elastic material, the driving force causes deformation rates in the part that is in phase with the force so there is no energy dissipation. The deformation rate in a purely viscous material is proportional to the applied force but has a phase difference of 90° dissipating the energy. Thus, in UW, the driving dynamic welding force depends on the material properties and shape of the product. When the ED heats, melts and flows to fill the interface joining the parts. With increasing temperature, the damping factor grows and the increasing vibrational energy is converted into heat by hysteresis losses [9].

The transformation of mechanical vibration into heat depends on a large number of mechanical and thermal properties of the material: the damping has to reach a certain level to cause high hysteresis losses, which are responsible for the elevation of the temperature. On the other hand, the material has to be stiff enough to successfully transmit the vibrational energy from the horn to the joint interface.

The polymer itself may not reach these mechanical requirements. Nanomaterials can effectively increase the mechanical performances of polymers both in terms of elastic modulus and damping, thanks to the energy dissipation that occurs at the interface with the matrix. Nanoparticles with a lamellar (2D) structure, such as graphene and its analogues (graphene oxide, GO, graphene nanoplatelets, GNP, etc.), can significantly improve the damping capabilities of nanocomposites [10] and also fracture toughness [11]. The nanoparticle shape factor and content can influence the mechanical behaviour of nanocomposites and in particular the damping factor (tanδ) [12].

In this work, the authors investigated the possibility of using Poly-vynil-butyral (PVB) reinforced with graphite nanoplatelets (GNPs) as a coupling layer in UW of TSC adherents. The effect of GNPs' weight content and flake dimensions on the temperature-dependent dynamic characteristics of nanocomposites and their influence on joint quality have been assessed. Specifically, nanocomposites with GNPs content varying from 0.5 wt% to 2.0 wt% and different aspect ratios have been fabricated using a lab mixer. Both the viscoelastic behaviour and morphology of the nanocomposites have been investigated. Finally, the interlaminar shear properties, through lap shear strength and short beam strength of UW joints have been investigated.

Materials and Methods

Poly-vinyl-butyral (PVB) (Mowital B60H) is a tough plastic resin commonly used for bonding. The presence of hydrophilic vinyl alcohol units and the hydrophobic vinyl butyral units confer both high adhesion to inorganic material and elasticity and toughness.

Two-dimensional graphite nanoplatelets (GNPs) are multilayer graphene obtained by the exfoliation of graphite. Nanoplatelets with different aspect ratios have been selected in this study and their geometry is listed in Table 1.

Table 1. Properties of selected nanoplatelets.

Nanoplatelet	SSA*	Lateral size	Thickness	Aspect ratio
MICRO850	14 m^2/g	4 μm	850 nm	4.70
AVA 1240	22 m^2/g	40 μm	12 nm	3333
G2NAN	30 m^2/g	30 μm	14 nm	2143

*SSA=specific surface area

Nanocomposites filled with selected GNPs were produced following a mixing and moulding process. Firstly, the polymer and the nanoplatelets are mixed using a Thermo Haake Rheomix for 10 min at a temperature of 150°C. Then, films of 200 μm thickness are fabricated using a hot platen press at 140°C and 200 bar for 20 min.

A number of 8 different coupons have been fabricated, varying the filler concentration and aspect ratio (Table 2). Also, an unfilled PVB film has been produced as reference.

Table 2. Fabricated nanocomposites.

Sample	***Filler***	***Nominal filler content*** [wt%]
Ref	Neat	-
1	AVA1240	2.0
2	G2Nan	0.5
3	G2Nan	1.0
4	G2Nan	1.5
5	G2Nan	2.0
6	MICRO850	0.5
7	MICRO850	1.5
8	MICRO850	2.0

Thermogravimetric analysis (TGA) (TA Instruments Q500) was conducted to evaluate the real filler/matrix composition of the films. Measurements were performed in an inert atmosphere, using nitrogen gas, with a temperature ramp of 10°C/min from room temperature to 700°C. The weight loss is evaluated at 500°C.

The thermal properties of the PVB/GNPs films were investigated by differential scanning calorimetry (DSC) using the DSC Discovery instrument. Each specimen was heated and cooled twice from 0 to 300°C at a rate of 10°C/min and the glass transition temperature (T_g) values were extracted from the DSC curves.

Dynamic mechanical analysis (DMA) was employed to measure the loss modulus and assess the viscous behaviour of the PVB/GNPs nanocomposites. A TA Instruments Q800 DMA equipped with a single cantilever clamp was used to perform a temperature sweep from 30 to 120°C at a heating rate of 3°C/min and a frequency of 1 Hz and considering an initial amplitude of 20 μm. Data are elaborated according to the ASTM D790 standard for the flexural behaviour of composites [13].

An optical microscope Olympus BX 51M, equipped with Linkam THM600 hot stage, was employed to assess the morphology of the material and the quality of the dispersion of the nanoparticles.

A carbon fabric/epoxy prepreg with a fibre volume content of 58% was used. 8 plies of CF/epoxy prepreg were stacked with a [(0/90)/ (45/-45)/(-45/45)/ (90/0)]s lamination sequences. The CF/epoxy stack were cured in autoclave at 120°C for 2 hours and 3 bar with vacuum bag, resulting in a laminate with a final thickness of 2 mm. Subsequently the CF/epoxy cured adherends were ultrasonic welded using the PVB/GNP film as coupling layer and ED.

Ultrasonic welding of individual coupons was performed using a Rinco Dynamic 3000 ultrasonic welder. The following process parameters were used: 500 N welding force, 36 μm peak-to-peak amplitude, 1000 ms welding time and 500 Ws maximum welding energy.

The coupons were saw cut from the cured CF/epoxy laminates to the dimensions of 36 x 12 mm for the Interlaminar Shear Strength (ILSS) tests (Fig. 1Fig. **1**) and 25 x 100 mm for the Lap Shear Strength (LSS) tests (Fig. 1).

ILSS tests were performed according to ASTM D2344 standard to evaluate the interfacial strength of the ultrasonic welded joints; the bonding characteristics of the ultrasonic welded joint was evaluated by LSS tests, according to ASTM D5868 standard. The tests were carried out with a 50-kN load cell in a Instron 68TM-50 Mechanical tester.

The interlaminar shear strength (ILSS) was calculated by dividing the peak recorded reaction force, F_{max} by the area of the cross section (A_{ILSS}), equal to 40 x 12 mm^2, as shown in Eq. 1.

$$ILSS = \frac{3}{4} \cdot \frac{F_{max}}{A_{ILSS}} \quad (1)$$

The LSS of the joints was calculated as the maximum load divided by the total overlap area. The total overlap area (A_{LSS}) was about 25 x 25 mm^2, Eq. 2.

$$LSS = \frac{F_{max}}{A_{LSS}} \quad (2)$$

A minimum of three specimens were tested per type of PVB/GN coupling layer used in this study.

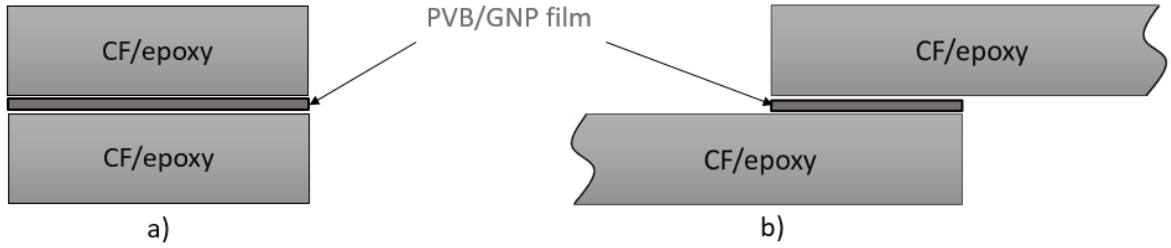

Fig. 1. Schematic representation of the CF/Epoxy/PVB joints in (a) ILSS and (b) LSS configurations.

Results and Discussion

The results of thermal analyses are reported in Table 3. The actual filler content is equal to the nominal value, as confirmed by TGA. Also, the glass transition temperature (T_g) of the polymer is not affected by the inclusions: it is equal to that of the unfilled polymer (73°C) for all samples.

Table 3. Results of thermal analyses conducted on PVB/GNPs nanocomposites.

Micrographs show excellent dispersion in the case of MICRO850 and G2Nan in contrast to AVA1240. The morphology of the material changes considerably according to the selected GNPs. In the case of AVA1240, the presence of agglomerates can be observed, with a non-uniform distribution of particles (Fig.2). The quality of the dispersion increases significantly in the case of G2Nan (Fig.3). In this case, the distribution of nanoparticles is uniform for all concentrations from

0.5 wt% to 2.0 wt%, with a slight level of agglomeration. Finally, the best dispersion was observed for MICRO850 for all contents, with a very good level of homogeneity and absence of clusters (Fig. 4).

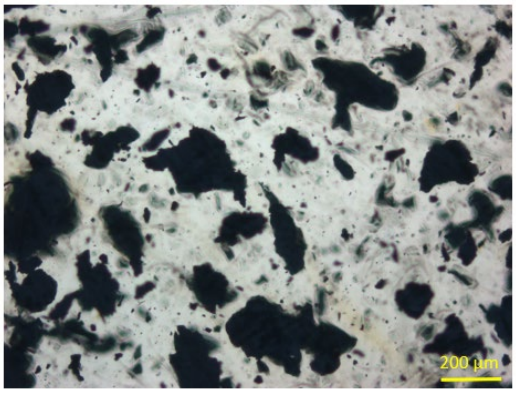

Fig. 2. Micrograph of PVB reinforced with AVA1240 at 2 wt%.

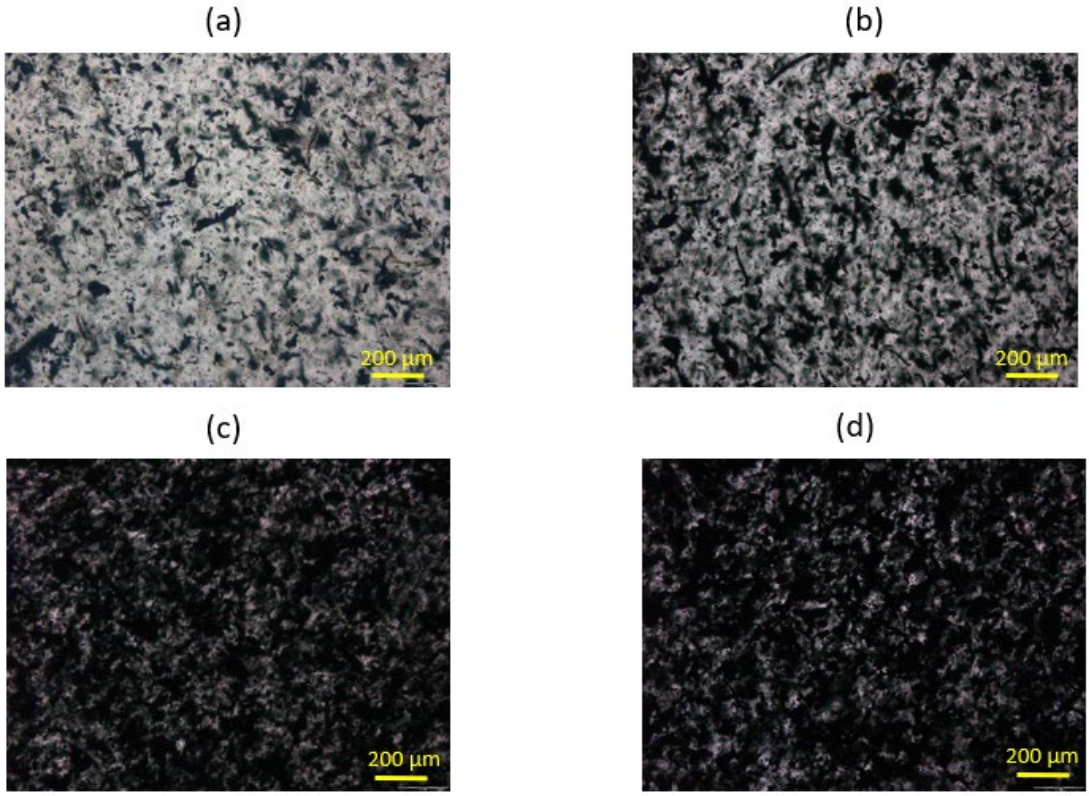

Fig. 3. Micrograph of PVB reinforced with G2Nan at 0.5 wt% (a), 1 wt% (b), 1.5 wt% (c) e 2 wt% (d).

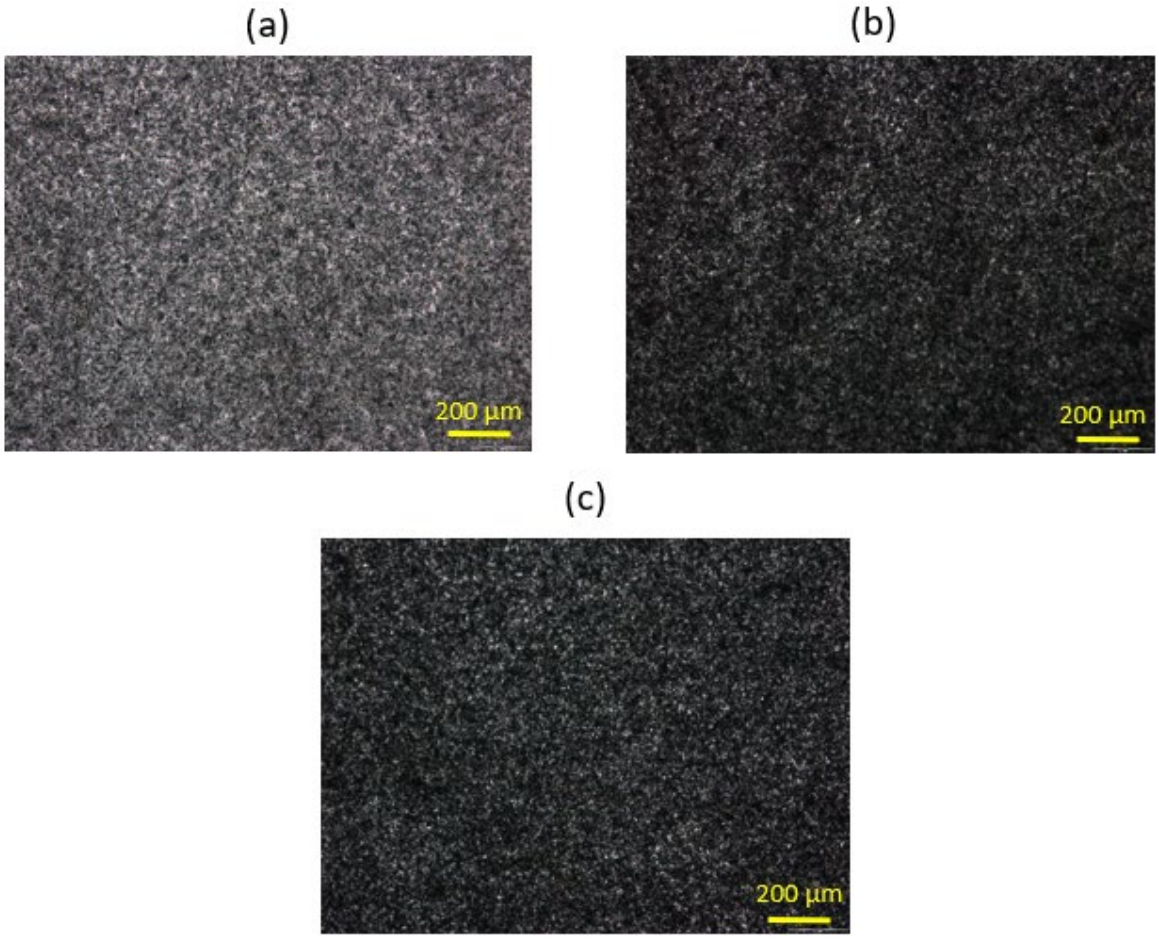

Fig. 4. Micrograph of PVB reinforced with MICRO850 at 0.5 wt%(a), 1.5 wt% (b), 2wt% (c).

The quality of GNPs dispersion is reflected in the mechanical performance of the nanocomposite. The results of the analyses carried out showed an improvement in the mechanical properties in the case of G2Nan and MICRO850 reinforced PVB compared to the unfilled polymer, and a deterioration in the case of AVA1240, both in terms of elastic modulus and damping.

In a viscoelastic material, the properties are intermediate between those of an ideal solid and those of an ideal liquid, as there is a phase lag between strain and deformation due to the time required to obtain molecular rearrangements. A measure of the elastic or pseudo-solid nature of the material is represented by the storage modulus (*E'*), while a measure of the viscous or pseudo-liquid nature of the material is represented by the loss modulus (*E''*). From a physical point of view, the storage modulus is related to the stiffness of the material and the loss modulus reflects the damping capacity of the material. The damping factor, tanδ represents the ratio between the viscoelastic and elastic response of a material and defines the dissipative capacity of the material. The results of the dynamic mechanical analyses conducted on the samples, in terms of storage and tanδ are reported in Fig. 5.

In the case of G2Nan, a maximum elastic modulus is observed for samples with a GNP content of 0.5 wt%, an increase of 9% compared to unfilled PVB. As the filler content increases, the possible presence of clusters leads to a decrease in the elastic modulus with respect to the neat PVB, albeit insignificant. The damping factor increases as the GNP content increases, with a maximum in correspondence of filler content of 1.5 wt%. This configuration provides a 33% increase in tanδ, without altering the elastic modulus of the material (2% reduction).

In the case of MICRO850, due to the small particle size, dispersion is uniform at all concentrations and the elastic modulus increases with increasing filler content. Again, a 30% increase in tanδ is observed for 1.5% GNP content.

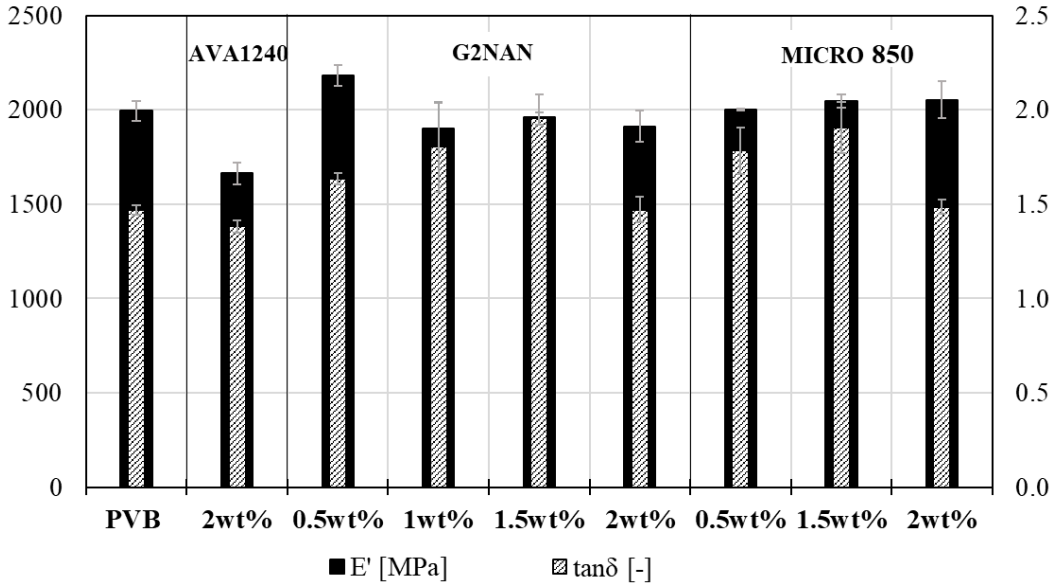

Fig. 5. Comparison between storage modulus at room temperature and damping ratio at peak of the tested nanocomposites.

In UW, the energy directors need to match damping and stiffness requirements to guarantee a certain level of hysteresis losses and to successfully transmit the vibrational energy from the horn to the joint interface respectively. Therefore, AVA1240 has not been considered for further investigation.

A strict correlation between the results of DMA and the short beam shear (SBS) is observed (Fig. 6). The mechanical properties of the coupling layer influence the strength of the joint. Welded joints with nanocomposites with high elastic modulus showed higher SBS with respect to the neat PVB, with a maximum of 40 MPa for PVB filled with 0.5 wt% of G2Nan. At low lamellar nanoparticles content, the fracture toughness of polymers improves, since the inclusions delay crack propagation [11].

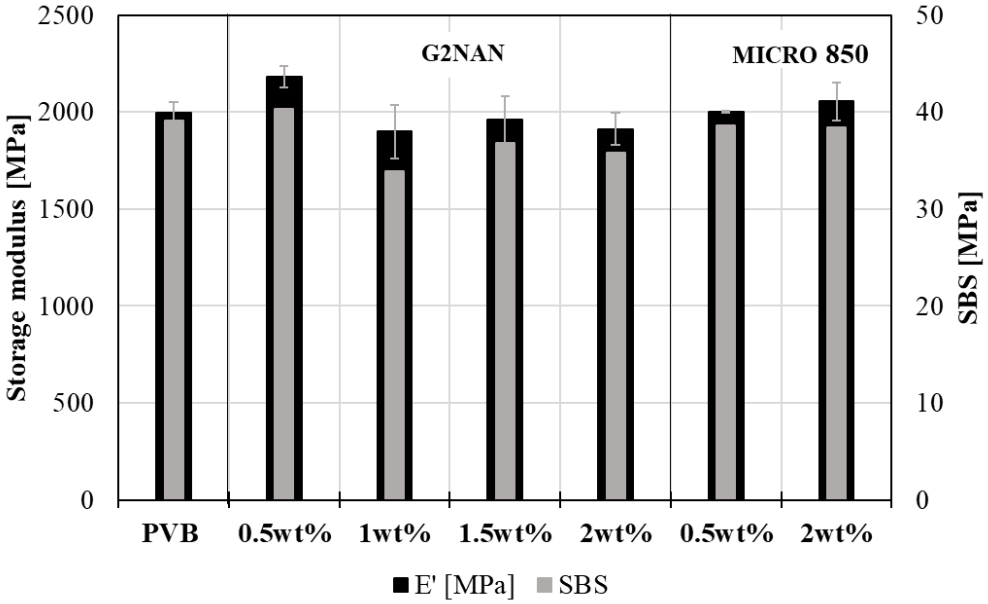

Fig. 6. Comparison between SBS and storage modulus

Lap shear strength has been assessed only for nanocomposites reinforced with G2Nan at different filler content. It is shown in Fig. 7 that this value is always higher than that of the neat PVB and it is maximum for the case of PVB filled with 0.5 wt% of G2Nan.

PVB filled with 0.5 wt% of G2Nan showed an improved quality of the joint with respect to the other samples. According to [14] the higher the material damping and the storage modulus (i.e. the higher the loss modulus) the higher the heat generation during welding and the lower the energy required for the welding process. It means that the ultrasonic weldability significantly depends on the loss modulus of the material [9]. Indeed, the LSS and E'' at 120°C (Fig. 7) show a similar trend.

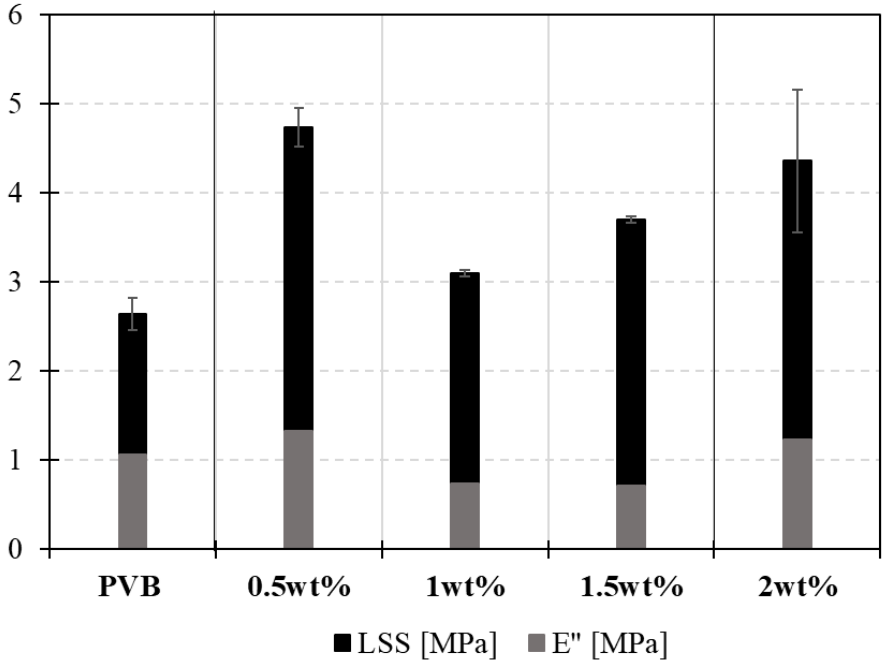

Fig. 7. Comparison between LSS and loss modulus.

Summary

The possibility of using PVB/GNP coupling films as energy directors in UW of TSC has been demonstrated. The influence of GNPs' weight content and flake aspect ratio on the mechanical properties of nanocomposites and joint quality has been assessed.

It was found that the use of lamellar nanoparticles can effectively improve the mechanical performances of polymers both in terms of damping and elastic modulus and consequently weldability. Unlike neat PVB, the inclusions act as reinforcement, supporting part of the load that is transferred from the matrix, both improving the elastic properties and the dissipative capabilities of the material. The high hysteresis losses ensure the elevation of the temperature during welding and the high stiffness ensure the transmission of the vibrational energy from the horn to the joint interface.

An improvement of 28% of loss modulus and 80% of LSS is shown for PVB reinforced with 0.5% of G2Nan, meaning that GNPs positively affect the damping capacity of PVB and therefore the joint strength.

In order to further optimize and increase weld strength future investigations will be addressed. Strategies will be aimed at modifying the thickness of coupling layers and adding the PVB reinforced films as an intermediate material co-cured with the TSC laminates.

Keywords: Additive Manufacturing, Carbon Fiber, Composite, Porosity, Post-Treatment

Abstract. This work aims to understand the effect of consolidation on parts obtained by material-extrusion additive manufacturing process. Three plates were manufactured with carbon fiber/PEKK tapes. Two of them were consolidated under pressure at 334 and 360°C corresponding to the maximum of the melting peak and the end of the melting peak of PEKK respectively. Another plate did not undergo any post-treatment after printing, it is used as a reference. The parts were characterized to measure their porosity by density measurement and X-ray micro-computed tomography. Subsequently, short beam shear tests and dynamic mechanical analysis (DMA) tests were carried out to assess the influence of porosity on the mechanical strength of the plates. As expected, the interlaminar shear strength (ILSS) decreases when the porosity increases. The highest ILSS is obtained for the part consolidated at 360°C due to a lower porosity. The highest storage modulus is obtained for the part consolidated at 334°C whereas the loss factor indicates a lower glass transition for the same part. This could be explained by a lower degree of crystallinity as revealed by DSC, compared to the part consolidated at 360°C.

Introduction

Additive manufacturing offers affordable opportunity to obtain complex shapes [1]. Material-extrusion based processes are the most used techniques of 3D printing. ASTM International's additive manufacturing (AM) technologies committee approved a new standard guide for the use of layer-based material extrusion (MEX) processes in additive manufacturing. MEX processes are used to fabricate polymer, or polymer composite, parts by depositing a filament or bead of material from an extrusion head. Initially, most of raw materials were filaments of polylactic acid (PLA) and acrylonitrile butadiene styrene (ABS). Indeed, because of their low thermal transitions, their printing temperatures fit any basic printing machine [2,3]. However, after printing, such printed parts often suffer from poor interlayer adhesion bonding and high porosity rate [4]. MEX is now driven by high demanding applications, which require high performance polymers. PEEK (polyetheretherketone) and PEKK (polyetherketoneketone) are high performance semi-crystalline thermoplastics whose glass transition and melting temperatures are around, respectively, 150°C and above 360°C [5,6]. Printing PEEK and PEKK is possible with machines equipped with a heating chamber to control the crystallization upon cooling. As shown by Wang et al. [7] who characterized the bending properties of PEEK, printed parts reached 190 MPa for the bending strength compared to around 200 to 300 MPa for an injection molded part [8]. Other works report similar trends regarding mechanical resistance for PEKK printed parts [9]. Indeed, printing of PEKK is a challenge due to its high deposition temperature of around 400°C and its very high viscosity. Such high temperatures induce harsh temperature gradients inside the part during

printing. Consequently, the crystallization of PEKK is not homogeneous along the z-axis direction. This gradient of crystallinity contributes to warpage defects due to anisotropic shrinkage. Also, a too fast crystallization could hinder macromolecular diffusion at the interfaces, the surface contact between filaments. Thus, the mechanical resistance between each layer of PEEK or PEKK printed parts remains very low as demonstrated by Rahman et al. who measure an interlayer resistance between 80 and 100 MPa [10]. A way to improve the mechanical properties of thermoplastics is the association with short or continuous fibers. Among fibers, carbon fibers have the highest elastic modulus and stress at break. Therefore, some studies have focused on printing carbon fiber/polyetherketoneketone (PEKK) composites which target aerospace, medical and any other demanding applications due to outstanding chemical resistance, flame retardancy and low smoke generation and toxicity [11]. When filled with short carbon fibers (100 to 300 μm), the performance of these composites is limited [12,13] as revealed by their brittle behavior under impact [14], but the short fibers increases the tensile strength up to 95 MPa against 80 MPa for the pure PEEK [15]. Addition of continuous fibers makes the material much more resistant [15]. The stiffness, low weight and stress resistance make continuous carbon fiber an ideal material to produce industry-grade composite parts. Unfortunately, long carbon fiber/PEEK printed parts also suffer from high porosity and poor interlayer adhesion as demonstrated by Luo et al. who found an interlaminar shear strength (ILSS) of 4 MPa for a 20%wt long carbon fiber filled composite, compared to an ILSS of 12 MPa when printing pure PEEK [16]. An option to overcome this flaw has been put forward by Van de Werken et al. who studied the effect of hot-pressing as post-treatment after printing. After applying a temperature of 250°C for less than 3 hours at 1.4 MPa, the porosity was decreases by a factor 2 to achieve 5% of porosity with an ILSS of 35 MPa [17].
9Tlabs is a company offering solutions to design and manufacture complex parts in no time. They propose additive manufacturing machines to produce high performance continuous fiber composites (carbon fiber with PEEK or PEKK matrix) with up to 60% fiber volume fraction. High volumes of structural composites can be manufactured in achieving up to 80% weight saving and 50% cost saving in series production, high reproducibility and great quality [18]. Their solution is based on a two step process: 1) a printing step 2) a consolidation step.

In this article, the effect of the consolidation step on the part performance was evaluated. The porosity rate and mechanical properties of the parts were measured on printed parts and after consolidation step at two different temperatures at 334°C and 360°C. The porosity was measured by density measurement and micro-computed tomography (μCT). The benefits and limitations of these techniques are discussed. The mechanical strength of printed parts was measured by interlaminar shear strength (ILSS). The material moduli were determined by dynamic mechanical analysis (DMA). An attempt to correlate these results to the porosity of parts is proposed to highlight the effect of compression post-treatment.

Materials

The composites plates were manufactured with a 9T Labs additive manufacturing machine [18]. 9T Labs offers a whole additive fusion technology including post treatment. The printing strategy is XY/Z with fiber direction along the Y-direction as drawn by the white line in Fig.1.

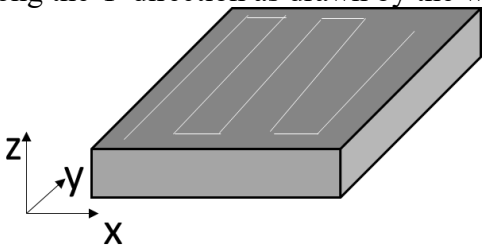

Fig. 1. Orientation of the printed plates with the building strategy (white line).

The material feedstock is a rectangular unidirectionnal carbon fiber pre-impregnated tape whose theoretical fiber volume fraction is 60 % [18]. The deposited tape contains a polyetherketoneketone (PEKK from Arkema company) matrix and AS4 carbon fiber. After printing, the parts are inserted into a mold, and a compression cycle is applied to densify the parts. This process guarantees high resistance complex shape parts. For the sake of clarity, the parts are 2- and 3-mm tick plates in this study. Three cases are compared i) Printed plate without consolidation (named UP), ii) Printed plates with a compression cycle at 334°C (CP-C1) and iii) Printed plates with a compression cycle at 360°C (CP-C2). The compression temperatures were chosen according to the thermal transitions of PEKK matrix. DSC (differential scanning calorimetry) were performed on about 10 mg of PEKK filament in aluminum pans with a Q200 TA Instruments DSC. The heating cycle is as follows: First heating ramp: 10°C.min^{-1} from 25°C to 380°C, cooling ramp: 10°C.min^{-1} from 380°C to 25°C, second heating ramp : 10°C.min^{-1} from 25°C to 380°C. Three samples were tested, only the second heating ramp of one sample is shown in Fig. 2. The filaments were dried at 140°C for 24h before testing. The glass transition is visible at 160°C, then the melting peak spreads from 300 to 360°C. The compression temperatures correspond to the maximum of the melting peak (334°C) and the end of the melting peak (360°C) for CP-C1 and CP-C2 respectively. The consolidation cycle is defined by a heating ramp at 15°C.min^{-1} under 30kN, an isothermal step at 334 or 360°C under 45kN for 180 s, followed by a cooling ramp at 7°C.min^{-1} under 45kN. Then, the parts are demolded when the temperature is below 160°C. The printing and post-treatment parameters are defined respectively in Table 1 and Table 2.

Methods

Before any characterization, all samples were dried at 140°C for 24h.

Short beam shear (SBS) tests were carried out on an Instron 4204 universal testing machine with a three-point bending device. The radius of the two supports and loading nose were 5 mm and 2 mm respectively, according to NF-EN 2463 standard. The cross-head speed was 1 mm.min^{-1}. For each configuration, at least three specimens were tested, the results were averaged. The strength of the SBS test was calculated from Eq. 1:

$$\tau_{SBS} = \frac{3}{4}\frac{P_{max}}{b.h} \quad (1)$$

with τ_{SBS} : Short-beam strength (SBS) (MPa), P_{max}: maximum load (N), b: sample width (mm), h: sample thickness (mm)
The sample density was measured by hydrostatic weighing in accordance with NF EN ISO 1183-1 standard. The density of the samples, ρ_s (g.cm^{-3}), was calculated by Eq. 2:

$$\rho_s = \frac{m_s}{(m_s - m_e)}\rho_{water} \quad (2)$$

with m_s : apparent mass of the sample in air (g), m_e : apparent mass of sample in water (g)
ρ_{eau} : water density
Then, the porosity was obtained by Eq. 3:

$$P = 1 - \frac{\rho_s}{\rho_f} \quad (3)$$

with ρ_f the density of the raw tape (according to the data sheet ρ_f= 1,58 g.cm^{-3}), ρ_s is the density of the sample and P is the porosity rate.

X-ray micro-computed tomography (µCT) was used to evaluate the porosity of the plates. Volume images were generated by a laboratory tomography device (Easytom RXSolution). The acquisition parameters were a tension of 150 kV and an intensity of 200 µA. 10 x 15 mm specimens were positioned on a rotation stage and 1440 projections of transmitted X-ray intensity field were recorded at each angular step of 0.25° by a flat panel detector (1920 x 1536 pixels) through an X-ray detector. Each projection was obtained by averaging ten images recorded at the same angular position. A volume image of the variations of the linear attenuation coefficient in the specimen was reconstructed from all radiographies by using a filtered back-projection algorithm. The distribution of grey levels in 3D images is due to local differences of density and so corresponds to a 3D representation of the microstructure of the specimen. Each volume image was reconstructed with the same voxel size of 13.48 µm. The pictures were treated with Avizo software. Each sample was divided into six parallelepipedic parts as seen in Fig. 3. The depth of the sample is not represented here but it is considered as well. Using a greyscale, a threshold is applied to separate the matrix and fiber part from the black part, i.e., the pores. The light grey part represents the clamping device used to hold the specimens: so, it is not considered for analysis. Furthermore, the air around the specimen is not counted as pores. The calculation of the global porosity rate is done by averaging the porosity rates of each zone.

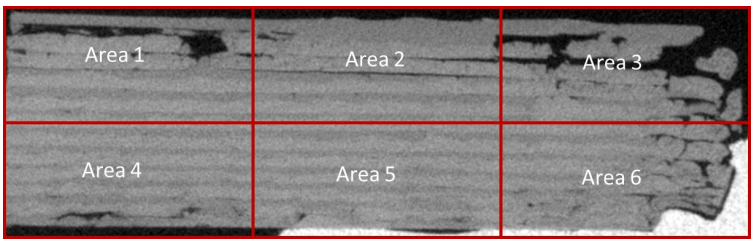

Fig. 3. Separations of area on XZ view.

Dynamic mechanical Analysis (DMA) was investigated using an ARES strain-controlled rheometer from TA Instruments in rectangular torsion mode. For dynamic analysis, sinusoidal strain γ* is imposed with a constant angular frequency ω. Viscoelasticity of polymers leads to a

phase lag between strain and stress σ* giving access to, in the linear viscoelastic domain, the complex dynamic modulus. Storage and loss moduli, G' and G'', were recorded as a function of temperature. Measurements were achieved from 25°C to 325°C with a 3°C.min^{-1} ramp. The angular frequency ω was 1 rad.s^{-1} and the strain γ was 0.1% for UP, 0.05% for CP-C1 and 0.1% for CP-C2 to stay within the linear viscoelastic domain. Sample sizes were 45 x 10 x 3 mm^3.

Results and discussions

Porosity.

Two different methods, hydrostatic weighing and micro-computed tomography were applied to evaluate the porosity. The results are presented in Fig. 4. The porosity for the reference plate (no consolidation) is 15% by tomography and 10% by hydrostatic weighing. The compression step at 334°C results in decreasing the porosity up to 3% by tomography and 7% by hydrostatic weighing. A higher compression temperature, 360°C, leads to a reduction of the porosity, below 1% whatever the technique. A high porosity is often reported for printed parts, for instance in the work by Tao et al. [4]. The compression step reduces the porosity. Indeed, the viscosity of the thermoplastic matrix decreases with temperature, resulting in easier polymer flow and closing of the pores. A representation of the theoretical structure of printed parts is schemed in Fig. 5.

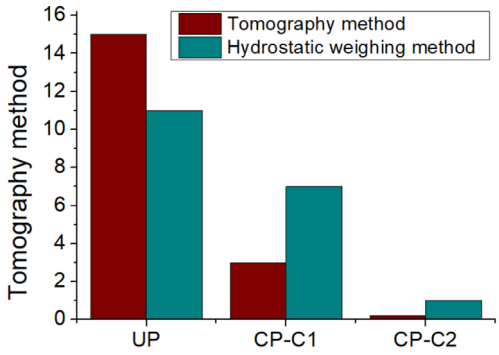

Fig. 4. Porosity for non-consolidated (UP), consolidated at 334°C (CP-C1), consolidated at 360°C (CP-C2) specimens.

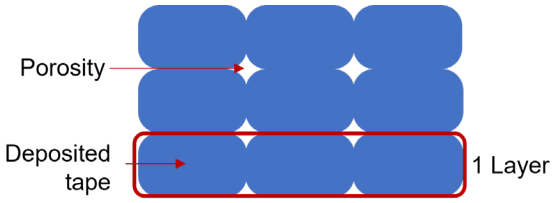

Fig. 5. Representation of the structure of a printing part (view XZ).

In the case of UP, besides pores presented in Fig. 5, delamination of the layers is observed. Indeed, the specimens were printed in a chamber without temperature control, resulting in low adhesion between tapes. Therefore, a higher porosity is measured on the specimen edges compared to the inner structure, as seen in Fig. 6. For the CP-C1 and CP-C2 plates, no delamination is detected by the software, leading to a better accuracy in the calculation of the porosity.

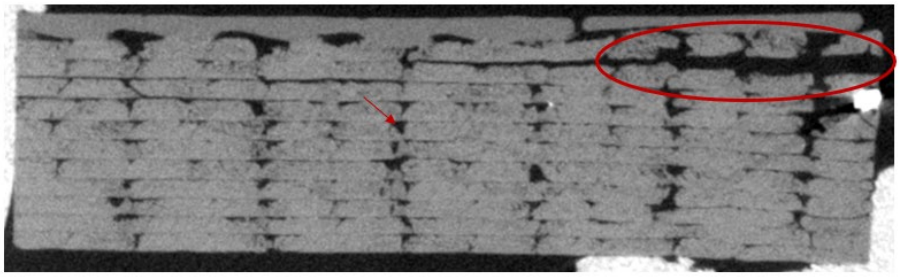

Fig. 6. XZ view of a slice of UP.

For the unconsolidated plate (UP), the porosity obtained by hydrostatic weighing is smaller than the one obtained from the density measurement. This is because external porosities due to

delamination are not considered in weighing, as water can seep into the narrowest pores on the sample edges.

For the consolidated specimens, the porosity is higher for hydrostatic weighing in both cases as seen in Fig. 4 for CP-C1 and CP-C2. The pores below 13,5 µm size (1 pixel) were not detected whereas hydrostatic weighing considers all pores whatever their sizes. A smaller pixel size would be necessary to detect smaller pores and to make both techniques to converge to the same porosity result. To sum up, CP-C2 has a much lower porosity than other specimens. The consolidation step at 360°C allows the PEKK matrix to flow more easily and to close the voids compared to 334°C. This temperature corresponds to the maximum of the melting peak. At this temperature, some crystalline lattices still remain, as a consequence, the viscosity is still too high to make the consolidation step effective.

Effect of compression on mechanical properties.

The results of SBS tests for unconsolidated specimens, compressed specimens at 334 and 360°C are shown in Fig.7a, b and C respectively. Interlaminar Shear Strength (ILSS) is defined by the first drops in stress on the curve. For UP, a more progressive and less brutal fall in stress is pointed out compared to the trend obtained for consolidated plates. ILSS results (calculated from the ISO 14130 standard) for the UP is 4,44$\pm$0,89 MPa whereas 42,54$\pm$2,36 MPa and 69,54$\pm$3,49 MPa were obtained for CP-C1 and CP-C2, respectively. The consolidation step has an impressive effect on ILSS with an increase of more than 800 % for CP-C1 and 1400 % for CP-C2. These results demonstrate the efficiency of the compression post-treatment after printing. A higher dispersion is noticed for UP whereas the curves for consolidated ones are closed one to each other. Moreover, increasing the temperature for the compression step increases the ILSS of about 40% when comparing CP-C2 and CP-C1. ILSS is related to interlayer adhesion. At 360°C, the viscosity is lower than at 334°C, giving more mobility to the macromolecules and a faster macromolecular diffusion across the layers. ILSS is mainly the contribution of two parameters: interlayer adhesion and porosity. We target to determine which one is the most influential on ILSS. For that, ILSS is plotted with the porosity in Fig.8. As expected, the ILSS value decreases with the increase in porosity. When the porosity tends towards zero, the ILSS value sharply increases. A hypothesis explaining such rise is related to the contact surface between tapes: Under pressure, the pore sizes decrease. Because of the elliptical shape of the tape section, this contact surface increases abruptly at the beginning and then slowly until the perfect contact between tapes is reached (flat surface). From a threshold, the effect of porosity is expected to be overlooked, giving a maximum ILSS value.

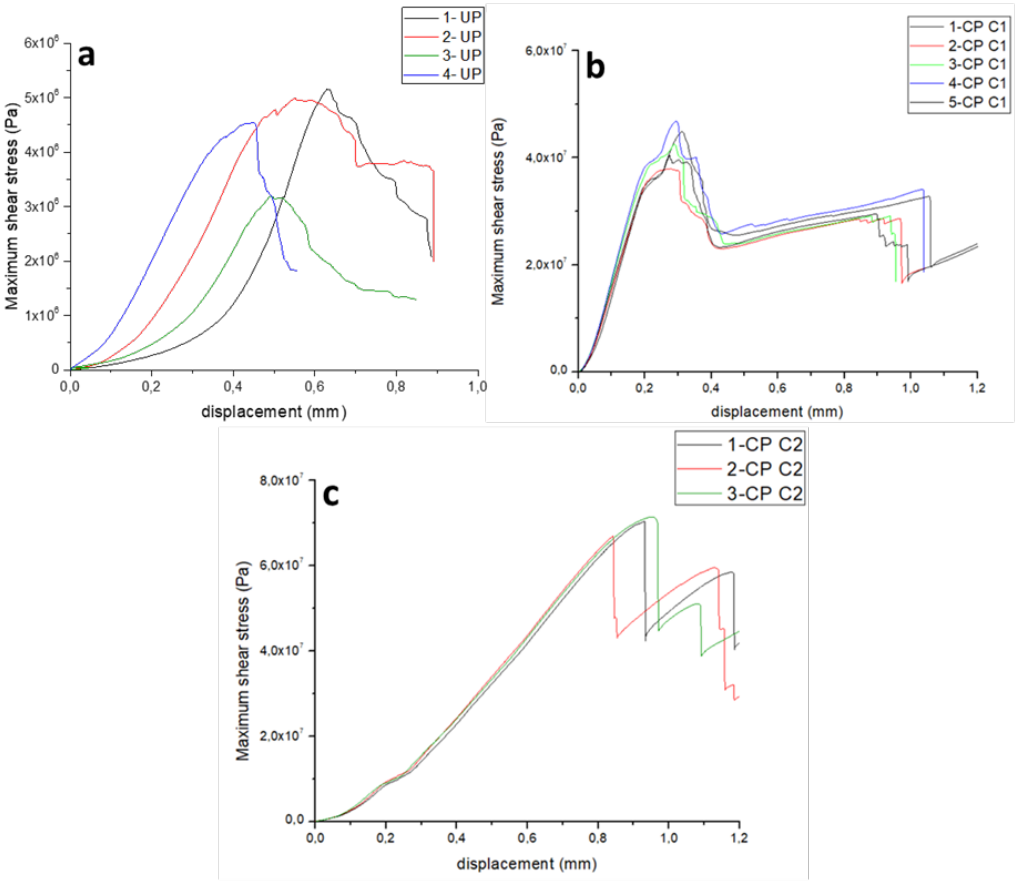

Fig. 7. SBS curves. a: plate UP ; b: plate CP-C1 ; c: plate CP-C2.

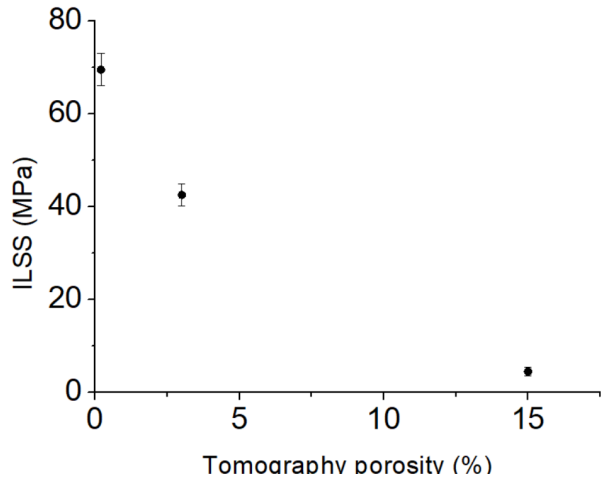

Fig. 8. Variation of SBS test results with porosity obtained by micro-computed. tomography

Effect of compression on dynamic moduli.

The dynamic moduli are presented in Fig. 9. In Fig. 9a, for all the specimens, a quasi-constant storage modulus G' is observed at the lowest temperatures up to 160°C, at this temperature, a sudden drop is associated to the glass transition (Tg). After the rubbery plateau, a last decrease towards 300°C corresponds to the softening of the amorphous phase of PEKK. As expected, G' for the unconsolidated plate is lower than for the consolidated ones. Surprisingly, the storage modulus in the glassy plateau is the highest for CP-C1. It means that the stiffness of the specimen consolidated at 334°C is higher than the one compressed at 360°C. Also, we notice a slight shift in the glass transition, around 170°C, with the lowest Tg for CP-C1. For the loss modulus G'' in Fig. 9b, a peak is observed at Tg and then a drop thereafter. The loss modulus (G'') is also higher in the case of CP-C1, which means that the material needs more energy to deform. In Fig.9c, the maximum of the ratio tan δ=G''/G' is shifted towards lower temperatures for CP-C1. This lower

Tg is associated with a higher macromolecular mobility in the amorphous phase. Also, this peak is broader and less symmetrical than the ones obtained for the UP and the plate consolidated at 360°C. This peak shape is often attributed to a higher polydispersity in chain lengths. In our case, it could stem from a higher dispersity in crystallite sizes. Indeed, in the case of compression at 334°C, the crystalline phase of the material has partially melted. This unmelted crystalline phase could hinder the crystallization during cooling, giving more time to the macromolecules to diffuse across the contact surface of the tapes. G' and G'' of CP-C1 are therefore higher than those of CP-C2. These results are supported by the degree of crystallinity results gathered in Table 3. The degree of crystallinity Xc is calculated from DSC curves with the Eq. 4:

$$Xc = \frac{\Delta Hf}{\Delta H_{100\%} * V_m} \quad (4)$$

With ΔHf the enthalpy of the melting peak of the first heating ramp, ΔH_(100%) the enthalpy of PEEK (considering the crystallinity of PEEK is close to those of PEKK) at 100% of crystallinity [19], V_m the volume fraction of matrix (0,4). Very high standard deviations of the degree of crystallinity are observed for UP and CP-C1 in Table 3 whereas those consolidated at 360°C are less disperse. This deviation indicates a non-homogeneity during crystallization. It means that the crystallization does not occur homogeneously within the part during consolidation at 334°C.

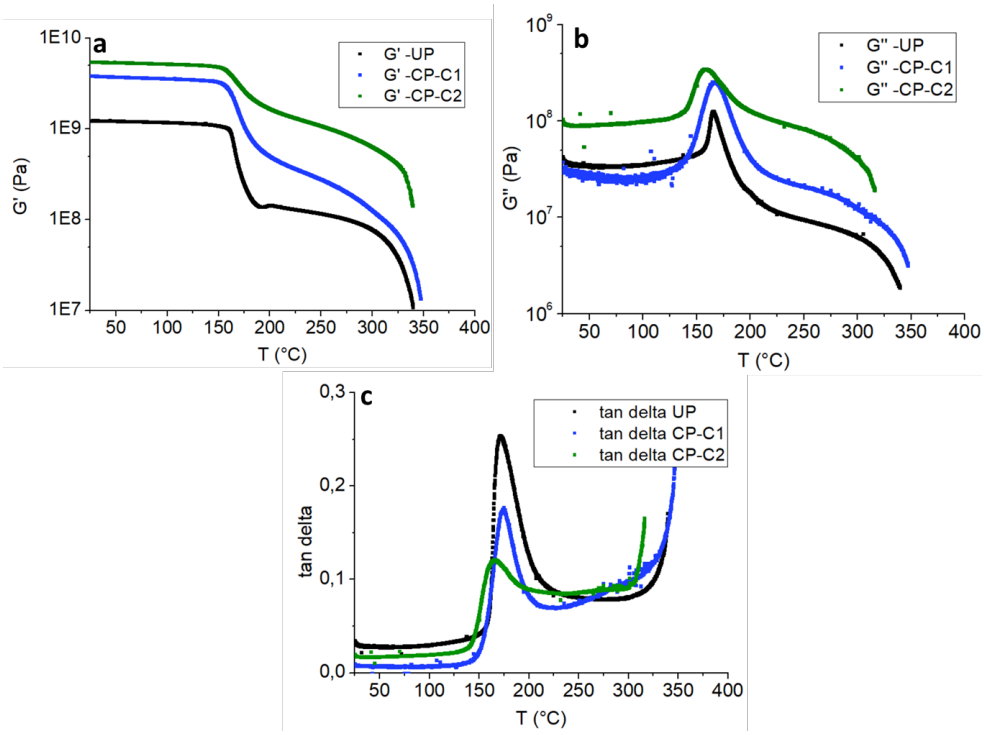

Fig. 9. DMA results for unconsolidated parts (UP), consolidated parts (CP) at 334°C (CP-C1) and 360°C (CP-C2): (a) storage modulus (G'); (b) loss modulus (G''), (c) tan δ.

Table 3. Degree of crystallinity of PEKK tapes and printed plates obtained from DSC curves

Material	Cristallinity (%)
PEKK	29 ± 3
UP	17 ± 2
CP-C1	17 ± 3
CP-C2	39 ± 15

Summary

To conclude, 9T Labs provides a complete additive manufacturing process to obtain printed parts with high mechanical strength. It consists of a printing step followed by a compression cycle. Two compression temperatures, 334 and 360°C were studied to determine the optimized conditions. When comparing to the reference plates (without the compression step), it reveals that the consolidation has a significant impact on part properties. The porosity was measured after printing on unconsolidated and consolidated parts by two techniques: tomography and hydrostatic weighing. The parts were characterized through short-beam strength tests, dynamic mechanical analysis, and differential scanning calorimetry. The aim was to compare the effect of the consolidation temperature at 334 and 360°C on porosity, ILSS and dynamic moduli.

The porosity was considerably reduced when the parts underwent consolidation post-treatment, the lowest porosity was obtained at 360°C, less than 1%, due to the PEKK matrix which is fully melted at this temperature. ILSS was initially near 4 MPa for the non-consolidated plates, whereas for those consolidated at 334°C and 360°C, ILSS were 42 and 69 MPa respectively. This result is higher than the ones found by Van Der Varken et al. [17]. This higher strength could stem from the reduction of porosity and increase of contact surface. ILSS results are clearly related with porosity, but the trend is not linear, indication the contribution of other phenomena such as macromolecular orientation. The highest storage modulus was obtained for the part consolidated at 334°C. A hypothesis could be linked to chains conformation: they are oriented in the extrusion direction whereas this organization is lost at 360°C. The loss factor (tan $\boldsymbol{\delta}$) indicates a lower glass transition for the part consolidated at 334°C. This lower glass transition is consistent with a higher macromolecular mobility in the amorphous phase and a lower degree of crystallinity. Further works will focus on understanding the effect of thermal cycles on crystal morphology and the role of crystallinity on interfilament adhesion.

Abstract. Epoxy Vitrimers are gathering attention as a development in the field of more easily re-processable and self-healing thermosets. Incorporating a catalyst should activate the transesterification reaction within the polymeric macromolecule inducing topological modification of the network. Reacting epoxy precursors with suitable anhydrides and acids will promote exchange reactions between esters and beta-hydroxyls, adding the vitrimeric behaviour. In the present work, a commercial epoxy system suitable for CFRP manufacturing has been modified to induce vitrimeric behaviour by exploiting the catalytic activity towards the transesterification reaction of Zn2+. Creep experiments confirm that the resin starts to flow above a critical "Vitrimeric" temperature (T_v). Moreover, the thermoformability of vitrimer-CFRP has been investigated by reprocessing CFRP coupons.

Introduction

Unlike thermoplastic polymers, thermosetting resins and their composite materials are very difficult to recycle. A stable cross-linked structure prevents long-range molecular mobility necessary to activate material flow at temperatures high enough to reform and recycle. As a result, thermosetting composites are hardly recycled, and most components are sent to landfills at the end of their service life.

Increasing environmental awareness and industrial competitiveness encourage introduction and development of repairable and recyclable structural materials to reduce polymer waste and extend their service life. Recently, the development of thermoreversible cross-linked networks has been introduced as a viable alternative to produce composite components that can be recycled and reformed as thermoplastic materials [1,2]

Introducing a thermoreversible covalent bond in the cross-linked backbone allows the topological reshuffling of polymeric networks and makes it possible to rework and reform the cross-linked material. The dissociative Diels- Alder reaction between furans and maleimides is a well-established approach for designing and synthesising covalent adaptable networks (CAN) [3]. As a further development in more easily re-processable and self-healing thermosets, vitrimers are gathering attention for outdoing the current drawbacks of CANs [4].

One possible mechanism that enables the vitrimeric behaviour in epoxy resins is based on transesterification exchange reactions between esters and beta-hydroxyls formed by reacting epoxy precursors with suitable acids/anhydrides [1,5]. Incorporating a catalyst activates the transesterification reaction and induces topological variations, stress relaxation and flow in the cross-linked networks, even though the total number of cross-links does not change [6,7].

However, there have been difficulties in realising such behaviour in rigid thermosets until 2011, when Leibler et al. [4] introduced a new group of materials named vitrimers. They applied the

well-established transesterification reaction to the hydroxyl and ester groups in an anhydride-cured epoxy matrix to create a reworkable thermosetting network.

During transesterification, the network's connectivity is altered via exchange reactions, inducing stress relaxation and plastic flow at elevated temperatures without depolymerisation.

In the presence of a transesterification catalyst, it was shown that elastomeric epoxy/acid and rigid epoxy/anhydride networks possess gradually decreasing viscosity with increasing temperature, as is characteristic of other vitreous materials such as inorganic glass. Shi et al. [8] investigated such systems' capability to be welded and reprocessed. Demongeot et al. [9] investigated the mechanism of action of the catalytic zinc species active in these materials.

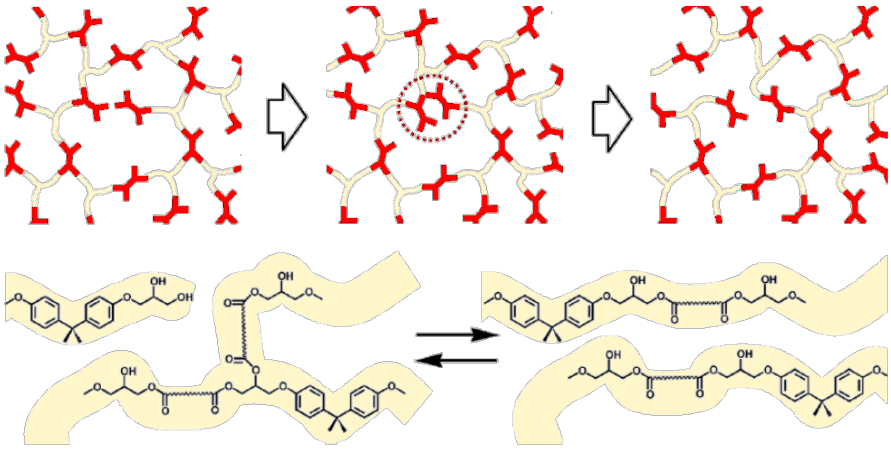

Fig. 1. Exchange reaction scheme and related topological changes. Adapted from [7,9].

In the present work, a commercial epoxy system (*araldite*® LY 3508 and *aradur*® 917-1 by Huntsman Corporation) suitable for CFRP manufacturing was selected for its modification as a vitrimer. Furthermore, zinc acetate was selected as a transesterification catalyst. Two formulations at a different stoichiometric ratio between epoxy precursor and curing agent have been prepared and modified by adding Zinc acetate into anhydride. Creep experiments showed a flow above a critical temperature (about 170°C) that confirms the achievement of a vitrimeric behaviour. In addition, a vitrimer-CFRP was realised using one of the formulations analysed and was thermoformed.

Materials and Methods

The used resin is a mixture of Bisphenol A diglycidyl ether (DGEBA) epoxy resin with an Epoxy Equivalent Weight (EEW) of 196.5 g/eq, tetrahydro-methyl phthalic anhydride (THMPA) curing agent and 2,4,6-tris(dimethyl aminomethyl)phenol as the catalyst, kindly provided by Huntsman corporation with product names *araldite*® LY 3508, *aradur*® 917-1 and Accelerator 960-1 respectively. The vitrimers formulations are based on ester interchange reaction, and Anhydrous zinc acetate (ZnAc2) (99.99%) was used as the catalyst, purchased by Merck Sigma-Aldrich. All reagents were used without further purification.

The Epoxy resin *araldite*® LY 3508 and cross-linking anhydride *aradur* ® 917-1 were mixed at room temperature with a mechanical mixer in a glass beaker until a homogeneous mixture was achieved. Subsequently, the Accelerator 960-1 was added and further mechanically mixed. The total weight of the prepared mixture was in the range of 100 g.

Two different formulations were realised, varying the epoxy to acyl ratio between 0.6 (M2) to 1.0 (M2A).

In addition, zinc acetate is added to the epoxy resin formulations to promote the ester interchange reaction and induce cross-linked resin's vitrimeric behaviour. First, an adduct is synthesised between tetrahydro-methyl phthalic anhydride (THMPA) and zinc acetate. Then, the

required amount of *aradur* 917-1 (20.00 g, 0.120 mol) and zinc acetate (3.22 g, 0.018 mol) are reacted in a round bottom flask at 120°C for 2 hours under nitrogen flow.

The THMPA/zinc acetate adduct is cooled to room temperature and used without further purification. Then, the epoxy vitrimeric mixture is prepared according to the above procedure while substituting *aradur* ® 917-1 with the THMPA/zinc acetate adduct.
After mixing, samples were degassed under a vacuum and cured for 1h @ 120°C and 2h at 140°C. Table 1 summarises the cross-linked sample condition realised.

Table 1. Cross-linked sample composition.

Sample Codex	LY 3508 [phr]	*Aradur* 917-1 [phr]	960-1 acc. [phr]	r epoxy/acyl ratio	$ZnAc_2$ * [%]
M2 **	*100*	*70*	*3*	0.6	-
M2A	100	40	3	1.0	-
M2-V	100	70	3	0.6	5
M2A-V	100	40	3	1.0	5

* $ZnAc_2$ percentage is calculated to the total acyl groups.

Experimental Methods

DSC was performed with a *Discovery DSC* of *TA Instruments* under a nitrogen atmosphere with a heating and cooling rate of 10°C min^{-1}, from room temperature to 250°C. About 10 mg samples were encapsulated in aluminium pans before measurements.

DMA experiments were conducted with a *Dynamic Mechanical Analyzer Q800* from *TA Instruments* in the single cantilever mode. Samples were measured from 30 to 160°C at 3 °C/min, a strain amplitude of 15 μm, and a frequency of 1 Hz. The samples were cut into a rectangular shape of 25 mm × 5.5 mm and a thickness of ca. 2.5 mm.

Creep tests were performed using a *Dynamic Mechanical Analyzer Q800* from *TA Instruments*. The Tension Film clamp with preload of 0.1 N was applied. The specimen dimensions were c.a. 10x5.5x2 mm^3. Five minutes of isothermal hold was used before each creep segment, starting from 70°C to 220°C with 50°C incremental steps to evaluate sample strain variation from the glassy to the rubbery state. The stress of 0.1 MPa was applied for 45 minutes.

The ability of the vitrimer composite to be thermoformed has been assessed by applying plastic deformation in a three-point bending configuration with a span of 50 mm. The forming temperature (200°C) was chosen according to the vitrimeric temperature (in the actual epoxy system T_v is expected at 220°C,[10]). The sample was kept at the temperature of 200°C for 600s. Therefore, a load was applied (displacement control mode) with a speed of 500 μm/min up to a maximum deflection of 10 mm. The force needed to deform the sample was 0.1 N.

Results and Discussion

The preparation of cross-linked systems with semi-flexible molecular structures facilitates topological interchange reactions; however, it reduces the glass transition temperature and elastic modulus. Therefore, a balance must be sought between the reactivity of interchange linkages and thermomechanical properties. It is well known that bifunctional epoxy precursors can be cross-linked with monocarboxylic anhydrides using either an excess or a defect of the curing agent. Usually, the reaction is promoted by the presence of substituted amines as the catalyst. If a stoichiometric ratio between epoxy and acyl groups is used, the cross-linked density is lower, but the presence of hydroxyl and ester groups highly facilitates the ester interchange reaction [11].

The transesterification reaction can be activated by the presence of Zn2+ ions at an elevated temperature beyond vitrimeric temperature (T_v), leading to a topological rearrangement.

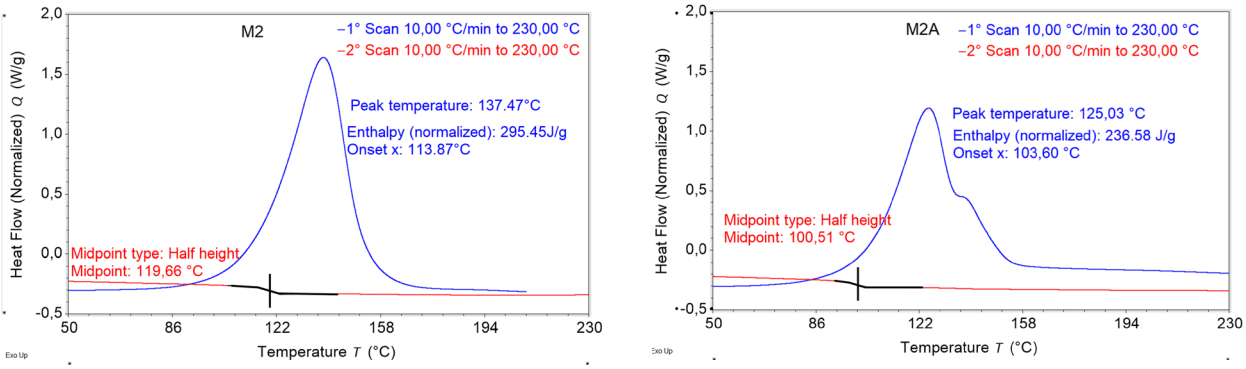
This study will discuss the influence of the THMPA/ZnAc2 molecular ratio on the epoxy formulations' mechanical properties. In addition, temperature-dependent creep experiments have verified the occurrence of molecular long-range rearrangements.

Epoxy mixture M2 described in Table 1 has been formulated as reference material. The epoxy is used with a stoichiometric defect, with a mole ratio of epoxy/acyl equal to 0.6. The acyl groups in stoichiometric excess can further react with -OH groups formed due to oxirane ring addition to carboxylic acid.

The curing behaviour and glass transition temperature of the M2 system are illustrated in Fig. 2a. The absence of an exothermic peak in the second heating ramp of DSC is a clear indication of a complete conversion. The observed T_g is about 120°C. The epoxy mixture M2A was subsequently prepared with a stoichiometric ratio between epoxy and acyls equal to unity.

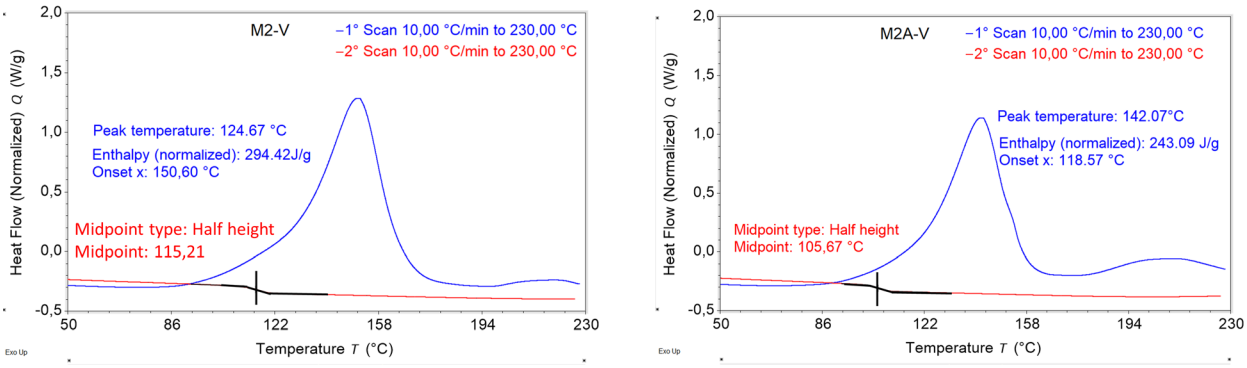
The cure of M2A system is illustrated in Fig. 2b (DSC Thermogram). As expected, the T_g drops to 99°C due to a lower cross-linking density.

To obtain a vitrimerized version of M2 and M2A, zinc acetate is introduced as a suitable catalyst for ester interchange reactions. The amount of zinc acetate has been fixed at 5% of the acyl groups, the obtained systems have been named M2-V and M2A-V, respectively.



a) b)

Fig. 2. DSC curves of the samples at different epoxy/acyl ratio. Reference resin a); stoichiometric ratio (epoxy/acyl 1.0, M2A) b).



a) b)

Fig. 3. DSC curves of the samples at different epoxy/acyl ratios. Modified formulation, "Vitrimers" M2-V a) and M2A-V b).

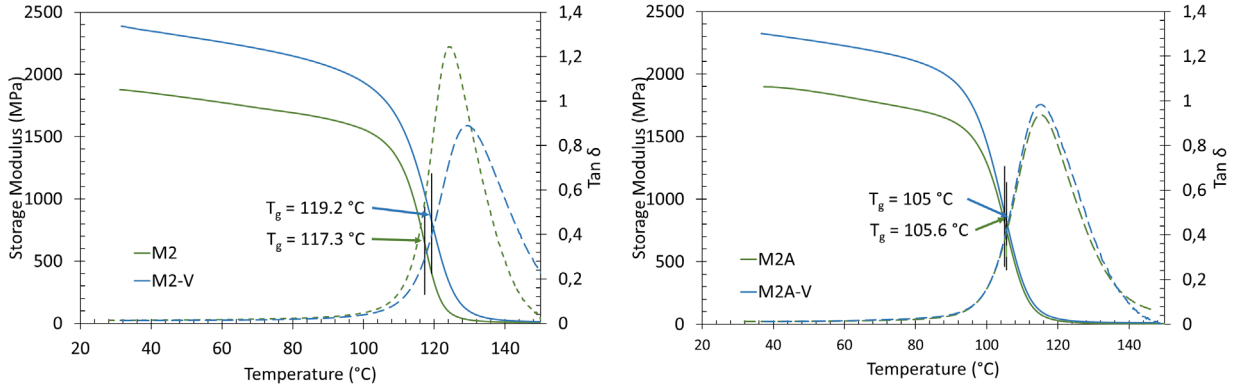
The zinc acetate influences the primary cross-linking reaction and activates a secondary reaction in the temperature range between 180 and 230°C, while the T_g of the cross-linked sample appears to be dominated by the ratio between epoxy and acyl groups (Fig. 3).

DMA experiments, shown in Fig. 4, have been performed in the linear viscoelastic deformation range to confirm cross-linked samples' glass transition temperatures and elastic modulus. The

glass transition temperature has been evaluated as the value at the inflection point of the storage modulus diagram.

The effects of catalyst addition and the different stoichiometric ratio between epoxy and acyls are shown in Fig. 5 and highlight three main phenomena:

a) The glass transition temperatures obtained by DMA confirm the corresponding values measured by DSC;
b) The addition of the Zn2+ catalyst produces an increase in the glassy elastic modulus;
c) The tanδ (ratio between loss and storage moduli) of vitrimeric systems (M2-V and M2A-V) @160°C is higher than corresponding conventional formulations (M2 and M2A, respectively). Indeed, this experimental observation could be related to a residual viscous flow, confirmed by following creep experiments.



a) b)

Fig. 4. DMA curves at different epoxy/acyl ratios M2 and its vitrimer a); M2A and its vitrimer b).

Table 2 summarises the thermomechanical properties of the analysed systems characterised by DSC, DMA and CREEP experiments.

Table 2. Thermo-mechanical properties.

Description	**T_g (DSC) [°C]**	**T_g (DMA) [°C]**	**Reaction Enthalpy [J/g]**	**Elastic Modulus [GPa]**
M2	119.7	119.2	295.5	1.88
M2A	100.5	105.6	236.6	1.89
M2-V	115.2	117.3	294.4	2.38
M2A-V	105.7	105.0	243.1	2.34

In addition to the DMA experiment, the explicit and robust confirmation of vitrimeric behaviour due to thermoreversible cross-linking rearrangements has been obtained by creep experiments.

Samples in the form of thin slabs have been subjected to creep experiments under tension deformation. The creep experiments have been performed in the temperature range between 70 and 220°C.

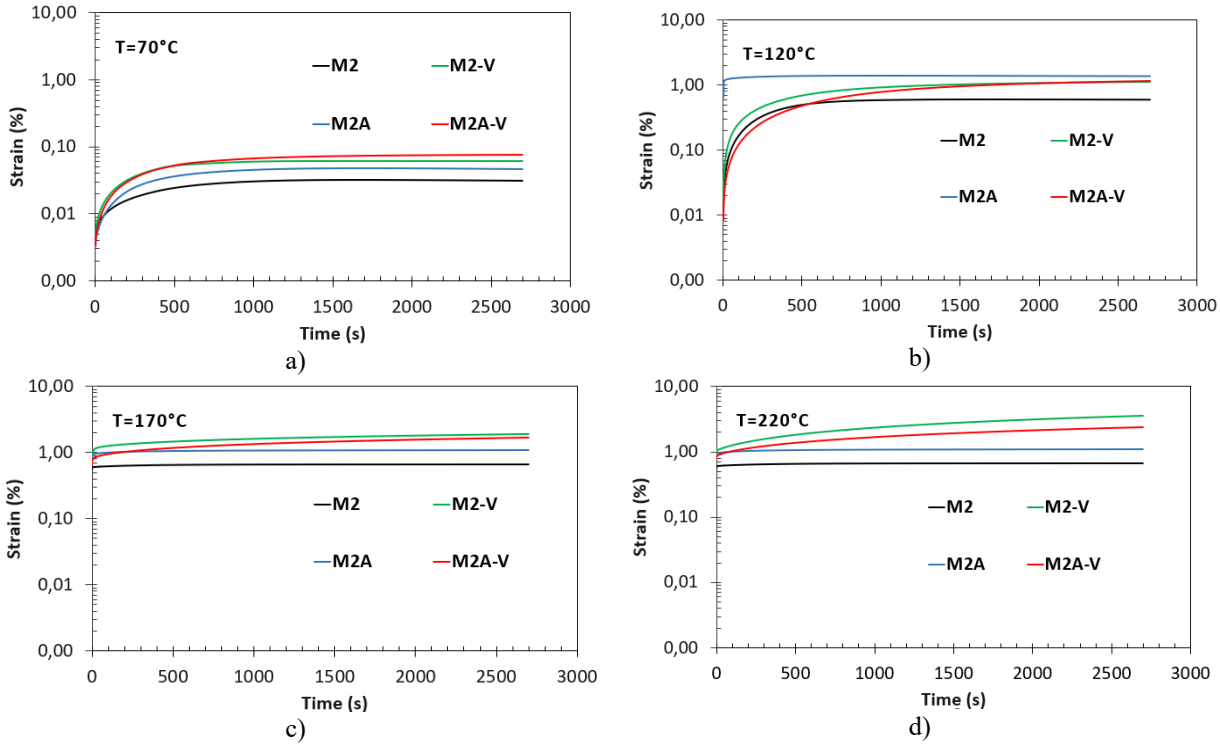


Fig. 5. Creep curves at different temperatures.

Specimen M2 and M2A showed stable behaviour; in fact, creep is negligible at each temperature. Even at temperatures higher than T_g, no molecular flow has been observed.

Things change when zinc acetate is added to the formulation. The presence of metallic ions strongly catalyses the ester interchange reaction, resulting in evident creep of samples subjected to tensile load at different temperatures, as reported in Fig. 5. The effects are higher in the case of the M2A-V sample with an equivalent amount of epoxy and acyls (r=1.0).

To verify the thermoformability of the vitrimeric matrix developed, a carbon fibre-reinforced composite has been realised using the matrix M2A-V.

The vitrimer-CFRP laminates were produced by hand lay-up and vacuum consolidation at 120°C (Fig. 6).

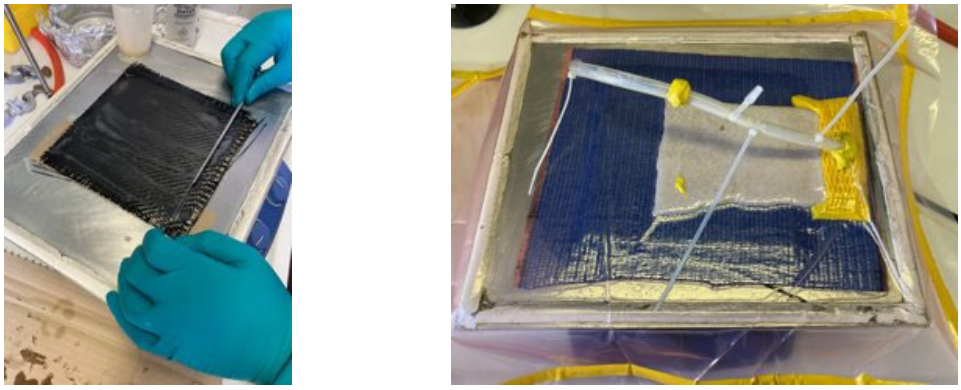

Fig. 6. Manufacturing procedure for vitrimer-CFRP.

Then, test specimens were cut to the dimensions 60x12 mm, and thermoformed following the procedure reported in Fig. 7.

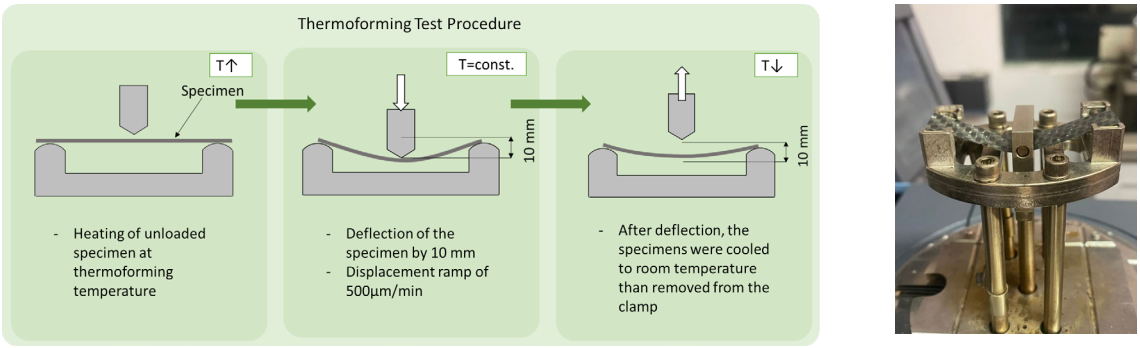

Fig. 7. Experimental set-up and 3-point bending thermoforming test procedure.

After the cooling stage, the sample was frozen in the deformed configuration, even if a spring-back (13%) had been detected. By observing the reshaped sample, no flaws or other defects have been observed, therefore, the polymeric phase is able to flow and is prone to be reprocessed to improve the sustainability of parts made by vitrimers.

Summary

The epoxy groups can efficiently react with carboxylic acids or anhydrides. Therefore, bi/multifunctional epoxy precursors can be efficiently cross-linked with carboxylic anhydrides, resulting in very stable materials with a glass transition temperature of 100-140°C and an elastic modulus in the range of 1.5-2.0 GPa.

In this work, two different formulations with the adjustable stoichiometric ratio between epoxy precursor and curing agent have been prepared. In order to promote the polymer modification into vitrimer, the catalyst Zn2+ has been introduced into the formulation by synthesising an adduct between ZnAc2 and the THMPA curing agent, with a catalyst concentration of 5 % than to acyl groups. The presence of metallic ions strongly catalyses the ester interchange reaction, resulting in evident creep of samples subjected to tensile load at different temperatures. Moreover, an empirical approach to investigate the thermoformability of vitrimer-CFRP has been presented with satisfactory results.

Even if epoxy vitrimers have shown important features for increasing the sustainability of composite materials, major challenges will have to be faced to transfer this from an academic concept into real-world materials. First of all, it is mandatory to increase the glass transition to meet the requirements of structural applications, in addition, industrialisation needs affordable catalysts to sustain mass production, by the way, their development is very promising.

Abstract. In the last few years, fused deposition modelling (FDM) has been explored as an innovative technology for processing thermoplastic green composite materials. However, not all FDM filaments are ecologically beneficial due to their release of toxic compounds during printing. Moreover, they have a dangerous environmental impact, as they are obtained from petroleum. The researches on biofilament manufacturing for FDM are of great interest, thus attracting a lot of attention. The low cost of such filaments could help minimize the use of petroleum-based plastics. In this frame, this work deals with a 3d printer PLA filament neat and additive by food flour waste percentage was created. The innovative filament was analyzed by calorimetric and thermogravimetric analysis, and its printability was evaluated by manufacturing specimens of suitable dimensions for flexural tests. The mechanical tests were carried out to assess the use of the innovative 3d printed biocomposite in place of traditional plastics in packaging or to make films for food use.

Introduction

Plastics derived from natural sources have attracted extraordinary attention as they do not contribute to the depletion of fossil resources, ensuring reduced carbon dioxide production during synthesis and transformation. Therefore, they generate a lower environmental impact than petroleum-derived ones. As a result, PLA is one of the most widely used bioplastics. Still, its intrinsic characteristics, such as fragility, often limit its use in particularly demanding applications unless strategies such as mixing with other polymers or including suitable additives are used. With these approaches, new environmentally sustainable materials are obtained, with better performance and which guarantee the reduction of environmental contamination associated with plastic [1-5].

The most common manufacturing technologies for thermoplastic-based green composites are extrusion, compression moulding and injection moulding [6]. Nevertheless, fused deposition modelling (FDM) has been explored as an innovative technology for processing thermoplastic green composite materials [7-11]. The many advantages of FDM, the reduction of production time and costs, and the possibility to create highly elaborated geometries are the most interesting aspects that make this manufacturing technique promising for making green composite components [12]. FDM has gained interest in several fields, such as aerospace, automotive, research, medical architecture, food, and design [13-15]. It is an additive manufacturing method which applies different thermoplastics materials for composites and biocomposites [16]. A thermoplastic filament is heated and crushed out on the printing plate by a nozzle. The product is created by depositing material layer by layer that solidifies after fusing to produce the components [17,18].

The market demand for 3D printing filament is estimated to reach high gain values by 2027 at an annual growth rate of about 20%. Plastic filaments have recently led the printing press industry due to the high demand for filaments [19]. However, not all FDM filaments are ecologically beneficial due to their release of toxic compounds during printing. In addition, they have a dangerous impact on the environment, as they are obtained from petroleum [20].

The growing use of industrial and domestic FDM 3D printing further increases plastic waste. Such technology could gradually displace and replace some cheap and non-biodegradable plastic waste in ambient conditions posing a threat to the environment. To address the above-described problems, the researches on biofilament manufacturing for FDM are of great interest thus attracting a lot of attention. The low cost of such filaments could help minimize the use of petroleum-based plastics. Although many works have been done on biomaterials, most concern biomedical applications [21-23].

In this frame, combining biodegradable polymers with agricultural waste, marine waste, or industrial residues from wood processing has gained particular interest in producing composite materials with high mechanical performance [1-5]. Often these fibres come from processing waste typical of the areas of research sites, such as flour deriving from hazelnut processing waste [24] or bamboo [25].

This work created a 3d printer PLA filament neat and additived by food flour waste percentage. The innovative filament was analyzed by calorimetric and thermogravimetric analysis, and its printability was evaluated by manufacturing specimens of suitable dimensions for flexural tests. The mechanical tests were carried out to assess the use of the innovative 3d printed biocomposite in place of traditional plastics in packaging for food use.

Materials

Investigated systems were based on a commercial polylactic acid (PLA) supplied by Biowares.r.l. with the trade name Luminy LX175 (density: 1.24 g/cm3, MFI@210°C/2.16 Kg: 6g/10 min, Tg: 60°C) and food flour waste (FW) supplied by a local pasta factory.

From PLA pellets (100% wt.), cleaned and filled filament (FW) was produced using a 3Devo Composer 450 Filament Maker (Utrecht, The Netherlands) with a single screw extruder equipped with four heating zones, reaching a maximum T=450°C.

For the extrusion of the PLA_FW, the four heat zones reached a temperature between 70° and 190°, in about twenty-five minutes, with a first increasing sequence to favor the melting of the granules of raw material inserted into the feed hopper (Fig. 1), and then decreasing to favor the extraction of the extruded filament. Once the temperature T=190°C was reached, the extruded filament was wound onto a reel via the rotating shaft of the extruder itself. At the exit, the filament is further cooled by two fans, as the extruder expels it through a nozzle at a temperature of about 170°, corresponding to the last heat zone. The diameter of the extruded filament has been controlled by a sensor which guarantees maximum uniformity of the diameter. Finally, neat and filled PLA filaments with a 1.75 ± 0.2 mm diameter were produced.

Materials Research Proceedings 28 (2023) 1879-1886 https://doi.org/10.21741/9781644902479-203

Fig. 1. Granules of raw material neat and infilled by flour waste.

3D Printer Setup

The samples were manufactured using the Sharebot 42 3D printer, which uses FDM (Fused Deposition Modeling) as an additive manufacturing technique. The 3D printer is 450x420x470 mm in size and has a printing volume of 250x220x220 mm, while the Z resolution is 50 microns. CAD 3D of the samples were modelled with Solidworks software. Then, they were imported into the Simplify3D software. The heated printing bed, the printing bed autocalibration system, the easy detach system and the filament sensor are integrated into the 3D printer. 100% infill density, a line infill pattern and a -45°/+45° raster orientation were adopted. Layers height was fixed equal to 0.2 mm. Plate temperature equal to 90°C, a deposition speed equal to 70 mm/s and an extruder temperature equal to 215°C were selected for all samples.

Thermal Analysis

Extruded compounds were thermally analyzed using a TA Instruments DSC Q2000 differential scanning calorimeter (New Castle, DE, USA) by applying a typical three-stage procedure involving a first heating step from 30°C to 220°C, a cooling step from 220°C to 30°C and further heating from 30°C to 220°C. All the steps were carried out on 8-10 mg of material at a rate of 10°C/min. Processing of collected thermograms allowed the evaluation of some typical parameters, such as the temperature and the enthalpy of the main transitions evaluated as the peak temperature and the area underlying the respective calorimetric signal.

Thermogravimetric analyses were carried out by a Perkin Elmer Pyris Diamond analyzer (TGA) model. At this purpose, materials were heated starting from a temperature of 25°C up to a temperature of 800°C in a flow of nitrogen at a heating rate of 10°C/min.

All the investigated materials were compared with neat PLA processed under the same conditions.

Mechanical Tests

Bending measurements determined the mechanical performances of the explored materials. Specifically, bending tests were conducted on 12.7x3.2x4 mm3 specimens, according to ASTM D790 standard [23] using a Galdabini QUASAR 50 materials testing machine with a test speed equal to 3mm/min.

For each sample, five specimens were tested to verify the reproducibility of the data.

Results and Discussion

Calorimetric results.

Table 1 summarises the results obtained from the calorimetric analysis of the materials under study. The glass transition temperature (T_g) and the melting temperature (T_m) values, characteristic of the hosting matrix, are not substantially affected by waste flours. On the contrary, the inclusion of this filler significantly increases the melting and cold crystallization enthalpy values (H_m and H_{cc}, respectively), slightly anticipating the cold crystallization temperature (T_{cc}). In other words, it is evident that the filler alters the crystalline structure of the host matrix and probably favours its crystallization.

Table 1. DSC results.

Material	T_g[°C]	T_{cc}[°C]	ΔH_{cc}[J/g]	T_m [°C]	ΔH_m[J/g]
PLA	59.2	124.2	8.9	150.3	14.9
PLA+1%FW	59.6	116	13.9	149.9	21.9
PLA+3%FW	58.9	117.7	15.9	149.5	21.5
PLA+5%FW	59.4	118.4	13.9	149.6	19.6

TGA results.

The results obtained on all examined samples are collected in Table 2 regarding key parameters. In addition, the temperatures corresponding to a weight loss equal to 1% and 5% ($T_{1\%}$ and $T_{5\%}$, respectively), the temperature at which the massive degradation of the material (T_d) occurs and the residual mass percentage remaining at the end of the applied thermal scan are reported.

The inclusion of waste flours causes a progressive reduction in the material's thermal stability. However, this effect, usually catalyzed in the presence of organic fillers, appears to be not marked up to a composition of 3% by weight.

In the presence of 5 wt% of FW, on the other hand, perhaps also due to the higher moisture content brought internally to the composite by the organic filler included, the first parameter $T_{1\%}$ is strongly anticipated.

Concerning the amount of the residue, this parameter, resulting to be not zero even for the reference matrix, increases with the filler content, assuming values not easily comparable with the nominal content of waste flours included.

Table 2. TGA results.

Material	$T_{1\%}$ [°C]	$T_{5\%}$ [°C]	T_d[°C]	Residue [%]
ExtrudedPLA	290	307	351	0.5
PLA+1%FW	262	285	320	1.1
PLA+3%FW	261	292	324	1.8
PLA+5%FW	160	286	322	3.1

Mechanical results.

Flexural tests results have been reported in Fig. 2 and Table 3 where the flexural strength, σ_f, and the correspondent maximum deflection, d_{max}, are reported for each material tested.

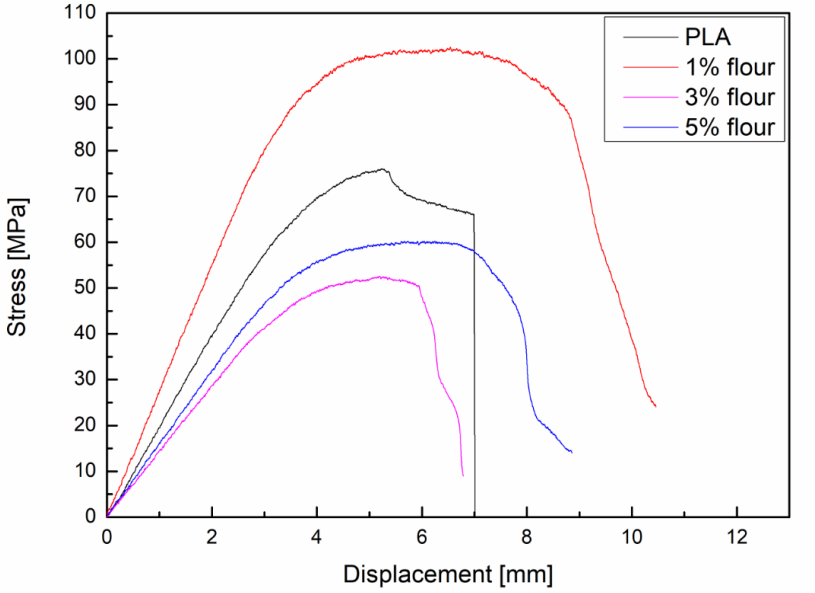

Fig. 2. Stress displacement curves for all materials tested.

As visible in Fig. 2, the printed samples with a percentage of flour waste of 1%wt show a maximum load higher respect to neat PLA, also offering the ability to hold the load over a longer displacement range. On the other hand, increasing the FW content determines increasing material embrittlement, as confirmed by the visual inspections of the bent specimens (see Fig. 3). Clearly, samples of extruded PLA or containing 1% wt of FW show a crack at the load's application point, while ones filled with 3% and 5% by weight of FW yield at the load application point undergo a brittle break.

Table 3. Flexural tests results.

Material	**$б_f$ [MPa]**	**d_{max} [mm]**
ExtrudedPLA	75.91± 2.5	5.20± 0.2
PLA+1%FW	100.21± 3.0	6.66± 0.5
PLA+3%FW	50.99± 2.6	5.30± 0.3
PLA+5%FW	58.61± 3.2	6.00± 0.6

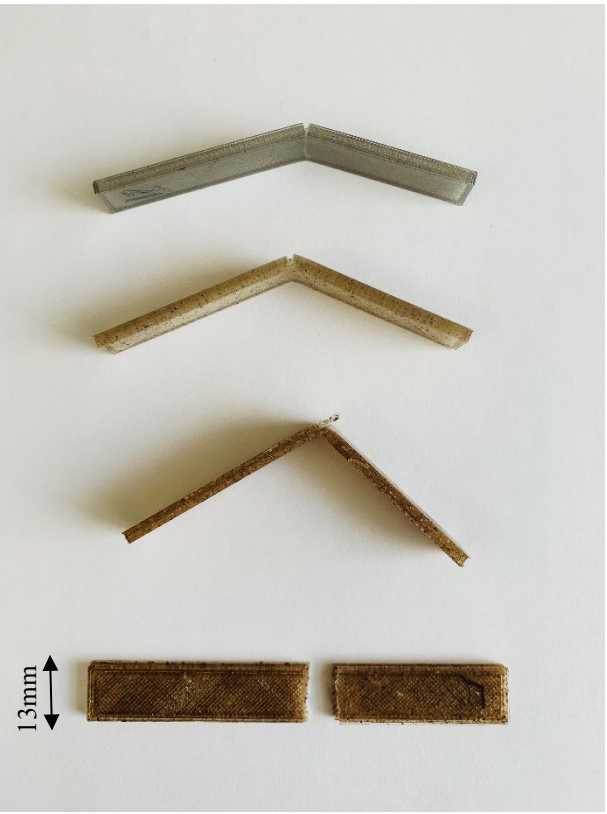

Fig. 3. Bending specimens after test.

These considerations are further highlighted by bending features values at break obtained for all the materials studied on at least 5 specimens tested for each sample (see Table 3).

Summary

The work's aim is to propose innovative biodegradable filament made of PLA and different flour waste percentages to explore the potential of 3d printed composites for sustainable industrial applications. The attention was focused on food flour waste in huge quantities on the national territory, especially in Southern Italy, where there is a large consumption of products such as pasta and bread.

The filament produced appears constant in diameter, equal to 1.75mm. Thermal and mechanical analysis of samples based on poly (lactic) acid-containing food flour waste have indicated an improvement in the mechanical parameters in bending behaviour compared to those characteristics of the polymeric reference matrix only for FW=1%. Also, material toughness decreases with the flour waste content over FW=1%. This behaviour is typical for micro composites, including filler having a poor chemical affinity with the surrounding matrix. It is supported by the morphological observations performed on fractured cryogenic sections of the samples.

Keywords: Vacuum Forming Process, Large Rapid Deformation, Nonlinear Behavior, DIC

Abstract. During the forming of a product with the thermo-vacuum forming process, a heated thermoplastic sheet is subjected to a complex and dynamic multi-axial deformation mode. In order to measure the relevant mechanical response of the material during processing, an experimental method that applies the relevant modes of deformation during forming is required. The bubble inflation technique combined with digital image correlation (DIC) allows having a complete data set regarding displacement, principal strains as well as local thickness reduction for material characterization. Bubble formation as a function of temperature would be investigated to determine the nonlinear terms of a material constitutive model for numerical simulation.

Introduction

Thermoforming is a material processing technology in which a thermoplastic sheet is radiatively heated above its glass transition point. The heated sheet begins to sag under its weight when it is in its softening range. In order to compensate for sag deformation and also make a uniform biaxial pre-stretching before forming into the desired mold shape, positive air pressure is exerted. At the appropriate temperature, the sheet is stretched to get the shape of a mold using both mechanical loading and vacuum. The thickness of the thermoformed product is determined as a critical parameter for product quality definition. In order to predict the thickness distribution of the thermoformed product, it is essential to characterize the strain and temperature dependency of material under relevant modes of deformation when it is subjected to large rapid deformation. Currently, a proper prediction of the thickness is still a challenge, due to a lack of proper understanding of the material behavior and the need for a specific experimental test that applies large and rapid biaxial or multi-axial deformation mode. Experimental work shows that a uniaxial tensile test is not sufficient to characterize the material behavior while it is subjected to the mainly multi-axial direction [1,2] in the vacuum forming process. Therefore, it is essential to examine the extension behavior of the material in biaxial directions with a suitable experimental method. There are different classical experimental methods to determine the biaxial extension behavior of the material. A basic rheometer test is a squeeze-flow technique where the specimen is compressed between two discs with a lubricated surface [3]. This kind of rheometer is well-suited for liquid-like high viscous materials while the forming range of thermoplastic material in vacuum forming is far away from the melting point and it is close to a solid-like state. Moreover, it does not cover large deformations. The biaxial in-plane technique is another well-known displacement-controlled method to characterize the behavior of the material. But gripping the material at an elevated temperature, sag deformation during heating, and the complexity of the clamping introduce uncertainties to this test setup. The plug assist technique is the other common method that is used frequently to capture relevant large deformation at a high strain rate corresponding to the vacuum

forming process. But this method has also a big drawback regarding the effect of friction and heat transfer through contact between plug and specimen. It could be concluded that a large biaxial extension can be achieved under pressurized air within another classical method named the bubble inflation test. This method seems to have the best fit to track the appropriate strain rates and large biaxial elongation deformations. This technique was initially applied by a British scientist, Treloar in 1944 [4]. A very simple conical glass tube was used in his test setup to purge by pressurized air to detect the natural rubber inflation with a thickness of 0.8 mm at ambient temperature. In 1951, Rivlin et al [5] utilized this method to calibrate directly the Neo-Hookean and Mooney-Rivlin rheological parameters of natural rubber by examining the equibiaxial state of the deformation at the pole of the inflated material using membrane theory. In 2001, Reuge et al [6] extracted the equibiaxial stress-strain data of elastomers at ambient temperature by measuring the elongation and curvature radius of the bubble of a specimen with 40 mm diameter at the pole using a 2D CCD video camera technique. In 2008, the bubble inflation test coupled with a 3D digital image correlation (DIC) device was adopted for the first time by Sasso [7] to capture the real-time strain field evolution of the rubbery-like material at ambient temperature. A similar effort was implemented to determine the stress field by computing the curvature tensor during inflating of the material at each surface point by Machado [8]. Cakmak et al. in 2013 [9] performed a biaxial bubble inflation test using a self-constructed test rig with a diameter of 120 mm over two different rubbery-like materials at -20°C, 20°C, and 60°C under low strain rate so that the stretch ratio near to 2 was reported at around 20 seconds. The main goal was to determine a master curve applicable to small and large deformations. To the best of the author's knowledge, the only research aiming to meet the extension modes relevant to vacuum forming process was performed by Turner et al. in 2019 [10] to investigate the biaxial response of 2 mm thickness PEEK in the temperature range between 130 to 160°C at the pole using a small size of bulge diameter 5 cm. Discrepancy reported on principal strain directions at the pole using DIC measurement was attributed to the extrusion process of the material. The tests at different temperatures and very high strain rates (less than 1 second) highlighted the nonlinear viscoelastic behavior of the material. However, the results were limited to the pole of the specimen and the shape of the bubble was not discussed.

As outlined previously, the bubble inflation technique combined with the optic method provides valuable real-time datasets including displacement, strains at different locations as a function of time as well as the local thickness reduction to fully understand the material behavior during the vacuum forming process. The objective of this work is to characterize the biaxial behavior of the Acrylonitrile Butadiene Styrene (ABS) material in the range of thermo-vacuum forming process. ABS is well suited for vacuum forming process fabrication. Formability at relatively low temperature, impact resistance, strength, and stiffness of this material makes it to be a good choice for economical engineering applications, especially for prototyping. In this work, ABS Epsotech single layer (AB AN2 V0, Tg=105°C) was used [11]. Forming temperature range of this material is 140°C up to 180°C. Although the aforementioned literature has provided a comprehensive understanding of the fundamental biaxial deformation behavior of mostly elastomers and PEEK materials, to the best of the author's knowledge, no studies exist concerning the extension behavior of ABS in more than one axis at forming temperatures. In the present work, a specific instrumented bubble inflation test setup with a 300 mm inner diameter was developed. The inner effective diameter is large enough to let the specimen expand avoiding any border effect. Moreover, It helps to investigate the shape of the bubble formation when it is subjected to large deformation at elevated temperatures which is helpful to calibrate the non-linear terms of the material constitutive model as a subsequent step of this work. Two different temperatures in the forming range (140°C and 150°C) were selected to examine the temperature-strain dependency of the material.

Instrumented Bubble Inflation Experimental Test Setup

A schematic view of the custom-made bubble inflation test rig is presented in Fig. 1. A circular ABS disc material with a diameter of 340 mm and thickness of 3 mm is mounted between two metal disks flanges, slightly clamped around the circumference providing an effective diameter of 300 mm of the material to inflate. Thinning of the material underneath the flange due to excessive clamping pre-load must be avoided since the thermoplastic material softens at elevated temperatures.

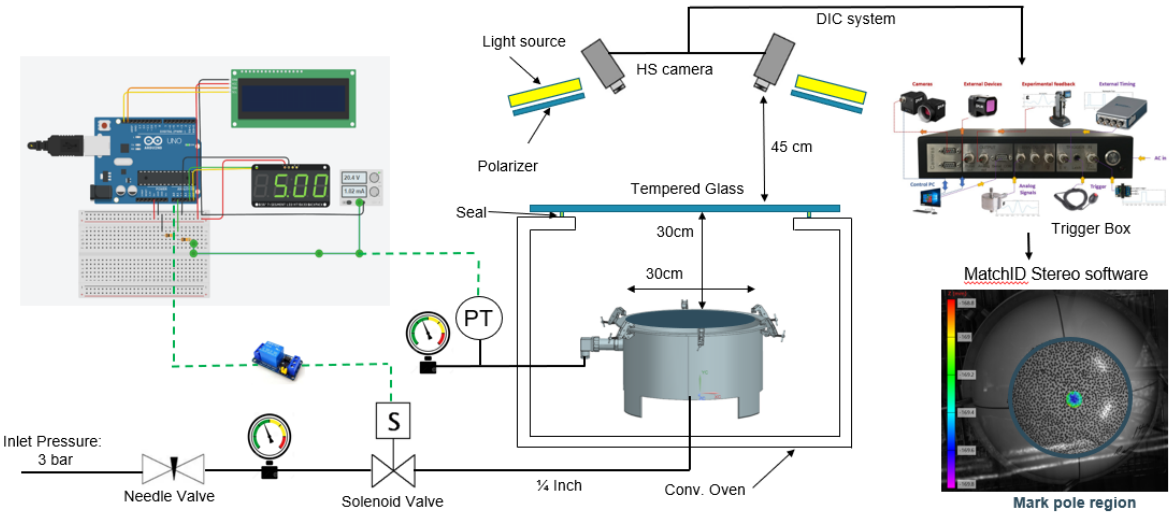

Fig. 1. Schematic annotated diagram of custom-made bubble inflation test rig.

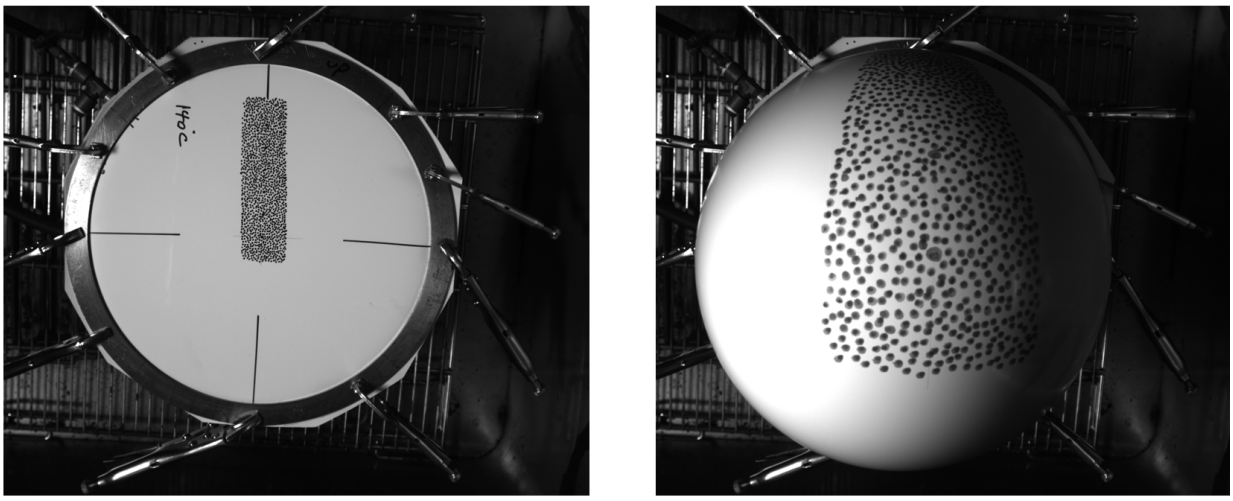

(a) (b)

Fig. 2. 3 mm ABS Epsotech disk with a diameter of 300 mm speckled by permanent marker mounted between flanges using 10 adjustable clamps inside the convection oven, a) reference state, b) deformed state after 3 seconds of applying pressurized air.

This can be troublesome, particularly when conducting high strain rate tests at higher temperatures due to the excessive formability of the material. To avoid this, it needs to balance the clamp pre-load force in such way to avoid the tearing failure of the specimen during inflation. Moreover, the material shows sufficient friction with the steel flanges at elevated temperatures to avoid slippage. It is noted that the polymeric material here works itself like a seal at high temperatures, the application of an additional sealant O-ring is thus unnecessary. A temperature-

control convection oven is used to heat the material to reach the desired temperature. The upstream pressure behind the solenoid valve was fixed at 0.3 MPa for all the tests. This pressure allows a large rapid deformation in less than 3 seconds. It is possible to increase the upstream pressure to 0.7 MPa to meet a higher value of strain rate in case of need. A voltage-type pressure transducer in the range of 0 to 25 kPa (0.5 to 4.5 V RSPRO) with an accuracy of ± 0.25 % is applied to measure the air pressure inside the cavity during inflation. It sends the analog voltage signal to the microcontroller to regulate the solenoid valve condition on 20 kPa as a default triggering set point. Pressure data is then synchronized to the actual DIC data for each image frame for stress calculation during time evolution. The full field surface deformation of the material during inflation is optically measured using two high-contrast 5 Megapixels cameras (Fujinon HF-SA) supports with 3.45µm sensor size with 12.5 mm focal length lenses under MatchID system platform [12]. The cameras are mounted at a 75 cm distance from the disc specimen ensuring that the whole region is under the Field of View (FOV). There is a tempered ultra-clear glass with a thickness of 5 mm in between. The distance between the glass and the specimen is 310 cm. A dotted random, non-repetitive, with high contrast speckle pattern with an average size of 3.7 pixels is made on the Region Of Interest (ROI) with dimensions of 40 x 140 mm using a permanent marker in each test (Fig. 2a). The minimum speckle size adapted by MatchID system is 3 x 3 pixels per speckle [12]. A surface of a combination of 3 to 5 pixels that represents a unique signature so-called subset, is utilized to correlate between the reference state and deformed state per each updated reference. Digital pair images are taken with 20 frames per second during all the following tests. The correlation settings adopted in MatchID stereo software can be found in Table 1. Moreover, in order to enhance the quality of the record images and make uniform light conditioning on the region of interest, a light source was employed. However this light conditioning is valid for the reference state, it makes a shiny reflection on a curved surface during the inflation of the material which moves from the corner to the center of the specimen. This issue is particularly annoying for DIC correlation and post-processing. To avoid this, cross-polarized filtration techniques were implemented by applying linear polarizers in front of camera lenses and light sources.

Table 1. Correlation setting using MatchID stereo software.

Parameters	Method
Correlation algorithm	Zero-Normalized sum of squared differences
Interpolation	Local Bicubic Spline Interpolation
Stereo transformation	Affine
Correlation progress	Spatial + update reference
Subset weight	Uniform
Subset size	45x45
Step size	3
Strain window [pixels]	15
Strain Tensor	Green Lagrange

Results and Discussion

Fig. 2a shows the ABS disc at the reference state which is subsequently inflated beyond the hemispherical stage shown in Fig. 2b at 140°C. It is done under instantaneous purging of 0.3 MPa pressurized air into the cavity by the quick opening action of the solenoid valve. The material was heated inside the oven for 90 minutes to make sure about temperature uniformity distribution across the specimen and through the thickness. The material starts to sag under its weight when it

gets the formability temperature range. The out-of-plane sagging displacement of the material measured using the DIC system is 2.8 mm and 14.93 mm for 140°C and 150°C, respectively at the pole of the material. Then, the 3D displacement of the specimen was incrementally correlated for 3 seconds of evolution time of inflation for all the following tests. Fig. 3 shows a typical contour plot of the out-of-plane correlation images of ABS material at 140°C. Fig. 4a shows the variation of the pressure inside the cavity during the inflation of the material at two different temperatures. The peak pressure value for 140°C and 150°C are 12.68 kPa and 9.66 kPa which occurs after 1.36 and 1.28 seconds of the test, respectively. After that, the pressure value decreases due to the continuous thickness reduction of the material while inflation is still ongoing even at a higher rate. Fig. 4b shows the out-of-plane pole deflection at these two selected temperatures. It is 238 mm and 273 mm at 140°C and 150°C, respectively. It is expected that the bubble deformation is to be truly biaxial only at the pole region [6]. In order to check the equibiaxiality behavior of the material at the pole, the correlation was first performed at the pole region to extract the strain variation of the material. Here, strain is calculated by applying a polynomial fit on the displacement data using MatchID post-processing stereo software. The Green-Lagrange strain was selected due to the large strain field for strain definition. The principal green strain in both directions at the pole at 140°C and 150°C are shown in Fig. 5a. Discrepancy between strains in the principal directions at 140°C is more pronounced which could be attributed to anisotropy generated during extrusion process manufacturing. By enhancing the temperature to 150°C, this effect is less pronounced and the material tends to behave like a truly biaxial extension. For a strain value less than 1, the material extends in the same manner at different temperatures. Strain dependency of the material begins particularly at strain higher than 1 so that the maximum principal strain reaches 11 at 150°C while it is 6 at 140°C. The strain gradient in Fig. 5b reveals how the rate of elongation begins to grow up from 1.5 seconds of the test to be doubled at the same time for higher temperatures.

Upon knowledge of the pole extension behaviour of the material at different temperatures, it is of particular important to detect the shape of the bubble formation during inflation by knowing the extension behavior of the material at different locations. It enhances the accuracy of the curve-fitting process afterward to find the non-linear terms of the mathematical models. The ultimate goal of this work is to calibrate the potential viscoelastic constitutive model using an inverse approach based on Finite Element Model Updating (FEMU).

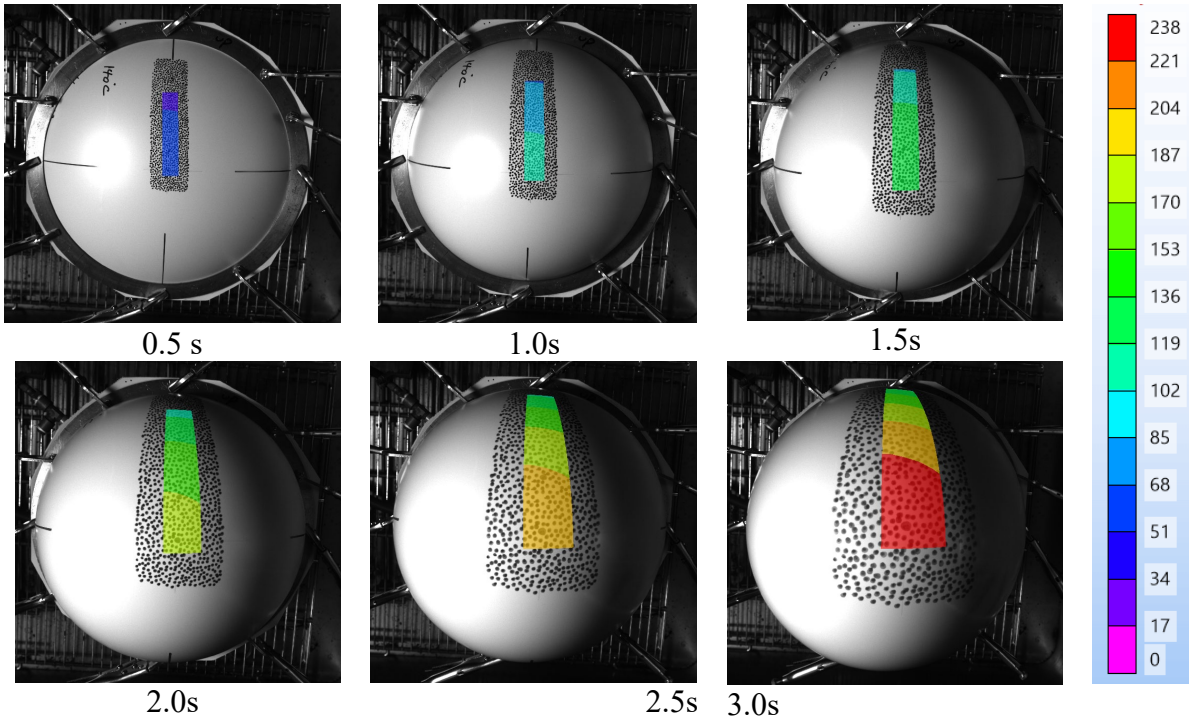

Fig. 3. Displacement magnitude [mm] of DIC inflation images sequence at 140°C during the time evolution.

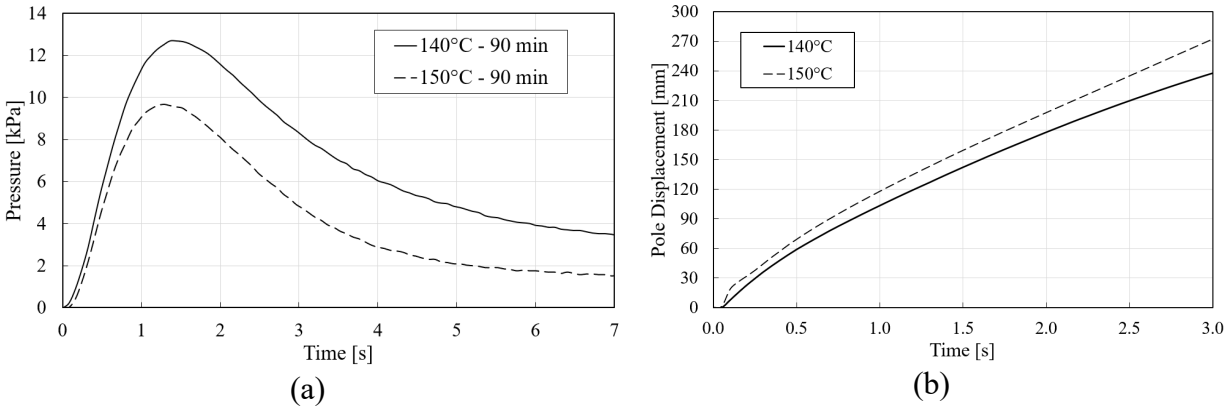

Fig. 4. (a) Pressure profile during inflation of the ABS material at 140°C and 150°C, (b) pole displacement within 3 seconds recording with 20 frames/sec using DIC cameras.

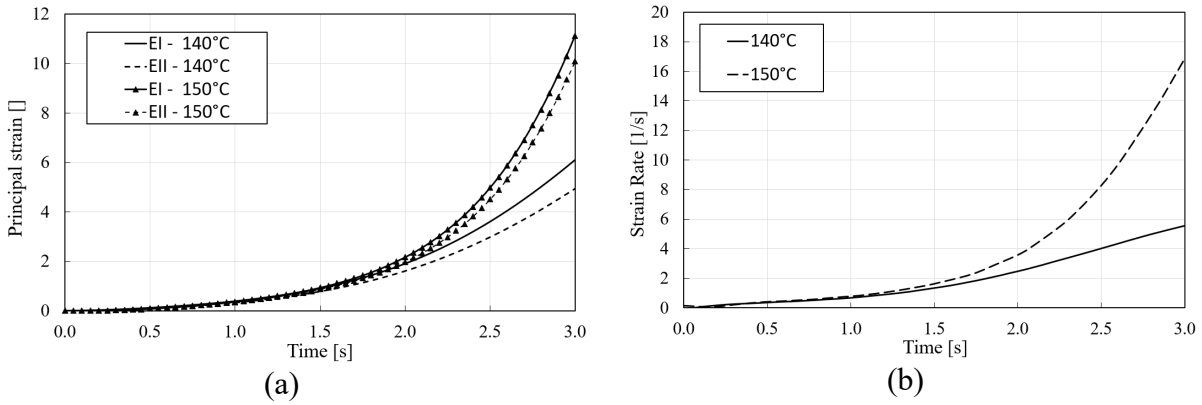

Fig. 5. Strain and strain rate variation at the pole against time during 3 seconds of inflation of 3 mm ABS at 140°C and 150°C, (a) maximum and minimum principal strains (b) strain rate.

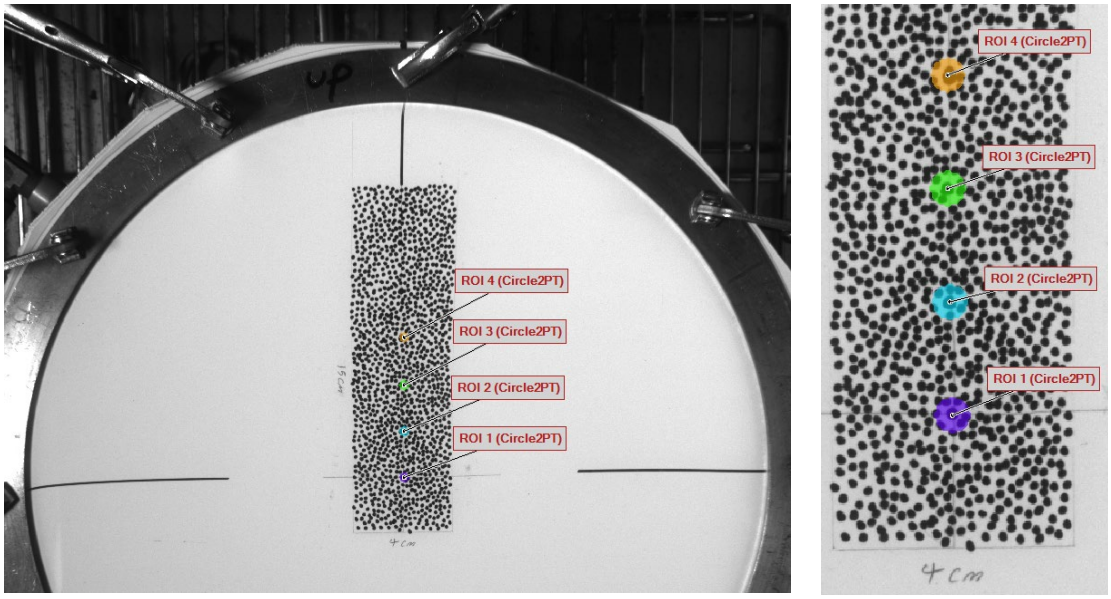
To meet this aim, 3 more points have been marked across the centrelines at a distance of 2 cm from each other as shown in Fig. 6(a). DIC data were averaged over a circle with a 5 mm diameter around each marked point shown in the zoomed view in Fig. 6(b). Fig. 7 shows the extension of the material on selected points at different temperatures. It is apparent that temperature increment induces the extension of the material, especially near the pole (ROI 2) which is in agreement with the aforementioned equal biaxial extension in two directions at the pole region versus the off-center location which is mostly unbalanced biaxial extension. It seems that by increasing temperature, a large amount of strain localizes disproportionately in a small region at the pole, resulting in prominent thickness reduction. This kind of extension distribution at higher temperatures tends to make a peaky bubble shape and eventually necks at the pole until failure. Fig. 8 indicates the rate of extension at 150°C versus 140 °C as evidence of the nonlinear behavior of the material. While the specimen at 150°C is softer, this also results in the material deforming at a higher rate than the material tested at 140°C; a maximum strain rate of 3.83 s-1 is observed at ROI 2 in comparison to rates of 10.8 s-1 seen in 150°C. The strain value at ROI 4 varies from 2 to 2.8 when the temperature shifts from 140°C to 150°C. The rate of extension at the locations far away from the pole is less influenced by temperature increment. In fact, thickness reduction at the pole region increases by a greater proportion than the material strain hardening at elevated temperatures.



(a) (b)

Fig. 6. (a) Extracting averaged DIC data over circle with 5 mm diameter around the points every 2 cm across the center line, (b) Zoomed view of 4 small circle Region of Interests (ROI).

To make it more tangible, the thickness reduction during the real-time inflation test is calculated considering the Green-Lagrange strain definition through the following formula [13]:

$$t_f = t_i \left(\frac{1}{\sqrt{(1+2\varepsilon_1)(1+2\varepsilon_2)}} \right) \quad (1)$$

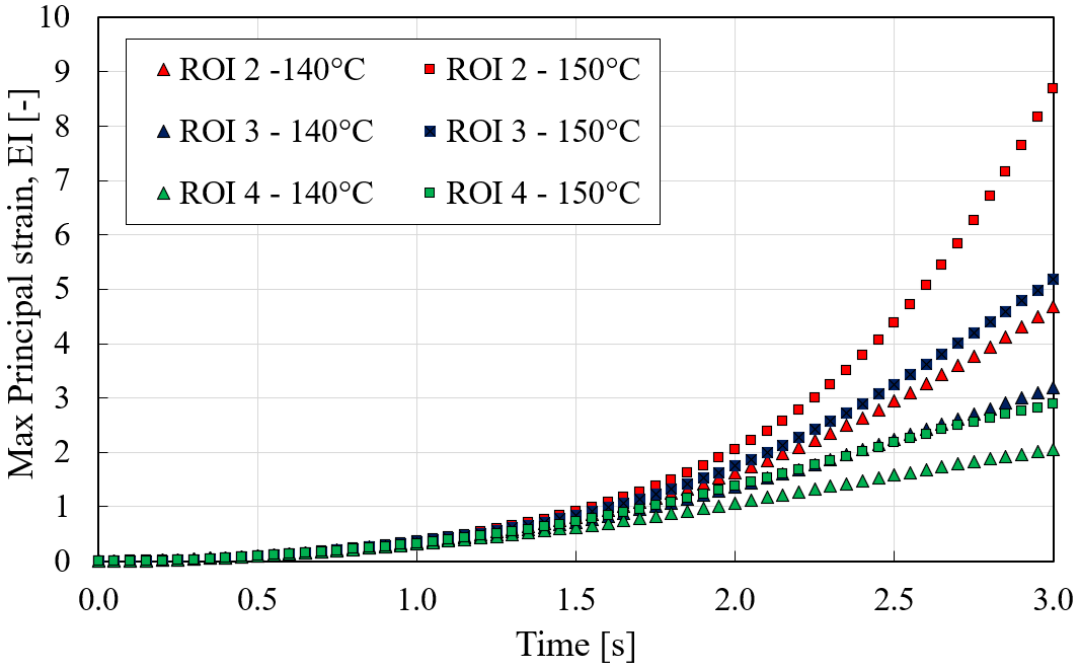


Fig. 7. Average strain of ABS material at three probes across the line with 2 cm distance to each other at 140°C and 150°C.

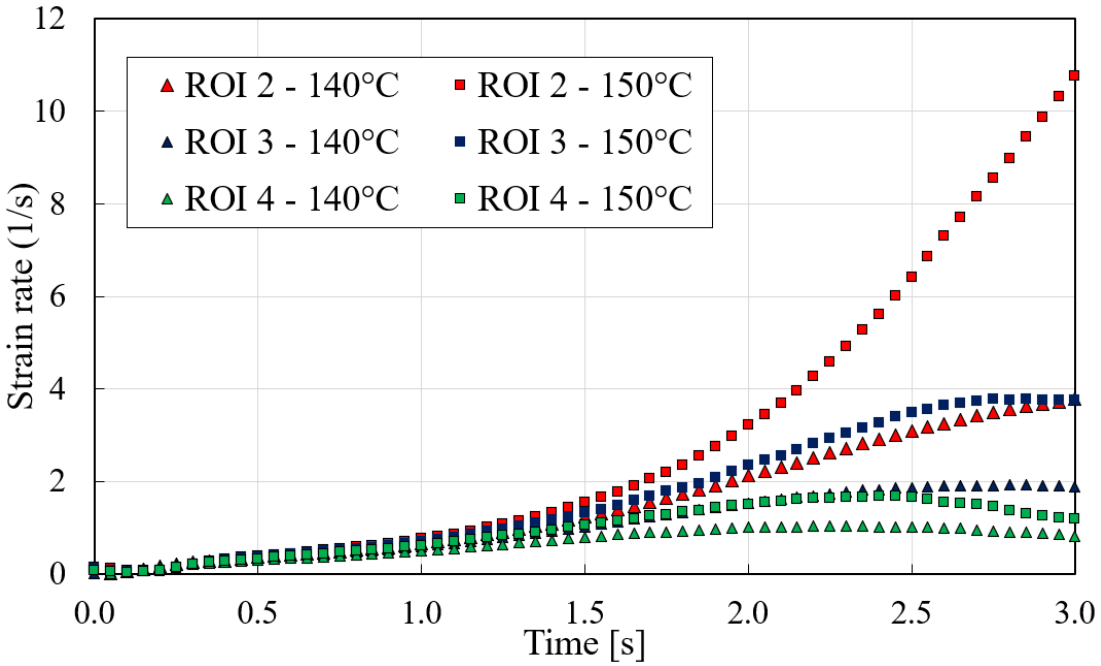

Fig. 8. Strain rate ABS material at three different locations across the line with 2 cm distance to each other at 140°C and 150°C.

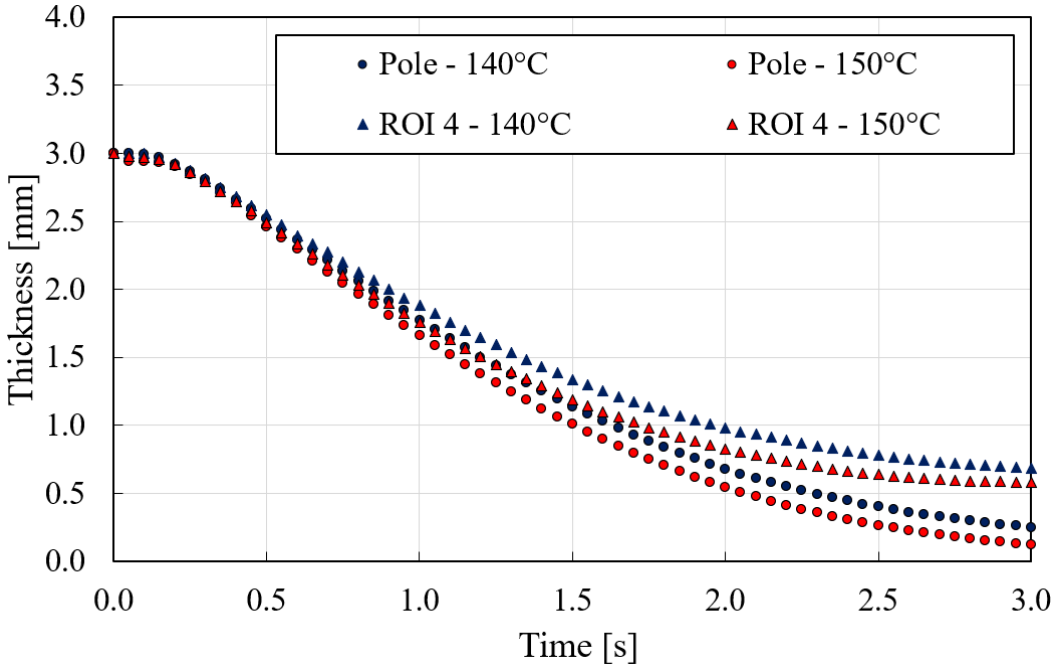

Fig. 9. Thickness variation against real-time at 140°C and 150°C.

Where t_f is the final wall thickness, t_i is the initial thickness, ε_1 and ε_2 are maximum and minimum principal strains, respectively. Equation 1 is only valid with the volume conservation of the sheet during inflation. Fig. 9 shows the effect of temperature increment on thickness variation at pole and ROI 4 (the last and furthest point from center) against time evolution. 52% thickness reduction (From 0.24 mm to 0.12 mm) at pole against 14% at the ROI 4 (From 0.67 mm to 0.57 mm) indicates the tendency of the material behavior to generate a narrow peaky bubble shape formation at elevated temperature. In other hands, strain hardening behavior at lower temperature leads to have more uniform stretching which is exhibited by delaying neck failure while at higher temperature strain hardening is drastically reduced which might be attributed to increasing mobility of the polymer matrix leading to have non-uniform deformation indicated by excessive thickness reduction at the pole.

Summary

In this study, the biaxial extension behaviour of a heated ABS sheet was examined using a custom-made bubble inflation test rig. DIC measurements were focused across the centreline to detect the bubble-shaped formation of the material as a function of temperature during inflation. It was exhibited that increasing the forming temperature results in an overall decreasing pressure level with larger material stretching at a higher strain rate. Biaxial strain discrepancy at the pole, attributed to anisotropy produced during the extrusion process of the sheet, is more prevalent at a lower forming temperature. Increasing the temperature from 140°C to 150°C reduces this effect resulting in a nearly equibiaxial extension in the two principal directions. Real-time strain values at different points across the centreline revealed a large amount of strain localized disproportionately in a small region at the pole by temperature increment, resulting in prominent thickness reduction. This kind of extension distribution tends to make a narrow peaky bubble shape at higher temperatures. The strong dependence of bubble shape as a function of temperature shown in this work is suggested as a convenient representative to calibrate the material non-linear model parameters aiming to elaborate the numerical simulation accuracy.

Keywords: Heat Transfer, Infrared Camera, Automated Fiber Placement

Abstract. This work takes place within the framework of the study and control of heat transfer taking place during the heating stage of the Laser Assisted Automated Fiber Placement (AFP) process. Understanding the interaction between the composite tape and the incoming laser radiation is a cornerstone for controlling the thermal history of the laminate. Laser incidence, fibre orientation and lay-up velocity have long been identified as key factors influencing the laser absorption by the composite and its increase in temperature. For the sake of simplicity, homogenous model is often used to describe phenomena inside the composite. However, the study of the radiative behaviour of laminates and tapes has shown that absorption occurs over a volume whose size depends on the carbon fibre architecture within the polymer matrix. Investigating heat transfer at micro scale is then crucial to fully understand the thermal phenomena occurring in the AFP process. In order to investigate heat transfer according to process parameters and especially to the orientation of the tape, a specific bench is developed in order to perform static heating a single composite with a laser diode. A full calibration of the bench was first performed including the response of the IR camera as well as the shape and power imposed by the laser source. Then, measurements for several orientations of the tape (0°,45° and 90°) were performed and thermal response measured and analysed.

Introduction

From their potential recyclability, bonding ability and tenacity in comparison with thermoset, the interest for thermoplastic composites steeply increased for years. Development of technical polymers with melting temperatures reaching 400°C made conceivable their use in structural parts, especially in aeronautics.

Among the manufacturing processes, Automated Fibre Placement (AFP) processes have been pointed out as suitable solutions to meet these expectations [1,2]. This process is based on the laying of narrow prepreg tapes with automated systems. The laser-assisted thermoplastic AFP process is promising to enable complex shapes manufacturing and in-situ consolidation. The process is simplified with three steps which are depicted in Fig. 1: heating, adhesion and consolidation phases. First, the laying tape and the substrate are heated such as both reach the matrix melting temperature. Heating phase must ensure that ply and substrate temperatures reach the matrix melting temperature without exceeding the matrix degradation temperature [3-5]. Then, the compaction roller pressurizes the ply (laying tape) and the substrate to increase intimate contact. Pressure and melting of the matrix enable bonding of ply and substrate with the inter-diffusion of polymer chains through the interface, called reptation [6]. Adhesion phase tries to maximize the degree of intimate contact [7,8] between ply and substrate based on pressure of the roller. Finally, the consolidation during cooling phase is an essential step to improve the

mechanical resistance through matrix crystallization. These statements make the prediction and modeling of heat transfers necessary steps to master the process under varying configurations: laying speed, materials properties, shape geometry, etc…

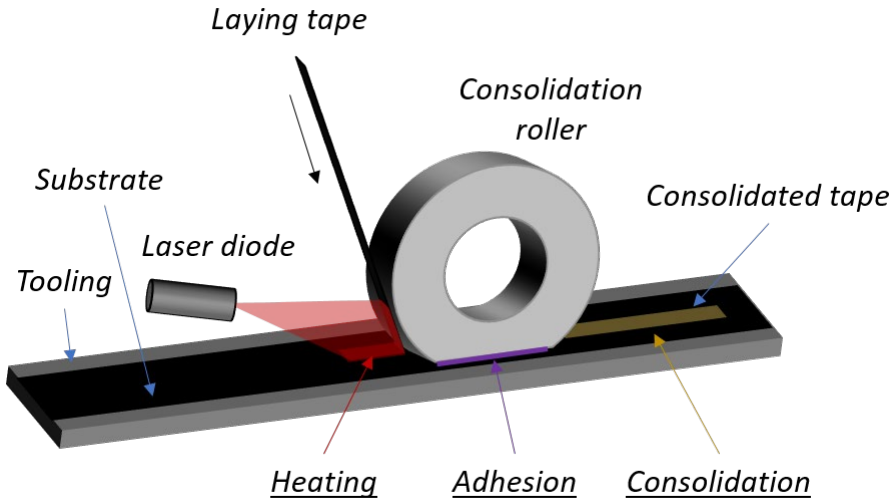

Fig. 1. Laser-assisted AFP process: heating, adhesion and consolidation.

In this article, we propose the development of an original bench representative of an AFP process enabling the precise measurement of a composite tape surface temperature heated by laser. The bench is specifically designed to study the effect of laser incidence angle and fibre orientation. Finally, a comparison with a novel numerical model is presented and discussed.

Material

The studied material is an AS7 carbon fibre [9] reinforced UD prepreg tape with a PEKK7002 [10] matrix. Fibres and matrix properties have been either extracted from datasheet, as density, considered constant in this study, or measured at laboratory with DSC for specific heat capacity and guarded hot plate for thermal conductivity.

A model of fibre conductivity with a weak transverse thermal conductivity (0.5 $W.m^{-1}.K^{-1}$) at core and a higher one on the edge (8.7 $W.m^{-1}.K^{-1}$) has been designed to account for the fibre thermal behavior. The skin thermal conductivity has been identified using the guarded hot plate measurement and a steady microstructure simulation.

Table 1. PEKK7002 and AS7 carbon fibre properties.

Experimental Setup

In order to remove the instrumentation constraints of the dynamic process, an experimental apparatus is developed to measure the evolution of physical values during laser-heating of a single tape, such as surface temperature and heat flux between tape and tooling.

The system is developed to facilitate unidimensional heat transfer through the tape thickness. It consists of two identical frames made of steel Z35CD17 (AFNOR), whose dimensions 100x20x6 mm, maintained in contact in the plane (O,y,z). Three thermocouples are placed along the central axis at respectively 250 µm, 1.25 mm and 3.25 mm from the surface and form a flux sensor which measures heat transfer between composite and tooling (Fig. 2). This sensor is also used to calibrate the laser heat flux. In both frames, respectively 11 and 10 type K 250 µm diameter thermocouples are placed at 250 µm from the surface to measure 2D heat transfer phenomena. The lower part of the system can be heated up to 400°C thanks to heating cartridges.

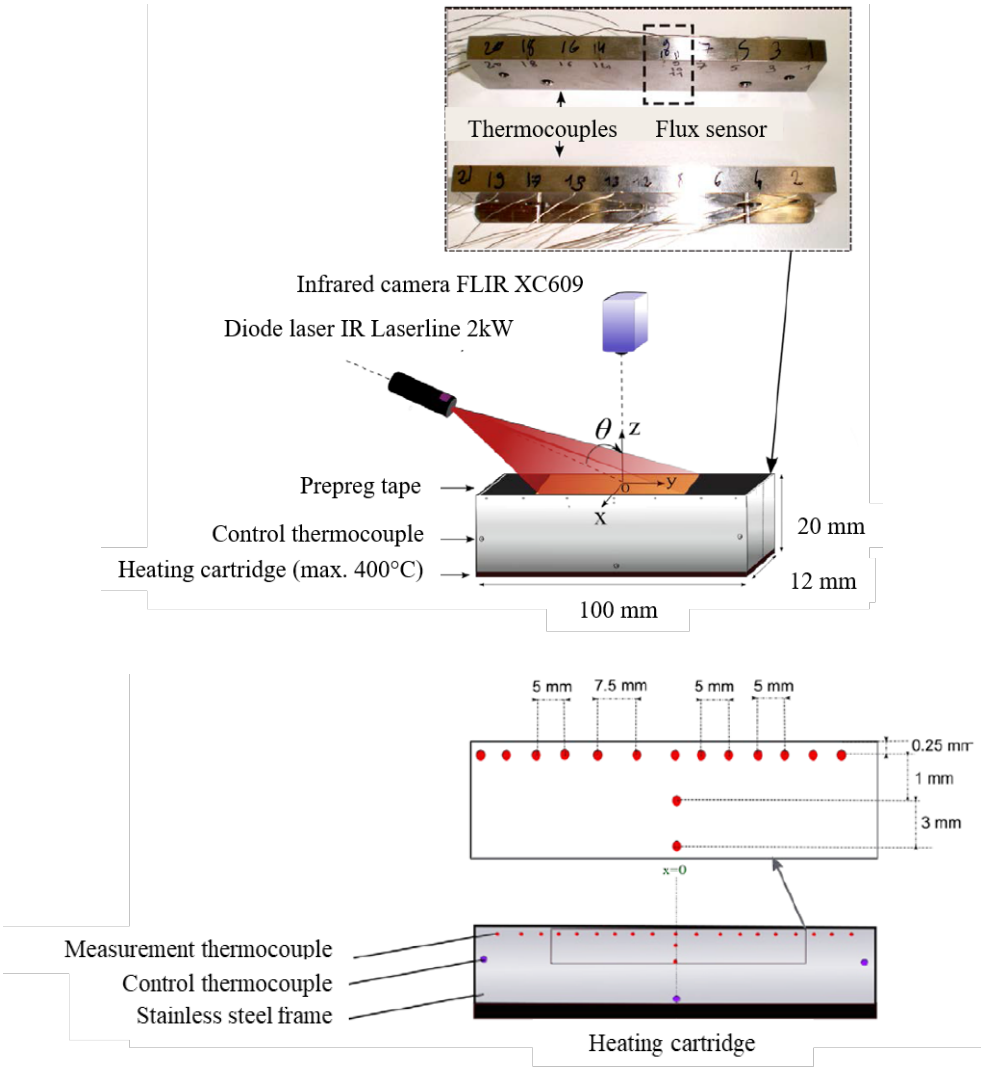

Fig. 2. Thermocouples positioning and flux sensor.

A FLIR XC609 infrared camera (Fig. 3) is maintained perpendicularly to the frame thanks to a metal support whose position is adjustable in the three axes (x,y,z) such as surface temperature is monitored in the plane (O,x,y). Heating of the tape is supplied with a laser diode LDM 2000-30 from Laserline with a maximal output power of 2000 W and of wavelength of 980 nm. The laser is mounted on a rotating arm which enables the adjustment of laser incidence angle from 0° to 70°

with respect to plane (O,x,y) and distance to tape from 150 to 200 mm. Due to bulk issues, the minimal incidence angle is 10° when camera and diode are both installed.

The tape is 12 mm wide, 60 mm long, 0.2mm thick and maintained at the tooling surface thanks to 50 N magnets. For safety issues, the whole system is installed within an opaque box.

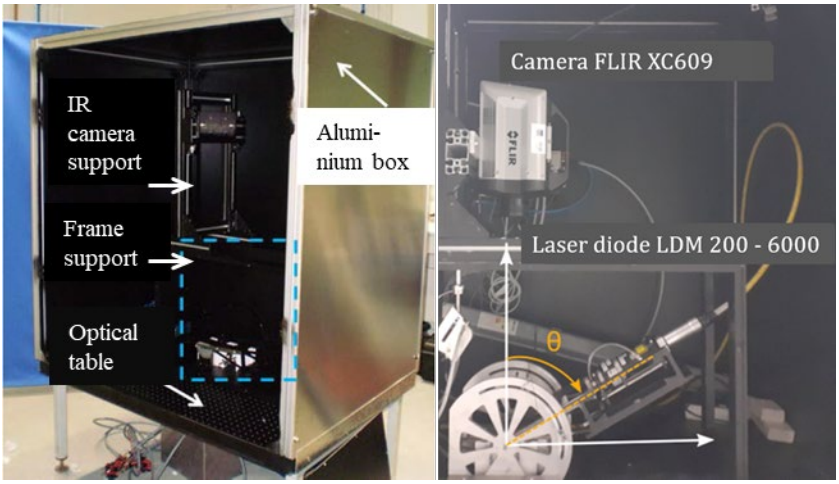

Fig. 3. Experimental apparatus.

Caracterisation of Laser Source in Normal Incidence

The laser spot is a 12x12 mm² square on which intensity is distributed in a top hat shape with a homogeneous and maximal value over a 6x6 mm² area and decreases exponentially on the edges. The nominal intensity, meaning the intensity in the central area is calibrated with the help of the heat flux sensor implemented in the metallic support. The evolution with time of an incoming heat flux irradiating the sensor surface is calculated with the Beck inverse method [11] supplied with the thermocouples responses. The usual algorithm was modified to retrieve the thermocouples response time.

During the campaign, the IR camera is removed so the laser diode can be positioned normally to surface (0°). A graphite coating of known emissivity is sprayed homogenously over the support surface. The thermal resistance of the layer is neglected as its thickness does not exceed a few dozen microns.

Calibration consisted in irradiating the surface during 100 ms at the minimum power of the laser diode. The distance with the surface was varied from 150 mm to 200 mm. Fig. 4 displays the evolution versus time of the heat flux density calculated using Beck algorithm. Overshoots can be observed at the beginning and end of irradiation. These are induced by the algorithm itself. Although its use benefits from making no assumption of the flux behaviour with time, the algorithm lacks accuracy for the identification of Heaviside functions with infinite first derivatives. The actual heat flux evolution with time is indicated with dotted lines on the graph.

The laser beam is slightly divergent and the heat flux density decreases with the distance from the surface. This evolution is linear with distance as displayed in Fig. 5.

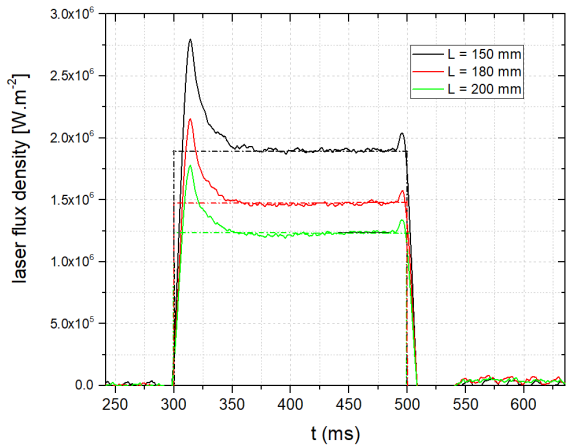

Fig. 4. Measurement of the heat flux density with time during a 100 ms pulse.

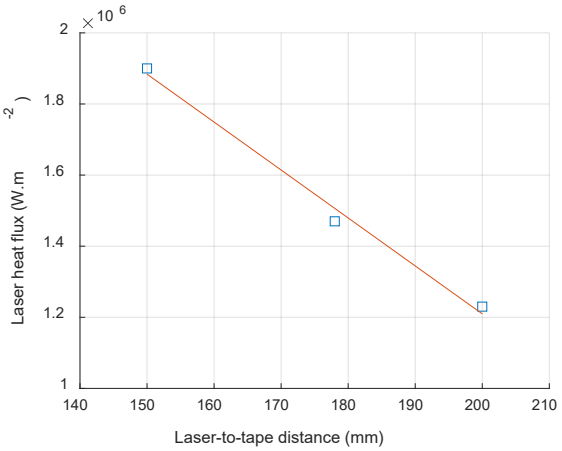

Fig. 5. Evolution of heat flux density with distance.

Tape Surface Temperature: Effect of Fibre Orientation and Incidence Angle

Tape surface temperature is measured regarding fibre orientation φ and laser incidence angle θ (Fig. 6). As temperature decreases with grazing incidences, the laser power density is adjusted in order to reach similar temperatures for every incidence angle and work in the same calibration range of the camera (Fig. 7).

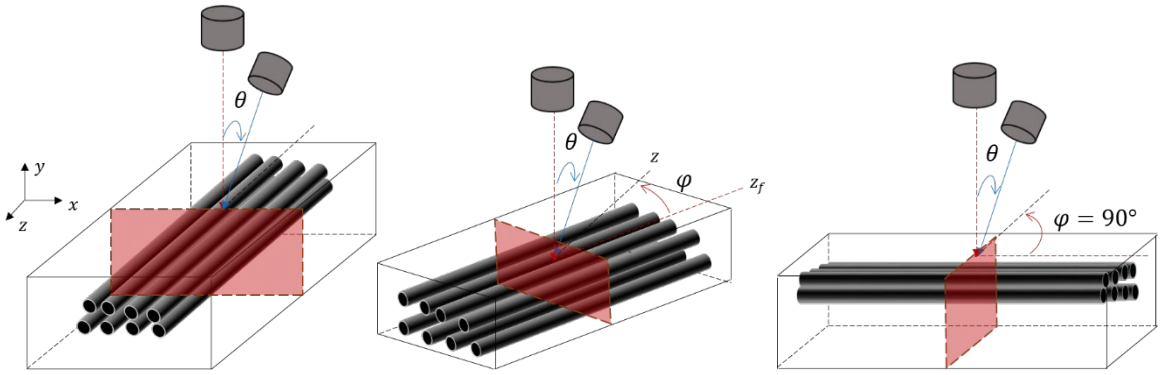

Fig. 6. Angles configuration: fibre orientation φ, incidence angle θ.

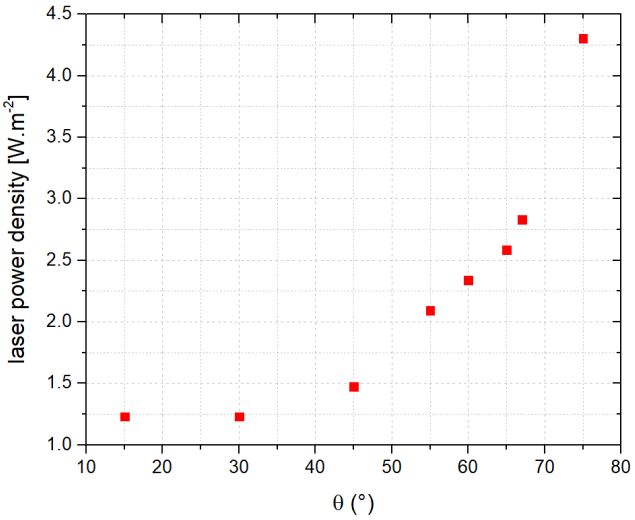

Fig. 7. Power density according to the incidence angle.

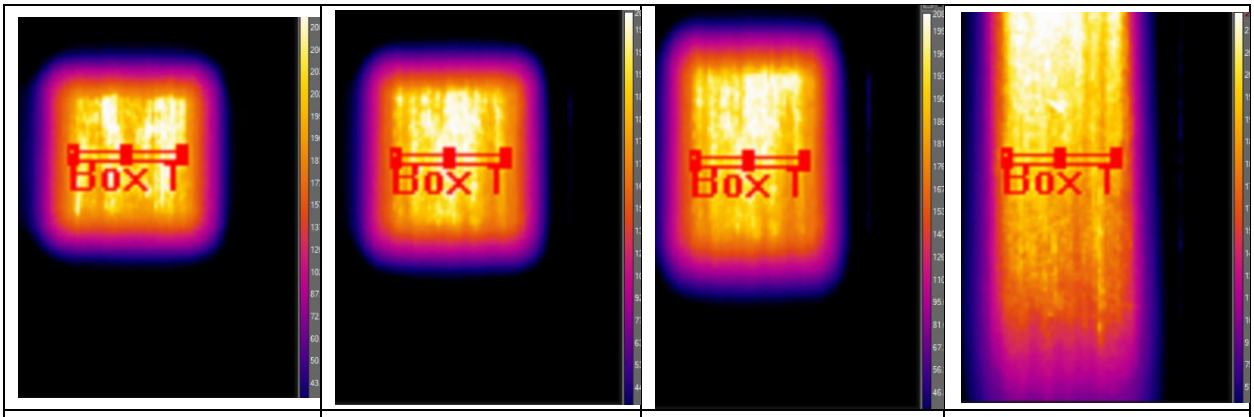
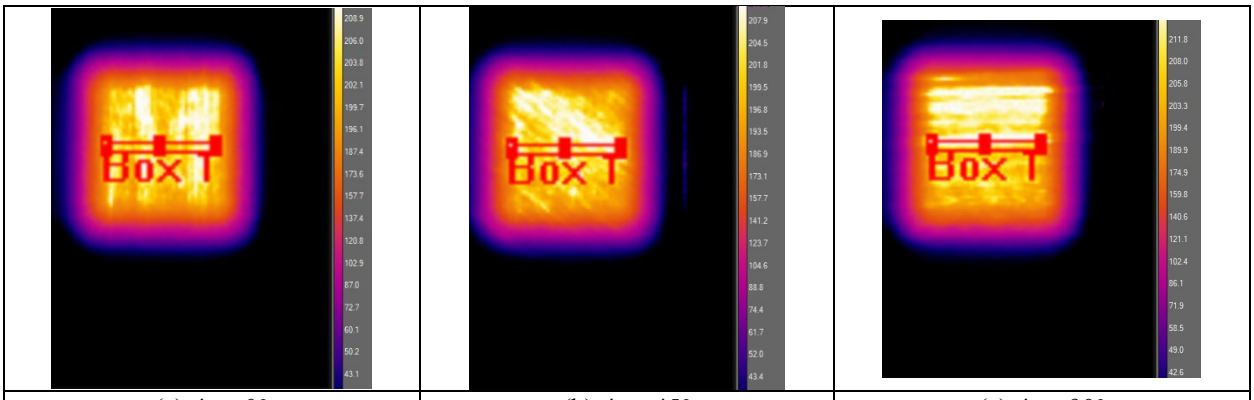


(a) θ = 15°	(b) θ = 30°	(c) θ = 45°	(d) θ = 75°

Fig. 8. Thermographs at φ = 0°.



(a) ϕ = 0°	(b) ϕ = 45°	(c) ϕ = 90°

Fig. 9. Thermographs at θ = 15°.

Fig. 8 displays the thermographs at end of heating t = 20 ms for trials on a tape positioned at φ = 0° and for increasing incidence angles θ. The expansion of the laser spot length with incidence is clearly noticeable. The temperature distribution over the irradiated surface also become less homogeneous as the incidence angle decreases. As a result, temperature is extracted and averaged over a slim area (represented by the red box) aligned with pivot point of the laser diode and where

the magnitude of the laser flux has been calibrated. Similarly, thermographs are presented for three fibre orientations: 0, 45 and 90° in near-normal incidence θ = 15 (Fig. 9). The temperature variability is noticeable and due to tape heterogeneity. The color contrast highlights the fibre orientation.

Series of 5 samples have been tested in the configurations φ = 0°, 45° and 90°, and θ = 15°, 45° and 60° on which the average temperature and standard deviation are determined. The measurement uncertainty u is estimated following:

$$u = \sqrt{u(T_{mean})^2 + u(\sigma_{mean})^2} \quad (1)$$

with:

$$u(T_{mean}) = \frac{1}{\sqrt{5}}\sqrt{\frac{1}{n}\sum_{i=1}^{n=5}(T_i - T_{mean})^2} \quad (2)$$

$$u(\sigma_{mean}) = \frac{1}{\sqrt{5}}\sqrt{\frac{1}{n}\sum_{i=1}^{n=5}(T_i - \sigma_{mean})^2} \quad (3)$$

The measurement uncertainty is caused by:

1. The resolution of the camera
2. The heterogeneity of the tape surface
3. The variability of the tape over the batch
4. The variability of the test and of the operator

Results are summarized in Fig. 10. Surface temperature increases during the 20 ms heating time to reach approximately 200°C for every incidence angle. The effect of fibre orientation on the surface temperature is shown negligible as temperature differences between various fibre orientations samples are inferior to the measurement uncertainty. These experimental temperatures are compared with a novel thermo-optical model at the microscale.

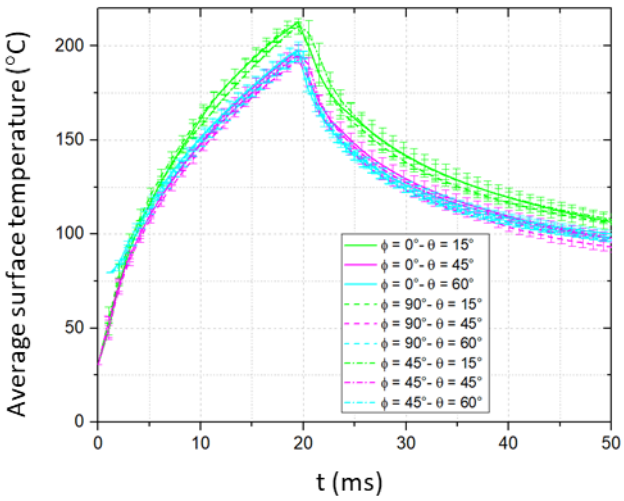


Fig. 10. Evolution of surface temperature as a function of fibre orientation (0, 45, 90°) and incidence angle (15, 45, 60°).

Numerical Model

A numerical thermo-optical model is designed at the micro-scale based on the tape microstructure. A cross-section micrograph (Fig. 11) of the experimental samples is performed and used to characterize the fibre distribution through the thickness. Image points out the heterogeneity of fibre distribution in the thickness with denser area close to the surfaces and a weaker fibre fraction at core.

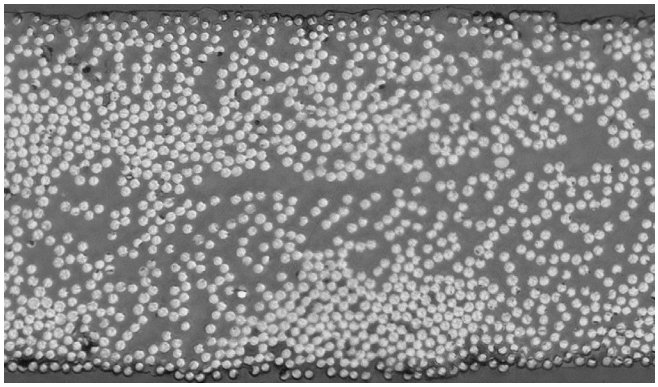

Fig. 11. Cross section micrograph of the tape.

An artificial microstructure is created based on the actual fibre distribution and used to perform a FEM simulation computed with Freefem++ [12].The matrix is considered fully transparent at the laser wavelength. [13]. Therefore, the laser beam is only absorbed by carbon fibres. A ray-tracing algorithm is developed to compute fibres areas heated by the laser beam (Fig.12) depending on fibre orientation and incidence angle. The laser beam is modelled by approximately 4000 scanning lines which are evenly spaced by a fraction of fibre element size. The intersection between the scanning lines and fibres is computed without considering refraction in the polymer matrix. Every heated carbon fibre element is tagged for the following thermal simulation in which a heat flux condition is applied based on the laser power density ϕ_{laser} and the carbon absorption coefficient α_{carbon}.

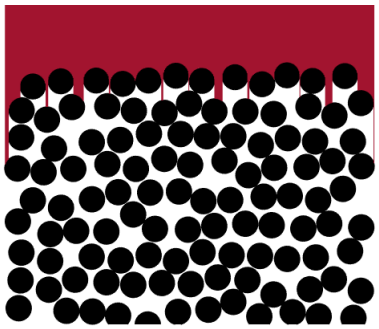

Fig. 12. Ray-tracing algorithm: detection of heated fibres by the laser beam.

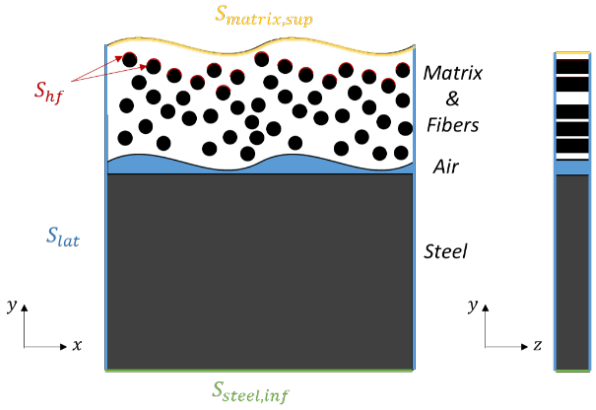

Fig. 13. Schematic of the problem: volume and boundary conditions.

The problem is modeled in Fig. 13. The heat equation is solved in the four physical volumes: fibres, matrix, steel and air.

$$\rho C_p \frac{\partial T}{\partial t} - div\left(\bar{\bar{k}} \cdot \vec{\nabla} T\right) = Q_v \quad (4)$$

with the following boundary conditions:

1. Adiabatic lateral surfaces S_{lat} (heat transfer is 1D): $\vec{\phi}.\vec{n} = 0$
2. Fixed temperature: $T = T_{amb} = 20°C$ on steel lower surface $S_{steel,inf}$
3. Dissipation by air convection on matrix upper surface $S_{matrix,sup}$: $\phi = h_{air}(T - T_{amb})$
4. Laser heat flux absorption on fibres heated elements S_{hf}: $\phi = \alpha_{carbon}\, \phi_{laser}\, \vec{q} \cdot \vec{n}$

where $h_{air} = 5$ W.m^{-2}.K^{-1} the air convection coefficient, $\alpha_{carbon} = 0.9$ the carbon absorption coefficient, $\vec{n}$ the normal vector to the element and $\vec{q}$ the resulting direction vector of laser heat flux, depending on fibre orientation and incidence angle.
The simulation is performed on 50 iterations with a 20 ms heating time which corresponds approximately to the exposure time in a manufacturing process context at a 500 mm.s^{-1} laying speed with a 12 mm laser beam width. It is also chosen to nullify the effect of back surface condition, meaning that diffusion time through the thickness is greater than 20 ms. The total time is set at 40 ms to study the cooling kinetic.

Experimental and Numerical Comparison

Average experimental and numerical surface temperatures are compared in Fig. 14 for near-normal $\theta = 15°$ and grazing $\theta = 60°$ incidences with respectively 1.31 and 2.49 MW.m^{-2} laser power density. Laser heat flux has been corrected to fit experimental and numerical temperatures.

Both incidences show an accurate approximation between experimental and numerical temperatures at the end of heating phase. The simulation confirms that fibre orientation has a negligible effect on surface temperature and the necessity to increase laser power to reach similar surface temperatures. Heating and cooling kinetics are also closed between experimental and numerical temperatures, meaning that heat transfers are rather well described by the model.

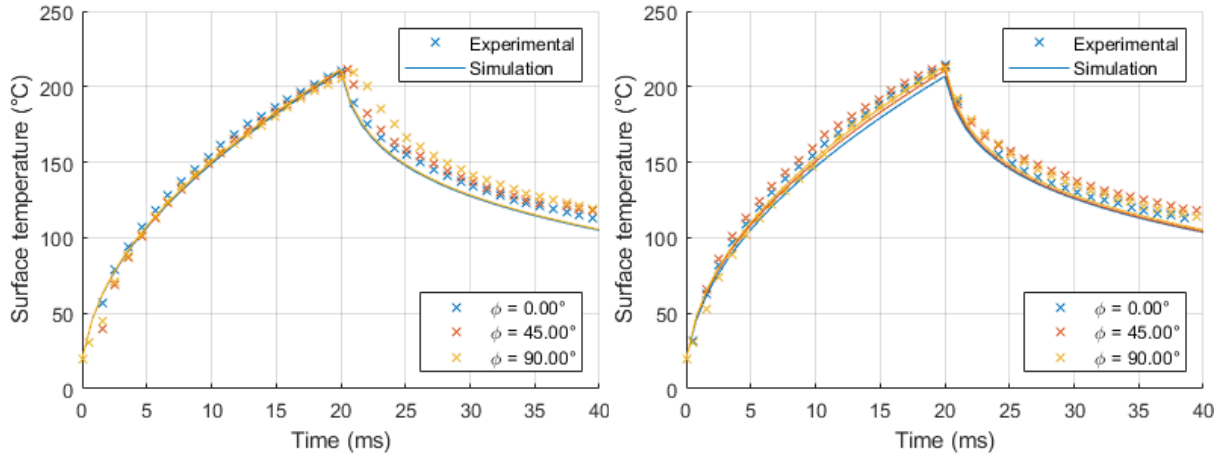

Fig. 14. Evolution of numerical and experimental surface temperature for (a) near-normal θ = 15° and (b) grazing θ = 60° incidences and three fibre orientations.

Summary
A specific experimental bench is designed to study heat transfer in the laser-heating of a single carbon fiber reinforced composite tape in a static configuration. The bench is instrumented with thermocouples and an infrared camera to measure laser heat flux and tape surface temperatures. A thermo-optical model is developed and approximates the evolution of surface temperatures. Both experimentation and simulation results highlighted the negligible effect of fibre orientation on surface temperatures. However, laser power has to be increased with grazing incidences to reach a similar surface temperature.

Keywords: Thermoforming, Friction Coefficient, Numerical Simulation, Thickness Distribution, T-SIM®, Polycarbonate

Abstract. In this work, friction coefficient between Polycarbonate and Aluminum was measured over the entire thermoforming temperature range by using a rotational rheometer with a specific geometry, following the B. Hegemann *et al.* [1] method. The effects of velocity, pressure and surface roughness were investigated. Then, numerical simulation were performed using a finite element code package for thermoforming (T-SIM®) with K-BKZ viscoelastic model. The objective of this work is to find which friction coefficient use in T-SIM simulation to be as close as possible to reality. For this, numerical simulation results for different friction coefficient were compared with experimental values to evaluate the predictive capacity. It was shown that friction coefficient is temperature dependent and rapidly increase above glass transition of polycarbonate. At room temperature, friction coefficient increases with an increase in roughness, but after glass transition, trend is reversed. Simulations with measured friction coefficients shows good agreement with experiment data.

Introduction

Thermoforming is a manufacturing process widely used in the industry for making 3D complex parts. An extruded polymer sheet is heated to be easily deformable and then vacuum formed on a cold mold. Despite the apparent simplicity of this process, it is actually a technical process, difficult to optimize, in which the material undergoes very large deformations in an anisotherm environment. Uneven thickness distribution is caused by localized variable deformations during vacuum forming. However, for manufacturers, a uniform thickness distribution and a high average thickness are very important parameters for the manufacture of high-quality parts. This thickness distribution is mainly affected by the viscoelastic behavior of the extruded polymer sheet [2,3,4] but previous work show that contact friction also has a huge impact on thickness distribution [2,5-8]. In the literature, the majority of authors study the effect of friction in the context of plug assist thermoforming. In this work, we will focus on conventional thermoforming, where the slip rate between the polymer and the mold is lower. Some studies claim that the friction coefficient does not depend on the sliding speed [1,5] but others show the opposite [9]. Several friction models exist but in this study we consider that the friction behavior between mold and polymer sheet can be simply represented using Coulomb friction law. This law defines friction coefficient as the ratio between the friction force and the normal force (Eq. 1):

$$\mu = \frac{F}{F_N} \tag{1}$$

Two friction coefficients can be defined : a static coefficient which corresponds to the minimum tangential force necessary to prime the slide and a dynamic coefficient which corresponds to the

tangential force necessary to maintain this slide. In this study, only the dynamic coefficient will be taken into account. The purpose of this work is to measure the impact of different parameters on the coefficient of friction between polycarbonate sheet and aluminum mold. The effects of velocity, pressure and surface roughness were investigated using a rotational rheometer with a specific geometry, following the method developed by B. Hegemann *et al* [1]. Measured friction values will be used in a numerical simulation of the thermoforming process and simulation results were compared with experimental data to evaluate the predictive capacity.

Materials and Methods

Polycarbonate is a technical polymer with excellent mechanical properties and good temperature resistance. It is easily thermoformable thanks to its good flow resistance and is used in many fields such as automotive, aeronautic or medical. For this study a commercial polycarbonate LEXAN 9030 from SABIC was used. The initial sheet thickness was 2,94 ± 0,05 mm. Temperature shrinkage is negligible (< 2%) in the extrusion or transverse direction. The glass transition temperature measured by DSC (rate: 10°C/mn) is around Tg = 149°C. Thermoforming molds and friction coefficient samples used for this study were made with Aluminum 5083 (AW-Al Mg4,5Mn0,7). Aluminum 5083 is a common aluminum-magnesium alloy with 4,5% magnesium.

Torsional Rheometer Test Method.

The friction coefficient measuring device used in this study is based on the B. Hegemann *et al.* [1] method. developed at the IPK-Stuttgart**.** An Anton Paar MCR302 rotational rheometer is used in parallel configuration. The upper moving plate is replaced by the mold material sample and the polymer is fixed on the bottom. The test arrangement is shown in Fig. 1a**.** After contact, the torque required to rotate both parts is measured and converted into a coefficient of friction. Applied normal force and rotation speed are easily adjustable over a wide range of values representative of the thermoforming process. The device is placed in a temperature-regulated chamber, suitable for making measurements from room temperature until forming temperature. Between each measurement, the upper plate is cleaned with acetone to remove any residual traces of polymer. In order to reproduce as much as possible a linear sliding during the test and minimize the velocity gradient, the contact surface is limited to one ring (Fig. 1b). Inner and outer radii are respectively 9 mm and 12.5 mm. As a result, the maximum speed rotation varies only about 15% around the mean value. The tested polymer sample is a 25 mm disc, glued on a disposable plate with a two-component epoxy adhesive resistant up to 180°C. Special attention is paid to the flatness of the experimental setup to ensure optimal contact.

Thus, assuming that the normal force is evenly distributed over the contact surface, and taking into account the geometry used, the average friction coefficient can be calculated from the following relation [Eq. 2] :

$$\mu = \frac{3}{2} \times \frac{\tau}{F_N} \times \frac{R_O^2 - R_i^2}{R_O^3 - R_i^3}. \quad (2)$$

where Γ is the measured torque, F_N the normal force and Ri and Ro are respectively the inner and outer radius of the ring.

Test settings.

With this method, friction coefficients were measured over a wide range of temperature, from room temperature to 180°C. First every 40°C up to 140°C, then, every 10°C from the glass transition temperature of polycarbonate samples (Tg = 149°C). Beyond 180°C, the epoxy adhesive fail and does not maintain the sample properly. This temperature range does not cover the entire forming range (up to 220°C for polycarbonate) but in reality, due to the low thermal effusivity of polycarbonate compared to aluminium, interface temperature is much lower and probably no more than 180°C. Some previous studies [1, 9] show that there is no significant influence of normal

force on friction coefficient. In order to verify this hypothesis, friction coefficients were measured at room temperature for several values of normal force (2, 5 and 10N). For higher temperatures, the normal force was limited to 2N because of MCR302 torque measurement limitation but also to limit compression deformations beyond glass transition temperature.

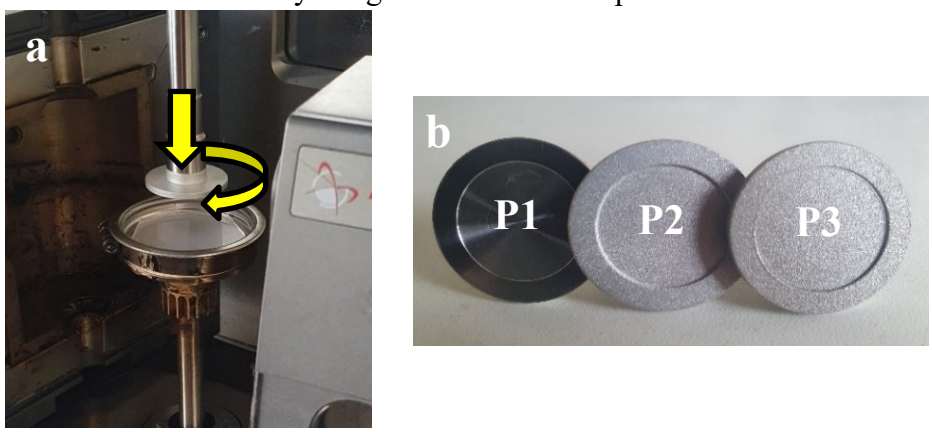

Fig. 1. (a) Modified rotational rheometer with aluminum upper plate and polymer sample on the lower plate. (b) P1, P2 and P3 aluminum plate with roughness of respectively Ra = 0,38 µm, Ra = 2,80 µm and Ra = 8,12 µm. Contact surface is limited to a crown of 9 mm inner radius and 12.5 mm outer radius.

In order to measure the impact of the sliding speed on the friction coefficient, different rotational speeds were investigated. In industry, the mold rising speed is typically within the range 25-100 mm/s. However, glide speed can be considerably less due to the frictional force and the sheet deformation resistance [5, 9]. Thus, for the sake of covering a representative sliding speeds range of the thermoforming process, friction coefficients were measured for three different rotational speeds of 4.4 rpm, 11.1 rpm and 22.2 rpm corresponding respectively to an average sliding speed of 5 mm/s, 12.5 mm/s and 25 mm/s. In addition, all these measurements were carried out for three different aluminium upper plates surface roughness, corresponding to different surface states of industrial moulds (Fig. 1b). The plate 1 (P1) corresponds to a smooth mold with Ra = 0,38 µm while plate 2 (P2) and 3 (P3) have been sanded with roughnesses of Ra = 2,80 µm and Ra = 8,12 µm respectively. The various tested parameters are summarized in Table 1. This experimental design allows the coverage of a wide range of friction coefficients values on all the thermoforming process parameter range.

Friction Measurement Results and Discussions

Fig. 2 shows the evolution of the coefficient of friction at room temperature as a function of the normal force for applied values of 2 N, 5 N, and 10 N. For the P1 plate with the smoothest surface, normal force does not affect the friction coefficient in the measurement range. For P2 and P3 plates, with a rougher surface, the friction coefficient increases slightly with normal force. Increase in the normal force must increase the penetration of the roughnesses into the polymer and therefore the friction.

Table 1. Friction coefficient measurement parameters.

	Roughness (µm)	Temperature range (°C)	Normal Force (N)	Rotation speed (mm/s)
Plate 1 (P1)	0,38	20	2 - 5 - 10	5 - 12,5 - 25
		60-180	2	
Plate 2 (P2)	2,80	20	2 - 5 - 10	5 - 12,5 - 25
		60-180	2	
Plate 3 (P3)	8,12	20	2 - 5 - 10	5 - 12,5 - 25
		60-180	2	

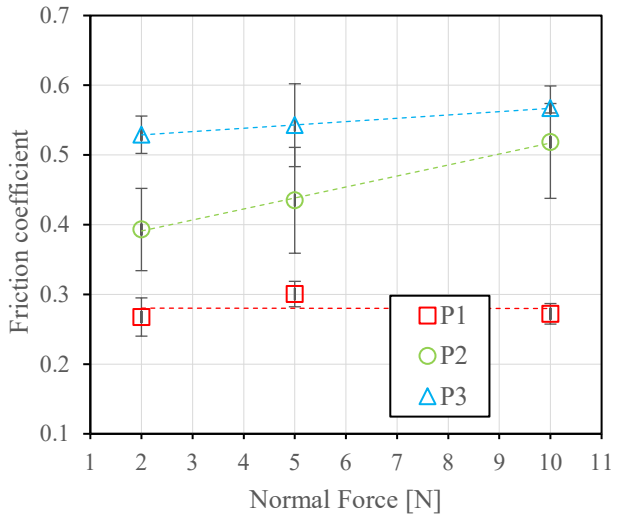

Fig. 2. Friction coefficient at room temperature for an applied normal force of 2N, 5N and 10N (Speed test = 12,5mm/sec).

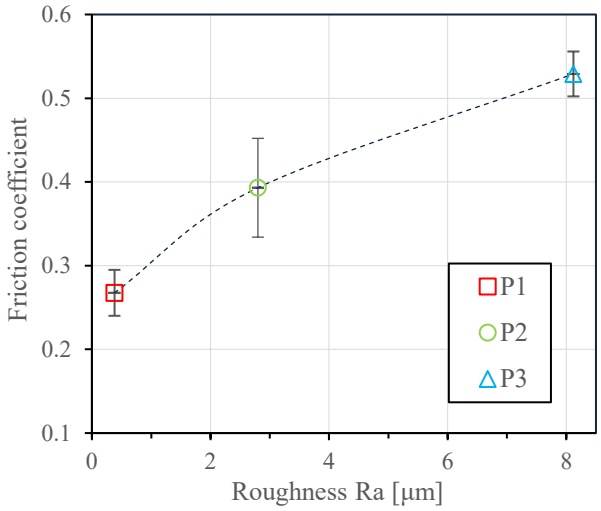

Fig. 3. Friction coefficient in function of roughness (Normal force = 2N, Speed test = 12,5 mm/sec).

Friction coefficient evolution with surface roughness at room temperature is reported in Fig. 3. Contrary to expectation the coefficient of friction increases with the surface roughness by almost following a linear relationship. This result contradicts previous studies [10, 11] assuming that the apparent surface contact reduction due to the roughness decreased friction. One possible explanation is that, in reality, the friction force can be divided into two independent contributions: an adhesive term representing the adhesion phenomena at the real contact level and a deformation term representing volumic deformations by "ploughing". This deformation term is sometimes not negligible at room temperature [12]. It is possible that in the case of the roughness profile of the P2 and P3 plates, the deformation term is important and increases the friction coefficient.

In temperature, for a 2N applied force, Fig. 4 shows that the friction coefficient is stable up to the glassy transition temperature (~150°C) and then increases more or less significantly with roughness. This results is consistent with literature [1, 2, 9]. However, there is a

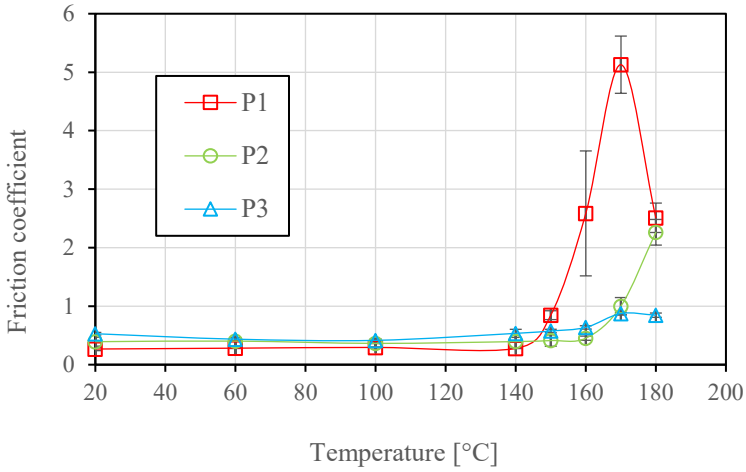

Fig. 4. Effect of temperature on friction coefficient for the three plates (Normal force = 2N, Speed test =12.5mm/sec).

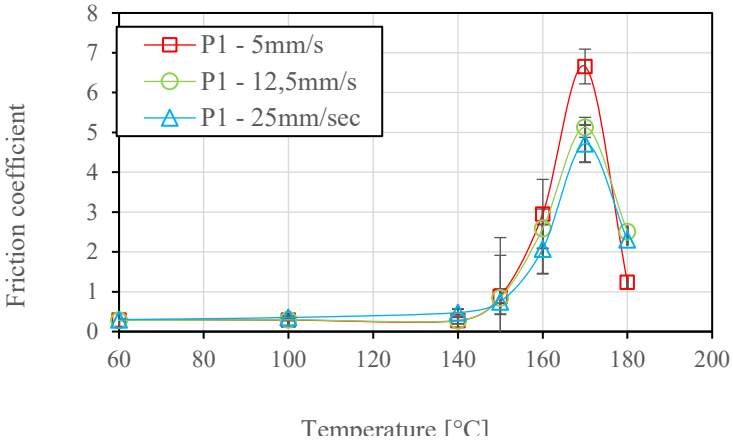

Fig. 5. Effect of speed sliding on friction coefficient in temperature for smooth plate P1 (Normal force = 2N).

decrease of friction coefficient in temperature as a function of the surface roughness. It is deduced that, unlike to ambient temperature, the drop in mechanical properties due to temperature increase reduces the deformation term effect on friction in favor of the adhesion term. Friction coefficient decline from 180°C can be explained by a totally sticky contact, the measured torque being linked to pure shear of the sample [1]. Fig. 5 shows the effect of the sliding speed on the friction coefficient for P1 plate. The decrease in the sliding speed increases friction. This sensitivity to speed and temperature relates the viscoelastic behavior of polymers and Time Temperature Superposition (TTS) principle. This behavior has already been observed in the case of elastomers [12] as well as on impact PS and PP [9]. The behavior is the same with the P2 and P3 plates.

Numerical Simulation and Experimental Comparison

T-SIM software.

The 3D numerical simulations were carried out using the commercial package code T-SIM® version 4.9 (Accuform) based on the finite element method and specially designed for the simulation of the thermoforming process. This software use a K-BKZ [13] type nonlinear viscoelastic constitutive model to describe large polymer deformations during forming. Friction Coulomb's law was applied on contact areas between sheet and mold, and the heat equation allows the calculation of thermal transfers during the process. The thickness distribution and polymer stretching were numerically investigated for the different experimentally measured friction coefficient values. Next, numerical results were compared with experimental thermoforming data obtained with two representative moulds presented in Fig. 8. The mold A has the same surface roughness as plate P1 (Ra = 0,41 μm) and the mold B has the same as plate P3 (Ra = 8,06 μm).

Viscoelastic model parameters.

During thermoforming, polymer materials exhibit nonlinear viscoelastic behavior due to large deformations and high strain rates over a wide range of temperatures. To describe this particular behavior, T-SIM use the K-BKZ type viscoelastic Wagner Model. This model shows good results for the simulation of the thermoforming process for ABS [2, 4], PS [14], or HDPE [15]. The Wagner model is expressed as follows (3):

$$\sigma(t) = \int_{-\infty}^{t} m(t-t')h(I_1, I_2)C^{-1}(t,t') \quad (3)$$

- $C^{-1}(t,t')$ is the finger strain tensor. I_1 and I_2 are invariants and depend on the solicitation type.
- $m(t-t')$ is the time dependent Memory function used to explain the linear viscoelasticity. The memory function is calculated from the discrete relaxation spectra obtained by small amplitude oscillatory shear (SAOS) experiment. Several experiments were carried out at different temperatures and the master curve was reconstructed thanks to the time-temperature equivalence principle and the Williams-Landel-Ferry (WLF) equation.
- $h(I_1, I_2)$ is the Damping of the two strain invariants used to describe the nonlinear viscoelasticity. T-SIM software uses the following damping function Wagner (4) :

$$h(I_1, I_2) = \frac{1}{1 + A\sqrt{(I_1-3)(I_2-3)}} \quad (4)$$

K-BKZ Wagner damping function was numerically determined using T-SIMFIT® v1.41 software from uniaxial tensile test data. Tensile test were carried out at 170, 180 and 190°C and for four different speeds of 1.25, 2.5 and 12.5 mm/sec corresponding to an initial elongation rate

of 0.1, 0.5 and 1 s-1 respectively. Fig. 6 shows the prediction from Wagner model for A = 0,095 in comparison with experimental data at 170°C.

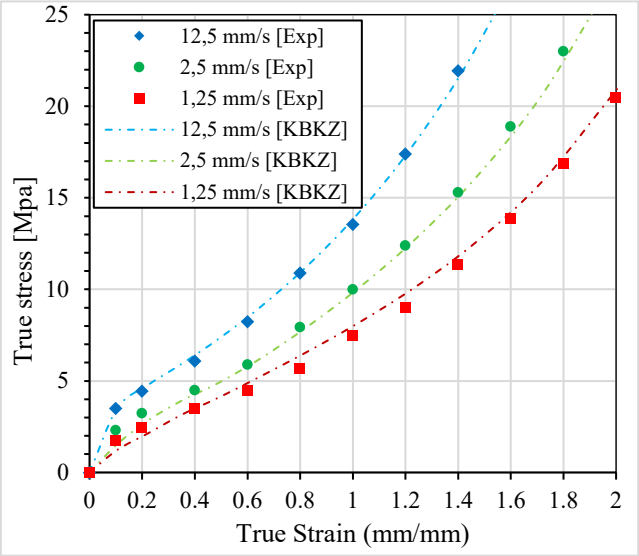

Fig. 6. Lexan 9030 stress/strain curve at 170°C. Experimental data are represented by symbols and KBKZ prediction by dashed lines for A = 0,095.

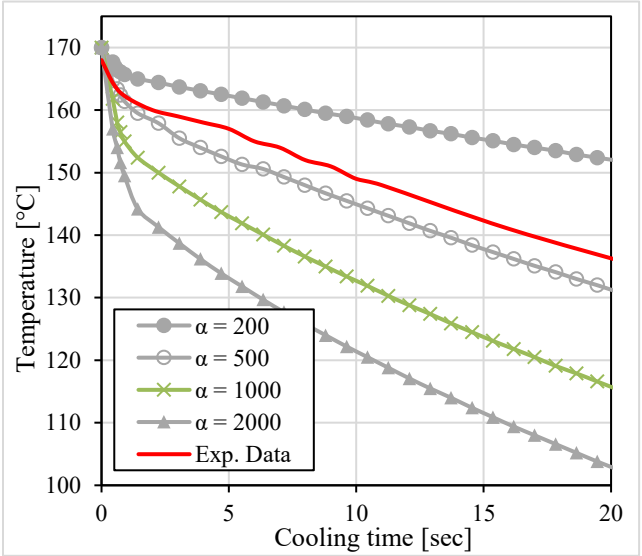

Fig. 7. Cooling of a Lexan 9030 sheet at 170°C during 20sec. Red line correspond to experimental cooling measured by thermal camera and gray lines are simulated cooling for different conductive exchange coefficient.

Heat transfer.

As shown above, the viscoelastic behaviour of polymers is highly temperature dependent. Therefore, it is necessary to well know the temperature throughout the forming cycle. For this purpose, a heat equation makes it possible to account for heat exchanges during the process. The polycarbonate thermal capacity and thermal conductivity were determined on a large temperature range by measurement in modulated DSC and HOT DISK device. The measured values are respectively Cp = 2.140 J/(Kg.K) and λ = 0.22 W/(m.K) at 180°C. In T-SIM, thermal properties are constant but in reality, they are temperature dependent, particularly around the Tg. For mold and sheet heat exchanges, the mold is only represented by its external surface and is assumed to be isothermal throughout the operation. The mold's thermal properties are not involved in it, and it is considered that the sheet-mold heat flow is monitored by a conductive exchange coefficient called "α". It may not hold a tangible sense, but it may however be experimentally determined : the cooling of a Lexan 9030 sheet at a temperature of 170°C, in contact with an aluminum mold at room temperature could be measured and then compared to simulated cooling for different α values (Fig 7). As a result, conductive exchange coefficients were found to be close to 500 W/m²/K, which is similar to a value obtained by Marotta and Fletcher [16]. Likewise, the convection exchange coefficient between polymer and ambient air is 8 W/m²/K.

Friction coefficient.

At the areas of contact between sheet and mold, sliding is managed by the Coulomb friction law. As with thermal properties, the friction coefficient is considered constant throughout the forming cycle. This study showed that in reality, the friction coefficient depends on several parameters and is largely temperature dependent for polymers. Several friction coefficients corresponding to the previously measured coefficients have been tested and the simulation will be compared with the experimental results.

Process parameters.

T-SIM software makes it possible to easily manage the various process parameters to best match the experimental parameters (see *Experimental thermoforming*) . The initial sheet temperature is 215°C. The mold rising speeds are respectively 20 cm/s and 10 cm/s for mold A and mold B. No pre-stretching were performed and a vacuum of - 0.2 bar is applied for 5s. A 60,000 polygons mesh permit to have an optimal compromise between precision and calculation time. Different process parameters are summarized in Table 2.

Experimental thermoforming.

Experimental thermoforming was performed on a laboratory scale thermoforming machine Formech 450DT. A thermal camera placed above the device allows sheet temperature profile recording in real time. The pressure during the forming cycle is measured by a manometer. Fig. 9 shows the experimental setup. The polymer sheet is heated with ceramic radiants until reaching a temperature of 215°C. In order to achieve the most uniform temperature distribution possible, the power of the external radiants is slightly increased to compensate heat losses by convection with ambient air. The rise of the mold is manually controlled. The average mold speed is around 20 cm/sec for mold A and 10 cm/sec for mold B, in order to avoid tearing the sheet on sharp angle. Then, a vacuum of -0.2 bar is applied for 5 to 7 sec to form the sheet on the mold.

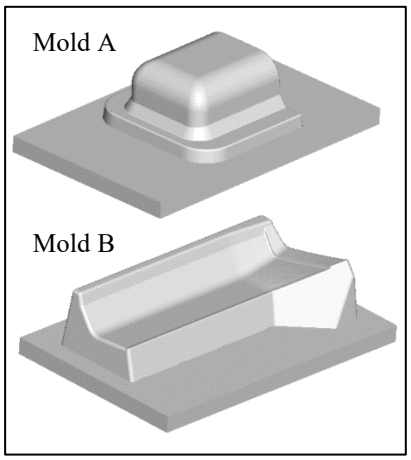

Fig. 8. Molds used for experimental thermoforming and simulation. Mold A has a surface rugosity of R = 0,41 µm corresponding to plate P1 and Mold B, Ra= 8,06 µm corresponding to plate P3.

Fig. 9. Experimental thermoforming setup with Formech 450DT thermoforming machine and thermal camera.

Table 2. Process parameter for numerical simulation with T-SIM®.

Process parameters	Mold roughness	Mold temp.	Sheet temp.	Mold speed	Convection coefficient	Conduction coefficient	Vacuum pressure
Mold A	0,41 µm	70°C	215°C	20 cm/s	8	500	0,2 bar during 5 sec
Mold B	8,06 µm	95°C		10 cm/s			

Simulation and Experimental Comparison Results

Several simulations were carried out with process parameters presented in Table 2. Four coefficients of friction were simulated as a function of the two molds: µ = 0.3 (minimum coefficient of friction for the polycarbonate-plate couple P1), µ = 0.75, µ = 1.5 and µ = 5 (corresponding to total stick) for the mold A and µ = 0.5 (minimum friction coefficient for

polycarbonate-plate P3) μ = 0.75, μ = 1.5 and μ = 5 for mold B. For each mold and friction coefficient, the simulated thickness distribution along the transverse (A-A) and longitudinal (B-B) axis is represented by a continuous line in Fig. 10 and Fig. 11. Experimental thicknesses has been measured on at least two different thermoformed parts using a digital micrometer is represented by diamond symbols. The thickness distribution can be divided in two regions: the upper part and the side parts. For mold A, uppers parts are located from 150 mm to 250 mm for transversal cut and from 225 mm to 375 mm for longitudinal cut. For mold B, uppers parts are located from 150 mm to 275 mm for transversal cut and from 75 mm to 425 mm for longitudinal cut. Other parts are considered as side parts.

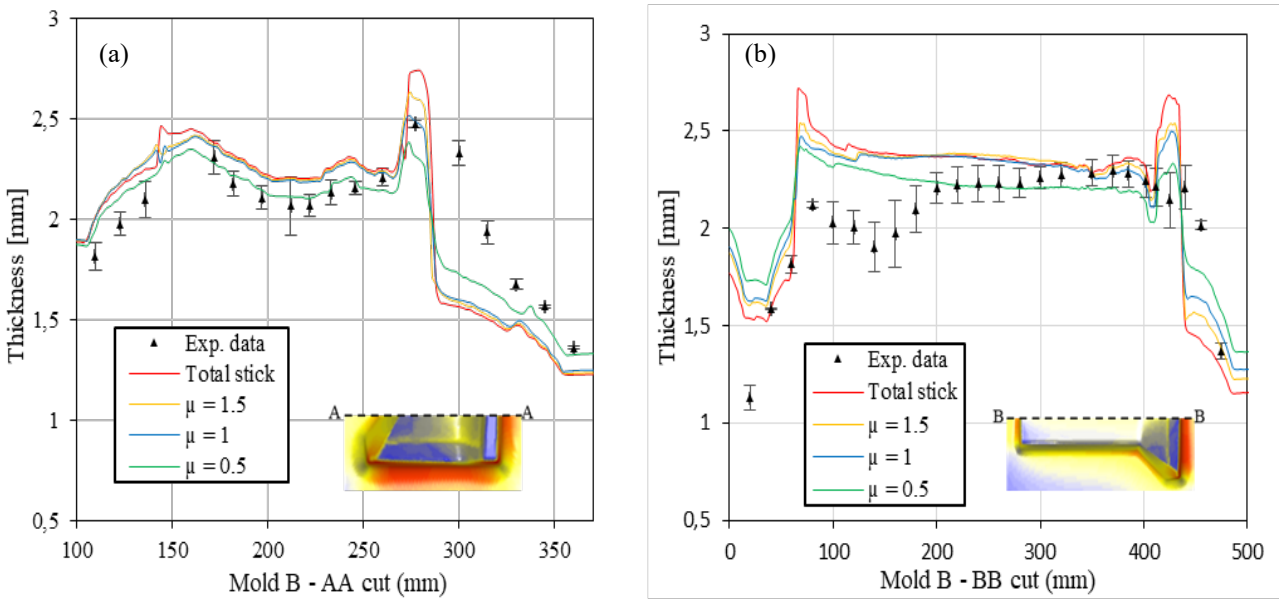

Fig. 11. Mold B thickness distribution along transversal (A-A) axis (a) and longitudinal (B-B) axis (b). Simulated data are in continuous line and experimental data are represented by diamond symbols.

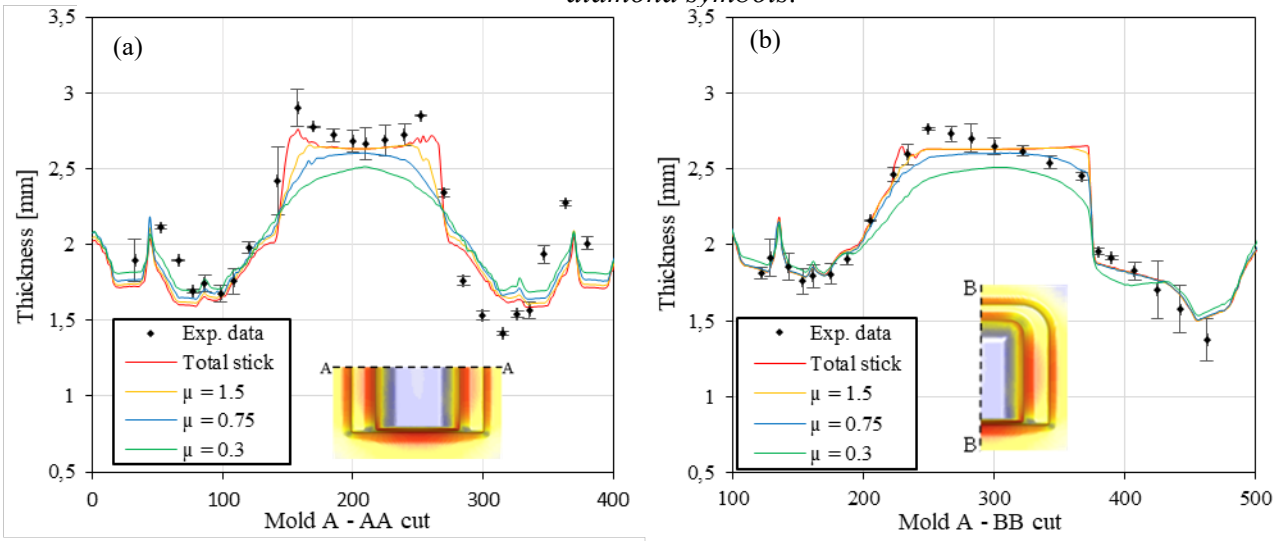

Fig. 10. Mold A thickness distribution along transversal (A-A) axis (a) and longitudinal (B-B) axis (b). Simulated data are in continuous line and experimental data are represented by diamond symbols.

The effect of friction coefficient variation is particularly visible on mold upper parts, the first in contact with polymer sheet during forming. The higher the friction coefficient, the greater the

simulated thickness. Indeed, when the friction coefficient is important or when the contact is completely sticky, the sheet cannot slide on the surface of the mold. Thus, the deformations are mainly concentrated on the side parts and in the corners. This phenomenon is amplified by the sheet cooling in contact with mold, witch limit the polymer ability to deform under stress. We can deduct from its results that a lower friction coefficient promote a more uniform thickness distribution especially when the mold geometry have a large upper planar surface.

Overall, for the two mold, simulated thickness distribution shows good agreements with experimental data. For mold A [Fig. 10a and 10b], average measured thickness on the upper part correspond to simulated thickness for high friction coefficient, see even, for total stick behavior on [Fig. 10a].

Its results confirm the friction coefficients measured previously: since the polymer sheet is still close to 215°C when in contact with the mold, P1 plate friction coefficient measurements predict sticky contact for this temperature. For mold B [Fig. 11a and 11b], average measured thickness on the upper part gets closer to simulated thickness for a friction coefficient between $\mu = 0.5$ and 1. Again, this correspond to friction coefficient value measured for plate P3 at this temperature. Based on this results, the sanding of the thermoforming tools makes it possible to limit the friction with sheet polymer in temperature and thus greatly improve the average thickness distribution.

Summary

A rotational rheometer with a specific geometry allowed us to measure the coefficient of friction from the ambient temperature up to the forming temperature for different speed of rotation and normal force. Effect of surface roughness were explored. It was shown that friction coefficient is temperature dependent and rapidly increase above glass transition. At room temperature, contrary to expectation, friction coefficient increases with an increase in roughness. One possible explanation is that, for this couple of materials, the friction deformation term is not negligible at room temperature and result in an increase of friction for rough plate. After glass transition, this trend is reversed and the smooth plate (P1) exhibit sticky behavior beyond 180°C. Simulations with T-SIM® shows good agreement with experiment data and confirms the friction coefficient values in temperature for the different roughnesses. For mold A (smooth surface corresponding to plate P1), best match is reached for a very high friction coefficient. For sand mold B (corresponding to plate P3), friction coefficients between 0.5 and 1 show best results. Based on this results, the sanding of the thermoforming tools makes it possible to limit the friction with sheet polymer in temperature and thus greatly improve the average thickness distribution.

Abstract. There are always debates on the use of power law to model flows having a local zero shear rate. This paper uses an original method to define a functional shear rate range with respect to the flow condition and identify an equivalent power law from a Cross-law fluid. The numerical and experimental results are compared to show the ability of the power law to model a flow having a low-shear region.

Introduction

Different viscosity models exist to represent the rheology behavior of polymers. The most simple behavior law for non-Newtonian materials is the power law [1,2]. The shortcoming of the power-law model to describe the viscosity at the zero shear rate was pointed out by several studies [3,4]. Some authors claim that the power law can be used with particular attention to the shear stress range [5], while some just use more complex models such as the Cross model [6] and the Carreau model [7] which better describe the low-shear regime.

The power law cannot be totally abandoned. Although the simplifications that the power law (compared to other complex viscosity models) can provide in numerical studies may seem small, it can still bring clarity for sensitivity analyzes [8] or facilitate the development of analytical formulations. It is important to know whether the power law can be used when a low-shear region exists in the flow.

In this paper, a power law, fitted to a Cross law for a specific shear rate range by an innovative thermo-rheological method [8], is used to model an annular polymer flow. The Cross law is also used to model the same flow for comparison. An experimental annular device [9] is used to measure the flow temperature variation due to viscous dissipation. The temperature measurements are compared to the predictions of the viscosity models. The numerical simulation results for the shear rate, viscosity, shear stress and velocity in the flow are compared as well.

Flow Geometry

We propose to perform analyzes on an annular polymer flow, which can be studied by using a Thermo-Rheo Annular Cell (TRAC) [9]. The structure of the TRAC is presented in Fig. 1, with thermocouples T_{1-4} installed on its central axis for flow temperature measurements. The polymer flow enters the duct from the left of the figure and is guided to the annular part ($z \geq 0$) by a 45° cone. The outlet is on the right side (Fig. 1). The central axis is not only for thermocouple instrumentation, but also for generating additional viscous dissipation in the passing flow, to extract information from the rheological behavior of the flow. The details on the flow model of the TRAC can be found in [9].

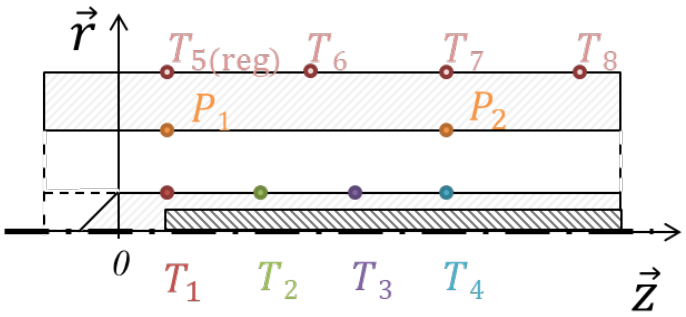

Fig. 1. Illustration of the TRAC.

Viscosity Models

The Cross law [6] (Eq. 1) is employed to represent the rheological behavior of the polymer :

$$\eta = \eta_0 / \left[1 + \left(\frac{\eta_0}{\tau^*}\dot{\gamma}\right)^{1-n}\right] \quad (1)$$

with η the viscosity, $\dot{\gamma}$ the generalized shear rate, η_0 the zero shear rate viscosity, n the power index at high shear rate regime ($0 < n < 1$ for shear thinning materials such as the polymers) and τ^* the critical stress level at the transition to shear thinning. According to the material database of the « Autodesk® Moldflow® » software, the Cross-law parameters for Polypropylene PPC 9642 at 195 °C are: η_0 = 3192.75 Pa.s, τ^* = 19996.2 Pa and n = 0.3387.

The power law [1,2], shown in Eq. 2, is used to compare to the Cross law.

$$\eta = K\dot{\gamma}^{n_p - 1} \quad (2)$$

with K the consistency coefficient and n_p the power-law index ($0 < n_p < 1$ for shear thinning materials). The power law is a straight line in logarithmic scale having the slope: $\left(d\ln\eta / d\ln\dot{\gamma} = n_p - 1\right)$. It should be noted that the Cross law also has a similar slope for $\dot{\gamma} \to \infty$: $\left(\lim_{\dot{\gamma}\to\infty} d\ln\eta / d\ln\dot{\gamma} = n - 1\right)$. The power-law parameters (K and $n_p \neq n$) are carefully chosen to compare with the Cross law of PPC 9642. This is detailed in the next section.

Procedure of the Study

A power-law curve can be drawn from two different viscosity points. In this paper, we use an innovative method to obtain viscosity points from temperature measurements. When the polymer melt flows through the TRAC, the temperature variation due to viscous dissipation is recorded at the central axis of the annular geometry. This temperature variation, for a given flowrate, is sensitive to one point on the material's viscosity curve. The point is called « critical point » in [8]. To identify critical points, the inverse method process can be designed with different approaches. But the process always takes temperature signals as the input variables and a critical point for each flowrate as the output result. Higher flowrates lead to critical points at higher shear rate regime. We need two different flowrates to obtain two critical viscosity points.

In practice, the TRAC is installed as a nozzle at the outlet of an injection unit. During injection, the polymer flows through the TRAC. Experiments are carried out with Polypropylene PPC 9642 at two different injection flowrates: 42.4 $cm^3.s^{-1}$ and 56.5 $cm^3.s^{-1}$. The corresponding simulations are brought off using the finite element model of the TRAC and the Cross-law viscosity model of the same polymer.

The main discussion of this study is whether the power law can perform as well as a more complex viscosity model rather than the identification of material parameters. To find an equivalent power-law curve of the Cross-law one, the identification of the power-law parameters is performed from the results of the simulations with the Cross law, that is to say by using the simulated temperature variation as a reference (Fig. 2). Two critical viscosities (580.3 Pa.s - 61.7 s^{-1} and 500.6 Pa.s - 80.5 s^{-1}) are obtained by applying the inverse method on the Cross-law simulation results, respectively at a flowrate of 42.4 $cm^3.s^{-1}$ and 56.5 $cm^3.s^{-1}$. A power-law curve (K = 5721.2 Pa.s^n, n = 0.4448) is drawn from these two points in Fig. 3.

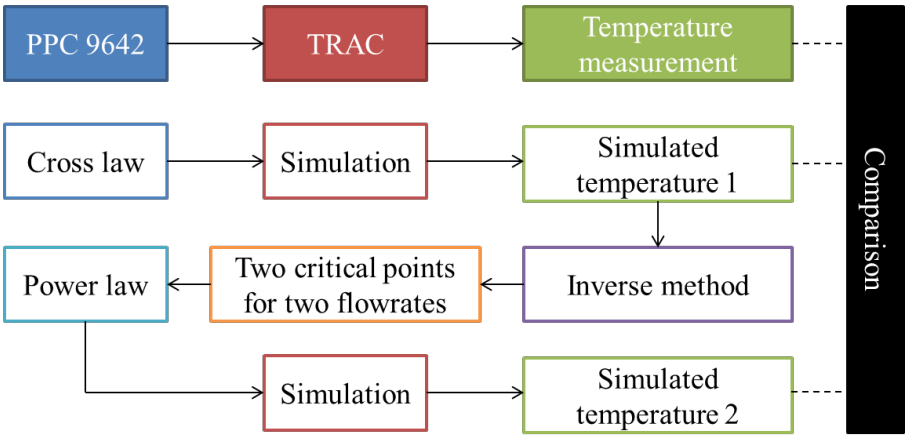

Fig. 2. Procedure of the study.

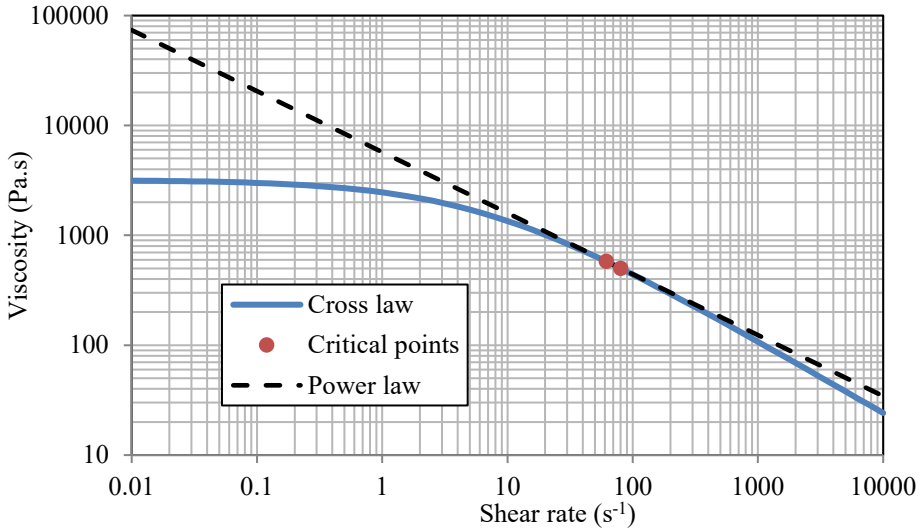

Fig. 3. Viscosity curves of the Cross law and the power law along with the critical points.

Fig. 3 shows that the critical points are on the Cross-law curve, because they are obtained from the Cross-law simulation results. The power-law curve, passing through the critical points, is close to the Cross-law curve only in a specific zone, near the transition region between the low-shear Newtonian zone and the high-shear pseudo-plastic zone. The difference between the two viscosity models can be seen at the high shear rate regime and especially at the low shear rate regime.

Other simulations at the same flowrates are carried out by using the power-law curve in Fig. 3 to replace the Cross-law viscosity model. In the next section, we will find out whether the power-law curve is good enough to describe the flow behavior and whether the critical viscosity points can represent a functional zone of a viscosity curve, by comparing the measurements of the TRAC,

the Cross-law simulations' results and the power-law simulations' results (Fig. 2). The simulation software used is « ANSYS® POLYFLOW® ». Shear rate, velocity and temperature profiles can be exported directly from the simulation tool. The viscosity and shear stress profiles are calculated from the shear rate profiles using analytical expressions (Eq. 1 and Eq. 2).

Results and Discussion

ΔT is the temperature variation relative to that of the initial state. The temperature variations ΔT due to viscous dissipation during injection (at 42.4 $cm^3.s^{-1}$ and 56.5 $cm^3.s^{-1}$) are measured directly by the TRAC and shown in Fig. 4. For an easy reading of the figure, only the temperatures measured by thermocouples T_2 and T_4 (Fig. 1) are presented. These flow configurations are also simulated with the Cross law and the power law. The results of the simulations are presented in Fig. 4 as well.

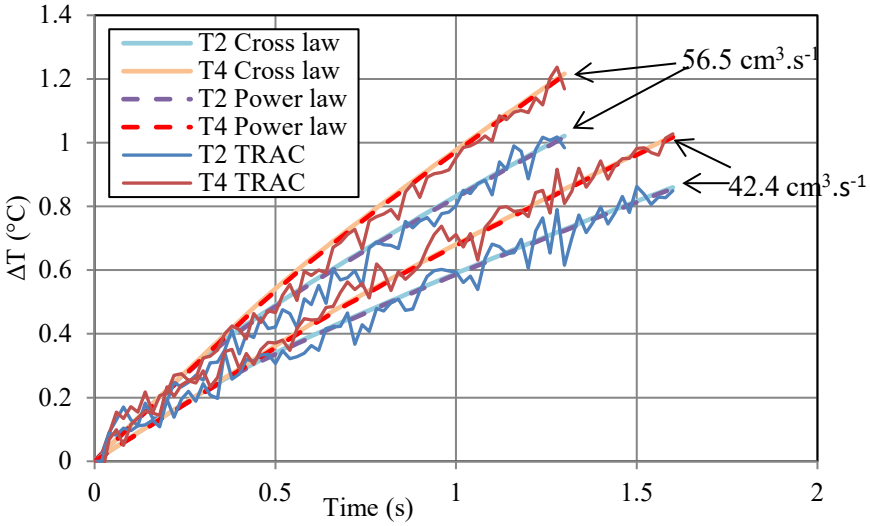

Fig. 4. Temperature variations (due to viscous dissipation during injection) measured by thermocouples T_2 and T_4 of the TRAC and simulated with the Cross law and the power law for different flowrates (42.4 $cm^3.s^{-1}$ and 56.5 $cm^3.s^{-1}$).

The increase in temperature due to viscous dissipation can be observed in Fig. 4. The higher the flowrate, the greater the temperature increases. The injection duration is shorter at the higher flowrate, because the injection volume is limited to the capacity of the machine.

The power law can predict the temperature measurements as well as the Cross law, as the power law is drawn from the critical viscosity points identified using the temperature variations of the Cross-law simulations. Indeed, the heat generated by viscosity dissipation within the flow is brought to the central axis by convection. The viscosity of the flow affects not only the viscous dissipation power (shear rate multiplied by shear stress), but also the velocity field (integral of shear rate) for the convection.

The steady-state shear rate profiles (at 42.4 $cm^3.s^{-1}$ and 56.5 $cm^3.s^{-1}$) as a function of radial position in the annular structure, are calculated respectively with the Cross law and the power law and presented in Fig. 5. The radius of the central axis (inner radius of the annular flow) is 4 mm. The outer radius of the annular flow is 10 mm.

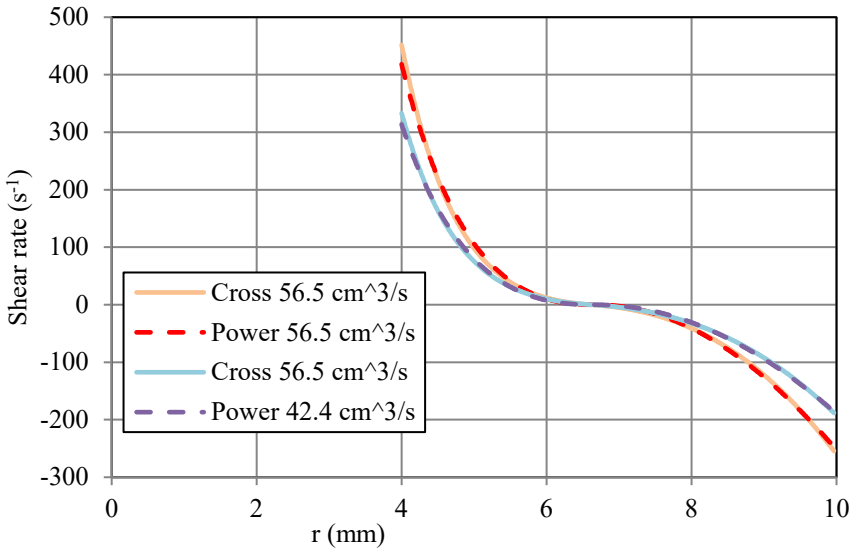

Fig. 5. Steady-state shear rate profiles as a function of radial position in the annular structure, calculated respectively with the Cross law and the power law, at 42.4 $cm^3.s^{-1}$ and 56.5 $cm^3.s^{-1}$.

The power-law calculations show lower absolute values of shear rate close to the inner and outer walls (r = 4 mm and 10 mm) of the annular geometry, compared to those of the Cross law. However, for example at r = 5 mm in the flow, the absolute values of shear rate obtained by the power law become higher than the Cross-law results. Although these differences are minuscule, they reveal that the power-law parameters that we identified with the innovative method minimize the prediction error across a certain depth of the flow domain.

The shear rates of the critical points in Fig. 3 are 61.7 s^{-1} and 80.5 s^{-1}. They have lower values than the maximum shear rates in the annular flow in Fig. 5. The maximum shear rates are on the surface of the central axis ($r = 4$ mm):

- 333 s^{-1} at the flowrate of 42.4 $cm^3.s^{-1}$;
- 452 s^{-1} at the flowrate of 56.5 $cm^3.s^{-1}$.

The power law is capable of delivering accurate predictions, because the power-law curve in Fig. 3 remains close to the Cross-law curve at the shear rate of 452 s^{-1}. The viscous dissipation method does not identify a power-law curve to fit the high-shear region beyond the maximum shear rate in the flow. By not doing so, the identified power law has less error in the relatively low-shear region (from 20 to 60 s^{-1}) on the left side of the critical points in Fig. 3.

Since the viscosity depends on the shear rate for non-Newtonian materials such as the polymers, we can plot the viscosity profile as a function of radial position in Fig. 6a. The main criticism of using the power law is that when a zero shear rate exists in the flow (Fig. 5), the calculated viscosity will reach a high or even infinite value in the low-shear region (Fig. 6a), which is not physical. However, Fig. 6b shows that the calculated shear stress (obtained by multiplying the shear rate by the viscosity) is not affected by the « zero shear rate problem » of the power law.

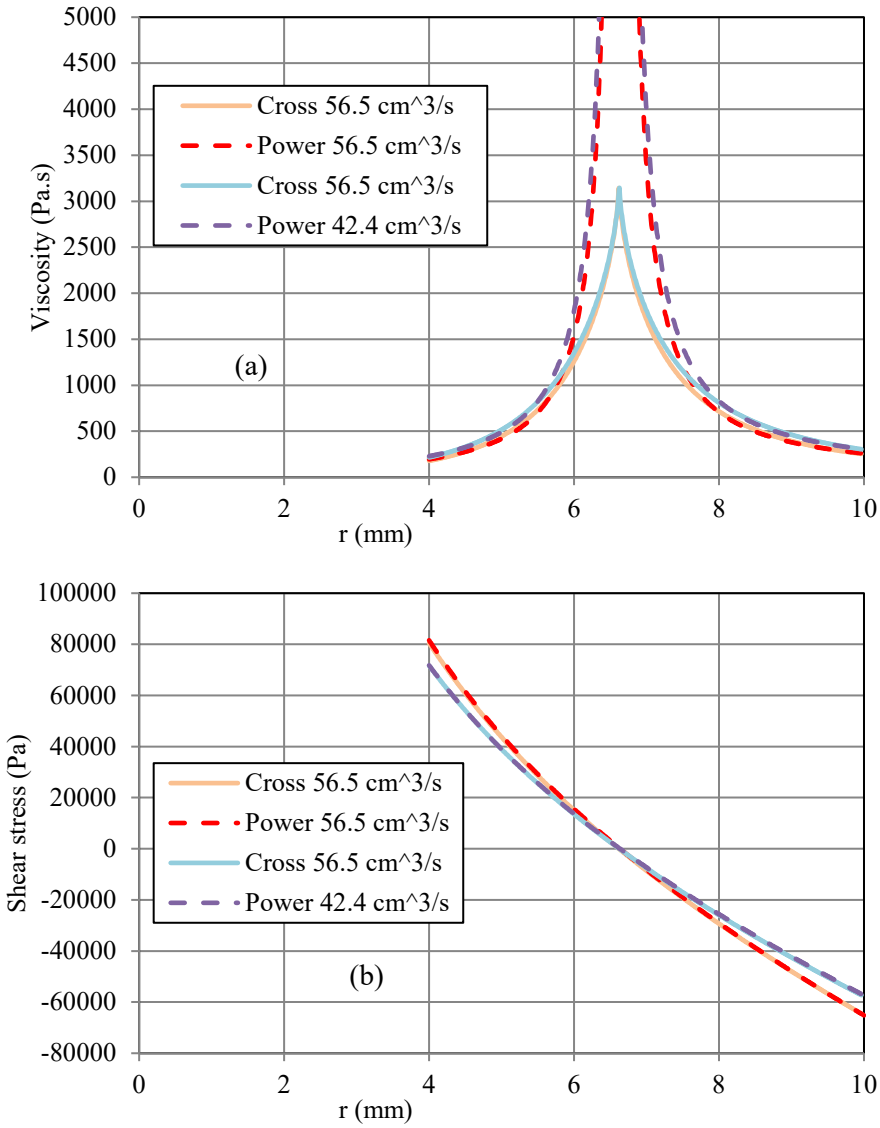

Fig. 6. Steady-state (a) viscosity and (b) shear stress profiles as a function of radial position in the annular structure, calculated respectively with the Cross law and the power law, at 42.4 $cm^3.s^{-1}$ and 56.5 $cm^3.s^{-1}$.

The velocity profiles are presented in Fig. 7. The predictions of the Cross law and the power law are almost the same on the velocity fields.

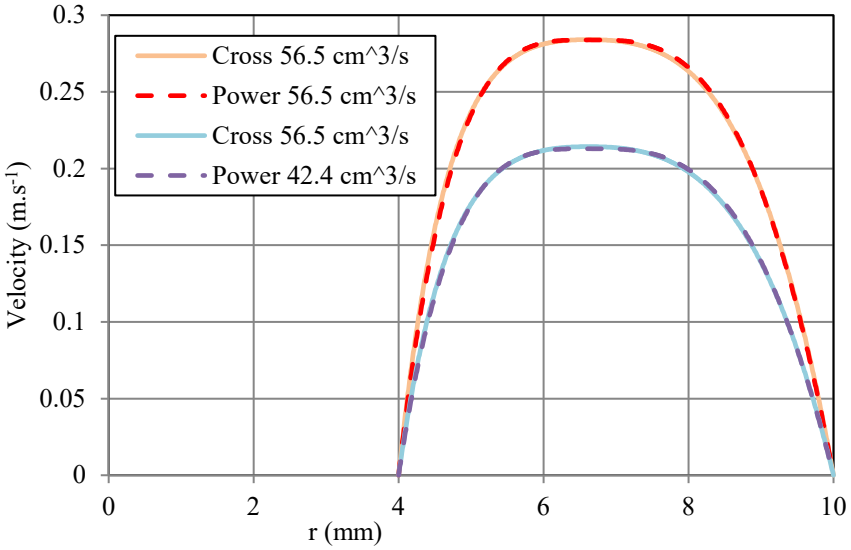

Fig. 7. Steady-state velocity profiles as a function of radial position in the annular structure, calculated respectively with the Cross law and the power law, at 42.4 $cm^3.s^{-1}$ and 56.5 $cm^3.s^{-1}$.

Fig. 7 shows again that the power-law parameters identified using the viscous dissipation method minimize the prediction error across a certain depth of the flow domain. This new method aims to identify parameters to reproduce the same heat exchange between the flow and the central axis of the annular geometry, rather than focusing on the pressure loss (like the classic capillary rheometry method [10]). Viscous dissipation and velocity profile are two of the key factors in this heat exchange.

If we aim to identify the power-law parameters using the simulated pressure measurements corresponding to each flowrate (42.4 $cm^3.s^{-1}$ and 56.5 $cm^3.s^{-1}$) to solve the pressure-flowrate equation of annular flow [11], this power law, different from the one identified with the viscous dissipation method, will be more accurate for pressure loss predictions but can be less accurate to predict velocity profiles especially at the center of the flow (« Power* » in Fig. 8). In general, the power-law calculations in Fig. 8 are still close to the Cross-law calculations. The power law identified with pressure measurements can have good performance as well.

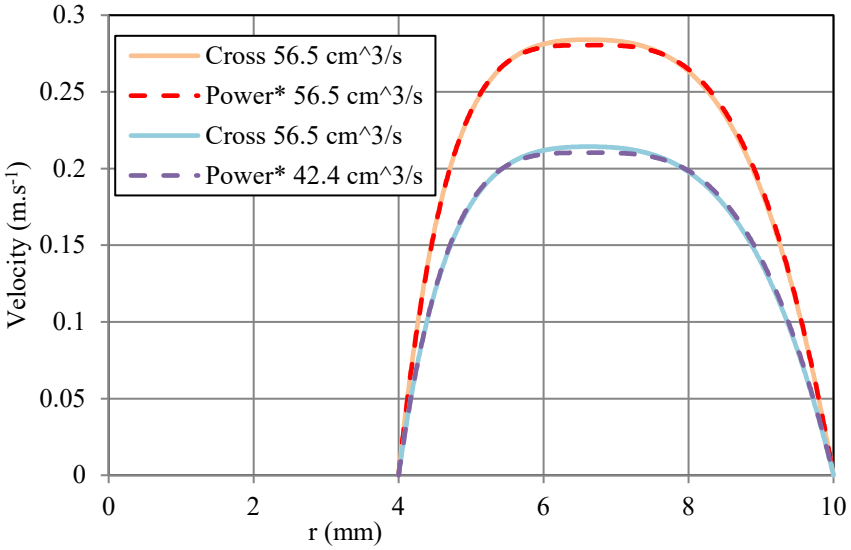

Fig. 8. Steady-state velocity profiles as a function of radial position in the annular structure, calculated respectively with the Cross law and the power law (identified with the pressure method), at 42.4 $cm^3.s^{-1}$ and 56.5 $cm^3.s^{-1}$.

The velocity values can be divided by the average velocity to obtain a dimensionless velocity profile. For a power-law type material, the dimensionless velocity profile depends on the value of the index $\boldsymbol{n_p = [\partial \ln \eta / \partial \ln \dot{\gamma}]}$, and does not depend on the flowrate [8,11]. For a Cross-law type material, the dimensionless velocity profile depends on the flowrate. In Fig. 9, a power-law type dimensionless velocity profile is drawn to compare with Cross-law ones for a large range of flowrates.

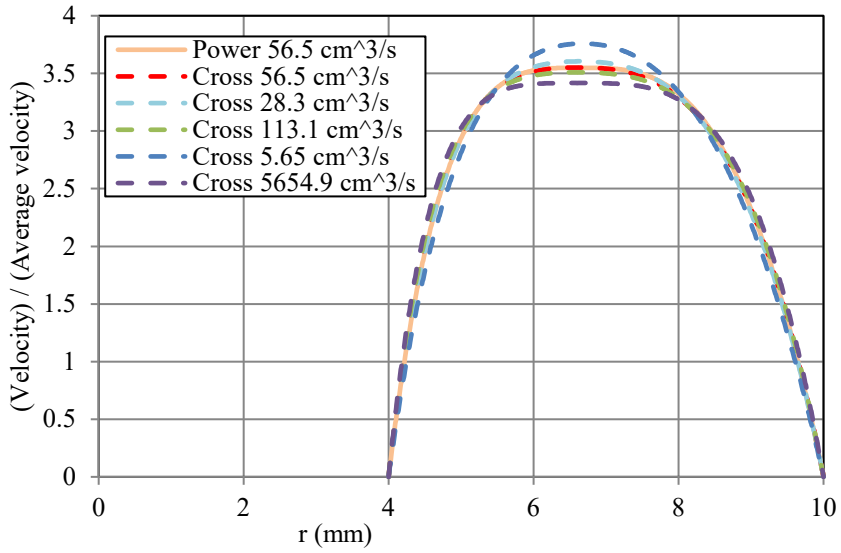

Fig. 9. Dimensionless steady-state velocity profiles as a function of radial position in the annular structure, calculated respectively with the power law (identified with the viscous dissipation method) and the Cross law for a large range of flowrates.

The power law identified with the viscous dissipation method is used to obtain the power-law type dimensionless velocity profile in Fig. 9. When the flowrate at 56.5 $cm^3.s^{-1}$ is multiplied or divided by two. The Cross-law type profiles are still close to the power-law one. When the flowrate is 100 times higher or 10 times lower, differences become significant.

Fig. 9 indicates that the identified local power law has a certain range of validity. For a different range of flowrates, the local power law may need to be re-identified. For example, a local power law with n_p close to 1 will give better results at low flowrates when the material is almost Newtonian. When the local power law is identified at high shear rate regime, it will have a larger range of validity compared to the one identified in the Newtonian-shear thinning transition region (Fig. 3). In this study, the flowrates (42.4 $cm^3.s^{-1}$ and 56.5 $cm^3.s^{-1}$) are chosen on purpose to obtain critical viscosity points in the Newtonian-shear thinning transition region, to show the potential of a power law which fits the Cross law only in a specific range.

Summary

An innovative viscous dissipation method is used to define an equivalent power-law curve from a Cross-law one. The temperature variations due to viscous dissipation, calculated by the power law and the Cross law, are both found to be accurate compared to the experimental measurements. Thanks to numerical tools, the shear rate, viscosity, shear stress and velocity profiles in the flow, respectively obtained with the Cross model and the power-law model, are compared. The comparisons show that it is possible to find a power law to approach to a Cross-law flow for a specific flowrate range. On the viscosity curve, this refers to a dominant functional segment for a specific shear rate range.

Although the calculated power-law flow can be close to the Cross-law one, the power law cannot reproduce exactly the same result of the Cross law. Using different methods to identify the power-law parameters lead to different calculation precisions in the flow domain.

In general, the power law can have competitive performance compared to the Cross law, when the power-law parameters are carefully chosen for a functional shear rate range of the material, even for the transition region between the low-shear Newtonian zone and the high-shear pseudo-plastic zone. This conclusion can be extended to other viscosity models, as long as they can be decomposed into straight line segments in logarithmic scale.

Abstract. Friction-spinning as an innovative incremental forming process enables large degrees of deformation in tube and sheet metal-forming due to a self-induced heat generation in the forming zone. This paper presents new process designs for energy and resource-efficient forming of gas cylinders by friction-spinning without the use of an external heat supply. The self-generated heat enables friction-spinning process to reduce the energy demand in the manufacture of gas cylinders, which are usually manufactured with external heat (mostly fossil fuels), by 95 %. Typical gas cylinder contours, such as flattened and spherical bottom ends and cylinder necks, are manufactured by friction-spinning of AW 6060 tubular profiles with specifically designed tool path strategies. It is shown that friction-spinning enables the manufacture of typical gas cylinder contours with sufficient wall thickness and the required gas tightness without the input of external heat. Thus, this process can contribute to an increase in the energy and resource efficiency of forming processes.

Introduction

Friction-spinning as an innovative incremental hot-forming process enables large degrees of deformation in the field of tube and sheet metal forming due to a friction-induced heat generation in the forming zone in an efficient way [1]. The self-induced partial heating of the components not only enables significantly higher degrees of deformation, but also a defined influence on the mechanical properties such as hardness, microstructure [1] and residual stress distributions [2,3].

However, friction-spinning is also suitable for meeting today's social demand for a reduction in emissions and energy consumption of manufacturing processes. This is illustrated by the example of the manufacture of seamless aluminium gas cylinders, which are usually manufactured using external heat [4]. Comparable incremental processes such as flow-forming [5, 6], metal-spinning [7, 8] or tube-spinning [9] usually use gas burners with fossil fuels for the manufacture of these aluminium gas cylinder contours to enable the necessary degrees of deformation and to ensure the gas-tight sealing [10]. Due to its self-induced heat generation, friction-spinning offers the potential to reduce the energy consumption of comparable manufacturing processes by 95 % [11]. In addition, by eliminating the necessity of external heat supply, the manufacturing process can be realised solely through renewable energy, which provides the possibility of climate neutrality of the manufacturing process.

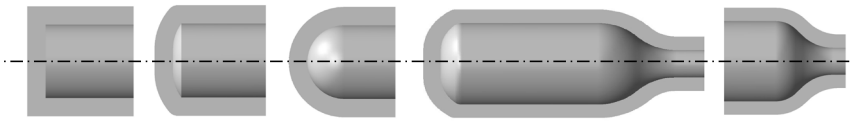

Fig. 1. Example of a gas cylinder and its typical contour elements: flattened and spherical bottom ends and cylinder neck.

Regarding the forming of flattened bottom ends of cylinders it has already been shown that friction-spinning enables the gas and liquid-proof sealing of tube ends with defined wall thickness distributions [12]. Nevertheless, when manufacturing complete gas cylinders, it is necessary to form more complex contours that comply with the standards for aluminium gas cylinders such as DIN EN ISO 7866 [13]. With the aim of energy and resource-efficient manufacturing of gas cylinders, such as the widely used carbonating cylinders, new process designs of the friction-spinning process are developed and investigated. The novelty of this process is that it eliminates the use of gas burners in the manufacture of gas cylinders, thus saving enormous amounts of energy. It also avoids the surface defects of the workpieces (such as surface oxidation) and impacts on the machine and the tools caused by the gas burner. To evaluate this novel process, essential process characteristics, such as force and temperature profiles, and also specific gas cylinder properties such as the workpiece contour, wall thicknesses and gas tightness are determined.

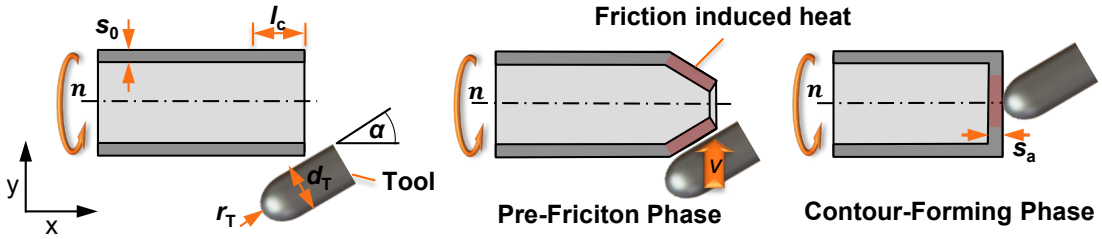

Fig. 2. Friction-spinning process for the forming of sealed-up tubes (flattened cylinder bottom ends. Rotation-speed n, feed rate f, tool-angle α, tool diameter dT, tool radius r_T, initial wall thickness s_0, wall thickness of the cylinder bottom end s_a, tool contact length l_c.

Process Design and Experimental Setup

Typical gas cylinder contours [13], such as flattened and spherical bottom ends and cylinder necks (*cf.* Fig. 1), are manufactured by friction-spinning of tubular profiles with specifically designed tool path strategies. The manufactured parts are assessed concerning their contour, wall thickness and tightness. Generally, the workpieces are manufactured using heat-treatable 3.3206 (EN-AW 6060 initial temper state T6) tubular profiles (100 x 40 x 5 mm) with the LUF in-house design friction-spinning machine (FSV) which is computer controlled by Sinumerik 840D by Siemens AG, Germany. The main spindle drive has a power of 100 kW and enables maximum rotational speeds of 3000 rpm. The tools used have a diameter of 20 mm and are made of the steel alloy 1.3343 (hardened).

The general process-design of the manufacture of sealed-up tubes (flattened bottom ends) by friction-spinning of tubes is subdivided into the pre-friction phase and the contour-forming phase (*cf.* Fig. 2). In the pre-friction phase, a conical basic contour is formed using the large contact area with the tool to induce heat to the workpiece by friction. In the subsequent contour-forming phase, different workpiece contours are formed by specific tool path strategies and the targeted selection of the tool contact area. In the case of a flattened cylinder bottom, the tool path is linear and directed radially (cf. Fig. 3, FB). For the manufacture of more complex contours, such as spherical bottoms and cylinder necks, special curved tool paths have been developed, but due to the limitations of the current version of the FSV machine control, these are interpolated by linear tool paths.

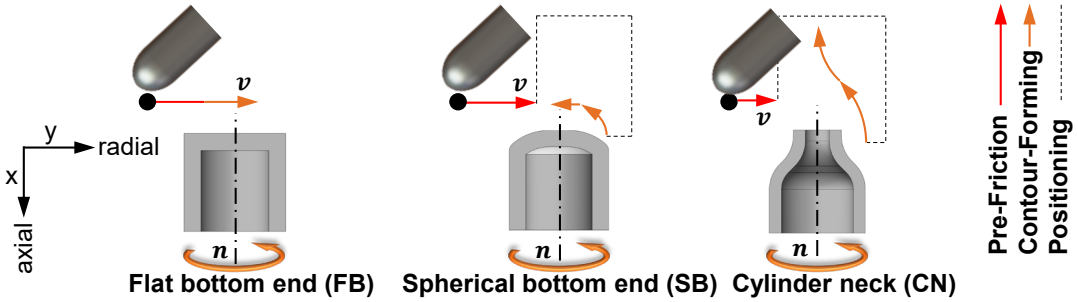

Fig. 3. Tool path designs for flat and spherical bottom ends and cylinder necks.

For the manufacture of the spherical bottom ends (Fig. 3, SB), the pre-friction phase is performed with a large contact area to induce heat and to form an initial cone shape by a linear path in the radial direction. The contour forming then is performed using the tip of the tool, i.e. a point contact and with a curved path that ends in a radial direction. By flattening the path of tool to the end, a centrical flattened bottom section can be realised, too.

For the manufacture of the cylinder necks (Fig. 3, CN), the pre-friction phase is also performed with a large contact area to induce heat and to form an initial cone shape by a linear path in the radial direction. In this case, this path is kept shorter so that the tube is not closed at the end of the process. Contour forming is then performed with the tip of the tool, and therefore a point contact, and with a curved path which does not close the end of the tube by ending in the axial direction. By the combination of tool path design SB and CN complete gas cylinders (*cf.* Fig. 3) are manufactured.

The manufactured parts are evaluated regarding their *contour* by:

- Axial cutting (separating) so that the cut surface lies exactly in the component axis.
- Repeatable positioning of the specimen with a measurement standard on a scanner.
- Image capture with 600 dpi.
- Digital determination of the wall thickness and contour by comparison with the measurement standard.

The *tightness* of the manufactured gas cylinder is demonstrated by applying a hydraulic pressure of 250 bar. For this purpose, a thread is cut into the open end of the gas cylinders to connect them with a pressure gauge, a locking valve and a hydraulic pump by hydraulic hoses (*cf.* Fig. 4, (b)). First, the air is pressed out of the hydraulic hose. Then a hydraulic pressure of 250 bar is applied with the pump, and the valve is closed. After one hour of pressure setting, the pressure is set again to exactly 250 bar and checked with the pressure gauge after 24 hours. The same procedure is also performed with helium at 25 bar.

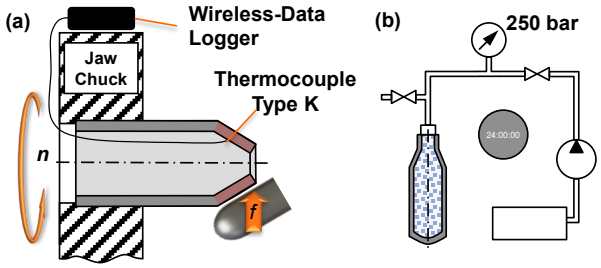

Fig. 4. Telemetric temperature measuring set-up in the friction-spinning process (a) and tightness measuring set-up (b).

The complexity of *temperature measurements* in the friction-spinning process results from its process characteristics (friction of the tool on the surface and rotation of the workpiece), and, with aluminium, especially optical temperature measurements are usually not feasible due to its

complex emissivity characteristics [14]. In addition, a basic black coating on the driven tool does not endure the forming process, so reflections of the ambient heat radiation cannot be ruled out. In a previous work, good results were obtained with a telemetric method using type k thermocouples with a radio data logger (measuring amplifier) [2]. Thermocouples type k are mechanically joined in corresponding holes at two discrete measuring points at 5 mm and 15 mm distance to the end of the tube (*cf.* Fig. 4, (a)). Thus, the measuring amplifier can be mounted on the rotating jaw chuck, and the measured values can be transmitted wirelessly, which will provide new valuable insights into the temperature profile of the friction spinning process even in optically non-measurable areas.

Force measurements are performed using a 6-axis load cell (50 kN, ME-Meßsysteme GmbH, Hennigsdorf, Germany) mounted between the tool holder and the support system. Forces are measured in the radial and axial direction of the workpiece.

Results and Discussion

Essential process characteristics, such as force and temperature profiles and also specific gas cylinder properties, such as the workpiece contour, minimum wall thicknesses were measured and tightness was proved.

Contour and wall thickness.

Starting with an initial wall thickness of 5 mm the thickness is reduced to at least 3.6 mm in the case of the flattened bottom end (a), 3.5 mm in the case of the spherical bottom end (b) and 3 mm in the case of the spherical bottom end (c). The cylinder neck's initial wall thickness of 5 mm is reduced to at least 3.9 mm (d). In all cases, the formation of burrs on the outer contour is observed (*cf.* Fig. 5, red marks). This is attributed to the interpolation of the curved paths by linear paths. Therefore, the burrs of the manufactured gas cylinders were removed by turning (e). It can be concluded from this that the manufacture of typical gas cylinder contours with the friction-spinning process is possible in principle, but the integration of accurate path curves into the process control is necessary. The inner contours of the bottom ends show curved shapes, especially in the centre, where the tube ends are joined. To create a more homogeneous inner contour, auxiliary tools may be used.

All the manufactured bottom ends are sufficiently joined, as shown in Fig. 5 ((a)-(c)). To prove this, three complete cylinders (e) were manufactured by the combination of the process designs of the spherical bottom end SB2 (c) and the cylinder neck CN (d). By testing three of the cylinders as shown in Fig. 4 (b), it can be stated that the manufactured bottom ends are tight, i.e. sufficiently connected to withstand a hydraulic load of 250 bar and are thus suitable as pressure vessels. In addition, the gas tightness of the cylinder was also assessed with helium at 25 bar using the same method. There was no measurable pressure loss over a period of 24 hours.

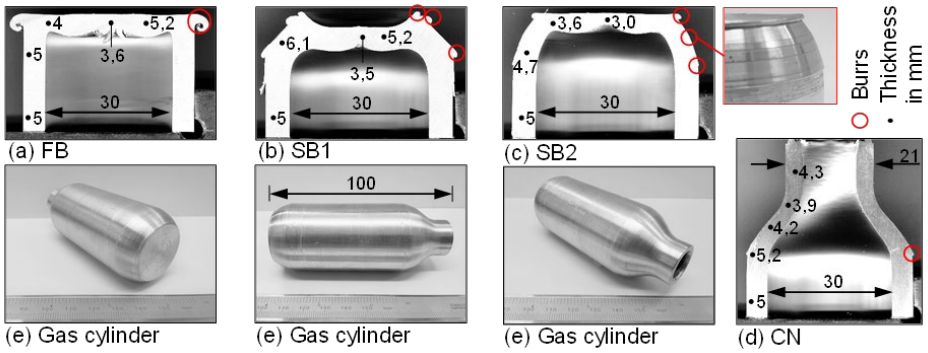

Fig. 5. Manufactured by friction-spinning: (a) flattened bottom end, (b - c) spherical bottom end, (d) cylinder neck and (e) gas cylinder. Rotation speed n = 1500 rpm, feed rate v = 30 mm per min.

Process Forces.

First, the process forces are measured to characterise the new process designs of the friction spinning process. Fig. 6 shows the force profiles and the maximum forces reached in the forming process of the cylinder necks (CN) and spherical bottom ends (SB) in dependence on the process parameters feed rate *v* and rotation speed *n*. In the pre-friction, phase the process forces increase sharply and reach a first peak after 4 seconds (*cf.* Fig. 6, (a-b)). The high level of process forces is maintained for a longer time in the case of the spherical bottom ends due to a longer pre-friction phase. In the contour-forming phase, the process forces do not increase as steeply as in the pre-friction phase. This is because the initial shape was already generated in the pre-friction phase and thus the deformation has a less abrupt onset. The comparatively shorter pre-friction phase of the cylinder neck forming process causes that the forces in the contour-forming phase are significantly greater than those of the bottom end forming process. The highest process forces occur in the horizontal direction (Fx) (*cf.* Fig. 6, (c-d)). They reach their maximum when the feed rate is high (90 mm/min), and the rotation speed is low (500 rpm). In the case of the cylinder necks 5512 N and of the spherical bottom ends 5320 N. Significantly lower maximum process forces are reached with a low feed rate of 30 mm per minute and a higher rotation speed of 1500 rpm. In the case of the cylinder necks 1339 N and of the spherical bottom ends 1767 N. As the process parameters significantly influence the process forces, the temperature profiles are also determined, as these have major influence on the yield stress and therefore can explain the occurring process forces.

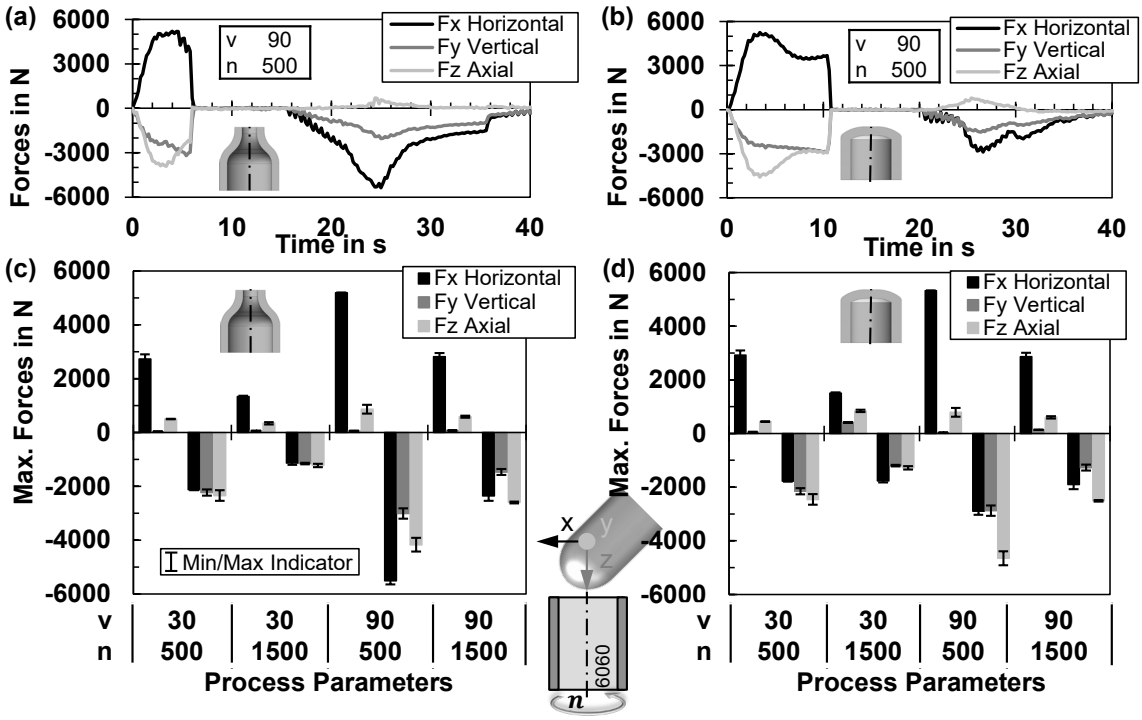

Fig. 6. Force profiles (a-b) and maximum forces (c-d) of the manufacture of the cylinder necks (CN) and spherical bottom ends (SB) by the friction-spinning process in dependence on the process parameters feed rate v [mm/min]and rotation speed n [1/min].

Temperature profiles.

Since the workpiece temperature has a huge influence on the yield stress, and thus on the process forces, corresponding temperature profiles were determined. Fig. 7 shows the temperature profiles of the manufacture of the spherical bottom ends (SB) by the friction-spinning process measured with thermocouple type k at 5 and 15 mm distance to the tube's end in dependence on the process parameters feed rate *v* and rotation speed *n*. Form the first contact with the tool, the

workpiece temperature strongly increases to a first peak at the end of the pre-friction phase. While re-positioning the tool for contour-forming the workpiece temperature decreases. In the contour-forming phase, the temperature again steeply increases to a second peak. In the following, heat is emitted until the reversal point for forming the flat bottom end, where a third peak of workpiece temperature is reached.

The described temperature profile is increased by the rotation speed and decreased by the feed rate so that a maximum workpiece temperature at 5 mm distance to the tube's end of 594°C is reached by a rotation speed of 1500 rpm and a feed rate of 30 mm per min (*cf.* Fig. 7, (a)). With a high feed rate of 90 mm per min and a low rotation speed of 500 rpm the maximum workpiece temperature reaches only 455°C. At a distance of 15 mm to the tube's end the temperature profile follows the same pattern, but with the same process-parameters maximum temperatures of only 558 and 387°C are reached (*cf*. Fig. 7, (b)). This is because the contact time with the tool is lower at this measuring point.

Derived from the determined temperature profiles the material bonding of the tube end in the centre of the bottom end is a solid-state bonding mechanism. This means that the adhesion is achieved by the diffusion of interfacial atoms, resulting in strong and uniform material bonding [15].

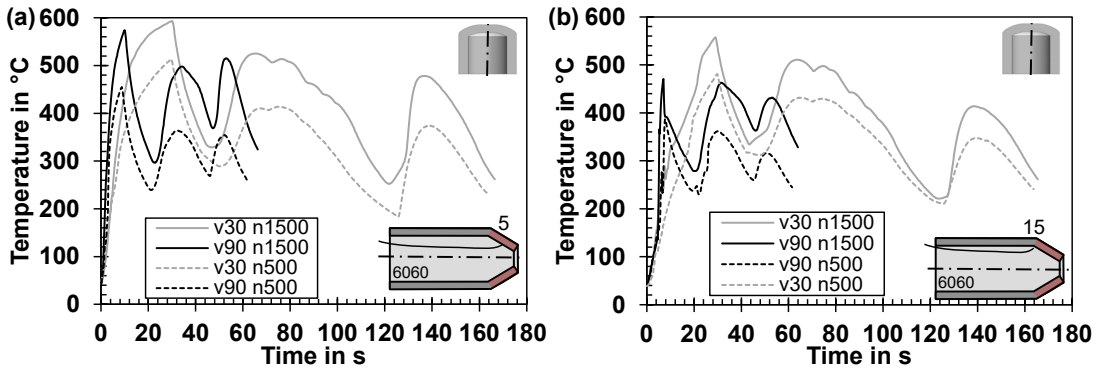

Fig. 7. Temperature profiles of the manufacture of the spherical bottom ends (SB) by the friction-spinning process measured with thermocouple type k at 5 and 15 mm distance to the tube's end in dependence on the process parameters feed rate v [mm/min]and rotation speed n [1/min].

In Fig. 8 the temperature profiles of the manufacture of the cylinder necks (CN) measured with thermocouple type k at 5 and 15 mm distance to the tube's end in dependence on the process parameters feed rate *v* and rotation speed *n* are shown. Form the first contact with the tool, the workpiece temperature increases sharply and reaches a first peak at the end of the pre-foaming phase. With the re-positioning of the tool for the contour-forming the workpiece temperature decreases. then, In the contour-forming phase the temperature again steeply increases to a second peak. In contrast to the manufacture of the spherical bottom ends, the highest temperatures are achieved in the contour-forming phase, which is attributable to the shorter pre-friction phase.

The described temperature profile is increased by the rotation speed and slightly decreased by the feed rate, so that a maximum workpiece temperature at 5 mm distance to the tube's end of 593°C is reached by a rotation speed of 1500 rpm and a feed rate of 30 mm per min (*cf.* Fig. 8, (a)). With a high feed rate of 90 mm per min and a low rotation speed of 500 rpm, the maximum workpiece temperature reaches only 485°C. At a distance of 15 mm from the end of the tube, the temperature profile follows the same pattern, but with the same process parameters only maximum temperatures of 551 and 403°C are reached (*cf.* Fig. 8, (b)).

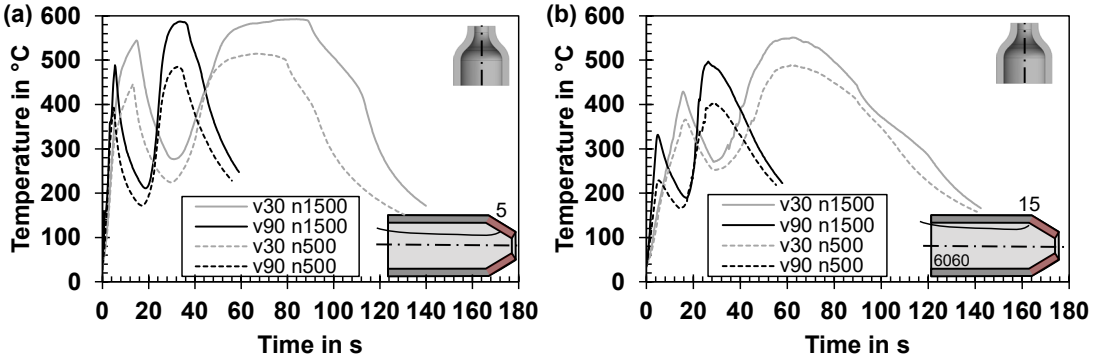

Fig. 8. Temperature profiles of the manufacture of the cylinder necks (CN) by the friction-spinning process measured with thermocouple type k at 5 and 15 mm distance to the tube's end in dependence on the process parameters feed rate v [mm/min]and rotation speed n [1/min].

With both contours, it can be seen that the higher rotation speed increases the workpiece temperature, which is due to more frictional heat input. This also interacts with the feed rate, which, if it is low, allows longer heat input. At the higher rotation speed, however, this effect is less. In this regard, the determined temperature profiles show a causal relationship with the determined maximum process forces. The higher the temperature, the lower the process forces, which is due to the lower yield stress. In this respect, the next step is to clarify to what extent the different temperature profiles cause recrystallization processes. This is investigated in the following through hardness tests.

Hardness.

Since there are process parameter-dependent temperature profiles and temperature gradients along the workpiece contour, corresponding hardness profiles were measured using the Vickers hardness test method according to DIN EN ISO 6507-1 [16] with a Nexus 4000 hardness testing device, Innovatest Company, Maastricht, Netherlands. First, an initial hardness of 86 HV0,3 was determined for the tubular profiles. Fig. 9 (a-b) shows that all specimens are softened by the manufacture process. On average of all measured parts, the hardness value (HV0.3) decreases by 38%. This is attributed to dynamic recovery and recrystallization due to the high workpiece temperatures combined with the high degrees of deformation [17]. Only at measuring point 5 of the bottom end which was manufactured with a high feed rate and a low rotation speed a significantly lower softening of 26% can be observed (*cf.* Fig. 9, (a)). This correlates with the observation that at a distance of 15 mm to the tube's end the maximum temperatures of only 387°C are reached, and thus the temperature at measuring point 5 is even lower (*cf*. Fig. 7, (b)). Under this condition, less dynamic recovery and recrystallization can be assumed and consequently less softening. However, the hardness profile over the entire contour cannot be influenced by the process parameters investigated.

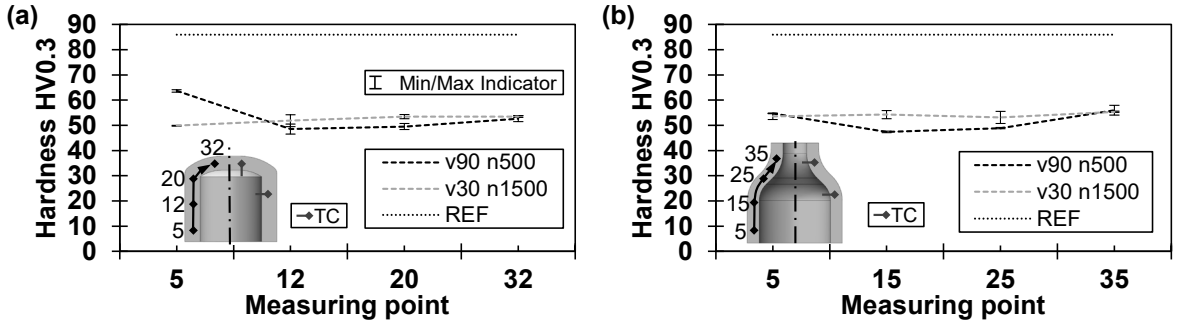

Fig. 9. Hardness profiles of the manufactured cylinder necks (CN) and spherical bottom ends (SB) in dependence on the process parameters feed rate v [mm/min]and rotation speed n [1/min].

Discussion.

In the experimental investigations, the resulting contours and the new process characteristics were evaluated. It is shown that friction-spinning enables the forming of the required contours for the manufacture of gas cylinders, and tightness, i.e. the essential property of gas cylinders, is fulfilled. The reduction of the wall thickness by up to 40 % does not lead to tightness failures. This is attributed to the fact that the friction spinning process allows sufficient material bonding of the cylinder's bottom ends through pressure welding-like processes, i.e. diffusion of interfacial atoms.

However, in terms of lightweight construction, the requirement arises to reduce the wall thickness to a rational minimum. Nevertheless, it can be assumed that there is a critical material-dependent standard dimensional ratio (SDR) to withstand this forming process, which must be determined in the next step. The use of tailored tubes will be investigated to overcome this limitation. For example, the internal flow-forming process developed at LUF can be used to manufacture these tailored tubes [18]. With this process, the wall thickness can be partially reduced to a specified minimum by flow-forming on the inner side of the tube, leaving the necessary wall thickness in the forming zone. The design and evaluation of this new process combination and chain will be part of future research. Additionally, a more homogeneous outer contour can be achieved by real curve paths and a more homogeneous inner contour can be achieved by the use of auxiliary tools. Furthermore, it should be investigated whether functional integrations, such as the forming of a thread, can be realised in the manufacturing process of the cylinder necks.

The investigated process characteristics, forces and temperature profiles are significantly influenced by the process-parameters feed rate and rotation speed. The process forces can be strongly affected and kept relatively low, leading to longer process times and higher workpiece temperatures. These process characteristics cause softening of the material due to recrystallization. However, gas cylinders usually have to be heat-treated before they can be introduced to the market with certification [19]. In the case of aluminium 6060, this is realised by annealing and ageing, which restores the initial mechanical properties. Furthermore, under this constraint, the processes can also be designed for a minimum energy consumption.

However, the actual power and the *total energy consumption* of forming machines strongly depend on their specific characteristics, which is why it is extremely challenging to compare different manufacturing processes performed on different machines, especially if the established processing is not transparent. And it also does not seem plausible to subtract the energy consumption of an empty run to obtain a pure transformation energy consumption, since energy is lost in specific amounts in every process despite the efficiency of the machine, and the actual energy consumption of comparable processes in the manufacture of these contours is unknown. In this work, however, we have demonstrated that the friction-spinning process at least does not require external heat input for the manufacture of these contours.

According to Lossen [11], depending on the process parameters, 70 to 735 kJ of pure forming energy is consumed during the friction-spinning process, which generates heat of about 500°C in the workpiece due to friction and deformation work. In comparison, the energy of 1300 to 1730 kJ is required to generate this heat in the workpiece (tube end of 40 x 5 x 80 mm of aluminium 6060) with an acetylene torch [11]. This calculation is based on a heating time of 30 - 40 seconds, a burner/torch surface of 1.13 cm² and 2.55 cm² and a mixture ratio of 1:3 [11]. In this context, it has to be stated that of course other potential forming processes also induce heat by deformation work, but with the friction-spinning process, the heat and thus the energy of an acetylene torch can be completely dispensed. Although the exact reduction of energy consumption cannot be determined reliably from this, friction-spinning provides the possibility to exclusively use renewable energy for the manufacturing process of gas cylinders and therefore can contribute to an increase in energy and resource efficiency.

Summary

In this paper, new process designs for energy and resource-efficient forming of gas cylinders by friction-spinning are presented. Typical gas cylinder contours, such as flattened and spherical bottom ends and cylinder necks, are manufactured by friction-spinning of AW 6060 tubular profiles with specifically designed tool path strategies. It is investigated how the process parameters influence the process properties and the mechanical properties of the workpiece. These newly developed process designs of the friction spinning process investigated here considerably expand the application possibilities of the process and also offer a great opportunity to increase energy efficiency in the manufacture of high-volume products. An essential factor here is the demonstrated adaptability of the friction-spinning process. The specific variation of the contact area of the bar-shaped standard tool enables, on the one hand, the free forming and, on the other hand, the targeted areal heat input by friction to extend the process limits. The synergetic combination of these two elements in one process design enables, for example, the production of contours typical of gas cylinders, which are difficult to manufacture without the addition of external heat in comparable and established forming processes. Thus, it is possible to limit the energy supply to electrical energy from renewable sources. Nevertheless, the actual energy consumption of this process compared to other processes and also the life cycle of the components manufactured with it, such as a carbonisation cylinder, still need to be investigated in future research.

Keywords: Sustainable Manufacturing, Additive Manufacturing, Machining, Turning, Roughness, Electron Beam Melting

Abstract. Sustainability is a crucial topic nowadays and Additive Manufacturing (AM) processes are becoming more and more widely used today also because, among its advantages, is claimed to be green technology. However, AM parts usually require postprocessing to improve their surface finishing and result assemblable. In this study, a Ti6Al4V cylindrical sample has been manufactured by Electron Beam Melting (EBM) and then post-processed by turning. Both dry and wet turning has been performed by using the same process parameters. Surface roughness has been measured both before and after each turning pass along the parallel and perpendicular direction to the cylindrical axis and energy consumption has been recorded during each turning pass. Results showed that both dry and wet turning led to a lower roughness along the perpendicular direction to the cylindrical axis than that along the parallel direction, as a result of the technological signature of the turning process. Also, they depict that the first turning pass results in higher cutting forces and, then, the highest values of energy consumption among all the turning passes, both in wet and dry turning. The Specific Energy Consumption (SEC) index has been investigated to evaluate the energy required to remove a unit volume of material; it reflects lower cutting efficiency in the material removal process.

Introduction

Sustainable Manufacturing (SM) is growing its attention focus more and more today both in the industry and research community [1]. The idea behind this concept is to manufacture parts for industrial applications with the objective to minimize the impact on the environment in terms of energy consumption, carbon footprint, and material waste. Additive Manufacturing (AM) is becoming more and more important today, as it plays a key role in the Industry 4.0 context. It consists in manufacturing 3D parts, previously modeled, by adding material layer by layer. AM is claimed to be a green technology because it holds great potential in improving materials efficiency, reducing life-cycle impacts, and enabling greater engineering functionality compared to conventional technologies [2,3]. However, the surface finishing of AM parts hardly ever meets the quality standard requirements, so postprocessing is always required. Machining processes, such as turning and milling, are widely used to reduce the roughness of the parts. Nevertheless, additional steps to manufacturing processes require unavoidably an additional amount of energy and resources. Cutting fluids are typically adopted in machining processes but their usage is crucial because, on the one hand, it helps to reduce friction, heat, and wear and so to increase the tool life but, on the other hand, it has not a negligible impact on the environment. Some studies exist in the

literature on the dry and wet turning of wrought parts but very few have been carried out on the post-process machining of AM parts [1-3].

In this experimental study, a Ti6Al4V cylindrical sample was manufactured by Electron Beam Melting (EBM) and then machined by both wet and dry turning under the same combination of process parameters to improve the surface finishing. Energy consumption has been recorded during the turning process process with and without lubricant. Also, the roughness has been measured before and after each turning pass. The sustainability index Specific Cutting Energy (SCE) is calculated to evaluate the energy required to remove a unit volume of material, that reflects lower cutting efficiency in the material removal process. The results obtained in this study aim to give some guidelines for better decision-making as a result of a compromise between energy consumption and roughness obtained from a sustainable perspective.

Material and Methods

A cylindrical sample, having a diameter D equal to 30 mm and a height equal to 103.38 mm, has been manufactured by Electron Beam Melting (EBM). Ti6Al4V plasma-atomized powders, having an apparent density of 2.57 g/cm3 [4] and a particle size ranging from 45 μm to 106 μm equal to 93.7%, have been used to manufacture the sample by means of an Arcam A2X machine in a vacuum (10^{-4}- 10^{-5} mbar), that is necessary for metals alloy having high affinity with oxygen and nitrogen. In addition, a helium pressure of 10^{-3} mbar has been applied to prevent electrostatic charging and smoke events leading to eventually process termination and powder spreading. The EBM machine worked in automatic mode: a hot tungsten filament cathode emitted electrons accelerated to 60 kV resulting in a maximum beam power of 3.5 kW. Layer thickness t and line offset h were chosen equal to 50 μm and 0.1 mm, respectively, to manufacture the sample by using the standard Ti6Al4V build theme [5].

Then, the sample was post-processed by turning to improve its surface finishing by means of a parallel lathe FEL-660HG. Turning inserts Sandvik CNMG 12 04 08-SM H13A with a turning tool holder Sandvik PCLNR 2525M have been used to perform the machining processes,
A length of 50 mm of the sample has been turned by using some lubricant oil Siroil Emulg and a length of 50 mm has been turned without the lubricant oil. Two new inserts have been used to perform the machining processes with and without lubricant oil, by selecting the same process parameters, to evaluate the roughness after the postprocessing by avoiding taking into account the wear of the tool. Table 1 contains the process parameters adopted to machine the sample, chosen according to the best results obtained in the literature [6].

Table 1. Process parameters adopted in post-processing of the Ti6Al4V EBM sample by machining.

Feed rate [mm/rev]	Depth of cut [mm]	Spindle speed [rev/min]	Number of cutting passes
0.22	0.6	300	4

The surface finishing of the sample was acquired both before and after the machining process both with and without lubricant by means of the confocal microscope 3D Optical Surface Metrology System Leica DCM3D. Then, Ra roughness parameter was measured, by selecting three profiles, along both the parallel and perpendicular directions to the axis of the cylindrical sample with the Leica Map software.

Energy consumption was measured during the machining processes by means of the power device Quality Analyser CA8331. It is equipped with three current sensors MiniFLEX MA193-350, four tension cables and four crocodile clips. Data over time can be visualized by the Power Analyser Transfer PAT2 software. The lathe adopted for this study has got a three-phase

connection without neutral (32 A 380 V) so three tension cables, three crocodile clips and three current sensors were adopted in this study to measure the tension and current over time, respectively [7]. By the measurements of the current and tension the device gives as output both power and energy consumption second by second.
Then, the sustainability efficiency index Specific Energy Consumption (SEC) for the machining process, with and without the lubricant, was calculated as follows [8]:

$$SEC = E_{removed}/m_{removed} \quad (1)$$

Where $E_{removed}$ is the total energy consumption to perform the turning process and $m_{removed}$ is the material mass removed, that has been measured by using a Gibertini ETERNITY 200 CAL balance. SEC was calculated after each turning pass to investigate its trend and to compare the results obtained in terms of energy consumption.

Results and Discussion

The first result that can be appreciated in this study is that the post-process machining of the Ti6Al4V EBM sample resulted feasible both with and without the lubricant oil, as illustrated in Fig. 1. Also, both solutions led to an improvement of the surface roughness removing the surface material with the process conditions mentioned above. Roughness was measured both before and after the machining process along the two principal directions of the cylindrical sample, according to international standard EN ISO 4287. Table 2 contains the results obtained in terms of surface roughness.

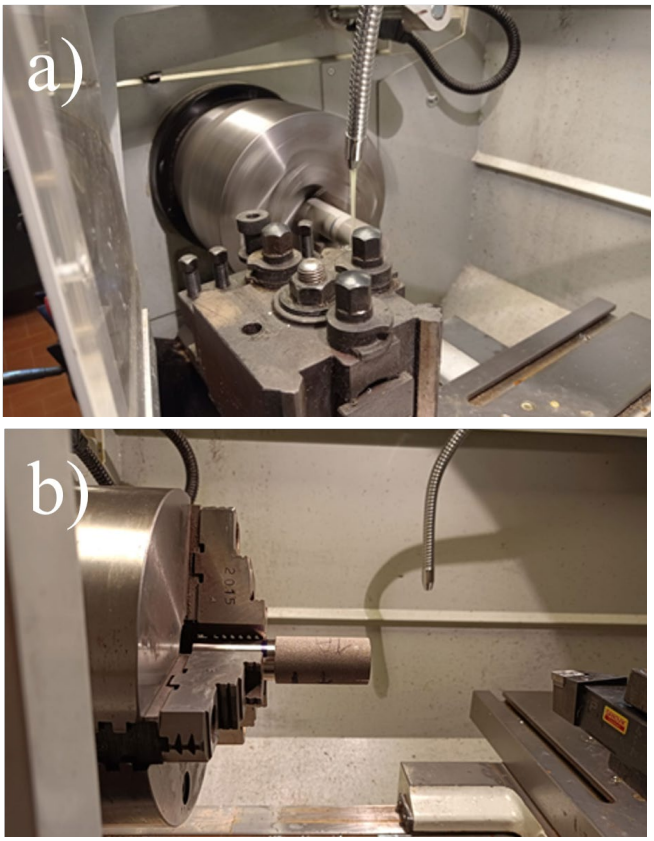

Fig. 1. Turning process of the sample a) with lubrication and b) without lubrication.

Table 2. Results obtained in terms of surface roughness along the parallel and perpendicular direction to the cylinder axis.

$Ra_{//}$ [μm] as built	$Ra_{//}$ [μm] with lubricant	$Ra_{//}$ [μm] without lubricant	Reduction % $Ra_{//}$ with lubricant	Reduction % $Ra_{//}$ without lubricant
30.73	1.86	1.54	93.94	94.99
$Ra_{\perp}$ [μm] as built	$Ra_{\perp}$ [μm] with lubricant	$Ra_{\perp}$ [μm] without lubricant	Reduction % $Ra_{\perp}$ with lubricant	Reduction % $Ra_{\perp}$ without lubricant
30.10	0.29	0.45	99.03	98.50

According to the results obtained, the roughness of the as-built sample along the parallel direction to the cylindrical axis is slightly higher than roughness along the perpendicular one. Then, it can be observable that the process parameters selected for this experimental campaign allowed to reach a roughness along the perpendicular direction $Ra_{\perp}$ to the cylindrical axis lower than that obtained along the parallel direction $Ra_{//}$. Indeed, reduction percentages of 93.94 % and 94.99 %, with and without lubricant oil respectively, have been obtained along the parallel direction whereas reduction percentages of 99.03 % and 98.50 %, with and without lubricant oil respectively, have been obtained along the perpendicular direction. These results are direct consequences of the technological signature of the turning process [7].

As mentioned above, energy consumption was measured during each turning pass as well as the material mass removed was calculated by measuring the sample mass before and after each machining process. Based on these measurements, SEC was calculated according to Eq. 1. Table 3 contains all the results obtained in terms of mass removed, energy consumption and specific energy consumption.

Table 3. Results obtained in terms of mass removed and energy consumption during the turning process.

Number of the turning passes	$m_{removed}$ [g] with lubricant	$m_{removed}$ [g] without lubricant	$E_{removed}$ [Wh] with lubricant	$E_{removed}$ [Wh] without lubricant	SEC [Wh/g] with lubricant	SEC [Wh/g] without lubricant
1	2.4	7.1	34.2	55.8	14.25	7.80
2	8.4	9.9	23.9	24.8	2.84	2.51
3	7.5	8.5	22.2	23.7	2.96	2.79
4	7.4	6	20.7	16.8	2.80	2.80

The first result observable regards the trend of the mass removed during each turning pass. At first, just a little amount of surface material of the sample has been removed, both with and without the usage of lubricants. This is because, in the beginning, the undulations are more pronounced according to the higher surface roughness of the as-built sample. The second turning pass allowed the removal of the highest amount of material both with and without the lubricant, by selecting the same process parameters. Results in Table 3 show that the trend of the mass removed over the number of turning passes is very similar between the two process conditions (with and without lubricant). However, a big difference in amount of removed material for the first pass exists (2.4 g with lubricant and 7.1 g without lubricant). This is due to the fact that the first turning pass is a roughing process, friction between the tool and the part is higher as well as the tool is at the beginning of his life. Thus, these conditions help the mass removal at the beginning. In total, the

mass removed with the lubricant is 25.7 g while the mass removed in total without the lubricant is 31.5 g.

Fig. 2 depicts the trend of the electrical energy consumption during each turning pass. It is important to premise that lubrication is activated by a sub-unite of the machine used for turning. The contribution of this pump in terms of power consumption is negligible. For this reason, in this study the attention was mostly focused on the energy consumption in dry and wet turning as a result of only different cutting forces during the process. Also in this case, the trend of data related to the machining process by adopting the lubrication is very similar to that the one without the usage of the lubricant as well as the curve related to the turning without lubricant is slightly shifted upwards. This is explained by the fact that the use of the cutting fluids reduces the friction between the tool and the workpiece resulting in a reduction of the heat generation and cutting forces [9], both with and without the usage of lubricant, as the power in machining is linearly dependent from the cutting forces [10] and the roughness of the as-built sample is the higher than that after each turning pass. For this reason, at the beginning of the machining process, the cutting forces are higher, and this explains why the highest values of energy consumption have been obtained during the first turning pass.

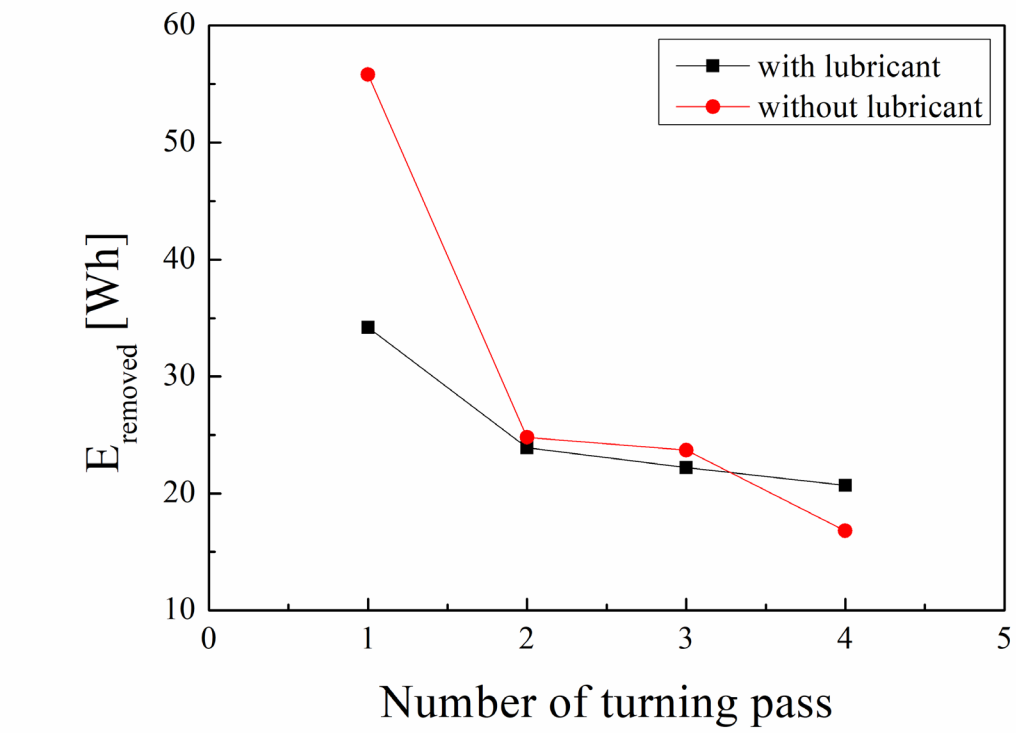

Fig. 2. Energy consumption to remove material after each turning pass with and without the usage of the lubricant.

Nevertheless, Fig. 3 shows that the SEC curve with lubricant oil is shifted upwards to the SEC curve without the lubricant. As indicates that from a sustainability perspective, even if the cutting forces are higher, dry turning can be considered more sustainable in terms of energy consumption than wet turning under the same process conditions. Fig. 3 depicts that at first there is a huge difference in SEC whereas data are very similar from the second turning pass to the end of the process.

By jointly investigating roughness and energy consumption during the turning of an EBM Ti6Al4V sample, it can be said that by selecting the process parameters of our study, it is

worthwhile to choose the dry turning rather than the wet turning since it leads to similar results in terms of surface roughness (Table 2) by reducing specific energy consumption to perform the turning process. This study could be improved by including more than one configuration of turning process parameters on EBM parts printed under the same process conditions and by also considering the cutting tool wear. In general, dry turning shortens tool life as well as lubricant has a negative impact on the environment. In this perspective, a joint investigation of surface roughness, energy consumption and tool wear will demonstrate the possibility to prefer dry turning to wet turning by using optimal process parameters.

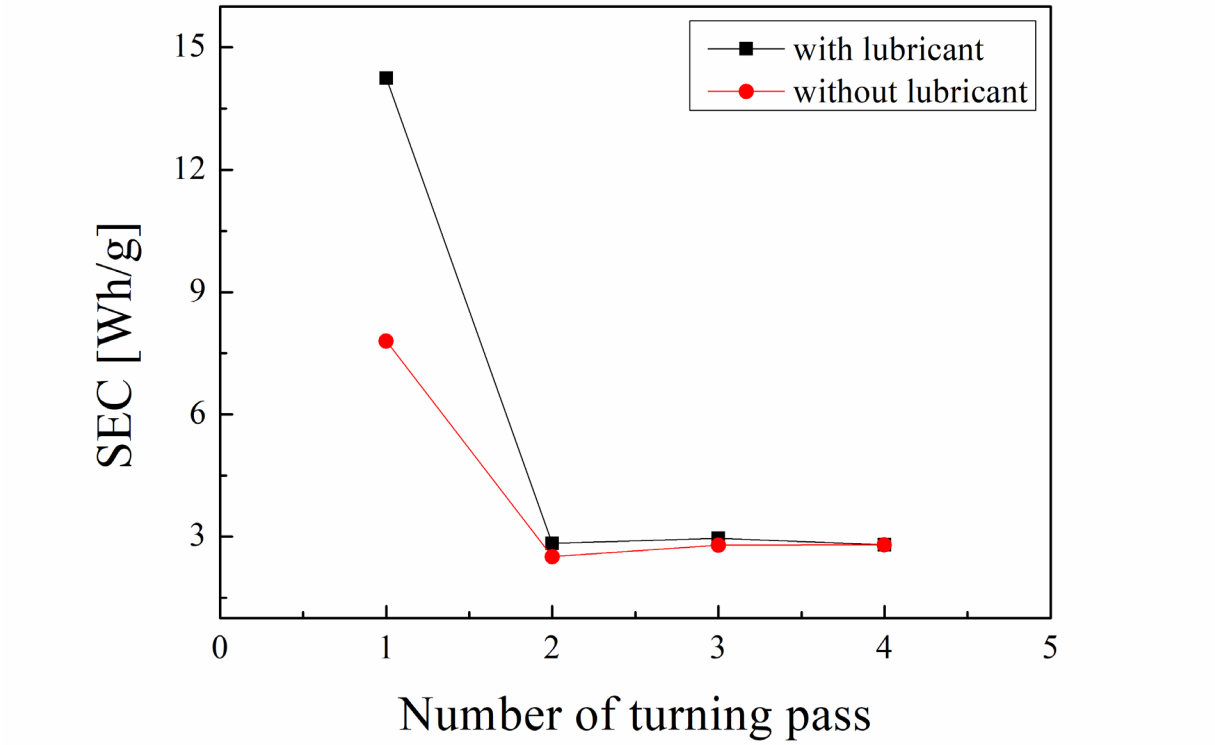

Fig. 3. Specific energy consumption after each turning pass with and without the usage of the lubricant.

Summary

This study demonstrates the possibility of choosing dry turning rather than wet turning as post-process machining for a Ti6Al4V EBMed cylindrical sample by reducing the sustainability index SEC without sacrificing its surface quality. The main results obtained and discussed in this study are:

- Roughness reduction percentages of 93.94 % and 99.03 % have been obtained by wet turning along the parallel and perpendicular directions, respectively. Roughness reduction percentages of 94.99 % and 98.50 % have been obtained by dry turning along the parallel and perpendicular directions, respectively. Thus, for the objective of this study, lubricant is not required to deliver a certain reduction in diameter and final surface finish.
- The same process conditions in machining lead to a lower roughness along the perpendicular direction to the cylindrical axis than that along the parallel direction, according to the technological signature of the turning process.
- The first turning pass, both with and without the lubrication, allows to remove just only a little amount of material as the surface undulations of the as-built sample are more pronounced and the roughness is higher.

- Wet turning leads to a removed mass of 25.7 g whereas dry turning leads to a removed mass of 31.5 g by selecting the same process parameters and by fixing the same number of turning passes.
- The first turning pass results in higher cutting forces and, then, the highest values of energy consumption among all the turning passes, both in wet and dry turning.
- Dry turning can be considered more sustainable in terms of energy consumption than wet turning under the same process conditions as the SEC curve with lubricant oil is shifted upwards to the SEC curve without the lubricant.

This study is among the first steps toward the sustainability assessment of post-process machining of additive manufactured parts. In fact, it is a preliminary investigation of sustainability implications in terms of energy consumption in both dry and wet machining of EBM samples. It is a first step to investigate how different the outputs in terms of both surface roughness and energy consumption are in machining the same parts having a simple cylindrical shape. The next step will regard the sustainability assessment and technological implications in machining a complex EBM part. Also, this study can be extended to other machining operations such as milling. The same cylindrical EBM samples could be post-processed by milling by selecting different process conditions by fixing the output in terms of total depth of cut, and then in terms of final surface roughness.

Also, the wear-cutting tool should be investigated for better decision-making as a result of a compromise between the energy consumption, tool life and roughness obtained from a sustainable perspective.

Keywords: Sheet Metal Remanufacturing, Energy Analysis, Circular Economy, LCA Sustainability

Abstract. New paradigms based on Circular Economy (CE) principles are needed for boosting the ecological transition and improving the energy and material efficiency. In this paper, a novel remanufacturing process chain for End-of-Life (EoL) automotive panels is first presented. The core of the recycling strategy is the reshaping of curved EoL automotive sheets through flattening by means of a hydraulic press. Flattening experiments together with press power consumption measurements have been performed on thin steel parts. While the experimental procedure demonstrated the technical feasibility of flattening "small-scale" steel parts, a more complete analysis on environmental sustainability was required. For this purpose, a Life Cycle Assessment (LCA) of the remanufacturing process chain proposed was set up. The results of the study demonstrated that flattening is a viable solution for reshaping EoL automotive panels, and that, for one kg of reshaped steel, approximately 2.2 kg CO_2 and 24 MJ could be saved.

Introduction

The production of metals accounts for about 8% of total global energy consumption [1]. Concerning the steel industry, the production of 1 ton of solid steel corresponds to a primary energy demand of 23.2 GJ [2]. Cullen et al. (2012) stated that the global steel demand is expected to increase tremendously [3].

Steel production and recycling is also strongly linked to the market dynamics, geopolitical instabilities or pandemic events. Those two factors can have a profound impact on the steel flow, availability and price [4-5]. Considering the presented issues, it is crucial for engineers and researchers to examine the entire process chain of sheet metals, including recycling, looking for potential resource efficiency improvements [6].

Recycling proved to have direct positive, demonstrating to be less energy demanding than raw material extraction and production [7-8].

Considering the recycling of End-of-Life Vehicle (ELV), recyclers use efficient processes to recover valuable materials like steel and aluminum alloys [9]. The quantity of metal recycled from end-of-life vehicles is a result of the technology available and the extent to which the technology is used in the scrap processing industry [10].

The steel production by EAF represents worldwide 28% of the total and reaches 46% in Europe (2017, [11]). EAF plants are mainly fed by metal scraps, thus being much less environmentally impacting than blast furnaces. Nevertheless, EAF has relevant impact on the environment, while approximately the half of the energy input is wasted during the process [12].

Considering the aspects aforementioned, there is the incumbent need of efficient methodologies, such as circular economy paradigms, to improve the material efficiency of EoL

steel sheets [3]. Increasing the material efficiency can be achieved by six strategies: Reduce, Reuse, Repair, Remanufacture, Recycle, and Recover [13]. Applying these strategies is not always straightforward because of practical problems: Cooper and Gutowski [14] listed the enablers and barriers related to the improvement of material efficiency. Political actions, legislations and the collaboration with associations or national institutions can be a driver for implementing sustainable solutions [15].

The the general opinion of the scientific community is that there is margin to find alternatives, whenever possible, to replace the conventional remelting of metal panels [16-17]. These practices can be divided mainly in two approaches: solid state recycling and direct remanufacturing for reuse of metal panels.

Solid state recycling involves the formation of a billet starting from shredded particles and/or powders. Several routes are possible, such as hot compression [18], hot rolling [19], cold/hot extrusion of chips, Spark Plasma Sintering (SPS) with compaction and extrusion [20], friction consolidation through a rotative die plunge [21], Submerged Arc Welding (SAW) of metal chips and metal waste [22]. Although technically feasible, in solid-state recycling, the material must be available in form of small pieces (or powder), requiring a shredding stage in the product's life cycle.

Reshaping strategies instead are meant to directly utilize a metal panel avoiding shredding and compaction and providing new shape or directly performing new stamping operations on it. For example, Ali et al. [23] proposed an innovative recovering strategy for large industrial scrap from the automobile industry producing metal facade systems for buildings. Other researchers such as Ingarao and Takano employed incremental forming to reshape aluminum alloy panels [1,24]. The proposed routines highlight the capability of reshaping panels, but the application of incremental forming could be potentially limited to small batches due to the need of programming the tool path case by case. Two other interesting studies were conducted by Abdullah [25] and Haase [26]. Abdullah developed a methodology for reusing EoL car bodies into mesh steel defining five sustainability indexes. Haase designed a lifecycle based on pre-used material (car roof) to obtain by stamping operations a brake disk cover part.

The present study presents first the main results of remanufacturing tests of thin steel parts through cold and warm flattening with a hydraulic press. The measurements of the press energy consumed during these tests are presented. The measurements were needed to setup a Life Cycle Assessment (LCA) of the remanufacturing routine through the SimaPro software package and to understand the different contributions of power consumption during the flattening cycle. The performed analysis showed the promising results obtained by flattening thin steel parts and the environmental benefits associated with it.

Flattening as a Viable Solution for Remanufacturing Eol Sheet Metals

In the framework of circular economy and environmental sustainability, this paper presents a novel remanufacturing cycle for car body panels. The concept proposed is to exploit EoL car bodies (preferably large panels) to produce metal sheets reusable for a new life, as described in Fig. 1. The largest panels, having often a given curvature, should be first trimmed, then flattened and eventually reshaped. A potential part to be reshaped from an EoL car is the car roof shown in Fig. 2.

The flattening process can be performed through a hydraulic press, whose tools are simply hard steel plates able to flatten car bodies of different models in a "short" time. The tooling costs are expected to be reduced due to the simple geometry. Flattened parts, once characterized, can be then used as regenerated blanks for subsequent forming or shearing applications. The proposed cycle clearly produces blanks which are not uniform and perfect, which might have some defects, but final imperfections are not necessarily a problem for some final intended uses and applications [27].

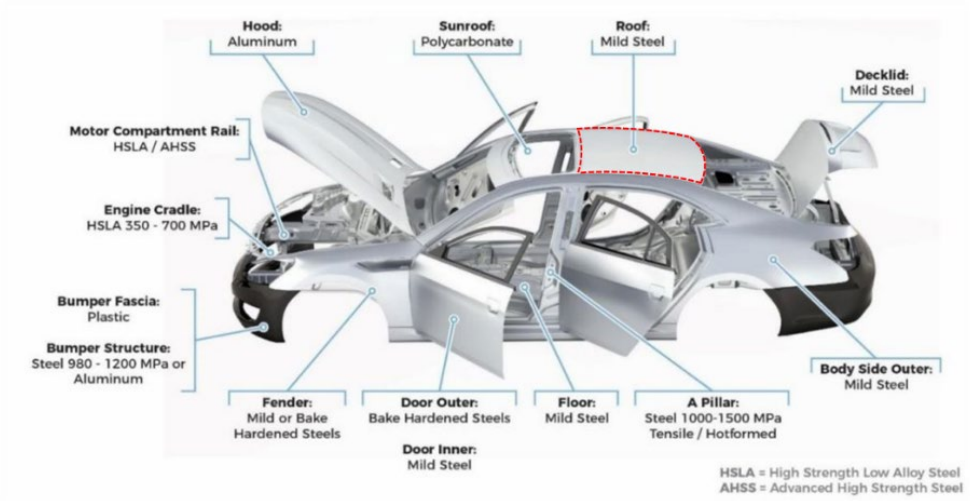

Fig. 2. Example of first use component (car roof) [28].

Flattening Experiments and Press Power Consumption Measurements

Considering the framework presented in the previous Section, tests were carried out to understand the feasibility of flattening curved parts and to test the influence of the main process parameters on the results of the flattening process. The press used for flattening experiments is a SACMI PH150. It is a double effect numerically controlled hydraulic press with maximum tonnage of 150 ton and heated dies (up to 600°C). The control system of the machine uses a pressure sensor applied to the hydraulic cylinder that is governing the press slide, which is in turn used to regulate the applied load. One linear encoder is mounted on the press slide and one on the extracting cylinder to control the vertical position of the punch. Pressure and position can be recorded as analogic signal by an external controller.

The parts to be flattened were obtained by shaping in controlled and repeatable conditions 0.8 mm thick virgin DC 04 sheets (EN 10130, 2006). The shaping process was performed with an Erichsen test machine imposing up to Erichsen Index (EI) equal to 6 mm. The flattening cycle, summarized in Fig. 3, is a sequence of different operations. First, the moving punch (represented in Fig. 3) moves fast (>10 mm/s) approaching the sample. Then, when the punch is close to the sample, the velocity of the piston is reduced to 1 mm/s and continued until the tonnage reaches a predefined set level. The vertical displacement continues at constant velocity until the press tonnage exceeds the set level, called dwell force (F_d). This force is reached when the sample is almost completely flattened. When the tonnage has reached the set value, the piston is held in position for a given dwell time (τ). After the dwell time, the tonnage is released, and the piston moves up.

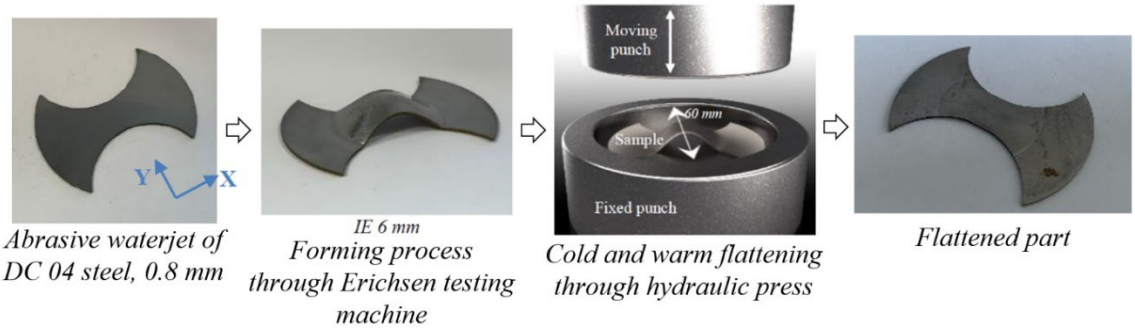

Fig. 3. Experimental procedure followed: shaping thin steel parts and then flattening through hydraulic press.

The main process parameters varied in the tests were: the pre-forming index *EI* (mm), the dwelling time τ (s), the punch and die temperatures T_T (°C), the dwelling force F_d (tons). The experiments showed that the best quality of the flattened part is achieved by warm flattening with short dwell time. Similar results can be achieved also by cold flattening. In general, flattening can be considered as a promising and effective process for recovering EoL panels.

The press power consumption has been measured under different conditions: during idle time, during flattening (considering different tool temperatures) and during the heating phase of the dies (with pump for oil recirculation turned off). Indeed, quantifying the energetic inputs of remanufacturing is fundamental to assess the environmental sustainability of the process and to understand the benefits with respect to conventional recycling by melting.

The press power consumed has been measured through LEM sensors, which can capture the current and voltage of the three phases. From those values, it is possible to compute the electric power absorbed by the machine. The sensors were mounted around the cables of the main power supply unit of the press, thus detecting all possible contributions of press energy consumption.

Results of the Press Power Measurements

The main results of the press power measurements are summarized in Table 1, while Fig. 4 shows the power consumed during one flattening cycle performed at room temperature. the measurements showed that keeping the dies at 160°C consumes around 1.9 kW. Instead, keeping the dies at 300°C requires on average 3.7 kW.

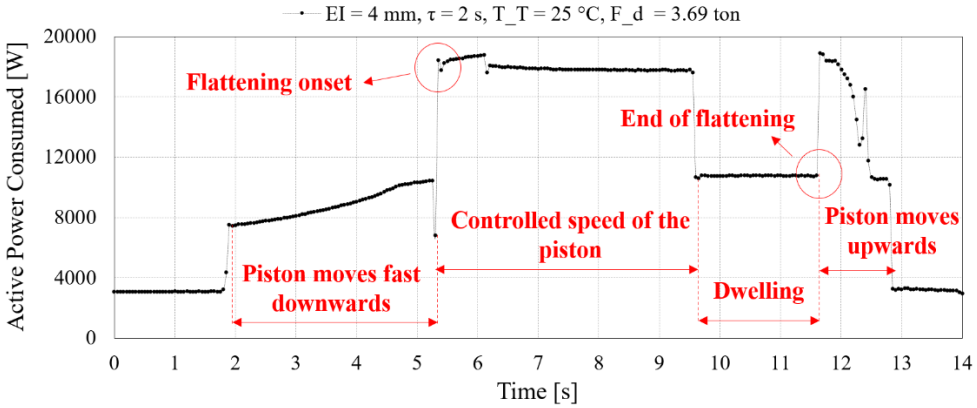

Fig. 4. Press power consumption during the flattening of a DC 04 specimen (0.8 mm) characterized by EI = 4 mm, τ = 2 s, T_T = 25 °C, F_d = 3.69 ton.

Table 1. Power consumption for different conditions tested.

Condition	Power consumption [W]	Duration
Idle phase, T_T = 25 °C	~ 3200	-
During dwelling, EI = 4 mm, T_T = 25 °C, F_d = 3.69 ton	~ 11000	Variable: 2 s or 60 s.
During dwelling, EI = 4 mm, T_T = 25 °C, F_d = 92.15 ton	~ 13000	Variable: 2 s or 60 s.
Heating dies, from 25 °C to 160 °C	~ 11000	≈ 25 min.
Dwelling, EI = 4 mm, T_T = 160 °C, F_d = 3.69 ton	~ 11500	60 s
Keep the dies at 160 °C (steady state)	~ 1900	-
Heating dies, from 160 °C to 300 °	~ 11000	≈ 30 min
Keep the dies at 300 °C (steady state)	~ 3700	-

Life-Cycle Assessment (LCA) of Remanufacturing a Car Roof

The experimental procedure presented in the previous Section is referred to a hydraulic press suited for flattening only parts inscribable in a circle with 6 mm diameter. Nevertheless, the measurements with LEM sensors were helpful to model the profile of power consumption of a press designed for flattening large panels (see Table 2), and to make reasonable hypotheses for setting up the LCA presented in the next Section.

In the framework of sustainable reuse of resources and materials, a LCA of the remanufacturing process was set up, focusing on the remanufacturing by flattening of two EoL panels, cut out of a car roof. In order to define the energetic inputs of flattening large and thin steel panels, the data reported in Table 2 have been used. These data refer to the technical performances of a hydraulic press designed and used exactly for the purpose of flattening sheet metals. The LCA is set-up with the aim of evaluating the embedded energy and the equivalent $kgCO_2$ emissions of the remanufacturing process chain and compare these values with the same indicators of:

- Sheets produced starting from virgin ore. According to a study performed by WorldSteel Association [29], the energy requirement for producing 1 kg or rolled steel (using a "cradle-to-gate" approach) is equivalent to 25.4 MJ, emitting approximately 2.35 $kgCO_2^{Eq}$. These values are close to others published by SSAB [30] and Arcelor Mittal [2].
- Sheets produced from EAF-based recycling plants, without the addition of DRI (Direct Reduced Iron) [31]. According to the work of Suer et al. the production of one kg of rolled steel is associated with a GWP = 0.74 $kgCO_2^{Eq}$ and a CED = 11 MJ.

Assumptions for Setting Up the LCA

- The two panels are extracted by means of an electric cutter from a car roof, which in turn is extracted from the chassis of the EoL car itself in 100 s. The power of the electric cutter is 1400 W. The cutting time of the panels from the roof is 360 s. The same cutter is used for both operations. These disassembly operations at the actual state are not employed by car recyclers, therefore they represent a crucial stage for the reshaping purposes presented. Furthermore, it is fundamental that the EoL panels are not damaged, thus becoming unrecoverable with this routine.
- The two flattened panels have a nominal area of 800x400 mm and 800x700 mm, a nominal thickness of 1 mm and total approximate weight of 6.9 kg. The entire car roof cut from the chassis of the car has a weight of 21 kg. The data presented were directly measured and are referred to a roof extracted from EoL FIAT Punto.
- The portion of the roof not used during flattening is assumed to follow the same recycling path that would have and EoL car, i.e. shredding, magnetic separation, melting in EAF, casting and

rolling. The LCA includes the stage of painting removal as well: for the mechanical de-coating phase, technical data of a commercial sheet metal brusher have been used, whose average power consumption is 4000 W and the operative time for brushing two panels is approximately 280 s. Considering a thickness of paint of 100 μm and the nominal area of the 2 panels (both sides) and considering the average automotive paint density (850 kg/m^3), the amount of paint removed by the brusher is around 150 g. This mass is assumed to be treated in an incineration plant.

- In the analysis, the impacts associated to metal scraps in the second station (namely the roof scrap, see Fig. 5) are not take into account because the study wants to assess the environmental benefits of recycling by reshaping a portion of the roof instead of smelting the same mass (i.e. 6.9 kg). What is not "re-shapable" for a second life by flattening is, in any case, assumed to follow the conventional recycling framework.
- For the calculation of the energy for flattening, Fig. 6 with the relative information reported were used. The analysis is not considering the wear of the various components such as press dies.

Table 2. Technical information of the hydraulic press used for flattening thin sheet metal panels.

Parameter	Value
Max tonnage	420 ton
Max tool temperature	300 °C
Maximum oil pressure	210 bar
Max pump throughput	70 L/min
Oil reservoir volume	500 L
Diameter pressing piston	505 mm
Max power principal electric motor (pump)	15 kW (30 A)
Max power heating system upper die	9.6 kW (14 A)
Max power heating system lower die	9.6 kW (14 A)

Hydraulic press designed for flattening sheet metal panels. Courtesy of Pezzato s.r.l.

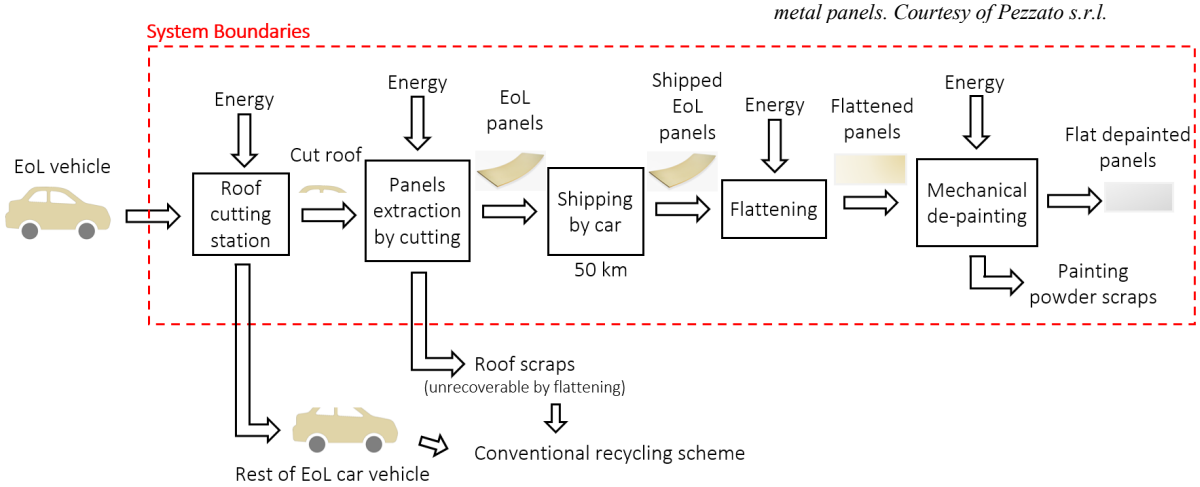

Fig. 5. Definition of the system boundary and flattening process chain with all inputs and outputs.

For determining the energetic input of the press for one flattening cycle, the following assumptions have been used: the press works for 8 hours/day; during the first hour, the press is consuming energy only for heating the dies (for 60 minutes at a power of 20 kW). The other 7

hours the press is performing flattening cycles. During this period, an average power consumption of 10 kW is assumed considering the contribution of idle stage (set-up), flattening and keeping the dies in temperature. Consequently, the total energy consumed is 90 kWh/day. Assuming the duration of one flattening cycle equal to 50s and the available working time, 504 parts per day can be flattened. Each cycle is consuming ≈ 0.18 kWh. For processing two panels, as in this case, a total energy of 0.36 kWh is absorbed by the hydraulic press. The software used for performing the LCA is SimaPro, with Ecoinvent 3 database.

Table 3. Data used for the LCA.

Stage	Input energy [kWh]	Input material	Output material
Roof cutting station	0.038	Dismantled EoL car	Cut roof (21 kg) + Rest of EoL car vehicle*
Extraction of two EoL panels by cutting the roof	0.14	Cut roof (21 kg)	2 bent EoL panels (6.9 kg) + Roof scraps* (14.1 kg)
Shipping by road vehicle of the 2 panels – 50 km by lorry (> 32 ton – EUR 4)	-	2 bent EoL panels (6.9 kg)	2 transported bent EoL panels (6.9 kg)
Flattening 2 panels (2 production cycles)	0.36	2 transported bent EoL panels (6.9 kg)	2 flattened panels (6.9 kg)
Mechanical de-painting of 2 panels (both sides)	0.31	2 flattened panels (6.9 kg)	2 depainted panels (6.9 kg) + paint scrap powder**

* Subjected to conventional recycling by melting, impacts not included in the LCA.
** EoL modelled through landfill incineration.

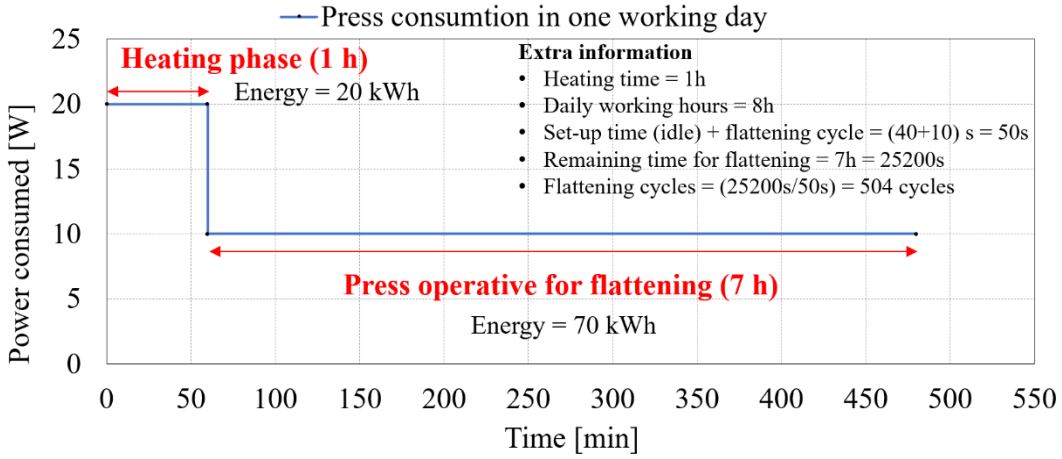

Fig. 6. Press consumption with additional information.

Results of the LCA and Discussion

The main results of the LCA analysis are summarized in Fig. 8, Fig. 7 and Table 4. Data in Table 4 are normalized with respect to 1 kg of flattened automotive steel panel (1 mm thick) or rolled virgin steel. The table highlights the benefits in terms of CO_2 emissions and energy potentially achievable if the proposed reshaping strategy is adopted. The values of Δ_{GWP100} and Δ_{CED} are computed with respect to the case of remanufactured panels.

The left-hand side of Fig. 7 shows clearly that the biggest impacts in terms of CO_2 emissions are related to the painting scrap incineration and electric consumption of flattening (the emissions are computed according to the Italian national energetic mix). The right-hand side of Fig. 7 shows that flattening and de-coating stage have the biggest contributions in energy consumption. Roof cutting station and transportation have negligible impacts, as visible in Fig. 8.

Table 4. Environmental benefits obtained by reshaping EoL panels through flattening.

	GWP100 kg CO_2^{Eq}/kg_{steel}	**CED*** MJ/ kg_{steel}	Δ_{GWP100} kg CO_2^{Eq}/kg_{steel}	Δ_{CED} MJ/ kg_{steel}
Conventional process**	2.35	25.4	≈ **2.2**	≈ **24**
EAF routine + coil production***	0.74	11	≈ **0.6**	≈ **9.6**
Reshaping by flattening***	0.144	1.42	-	-

* CED = Cumulative energy demand.
** Data from literature – Production of steel coils with "cradle-to-gate" approach. [29]
*** Data from literature – Production of steel coils from EAF-based recycling steel production. [31]
**** Modelled in SimaPro, including landfill incineration of the paint.

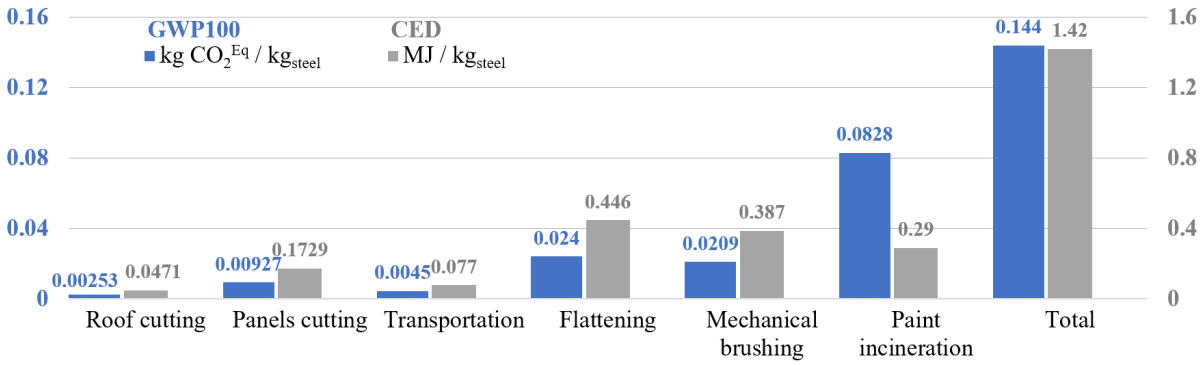

Fig. 8. Different contributions of the different stations in the flattening process chain proposed.

Summary

The work demonstrated different important conclusions, listed below:

- From a technical perspective, flattening is a viable solution for giving a second life to panels deriving from a previous usage (for instance automotive car bodies). The larger the area of the panels to be flattened, the higher the tonnage required by the press, but the higher the "material efficiency" recovered.
- The LEM sensors used for measuring the press power absorption allowed to quantify easily different contributions of energy consumption, such as: moving the piston, idle phases, heating up the dies, keeping the dies in temperature and performing flattening.
- The LCA analysis demonstrates to be a helpful tool to quantify the environmental impacts of all the stages of the flattening process chain. The study showed the tremendous benefits in terms of CO_2^{Eq} emissions and energy that could be potentially achieved by implementing reshaping and remanufacturing strategy of sheet metals.

The implementation of such process chain, considering the huge volumes of EoL cars, could be a potential strategy for reusing efficiently sheet metals in a circular economy business model for automotive car makers or car dismantlers. Enhancing material efficiency through remanufacturing and reshaping is therefore a solution for boosting the ecological transition and meeting the future targets of net zero CO_2 emissions. Lastly, it is important to mention that flattening shaped and formed sheet metals is not always feasible, especially for EoL components with high strains and thinning levels.

Keywords: Recycling, Aluminium, Friction-Induced, Energy Efficiency

Abstract. In order to reduce global energy consumption in production and industry along with the associated CO2 emissions, existing resources must be used more efficiently. This includes the energy-efficient and comprehensive recycling of a wide range of metals. Especially for the production of aluminium, there is a large potential for saving energy using efficient recycling processes. With regard to the recycling of aluminium studies have shown that solid-state recycling processes are significantly more efficient considering the used energy and resources compared to the conventional, smelting-metallurgical recycling process. In this paper, the direct and energy-efficient friction-induced recycling process (FIRP) based on the conform process is further described and analysed in terms of the temperature-property relationships. For this purpose, the influence of the processing temperature on the microstructure and properties of the recycled semi-finished products is investigated using the toll system that enables an ECAP forming. Specific sections of the (in theory) infinite, recycled semi-finished product are taken and analysed at different process temperatures of the solid state recycling process. Based on these sections, the properties in terms of mechanical hardness, strength, ductility and grain size are analysed and a degressive relationship between process temperature and mechanical hardness up to a temperature of 270 °C can be shown. Applying the Hall-Petch relationship, it is analysed whether there is a correlation between the strength and the microstructure in the form of the grain size.

Introduction

In order to achieve the climate targets set in the Federal Republic of Germany for 2030 with regard to the CO2 emission reduction, emissions must be reduced in all sectors [1]. Aluminium is used as a construction material in a wide application range. Examples of aluminium applications are building facades or the use in the area of vehicles for lightweight construction. In the automotive sector, aluminium is used for lightweight construction to substitute components that are usually made of steel. Due to the low density of aluminium, the mass of the vehicle in operation can be reduced, thus saving emissions. Other properties that further expand the range of applications for aluminium are its good corrosion resistance and the (theoretical) possibility of infinite recycling [2]. However, due to the high emissions, primary aluminium production represents one of the most energy-intensive production processes. The production of one kilogram of aluminium primarily produced from bauxite requires 155.9 MJ of energy. This amount of energy is determined under the assumption of a parity of the underlying energy supply from coal and hydropower plants [3,4]. This value tends to be underestimated due to developments in recent years. Primary aluminium production has shifted significantly in recent years, so that by 2020 most primary aluminium was produced in China [5,6]. At the same time, the share of coal-fired power plants in total electricity generation in China has increased, so that it is more than 60% between 2015 and 2020 [7]. Also not taken into account in such energy balances are various expenses such as the mining and transportation of bauxite as well as aluminium and its precursors. In addition to the high energy consumption, primary aluminium production has a strong impact on the environment and nature due to the mining of bauxite.

One possibility for recycling old as well as new scrap is the secondary production process, which describes the conventional recycling strategy. Heavily contaminated scrap usually has to be freed from oils, greases and other impurities. The processed scrap is then fed into a melting furnace (melting temperature of aluminium is about T_m = 660 °C), melted down and subsequently cast into ingots. These ingots are usually processed into profiles or similar using further processes such as an extrusion process [2]. The amount of energy required for the conventional recycling process is significantly lower than the energy required for the primary manufacturing process. Nevertheless, primary aluminium must be included in the production process to some extent, which significantly increases the total energy requirement. If, in addition to the energy required to melt the aluminium, the effort required to dispose of the resulting salt slag is also included in an energy balance, the energy requirement is around 17.7 MJ/kg [8].

Despite the already significantly improved energy balance of the conventionally recycling strategy, there are extensive efforts to further optimize the aluminium recycling process. This is being done both from an energy point of view in the form of a further reduction in the amount of energy used and in an effort to avoid the creation of environmentally harmful salt slag. One way to reduce the amount of energy required is a lower processing temperature in the recycling process [9]. In case the aluminium scrap does not need to be heated to the melting temperature and can be processed at significantly lower temperatures, energy can be saved. Due to this lower processing temperature compared to the melting temperature, solid-state recycling processes are suitable here [10]. An example of such a process is the recycling of pre-compacted aluminium chips using a conventional extrusion process. Due to the fact that large quantities of alloy-pure and uniform aluminium chips are often available from the machining sector, more studies have been conducted in the field of recycling aluminium chips using solid-state recycling processes in recent years. Two advantages of this recycling approach compared to the conventional, melting-metallurgical recycling process of aluminium chips are the significantly lower amount of energy and the saving of material, which is otherwise disposed of in the form of oxides in the salt slag. Furthermore, solid-state recycling processes are usually a direct recycling process. This implies that the produced goods are not in the form of raw shapes such as ingots, but can be directly produced as user-specific geometry such as complex profiles [11]. The basis for achieving good properties comparable to conventionally manufactured products is a major degree of deformation of the parts to be recycled at high temperature at the same time. Only in this way the natural and very hard oxide layer on the aluminium can be destroyed and a high bonding strength between the individual particles be achieved [12]. Friction-induced solid state recycling processes include friction stir extrusion and friction stir consolidation [13]. The processing of aluminium chips with the friction stir extrusion process show that the temperature is a very strong influencing variable of the process forces as well as the properties of the recycled products [14]. Products with a full density and good mechanical properties can be produced, but the discontinuity is a limitation for the process [15].
Another solid-state process for recycling aluminium chips has recently been investigated at the Department of Forming and Machining Technology (LUF) at Paderborn University. Compared to the recycling process based on conventional extrusion, the friction-induced recycling process (FIRP) provides the advantage that profiles can be produced in unlimited lengths. In previous investigations, it was shown that a full profile with good mechanical properties of the wrought alloy EN AW-6060 could be produced in the stationary production phase of the friction-induced recycling process. Hardness measurements show a homogeneous distribution of properties over the entire cross-sectional area. The profiles produced show significant grain refinement within the microstructure compared to reference wires. Also for this recycling process a reduction of energy input could be achieved compared to secondary aluminium production [16,17].

The central motivation for the investigations presented here on the continuous and friction-induced recycling process is the investigation of the process parameters and influencing variables

necessary for solid state recycling. The friction induced recycling process is well suited for these parameter studies due to the steady state nature of the process. Within this stationary state, the key parameters of temperature, torque or extrusion pressure as well as the processed mass flow rate show constant characteristic values. A detailed analysis of the conditions required for the production of profiles is well possible in the steady state of the friction-induced process and is investigated in this publication as part of the determination of the microstructure properties correlation.

Processing Principle and Materials

The machine set up shown in Fig. 1, a) provides the basis for the investigations concerning the friction-induced recycling process described in the following. By using the here presented setup a wide variety of aluminium scrap, in terms of geometric size, can be processed. Therefore the material to be recycled is fed into the groove (6x7 mm) of the rotating wheel at a constant mass flow rate. The wheel is fixed on the output shaft of a powerful geared drive, which rotates at a constant rotational speed in the range between n = 6 - 11 rpm for the investigations described in this paper. A tool insert continuously reduces the cross-sectional area of the wheel groove by engaging in the groove of the wheel. This steadily compacts the aluminium chips, which initially have a very low bulk density. While the aluminium particles rotate within the wheel groove, they are compressed and plasticised, so that at the end the density of the aluminium is increased to ρ = 2.7 g/cm^3. Following the quarter turn, the entire cross-sectional area of the wheel is filled by a counterholder which deflects the material. The additional deformation of the deflection further breaks up the oxide layers of the material. Subsequently, the material is extruded through a shaping die in a manner analogous to extrusion.

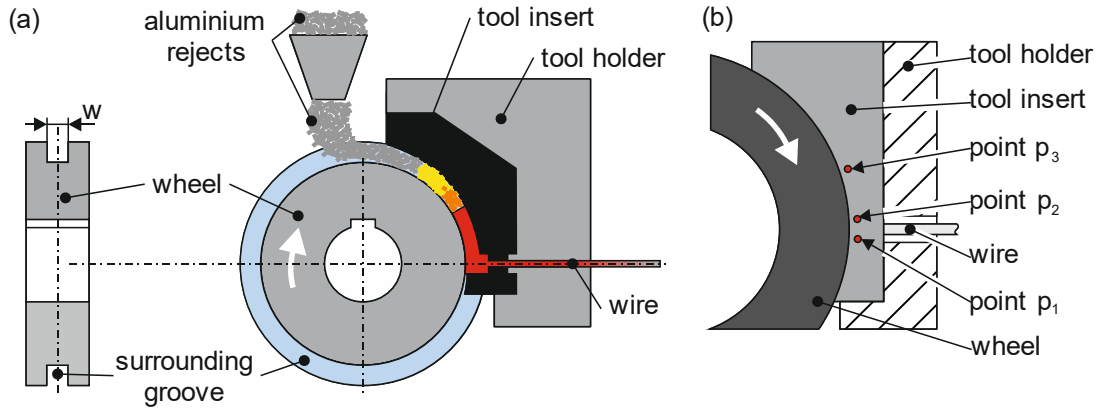

Fig. 1. Set up for the friction-induced recycling process. (a) Tool system. (b) Illustration of the temperature measuring points.

Central indicators of the friction-induced recycling process are the temperature as well as the torque applied by the gear motor (SIMOGEAR parallel shaft gear motor, Siemens AG). The torque is determined from an average value of the electrical power consumption of the frequency converter (SINAMICS G120, Siemens AG). The direct temperature measurement inside the extrusion channel to determine the true material temperature is very difficult. Instead, a tactile measuring principle is used to record the real temperature on the outside of the die insert at different measuring points depicted in Fig. 1, b). Type K thermocouples (G/G-24-KK-IEC, Therma Thermofühler GmbH) and an MX440A measuring amplifier (Hottinger Brüel & Kjaer GmbH) are used for this purpose. In validation tests it has been proven that this type of temperature measurement approximates the actual forming or extrusion temperature well. This could be demonstrated with the measurement of the temperature a few millimetres in front of the extrusion

channel as well as the exit temperature of the recycled wire, which corresponds to the temperature measured on the outside at points p_1 and p_2 in the stationary state.

Irrespective of the possibility of processing a wide variety of aluminium scrap, only aluminium chips are used for the investigations in this paper. The reason for this is the fact that these can be produced specifically under constant cutting conditions. This results in a constant chip size, which is necessary for setting a constant mass flow in the feed and thus also constant test conditions. The cutting conditions used for the production of the aluminium chips of the alloy EN AW-6060 (T66) as well as the resulting chip geometry are given in Table 1.

Table 1. Cutting conditions and resulting geometry of the chips used.

Machining parameters		Chip Size (Material EN AW-6060)	
Cutting speed	v_c = 1425 m/min	Raw Material	plate 300x200x20 mm
Feed	f = 0.2 mm	Chip length	$l_c \approx 1.9 \pm 0.12$ mm
Cutting depth	a_p = 2 mm	Chip width	$w_c \approx 1.5 \pm 0.1$ mm
Cutting width	a_e = 0.5 mm	Chip thickness	$t_c \approx 0.095 \pm 0.007$ mm

Results and Discussion

For a wide industrial application, the productivity of a process is an important decision parameter for the operational application in addition to the economic efficiency. The rotational speed of n = 6 rpm used in previous investigations results in a lower discharge and heating rate compared to conventional extrusion. This is to be improved in a first step by increasing the wheel rotational speed to n = 11 rpm in combination with a proportional increase in the filling rate. With the relationship described above, the discharge rate can be almost doubled. Fig. 2 shows the measured values of temperature and torque recorded in a test with n = 11 rpm. The torque is calculated from the electrical power consumption of the frequency inverter and represents an average value due to natural fluctuations. The three measuring points relevant for the temperature measurement are shown in Fig. 1, b) above. Points p_1 and p_2 are located below and above the extrusion channel, respectively. Measurement point p_3 is located further up on the tool, which can be seen as an explanation for the consistently lower temperatures compared to the other two measurement points.

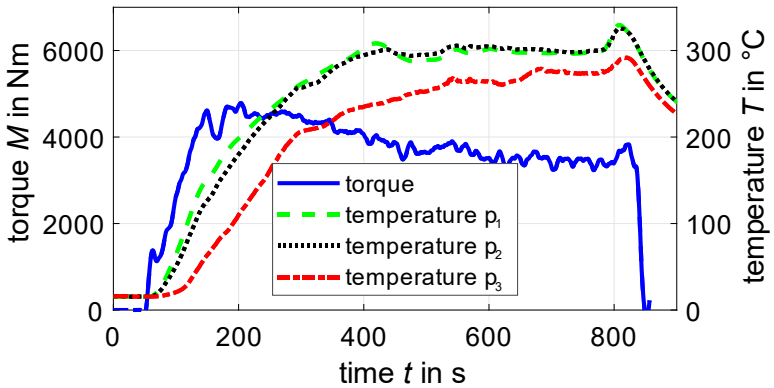

Fig. 2. Torque and tool/process temperatures for different measuring points.

At the beginning of the process (after approx. 45 seconds), the torque rises sharply when the gear motor is switched on and the chips are directly fed in, and initially remains at a high plateau. Analogous to the torque, the temperature readings also initially show a sharp increase. After a total time of approx. 435 seconds, a steady state is reached at nearly T = 300 °C with respect to the temperature values of measuring points p_1 and p_2. From the time the stationary process state is

reached the temperatures of these measuring points remain constant except for a slight increase when chip filling stops at the end of the process. With a delay of approx. 160 seconds, the torque also reaches a stationary state at $M = 3450$ Nm. In a direct comparison of the results presented here for the high rotational speed of $n = 11$ rpm compared to the previously published results with $n = 6$ rpm, there is a clear increase in the heating rate, so that the steady state is reached significantly earlier.

Temperature property correlation.

The aim of the investigations presented here is to describe the relationship between the mechanical strength and the temperature that prevails in the process. Due to the homogeneous temperature distribution within the die insert, the process temperature is equated with the temperature measured at the first or second point on the outside. To illustrate the influence of different rotational speeds (n = 6, 8, 10, 11 rpm) on the temperature balance as well as the mechanical properties, investigations and measurements have been carried out at different rotational speeds which shows macroscopic good properties of the recycled wires. For all four rotational speeds investigated, the process temperature is assigned to a specific location on the extruded wire by means of a time-dependent marker. This enables a precise analysis of the individual test points after the extrusion process to reveal the correlations between rotational speed, temperature and mechanical properties. The temperature was determined for all three rotational speeds at point p_1. Depending on the rotational speed and thus also the discharge rate, between 6 and 22 test points were recorded for each rotational speed. Even in the instationary process state for low temperatures < 200 °C, a homogeneous wire is produced with only minor inhomogeneities on the surface (see Fig. 3, a). Following the test, the wires were cut at the previously defined test points, embedded and subsequently subjected to a hardness test. The measured value of each test point represents the average of five individual measurements on the head surface (see Fig. 3, a) to counteract and compensate any uncertainties. Fig. 3, b shows these average values for the test points of all four rotational speeds (marked in colour) along with the temperature assigned to the respective point. For all four rotational speeds considered, the hardness decreases in the instationary start up phase as the temperature increases until the temperature of 270 °C is reached. In general, the original strength of the starting material is significantly reduced.

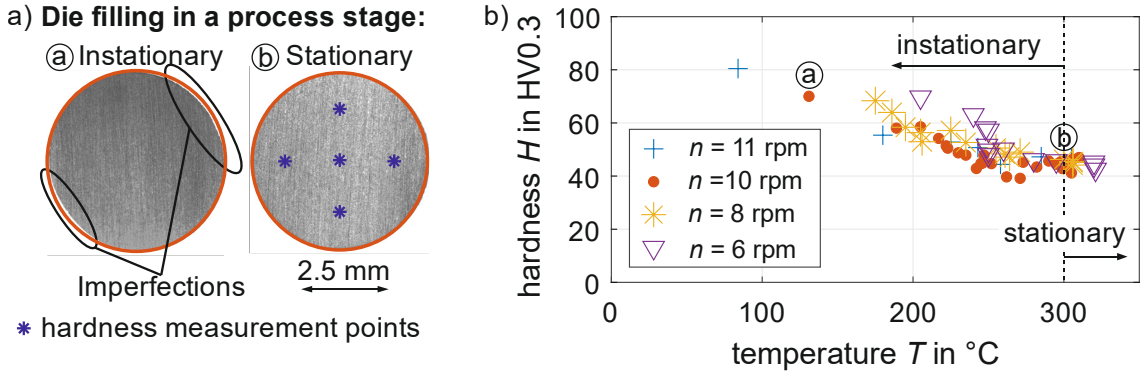

Fig. 3. Temperature-dependent development in, a) die filling, b) hardness as a function of temperature T and rotational speed n.

The mechanical hardness of the tubes used to machine the chips is about $H = 90$ HV 0.3 (in a T66 condition). The application of temperature in the extrusion process significantly reduces the strength or measured hardness due to recrystallisation. This reduction in the initial strength of the material due to the introduction of temperature has also been observed in comparable processes such as friction spinning. In the context of friction spinning, which also obtains the temperature from the friction between the forming tool and the workpiece, similar hardness values of between $H = 40$ - 50 HV 1 are obtained following the process [18].

Considering the temperature range above 270°C, which represents the steady state, it first becomes apparent that, due to the only slight temperature change, many measuring points show almost identical hardness values. This confirms the previously made assumption of constant properties within the steady state. Due to the fact that the stationary process state has been reached, no further heating will take place in the natural process. Regarding the influence of the rotational speed on the hardness, it can be summarised that in the stationary state of the temperature range considered the hardness is not influenced by the rotational speed. A check of the behaviour for temperatures above 310°C measured on the outside of the die must therefore be carried out in future investigations at higher rotational speeds, using modified tools or with the aid of heating cartridges.

One requirement for the use of products made from recycled materials is a consistent and reliable workpiece quality. In the friction-induced recycling process which is investigated in this paper, a steady state is established when a defined temperature level (for the above described trial with n = 11 rpm the stationary temperature is nearly 300°C) is reached. In the following, the extent to which the workpiece quality is consistent from the time the steady state is reached is analysed. The hardness distribution on the cross-sectional area of wire sections in the steady state of the friction-induced extrusion process of the high rotational speed of n = 11 rpm is analysed. Six wire sections from l = 2.5 m to l = 5 m were tested. It can be shown that the hardness values on the head surface vary only slightly around the respective mean value of the section. The standard deviation of the respective sections must therefore also be compared to the reference wire. The mean value of all 78 measurement points is H = 47.8 HV 0.3 with a standard deviation of SD = 2 HV 0.3. The consideration of the results of tensile tests also show a uniform average tensile strength of R_m = 155 MPa with a standard deviation of SD = 4.5 MPa. From these measurements, it can be concluded that friction-induced extrusion can be used to produce semi-finished products within the steady state that exhibit a homogeneous distribution of the mechanical property of hardness and tensile strength. The hardness and tensile strength of the recycled samples are comparable to the properties of semi-finished aluminium products of the alloy EN AW-6060 in the solution-annealed and softened T4 condition according to EN 755-2:2016. The softening can be attributed to the dynamic recovery and recrystallisation caused by temperature and deformation.

Microstructure Strength Correlation.

The decreasing strength of the recycled wires with increasing temperature will be explained in the following based on an analysis of the microstructure (grain size) on the cross-sectional and the longitudinal-sectional area surface of the wires. For this purpose, four sections produced at different temperatures, at the rotational speed of n = 10 rpm are embedded and electropolished for each area. The aim of this is to observe the microstructure and analyse the grain size. Fig. 4 shows the development of the microstructure and thus also of the grain size for four different test points, each at a different temperature.

The first test points (I) were generated at a temperature of T_1 ≈247°C and shows small, uniformly distributed grains with an average grain size of $d_{k,1} \approx 3.5$ µm on the cross-sectional and $d_{k,1} \approx 3.9$ µm on the longitudinal-sectional area. For the second as well as the third test point, the grain size increases with the temperature. This is valid for both the cross-sectional and the longitudinal-sectional area independent of smaller deviations between the two different areas. For the highest temperature considered of $T_4 \approx 310$°C, an average grain size of $d_{k,4} \approx 6{,}3$ µm on the cross-sectional and $d_{k,4} \approx 6{,}4$ µm on the longitudinal-sectional area can be measured. From these results, a clear progressive relationship between temperature and grain size can be determined.

The reduced hardness and growing grain size with increasing process temperature can be described by the microstructure restructuring due to recrystallisation in agreement with the Hall Petch relationship. In general, a dependence of the mechanical properties in terms of a hardening or softening can be made as a function on the grain size. This relationship is described by the Hall-

Petch equation. The yield strength or 0.2% yield point σ_y is determined on the basis of the material constant σ_0 which take the required stress for dislocation movement into account and a constant of yielding K as well as the average grain size d according to Eq. 1 [19,20].

$$\sigma_y = \sigma_0 + K \cdot d^{-1/2} \quad (1)$$

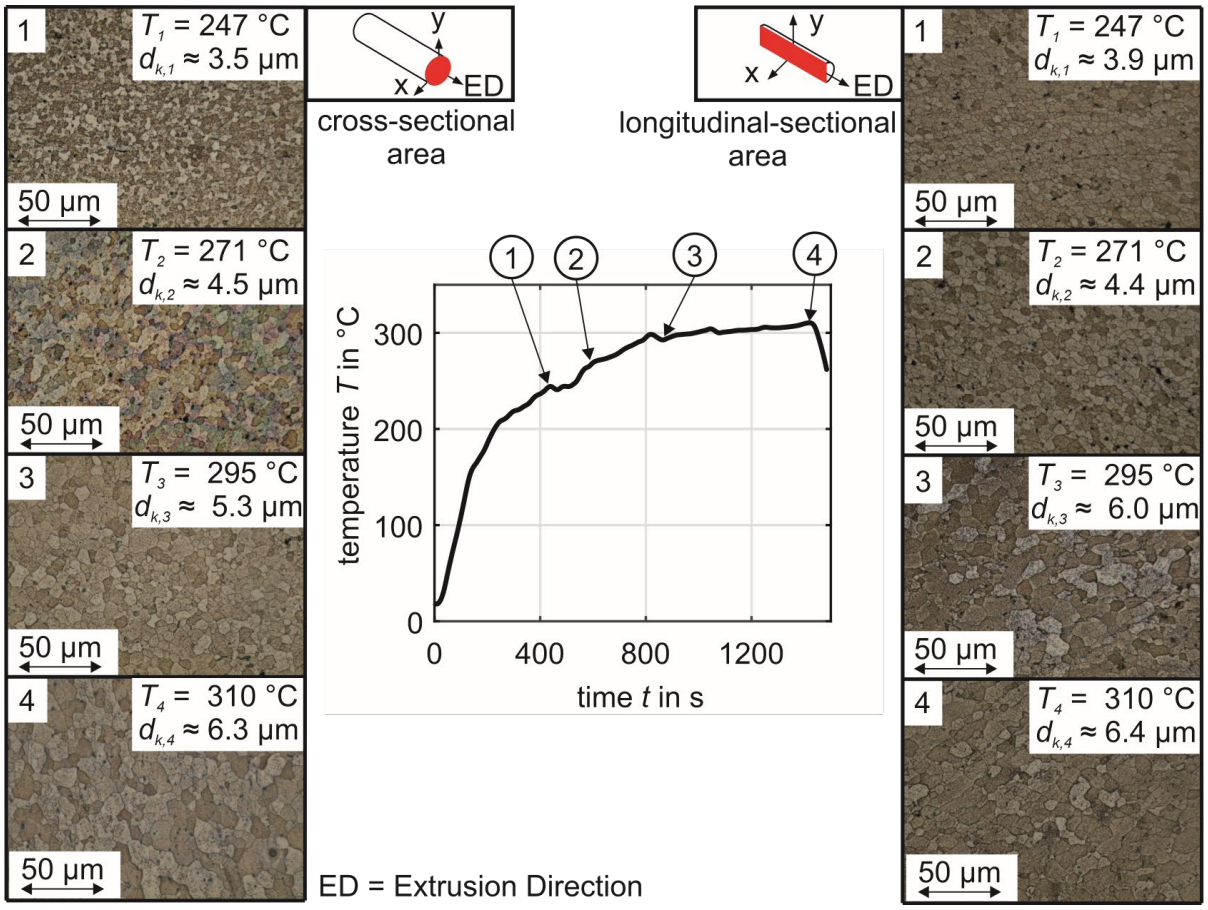

Fig. 4. Change in microstructure of wires produced at 10 rpm as a result of temperature changes measured on the outside of the tool.

As previously described, the grain size changes as a function of temperature in the friction-induced recycling process for both considered intersections. In order to verify the validity of the Hall-Petch relationship for this process, tensile tests of the individual sections are carried out. The results of the tensile tests in comparison to the temperature and the grain size are show in Table 2.

Table 2. Change in temperature, grain size, and yield strength.

Point of investigation	Temperature T in °C	Grain Size cross-sectional area d in µm	Grain Size longitudinal-section area d in µm	yield strength σ_y in MPa
1	247	3.5	3.9	104
2	271	4.5	4.4	98
3	295	5.3	6.0	95
4	310	6.3	6.4	93

Due to the steady increase in temperature, the tensile tests for the four points described above represent a temperature interval of ± 5°C around those used to determine the grain size. Each result of the yield strength shown in Figure 6 represents the average of two to four measurements (depending on availability). For the cross-sectional area, the constants are determined to be σ_0 = 59.8 MPa as well as K = 82 MPa µm$^{1/2}$ with a high coefficient of determination of R^2 = 0.988, and for the longitudinal-section area, the constants are determined to be σ_0 = 59.5 MPa as well as K = 85 MPa µm$^{1/2}$ with a coefficient of determination of R^2 = 0.9. In studies on the microstructural changes of equal channel angular pressing, a constant of K = 114.3 MPa µm$^{1/2}$ has been determined for the alloy EN AW-6060, which is also investigated in this paper. For the nearly pure EN AW-1100, a slightly lower constant of K = 105 MPa µm$^{1/2}$ is determined [20]. Other sources calculate K = 65 MPa µm$^{1/2}$ [21] or K = 70 MPa µm$^{1/2}$ [22] for the pure aluminium. The values investigated within the scope of this paper shows certain, but not too large deviations from the literature values. However, this can also be attributed to the smaller number of study points considered (n = 4). In general, it can be stated that both the results obtained from the experimental work in terms of yield strength and grain size correlate according to the Hall-Petch relationship and the strength mechanisms can be attributed to the change in grain sizes. A direct comparison of the friction-induced recycling process with similar forming processes for the production of semi-finished products shows that (when using the tool system of the friction-induced recycling process described here) a lower process temperature occurs compared to hot extrusion. This, coupled with the significantly shorter contact time of the process temperature in the recycling process, can be used as an explanation for the significantly smaller grain size of the recycled profiles compared to profiles produced with the hot extrusion process [23,24].

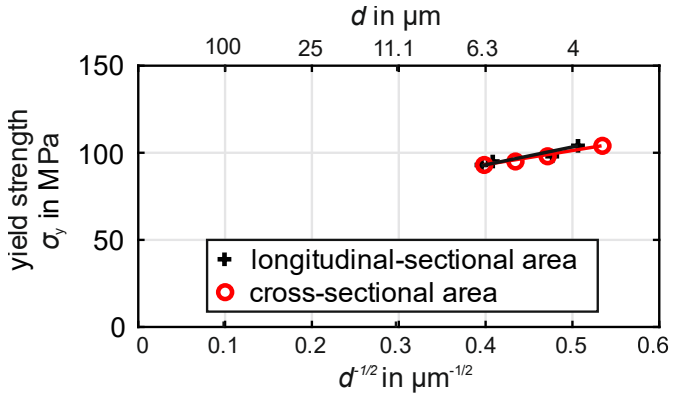

Fig. 6. Dependence of the mechanical strength (yield strength) on the grain size.

Summary
This paper presents further investigations on the energy-efficient and resource-saving friction-induced recycling process. Depending on the tool system used, a steady-state process condition is established after the heating phase, which was demonstrated by constant hardness values in the temperature range above 270°C. Further investigations also show a dependence of the microstructure in the form of the grain size as well as the strength in terms of the yield strength, which are modelled and represented using the Hall-Petch relationship. Considering the best practise in developing a resource and energy efficient recycling process the rotational speed of the wheel does not affect the hardness of the recycled profiles in the stationary production phase. Using higher rotational speeds can be useful to increase the output while recycling particles/ chips with a low density. First fundamental research shows the possibility of raising the processing temperature by increasing the extrusion channel length of the tooling system due to the increase in frictional surface considering the stationary production phase. These and further possibilities (e.g. modification in extrusion ratio) to affect the process temperature and mechanical properties of the products will be the aim of future investigations.

Keywords: Sheet Metal Forming, Sustainability, Wooden Tools, Flexibility, Mass Customization

Abstract. Conventional, dies are manufactured subtractive for sheet metal forming. Beside the forming process, high tooling costs, material exertion and energy consumption, the die production offers chances for economic improvements. Especially, individualization and mass customization for small batch series require sustainable low-cost tooling approaches, where sustainable advances through biologicalization may offer new possibilities. In this work, sheet metal forming tools are manufactured by laminated black locust dies to reduce the overall ecological impact. The deformation and wearing behavior of the wooden tools is investigated during a drawing operation for low batch size of an automotive conventional sheet material.

Introduction

Following the Kyoto Protocol, the Paris Agreement declared and signed by 197 nations clearly postulate the goal to limit the global human made temperature rise by 1.5°C [1]. To ensure this, more sustainable approaches in all areas (e.g., production, infrastructure, food) are required to reduce the manmade ecological impact. On the other hand, a paradigm change from economy of scale to flexibility and customization in any production and consumer industry continuously increasing the demand for highly individualized mass customization of small batch sizes [2]. To enable flexibility in metal forming under the geo-political restrictions, new approaches are required to reconcile both goals in an increased globalization and price competition [3].

Even though flexibility is intrinsic for generic forming tools (e.g., freeform bending), it may be increased via agile or smart production systems [4]. On the other hand, shape-related tools in forming applications (e.g., rotary-draw-bending, deep drawing) require more resources when aiming for mass customization and individualization, since there is typically just one tooling form for each desired part geometry. Shape-related tooling approaches produced by additive manufacturing can reduce the base material consumption for customized forming tools but result in high energy consumption during the additive tooling process. Whereas sheet metal forming processes are often layout for high batch volume production, an individualized low batch size mass customization does need to fit the economic restrictions of the production process [5]. Biologicalization may offer an alternative approach for higher flexibility in metal forming, particularly when aiming for small batch size production. Biologicalization has been defined as "*The use and integration of biological and bio-inspired principles, materials, functions, structures and resources for intelligent and sustainable manufacturing technologies and systems with the aim of achieving their full potential."[2].* When Potting et. al postulated the circular economy in 2017, they defined 9R-strategies to layout a more sustainable production scheme from linear to circular economy [6]. Within the 9R-strategies there are several approaches to reduce natural resource

consumption and environmental pressure. When combining the 9R-strategies with biologicalization this reveals a potential for sustainable manufacturing technologies and systems.

Since there is no suitable and economically approved technique to ensure individualized and flexible small batch size production in deep drawing [7], further investigations have to be proceeded. This study reveals a biobased approach following alternative tooling approaches by additive manufacturing [5,6]. The performance of composite structures from black locust (robinia pseudoacacia) tools for sheet metal forming is evaluated experimentally based on the rubber pad forming process.

Literature Review

In sheet metal forming, deep drawing is a common used forming process, where blanks are peripheral restrained by blankholder units and radially drawn into a forming die (cavity) by a punch [10]. Deep drawing is a forming operation where material flow is allowed under the blankholder, aiming for constant material thickness, whereas stretch forming results in a thickness change [11,12]. Since both production methods typically aiming for mass size production, grey cast tooling molds with post-mill shaping are the conventional way of manufacturing [13]. The performance of drawing tools is mainly determined by the tool wear behaviour on highly stressed areas (radii, cavity inlets). Depending on the lot size, sheet material (hardness, thickness and strength), desired part surface quality, surface treatments and lubricants must be considered during tool design [14]. Rubber Pad forming (RPF), a specific deep drawing process, is widely used for automotive and aerospace applications, where one of the form-shaping tools is replaced by a rubber pad (Fig. 1). Advantages, compared to a conventional deep drawing process which consist at least of two complementary tools, can be stated in one flexible pad alignment for different shape geometries, high part surface quality, elimination in misalignment of tools, low tooling costs, no additional lubrication, avoidance of galling on the sheet metal and friction defined specific geometries [15,16]. Despite the benefits, a limited lifetime of the flexible pads, higher production cycle times and higher necessary press capacities due to the energy loss are the drawbacks of this technique [17]. RPF reveals economic and technological advantages for small batch size production [18], which makes it suitable when aiming for higher forming flexibility and mass customization. In Addition to this, the substitution of metal-based tooling materials through biologicalization may improve the ecological value of the process, when renewable tooling materials could be used for in a suitable process window.

Related Research

Higher product individualization, mass customization and changing consumer requirements regarding technical applications, lead to increasing derivatives in all production sectors. To ensure these demands without contravening geo-political restrictions, alternative approaches in

manufacturing are inevitable. Biologicalization and alternative equivalents are auspicious odds to cover the demands of the present production era.

Additive manufacturing (AM) as one of the major innovations in individualized mass customization and production offers a wide range of applications to substitute conventional manufacturing systems [7,19]. AM offers the opportunity to adapt optimized structures and to manufacture them precise without surplus material [20]. In manufacturing, AM was successfully implemented as tooling material e.g., sheet metal forming [8,9,21,22].

Along AM, biologicalization is a suitable mechanism to adapt nature based optimization and material range to sustainable manufacturing systems [2]. [23] studied the performance of wooden based tooling material for a deep drawing process in a feasibility study. The manufactured wooden based forming tools glued together of 4 mm black locust (BL) sheets. The investigated a good performance on low batch size (<500 parts) for radii greater 5 mm. [24] examined the performance of polymer and wood based tools for sheet metal forming for a batch of 500 parts each. The revealed an overall feasibility for radii of 7 mm with slightly higher deformation on the densified wood-based compared to the polymer tools.

Methodology

Preceding investigations.

The aim of the present study is the investigation of a potential substitution of conventional tooling materials for sheet metal forming applications through biologicalization. For comparison, similar process boundaries were applied as in the preceding studies [8,9], where the mechanical stability of fused deposition modeling (FDM) printed dies from polylactic acid (PLA) with solid and reduced infill was investigated in forming DC03 (0.7 mm) sheet metal parts in a rubber pad forming process featuring a polyurethane pad (shore hardness 40). Based on the previous work, the load collective of the drawing process was adopted for composite layered tools of BL.

Mechanical characterization of black locust.

Black locust is a hardwood that can be grown and harvested in nutrient-poor and dry locations, offering good mechanical properties compared to alternative wood or biobased materials. According to [25,26] black locust offers the highest mechanical properties for all native wood species. The mechanical characterization (tensile, compression, bending, hardness) was performed on a Zwick Roell Z250 universal testing machine i.e., for the following geometries, according to relevant standards DIN EN ISO 527-1, *DIN 52192* and DIN 52186 respectively (see. Fig. 2):

Fig. 2. Black locust test specimen for mechanical characterization.

The results are summarized in Table 1, next to data from relevant literature [27-30].

Table 1. Mechanical properties for black locust.

Simulation of pristine and composite black locust specimen.

Following the mechanical characterization, the pristine longitudinal compression specimens were implemented in a simulation based on the Finite Element Method (FEM) in the Software LS Dyna. Based on the work of [31] two pre-defined material models were included for the simulation of BL specimen:

- MAT_143 (MAT_WOOD)
- MAT_058 (MAT_LAMINATED_COMPOSITE_FABRIC)

Implementing the base parameter gained from the mechanical testing both models were superimposed over the test curves of the BL samples (see Fig. 3). To estimate the performance of wooden based composite drawing tools from black locust, further numerical investigations were carried out. Assuming a deformable body for the forming dies an element stress analysis was performed, according to [9]. Even though the recent studies imply a deformable polymer die made from PLA, the volumetric analysis should reveal the performance of a deformable wooden composite structure from black locust. Since the RPF process applies the process force on the active tool (die) nearly lossless through the rubber pad, the stress distribution on a deformable body was assumed to be similar. From the analysis, the contour plot revealed the 3D element stress distribution through the die and emphasized the high stressed area along and into the radius inlet of the die cavity. Whereas the quantitative information is based on the PLA die, the qualitative outcome was assumed to be similar for the wooden composite die (see Fig. 4).

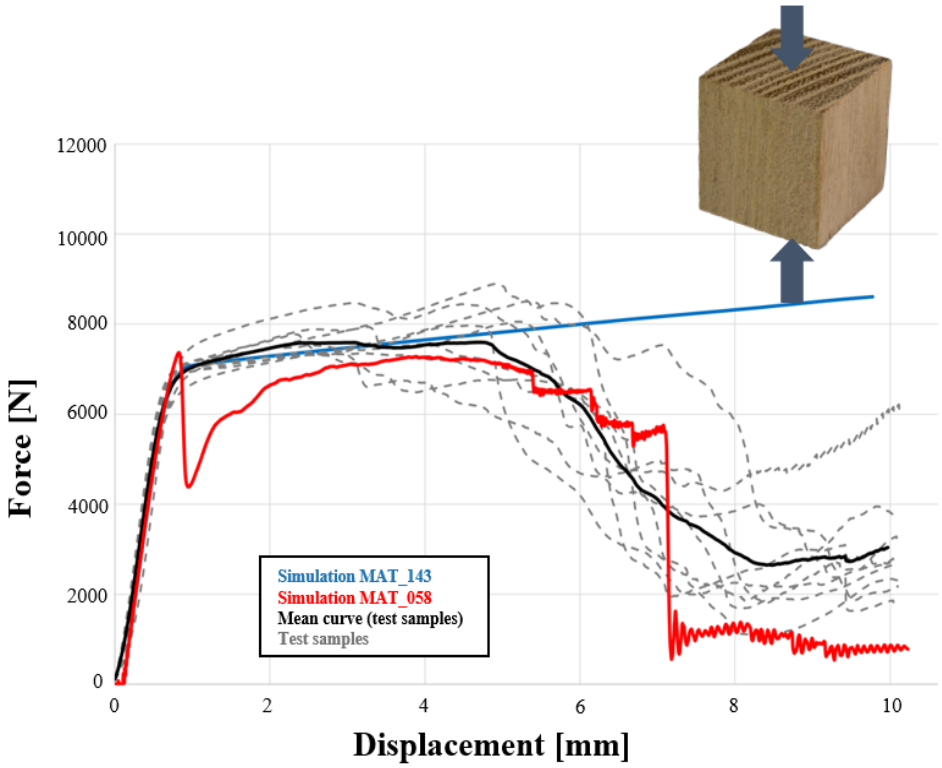

Fig. 4. Numerical validation with LS Dyna for longitudinal compression specimen for black locust.

From the stress contour plot gained from a linear static finite element simulation with ALTAIR Optistruct it is evident, that the drawing radius was heavily loaded while the cavity of the die faced minor contact forces except from the apex of the dome geometry. The load case, as maximum contact pressure over time, for the linear static finite element analysis was gathered from a forming simulation by PAM STAMP 2020.0. The hexahedron elements were discretized with a nominal

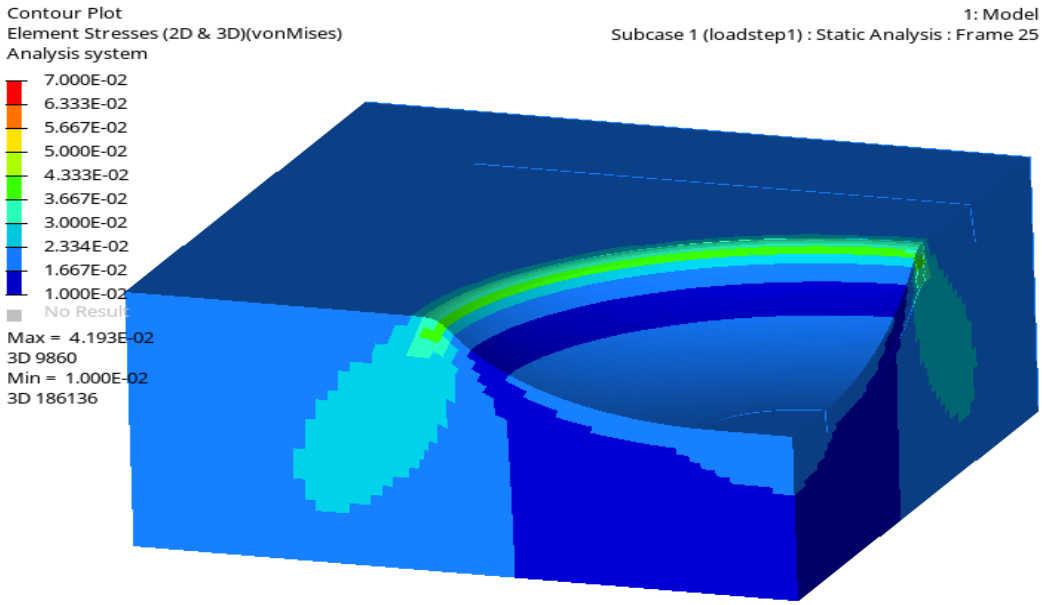

Fig. 3. Stress contour plot for deformable tool die.

size of 1.0 mm assuming an isotropic v. Mises material with young's modulus of 1.7 GPa. According to [9] the boundary conditions were displacements of the bottom surface of the die are constrained in surface normal direction.

Drawing results for wood-based forming tools manufactured of black locust.

Based on previous characterization and numerical analysis as well previous investigations from [8,9], two composite structures were rectangular aligned out of 3mm black locust sheets glued together with polyurethane (see Fig. 5), according to [23].

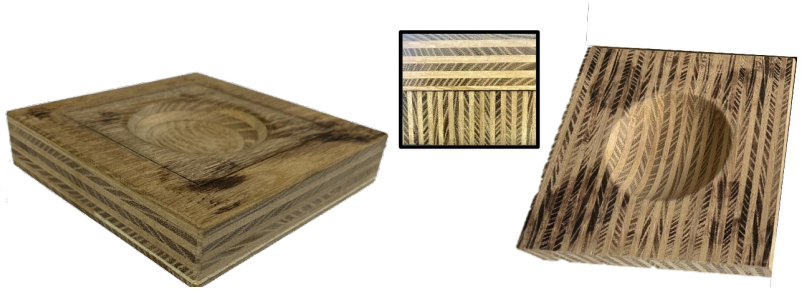

Fig. 5. Black locust composite drawing tools: horizontal (left), perpendicular (middle) and hybrid structure with 2mm sheet metal (right).

Solid black locust planks were cut into thin veneer sheets and sanded with coarse mesh (P80) on a surface sander prior to composite bonding. The bonding performed using a hydraulic veneer press without affecting or damaging the mechanical performance of the wood layers. The drawing dies included two composite (horizontal and perpendicular stacked) and, due to high process forces on the radii inlets (radius of 2.5 mm), two composite-hybrid structures (horizontal and perpendicular stacked each topped with a 2 mm sheet of tool steel grade 1.2312). All dies were operated on a uniaxial testing machine along with a 40-shore hardness polyurethane pad. For each die version, a batch of 64 parts from 0.7 mm DC04 sheet metal was drawn with 175 kN on the universal testing machine.

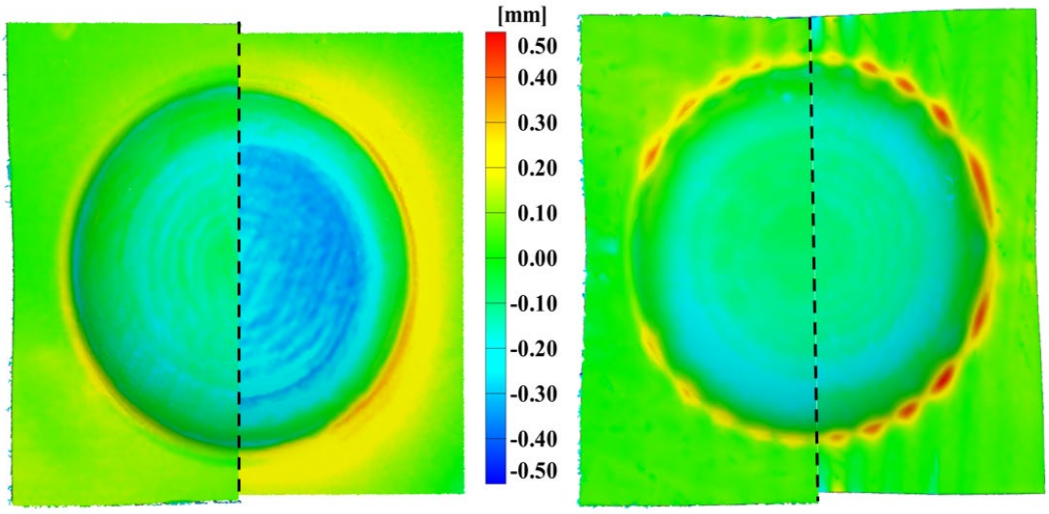

Fig. 5. Optical correlation for unused BL dies and the corresponding blank sheets of the first stroke (left half) and the 64th stroke (right half), for black locust horizontal (left application) and perpendicular (right application) composite die.

Due to permanent deformation of the wooden based forming tools, an optical analysis via optical surface scan was accomplished. Fig. 5 shows the spatial deviation for drawn sheet metal parts on wooden based forming tools (see. Fig., left and middle), where the left part shows the performance of the 1st and 64th part drawn on a black locust composite horizontal stacked and the right part shows the performance of the 1st and 64th part drawn on a black locust composite perpendicular stacked, respectively. The spatial deviation on the radii inlets correspond to the high stressed area in the contour plot (cf. Fig. 4).

Since Fig. 5 revealed qualitative differences of the forming behaviour between the first and 64th stroke for all drawn metal sheets, a comparison for the high stressed area along the radii inlet (cf. Fig. 4) was carried out to identify the drawing radius deviation of sheet metal parts on all BL dies (Fig. 6).

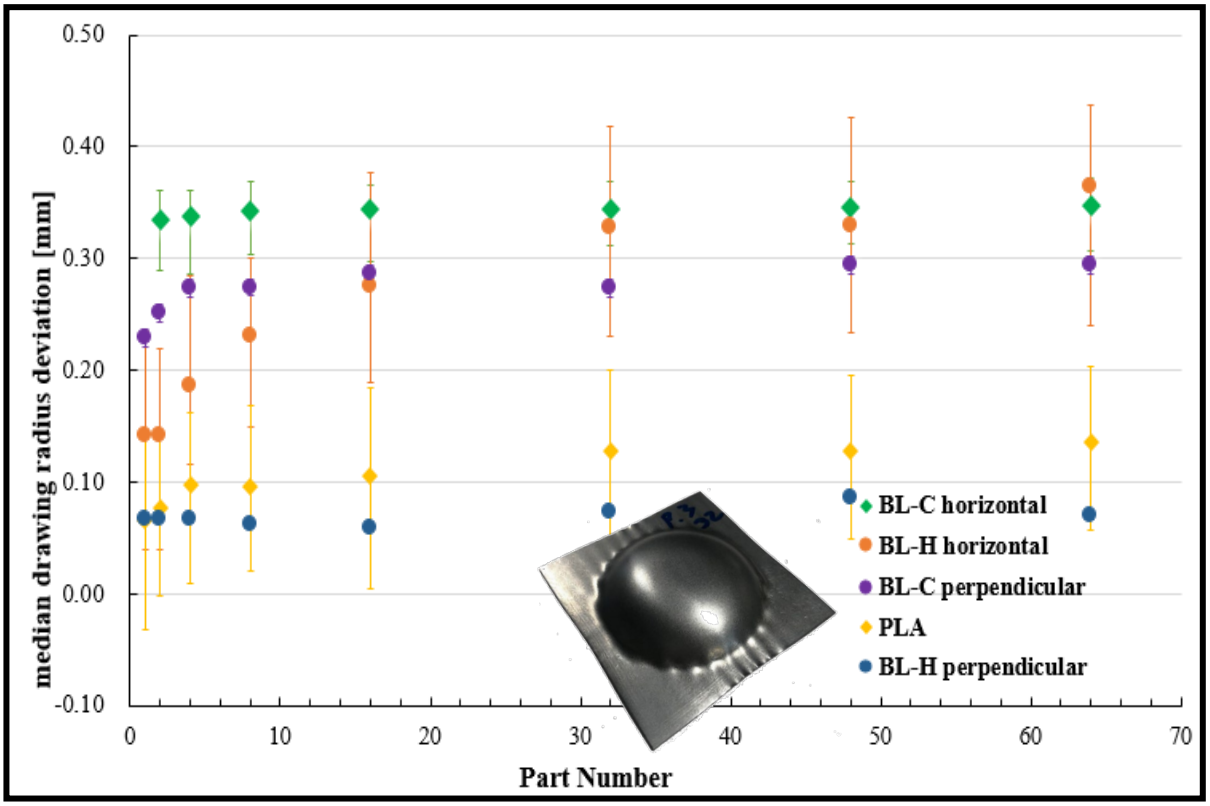

Fig. 6. Spatial deviation within the drawing radius for comparing the sheet metal parts produced by the BL-RPF process for different layouts. Statistical evaluation of a small batch series of metal parts indicates degressively increasing deviations from 0.09 mm (BL-H perpendicular) to 0.34 mm (BL-C horizontal).

Fig. 6 depicts the spatial drawing radii deviation up to 64 blank parts, drawn on BL dies with different stack layouts, showing the highest deviations on the BL-C horizontal die, whereas the hybrid BL-H perpendicular die reveals the lowest deviation. Along the batch size production, the deviation increased for all versions, which refers to the high contact stresses and the deformation behavior of the BL dies. Even though the metal parts drawn on the BL-H perpendicular die stabilize immediately after the first part, the remaining dies increased the radius deviation on the metal blanks roughly up to the 32nd part, which indicates a stabilizing character of BL dies in general, even without the hybrid components.

Summary
Biologicalization through wooden based forming tools offers chances to enhance flexibility and mass customization in sheet metal forming. While a solid and a topology optimized forming die manufactured by fused deposition modeling (FDM) successfully utilized for sheet metal forming in previous studies [8,9], in this study, the performance of the identical die geometry was investigated for different wooden based forming tools from black locust (robinia pseudoacacia). The wooden based tools are compared to a solid die from polylactic acid (PLA) regarding dimensional accuracy of formed sheet metal products. On each die variant, batches of 64 parts (steel grade DC04) are drawn in a rubber pad forming process and examined by optical correlation scans. The tests depict an overall comparable forming behavior of all die variants introduced to the process, while hybridization with tooling steel on the surface of the tooling dies lead to smaller drawing radius deviations on the cavity inlet. Slight permanent deformations are indicated along the drawing radii of all black locust forming tools caused by high contact stresses. Concluding, the wooden based forming tools revealed a suitable drawing performance for small batch size production. Future research should focus on high stressed areas of forming tools and appropriate replacement strategies via conventional metal inlays. In addition, further analysis of the deformation behaviour of wooden based tools could be conducted in numerical simulations as well as in forming tests to investigate the influence of local mechanical tool properties (e.g., local tool stiffness) on the product geometry.

Abstract. In order to promote aluminum scrap recycling and reduce remelting losses, solid-state recycling processes are subject to increasing academic attention. These processes range from severe plastic deformation (SPD) to diffusion-based processes like field-assisted sintering (FAST). In this study, a FAST-based recycling route consisting of precompaction, FAST, and impact extrusion of dry machined EN AW-6082 and EN AW-7075 aluminum chips was used to create multi-material parts from different aluminum alloys. To examine the effect on the resulting part quality, two different hybrid material layouts were created during cold compaction of the chips. The subsequent sintering process took place in a field-assisted sintering (FAST) machine at 400°C and 500°C for a duration of 5 min under a pressure of 85 MPa, allowing for the analysis of inter-chip diffusion. These sintered blanks were then cold-formed by impact extrusion. Metallographic and computed tomography analyses as well as hardness measurements were performed for property evaluation before and after heat-treatment.

Introduction

Aluminum alloys are widely used for products in all industrial sectors and numerous applications. In line with global economic growth, the global production of primary aluminum increased by 20 % from 49 megatons in 2012 to 59 megatons in 2016 [1]. In 2019, this production increased to 66 megatons globally [2]. Combined with 33 megatons of recycled secondary aluminum, the global annual aluminum industry processes 100 megatons, with a strictly increasing tendency. Considering the high energy requirements for the production of primary aluminum of roughly 13 MWh/t [3,4], the use of aluminum scrap for the production of secondary aluminum offers great potential for energy savings, as it requires only 5 % (0.7 MWh/t) of the primary process' energy demands [5]. Consequently, the fraction of secondary aluminum in global production is increasing [6], however with significant regional differences in scrap return rates [7].

As with most metals, the production processes mainly include casting, forming and machining. Aluminum products are either cast directly after the metallurgical production of the alloy or it is processed into semi-finished products, e.g. bars or sheets. These are then later formed or machined into the desired product. Most processing steps involve material losses, due to flash formation, burn-off, chip production and other reasons. Generally, primary scrap (e.g. from casting) can be directly recycled. However, contaminations and the high specific surface of chips and fine flash lead to oxidation and metal losses between 5 and 20 wt.% during conventional melt-metallurgical recycling [8]. Therefore, the development of solid-state recycling (SSR) techniques promises

advantages in material yield and energy consumption and may help to reduce material losses in a circular economy.

The origin of these SSR techniques dates back to 1945 when *Stern* received a patent on the recycling of aluminum scrap by hot extrusion [9]. Later, further investigation took place, while most research is younger than 20 years. *Gronostajski et al.* studied the extrusion of aluminum chips after ball milling and sintering [10] and the direct extrusion of the milled chips without sintering [11]. In both cases, nearly complete densification was achieved with tensile strengths of over 90 % of the base material reference [10,12]. The hot extrusion process was further studied by other researchers, focusing on bond formation [13], secondary extrusion [14], resulting material properties [15] and mathematical modelling [16]. These investigations share the general idea of applying pressure and temperature to the material during deformation and are part of a group of processes designated as severe plastic deformation (SPD) processes. The aim is to break up or disrupt the oxide layers covering the chips by applying pressure and deformation and thereby enable welding of the chip surfaces [17,18]. Other examples for SPD processes are equal channel angular pressure (ECAP) extrusion [19] or cyclic extrusion compression (CEC) [20]. With SPD processes, part geometry and deformation are determined by the process itself, with restricted process windows and therefore limited opportunity to consider part requirements.

An alternative approach involves the sintering of aluminum chips and a consolidation due to diffusion processes. While conventional die pressing and sintering requires milling of the chips into powder, pressure assisted sintering processes allow the direct processing of the chips after precompaction. Different authors were able to process aluminum chips by spark plasma sintering (SPS). *Paraskevas et al.* produced fully densified specimens from AA6061 and AA6082 chips by sintering at a temperature of 490°C and 200 MPa of axial pressure [21]. *Koch et al.* investigated the same alloy EN AW-6082 processed at different process parameters of 400°C and 40 MPa by field-assisted sintering technology (FAST). The sintered specimens were cold extruded and heat-treated (T6) to surpass the mechanical properties of the heat-treated reference [22]. A comparable pulsed electric current sintering (PECS) process was investigated on a smaller scale by *Cislo et al.*, using a Gleeble 3800 and a sintering temperature of about 450°C with a pressure of 64 MPa. The results showed an inhomogeneous microstructure and defective areas together with bonded parts [23]. While there are differences in the machinery used as well as in the application of the electrical current, the afore mentioned processes SPS, FAST and PECS share the same basic concept of directly heated pressure assisted sintering and are summarized using the term FAST [24]. They are in contrast to conventional hot pressing with indirect heating, which *Fogagnolo et al.* used for the recycling of AA6061 chips. These were sintered at a temperature of 500 °C and a pressure up to 700 MPa for 50 min. Nevertheless, the resulting microstructure required the authors to add hot extrusion as an additional consolidation process [25].

In summary, a variety of processes is proposed for SSR of aluminum chips. Especially FAST processes allow the consolidation of precompacted chips without major billet deformation. In this study, this aspect allows the production of hybrid specimens consisting of different aluminum alloys by recycling. This possibility is an inherent advantage compared to melt-metallurgical recycling and may help to improve part performance or to reduce the overall demand for high quality secondary alloys by a load-adapted component design. With forming operations, the sintered hybrid layout is deformed and adjusted to part requirements. At first, however, the general concept of layout creation and deformation is characterized and evaluated in the presented study. Furthermore, effects of material layout and sintering temperature on the resulting part geometry, defects and microstructure are investigated.

Experimental Setup

For the investigation, aluminum chips of the alloys EN AW-6082 and EN AW-7075 were used. The chips were produced by milling without the use of lubricant to eliminate the need for cleaning and its influence. The resulting chips' dimensions were measured manually and are given in Table 1 as mean values with standard deviation.

Table 1. Chip dimensions and apparent density.

Alloy	Length in mm	Width in mm	Height in mm	App. density in g/cm³
EN AW-6082	9.95 ± 1.80	1.01 ± 0.20	0.37 ± 0.05	0.25
EN AW-7075	6.42 ± 2.00	0.93 ± 0.07	0.18 ± 0.07	0.145

The chips were precompacted into briquettes using a manual hydraulic press with a pressure of 170 MPa. The precompacting step allowed different hybrid alloy layer designs:

(S) An axial layering consisting of three stacked briquettes with 30 g of chips each, 90 g in total. One briquette of EN AW-6082 was stacked between two briquettes of EN AW-7075.

(R) A radial layering created with the help of a specialized hollow punch tool. The inner core with a diameter of 15 mm consists of EN AW-7075 chips. For the outer material, EN AW-6082 chips were used.

All briquettes had an outer diameter of 35 mm. Fig. 1 shows a schematic of the cold compaction setup as well as the resulting hybrid layouts.

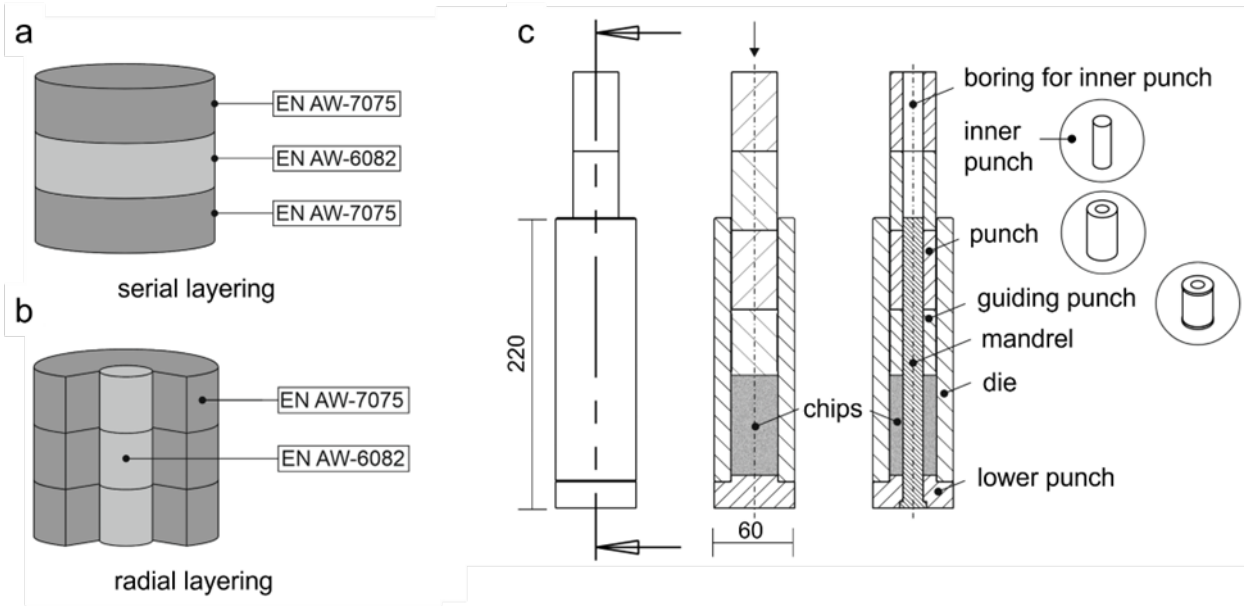

Fig. 1. Layout of the hybrid aluminum specimens, (a) axial layering strategy, (b) radial layering strategy and the used compaction tool (c).

After cold compaction, the three stacked briquettes were sintered using a Dr Fritsch DSP 507 FAST machine. The machine uses electrical current (DC) to directly heat the chip material by Joule heating. The temperature was measured by three thermocouples within the sintering die, with the highest value (generally TC 2) used for process power control. The tool setup with its components is depicted in Fig. 2.

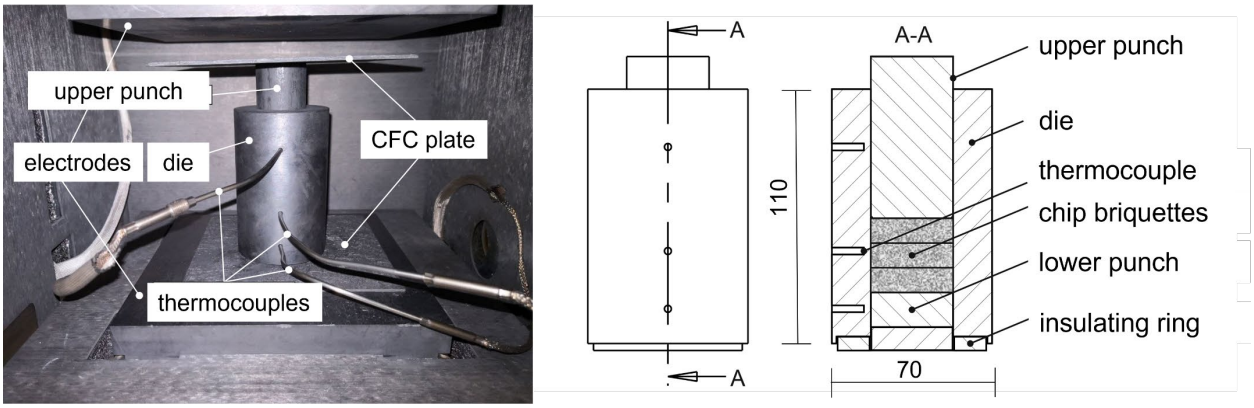

Fig. 2. Experimental setup of the field-assisted sintering process (left) and schematic representation of the sintering tool (right).

The hybrid layouts S and R were both sintered at two different temperatures of 400°C and 500°C for 5 mins resulting in 4 variants SL, SH, RL and RH. The sintering parameters given in Table 2 were based on previous experiments [22] and resulted all in above 99 % rel. density.

Table 2. Process variants.

Variant	Layout	Sintering temperature (°C)	Sintering time (s)	Sintering pressure (MPa)
SL	Serial	400	300	85
SH	Serial	500	300	85
RL	Radial	400	300	85
RH	Radial	500	300	85

After sintering, the specimens were air cooled and then analyzed using a Nikon XT H 160 computed tomography (CT) scanner. The scans were carried out using a current of 100 µA and an acceleration voltage of 150 kV resulting in a power of 15 W. By using a distance of 15 mm from the radiation source, a resolution of 40 µm could be achieved. The volume reconstructions were calculated with the help of Nikon CT Agent and analyzed with Volume Graphics VGStudioMax 2.2 software.

After performing the CT scans the specimens were formed using cold impact extrusion. Before extrusion the specimens were heated to 110°C and lubricated with LUBRODAL 24 W in a 1:2 solution with water. The resulting lubricant layer was dried for 24 h. The forming operation was carried out on a Weingarten PSR 160 screw press at room temperature. The diameter of the cylindrical specimens was reduced from 37 mm (including insertion tolerances for sintering and extrusion) to 16 mm, resulting in a mean plastic strain of $\varphi = 1.6$. The die shoulder angle was $2\alpha = 60°$ and the resulting extruded length was between 62 mm and 66 mm.

Subsequently, the specimens were scanned again by computed tomography. Furthermore, longitudinal sections were cut and investigated metallographically. Hardness measurements (HV 0.01) were performed within 5 mm of the interface in the centre of the shaft using a Shimadzu HMV-G automatic hardness testing device with a Vickers indenter and a force of 98.07 mN. EDX-line scans at the hybrid interface were performed on the SL and SH variants using Octane Elect Pro EDX detector by AMETEK Inc. in a Mira 3 SEM by Tescan. The cut specimens were then heat treated using a solution annealing temperature of 480°C. Water quenching cooled them rapidly to room temperature before cold aging. Finally, hardness measurements and metallographic examinations were repeated.

Results

The intermittent CT scans allowed the observation of the material distribution before and after cold extrusion. Combined with the metallographic analysis of the extruded specimens their deformation behavior and microstructural characteristic were investigated. The different alloy compositions cause transmissivity differences which allow the different materials to be distinguished. This results in EN AW-7075 material appearing brighter than EN AW-6082.

Before extrusion, the serial layouts SL and SH show a slight curvature of the axial interfaces in the CT images in Fig. 3. This is caused by friction forces acting on the outer diameter of the briquette stacks during sintering. As only the top punch moves in relation to the sintering die, this distortion, which is typical for one-sided compaction of powders, occurs.

After extrusion, the images show an elongation of the center of EN AW-6082 material into the surrounding EN AW-7075 material. This results in one half of the shaft being radially layered, however with a conical geometry of the interface. Consequently, the bonding surface between the two alloys was enlarged. The extruded SL specimen shows cracks at this interface near the extrusion shoulder, while for the SH-specimen no cracks could be observed.

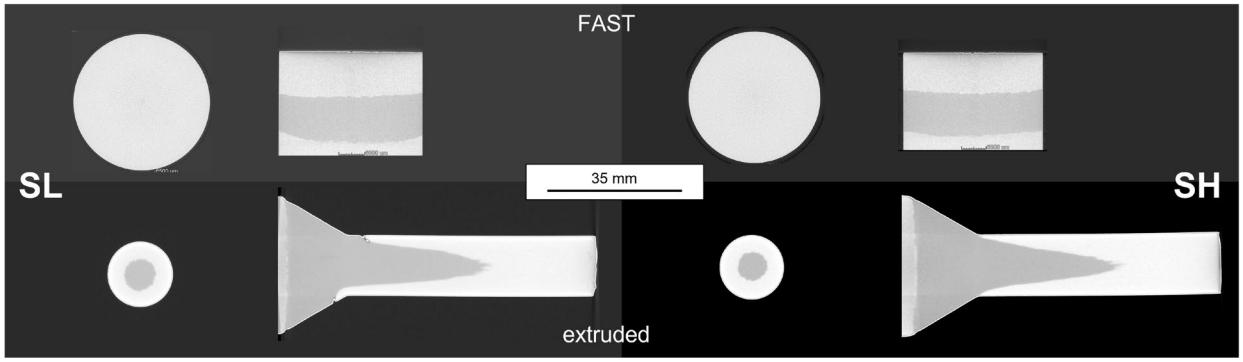

Fig. 3. CT imaging of the sintered (top) and extruded (bottom) serial specimens sintered at 400°C (left) and 500°C (right).

The radial layouts' material distribution before extrusion shows very limited deviation from the ideal concept, as can be seen in Fig. 4. There is no significant distortion of the interface during sintering and both alloys are still in coaxial arrangement. The extruded specimens exhibit a conical expansion of the softer EN AW-6082 material near the tip of the shaft, followed by a long section of uniform cross-section and material proportions. Both, the RL and RH specimens show cracks at the briquette interface at the tip of the extruded specimen. These are of reduced severity for the RH variant, which was sintered at higher temperature.

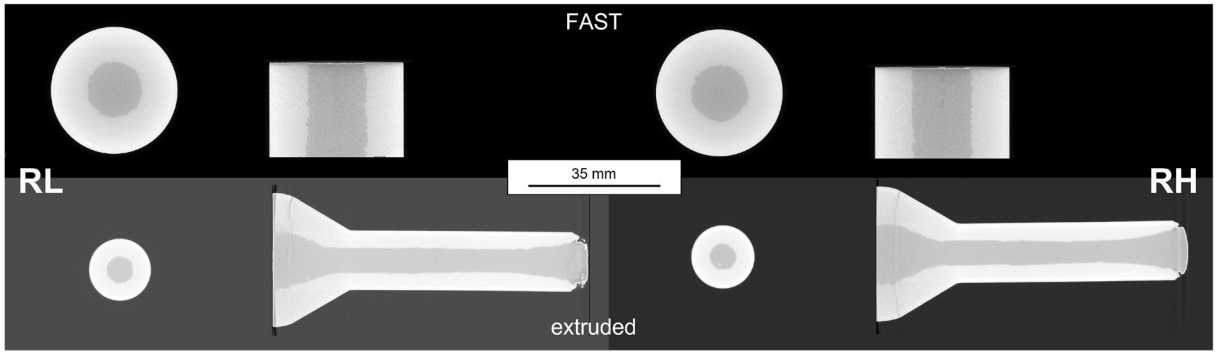

Fig. 4. CT imaging of the sintered (top) and extruded (bottom) radial specimens sintered at 400°C (left) and 500°C (right).

During the FAST process, changes in the microstructure occurred depending on the sintering temperature. After sintering at 400°C, the SL and RL variants showed a densified structure with some defects and the chip boundaries clearly visible as dark lines (see Fig. 5). The original sheared grain orientation is still prevalent within the individual chips of both alloys. By increasing the sintering temperature to 500°C for the SH and RH variant, the number of visible defects was significantly reduced and the former chip boundaries appear thinner. Additionally, grain growth and recrystallization can be observed for the EN AW-6082 material. At locations of thin or with missing chip boundary layer, grain recrystallization occurred across the interface, resulting in the visual disbanding of the dark oxide lines. In case of the EN AW-7075 material, the sheared microstructure of the chips remained visible within all four variants. After sintering at 500°C, the interface between both alloys shows signs of diffusion processes, indicated by a separation of the chip boundary oxide layer and the line of color change after etching.
Fig. 6a shows the results of the EDX line scans across the interface. The Al signal increases abruptly when crossing the interface of the SL specimen from EN AW-7075 to EN AW-6082, as the alloying element concentration drops. However, the graph for the SH specimen shows a gradual increase, confirming the metallographic observation of a pronounced diffusion zone. The microhardness results for the sintered conditions given in Fig. 6b show low values of 80 to 100 HV 0.01 for EN AW-7075 and 40 to 60 HV 0.01 for EN AW-6082 material. The values increase with increasing sintering temperature for both alloys.

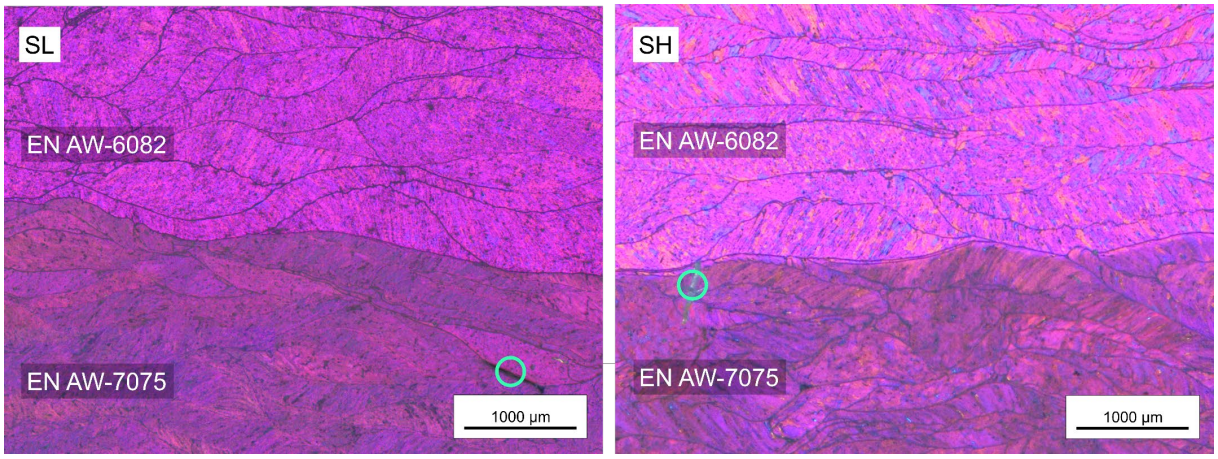

Fig. 5. Micrographs of the etched microstructure of the variants SL and SH in sintered condition. Defects are encircled in green.

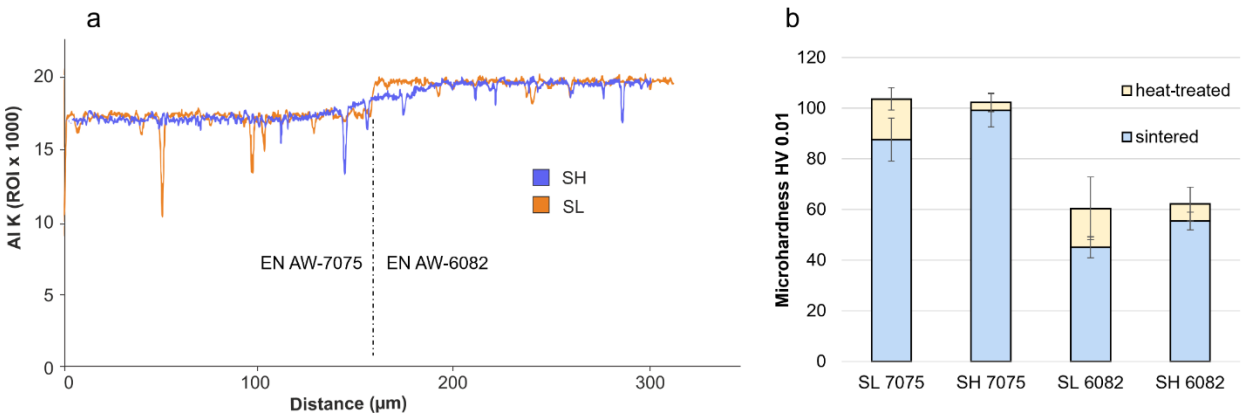

Fig. 6. Results of the EDX line scans (a) and the microhardness measurements (b) on the SL and SH variants.

After impact extrusion, the sintered microstructure is re-orientated in the direction of extrusion. Chips and chip boundary layers are stretched and elongated in the same direction (Fig. 7). This leads to the optical pronunciation of defects perpendicular to material extrusion, which were higher in number for the RL and SL variants than for RH and SH.

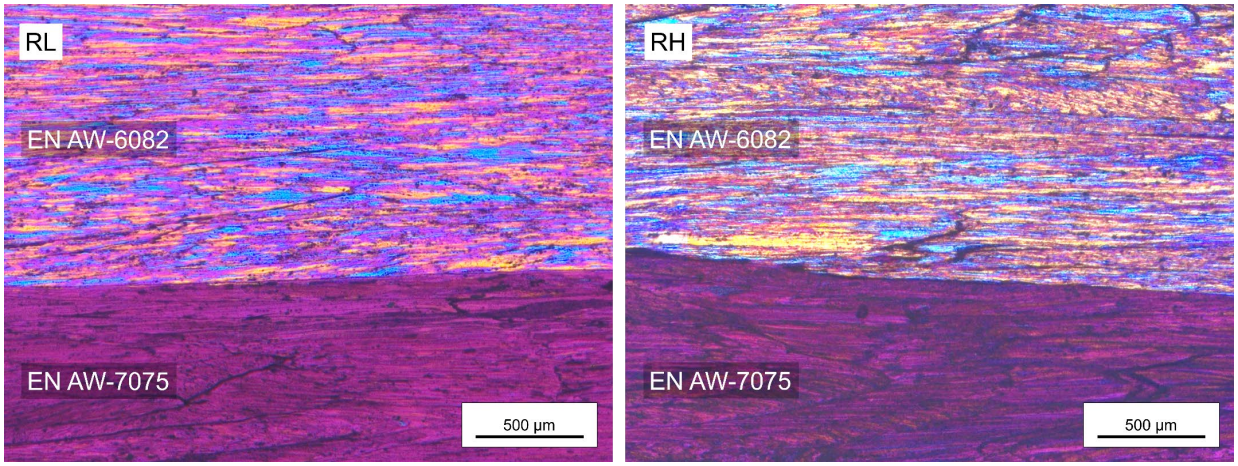

Fig. 7. Micrographs of the alloy interface of the radial variants RL and RH after extrusion.

After solution annealing and short cold aging, this deformed structure is recrystallized throughout the specimens. Fig. 8 shows metallographic images of the SH variant after the heat-treatment. While both alloys show coarse grains and few distinct chip boundaries, the material's orientation is still obvious in the EN AW-6082 and near the edge of the extruded shaft in the EN AW-7075 material. Furthermore, the interface shows a broad gradient in the etching/coloring, indicating growth of the diffusion zone. The results of the microhardness measurements in this heat-treated condition are given in Figure 6b. For both alloys, there is a significant increase in hardness over their respective low temperature variant in as-sintered condition. Compared to the values obtained from the SH variant, the hardness increase is smaller with only 4 HV 0.01 in case of EN AW-7075 and 7 HV in case of EN AW-6082 material.

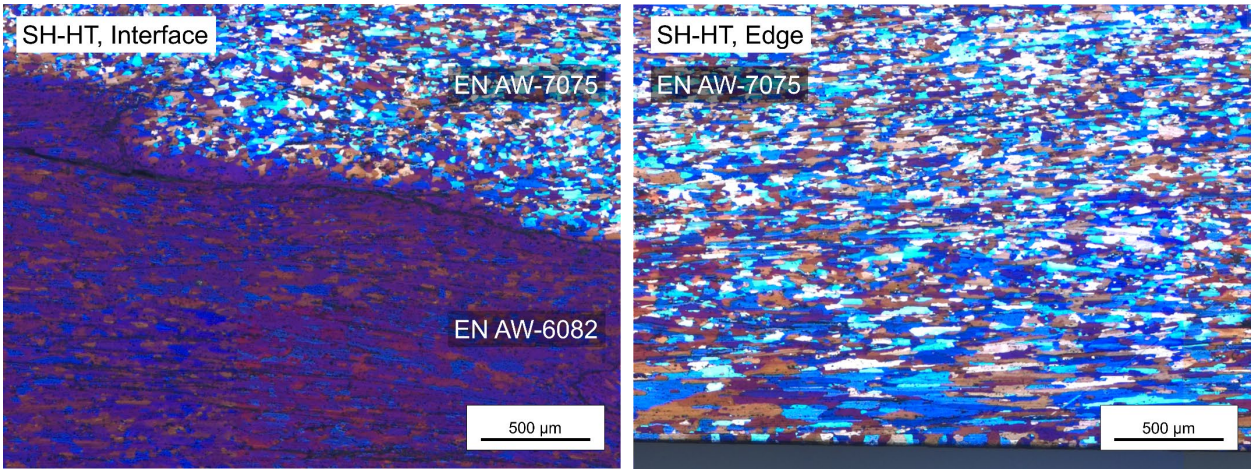

Fig. 8. Micrographs of the alloy interface of the edge of the part of the SH variant after extrusion and heat-treatment.

Discussion

The results indicate a significant influence of the sintering temperature on the diffusion processes across chip boundaries as well as on the microstructure within the individual aluminum chips. In previous work, tensile specimens were produced using the identical FAST process at 400°C for 5 min to recycle EN AW-6082 aluminum chips. After extrusion and T6 heat-treatment, the resulting tensile strength was comparable to the reference material in T6 condition at 379.8 MPa ultimate tensile strength and 354.7 MPa yield strength [22]. This indicates, that the presence of visible boundary layers between the chips may be tolerable for quasistatic properties. However, raising the sintering temperature to 500°C seems to activate diffusion mechanisms, which are not active or significantly reduced at 400°C. Due to the hybrid nature of the investigated specimens, this change could be observed in the material's response to etching and the EDX scans. Furthermore, recrystallization across the chip boundaries becomes more prevalent with higher temperature, effectively disrupting and dissolving the oxide layers. All defects, that were observed occurred in between chips. Hence, it may be assumed, that sintering at higher temperatures leads to increased formability and fatigue properties, because of fewer and smaller defects in the material.

The bond quality between the chips at the interface gains importance when creating hybrid parts form different alloys. These have different elastic and plastic material properties, which result in increased stresses on the interface during forming. This can be seen in Fig. 3 and 4 and is a challenge for all hybrid forming operations [26]. In the presented recycling process, defects were not reduced during cold impact extrusion, but deformed and elongated. Therefore, the FAST process needs to densify and consolidate the chips to a degree, which does not depend on further improvements through cold forming with low to medium plastic strains. Solution annealing after cold forming leads to complete recrystallization of the deformed microstructure after extrusion. The forming process still affects grain size and shape on the edge of the part. It is unclear whether this is due to increased local plastic strain or due to temperature gradients during annealing. In any case, the microstructure is reset to a condition with hardness similar to the as-sintered state and with a coarser and more homogeneous grain structure.

Finally, the presented recycling process allowed the production of hybrid parts with the potentially harder EN AW-7075 and the softer EN AW-6082 in two different layouts. The CT images indicate a nearly ideal macroscopic distribution of both alloys. However, metallography shows some curvature and localized interference of individual chips. The presented layouts were developed with potential application under torsional loads, using EN AW-7075 in the load-bearing outer area.

Summary

In summary, hybrid parts were successfully produced from aluminum chips of EN AW-6082 and EN AW-7075 alloys with a nearly defect-free structure. The geometry and distribution of both alloys within the billet after FAST and the final part after extrusion show little variance. Combined with reduced defect concentration and increased inter-chip diffusion due to increased sintering temperatures, promising results could be achieved. Using the presented process, the production of hybrid components directly from scrap material is feasible and can potentially be used to either compensate for inferior starting material with higher quality chips or to maximize part performance under certain loading conditions. Both aspects will be subject of further research.

Keywords: Sustainability, Mechanical Properties, 3D Printing, Life Cycle Analysis

Abstract. In the Concurrent Engineering (CE) approach, several aspects of the life cycle of a product are considered at the same time during the design phase. This allows to respond more quickly to the market needs and improves the final products quality. However, with this approach, the design phase could result more time consuming and expensive and needs simple and easily applicable optimization models. For this reason, a new multi-criteria decision model is proposed in this paper. Additive manufacturing technologies for high performances polymers are gaining increasing interest as they are a valid option for the manufacturing of structural components. For these reasons, high performance 3D printed isogrid structures in short carbon fibers reinforced polyamide were selected as a case study. Production processes of as-printed and dried isogrid structures were carried out; mechanical characterization and environmental and cost analysis were performed on the considered scenarios. Following the proposed model, the results of the analyses were used to calculate a single value indicator for each product. In this way, it was possible to compare the different alternative and select the optimal solution.

Introduction

Nowadays, the development of increasingly complex industrial products, the increased competitiveness of companies, the need to reduce production times, and countless regulations and design standards are forcing engineers to develop high quality products that are as environmentally sustainable as possible and at the lowest cost, in order to be competitive in the global market.

In this context, Concurrent Engineering (CE) has become the foundation of modern engineering as it allows an optimal balance between cost and quality to be achieved. CE was born in the 1980s and represents a set of methodologies and tools that enable an integrated approach to product design and related manufacturing processes. The areas of product development that can be considered simultaneously during the design phase can cover all phases of the product life cycle, from conception to end-of-life. CE moves away from the traditional sequential approach in the execution of the design, process planning, production, and demanufacturing phases, and the individual activities are performed in parallel, so that the product can be evaluated over its entire life span, starting as early as the design phase [1,2].

CE is crucial when products of high complexity, with long development phases and the difficulty in predicting the impact of design decisions on next phases of the product life cycle is high; this is often coupled with the need to respond to a rapidly changing demand that inevitably requires shorter product life cycles.

It is obvious that, in such a complex context, the role of the engineer within companies is strongly oriented towards decision-making and the process of making decions in the short, medium or long term can determine the success or failure of production activities. Therefore, it's crucial to develop decision-making techniques that make decision-making more efficient and easier. The decision-making process starts with the identification of the problem and the objectives to be

achieved, followed by the choice of decision criteria, their weights and the definition of a performance index to be maximised or minimised [3]. Consequently, to improve the performance index, alternative solutions must be developed, analysed and compared in order to choose the best alternative. It is also crucial that a mechanism of continuous implementation of the identified solutions is triggered through constant monitoring of the results achieved. The choice of criteria is not unique but depends on the specific case of application [4].

Traditionally, the decision criteria to be related to system performance are those represented in the production tetrahedron: time, cost, flexibility and quality. To these is added sustainability.

The concept of sustainability was first introduced in 1972, during the first United Nations Conference on the Environment, and, in 1987, within the so-called Brundtland Report, a sustainable model was defined as one that meets the needs of the present without compromising the ability of future generations to meet their own needs [5].

Environmental sustainability is becoming a cornerstone in industrial production and in general in any activity of modern society, thanks to the realisation that the planet's resources are not infinite but must be preserved, without waste, respecting ecosystems and biodiversity.

Thus, the need for environmental sustainability is linked to environmental protection, but in recent years, in addition to considering the ecological aspects, it has also been declined from an economic and social point of view.

There are qualitative evaluation criteria, such as checklists and guidelines, or methods capable of quantifying the environmental impacts of a system according to different impact categories; among these, Life Cycle Assessment (LCA) is the most widely used methodology. LCA quantifies environmental impacts, considering resource consumption and atmospheric emissions, and can be applied to the entire life cycle (from cradle to grave) [6-8].

In this context, a new mathematical model is proposed as a decision-making support for industrial applications that can be used as a product/process optimisation tool. The literature lacks a model capable of considering multiple decision criteria and simple to apply. Unlike the theoretical approaches present in the literature, this model has the possibility of being easily usable at an industrial level due to its mathematical simplicity and application. In fact, the novelty of this paper lies in the ease of application of in industrial context and the possibility of being adapted to specific cases (products/processes) in a short time.

In this regard, was examined the case of composite isogrid structures made by additive manufacturing processes [9]. The mechanical performances, the economic and environmental sustainability and production time of isogrids in different configurations (as-printed and dried) were evaluated. In addition, through the application of the theorised model, various scenarios were compared.

Materials and Methods

In a concurrent engineering perspective, it is crucial to develop quantitative models to consider multiple variables and criteria at the same time. Their ease in application is also required to be applied in an industrial context and help the design process.

The model here presented may include whichever factor the decision makers want to take into account as long as it can be evaluated in a quantitative way. Hence, it pairs well with procedures such as Life Cycle Assessment, flexibility and quality assessment tools that quantifies aspects of a process or a product that would be otherwise difficult to measure [6,10]. Moreover, the model can also consider traditional criteria such as cost (or Life Cycle Costing) and mechanical properties. It can be used to compare both products or industrial processes that have similar functions or yield to similar outputs. The mathematical model allows the comparison between different alternatives by calculating a performance index for each of them; the lower the index, the better the alternative. The index is calculated as sum of dimensionless parameters, each of which is the ratio between the criteria value for the considered system and that of the reference scenario.

An arbitrary number of parameters can be taken into account, depending on the design requirements; in this way, even complex decision problems can be easily solved. In addition, the model can be used to optimize a given process or a product by estimating the value of the performance index as key process parameters vary.

The general model is as follows:

$$I_i = p_i \frac{t_{0_i}}{t_{0_r}} + p_2 \frac{C_i}{C_r} + p_3 \frac{F_i}{F_r} + p_4 \frac{L_i}{L_r} + p_5 \frac{E_i}{E_r} + \cdots = \sum_j (p_j \frac{K_k}{K_r}) \quad (1)$$

where:

- I_i is the performance index for the i-th alternative
- p_j is the ponderation factor of the j-th decision criteria evaluated according to the company policies and the specific case study. Tools similar to a Weighted Decision Matrix can be employed to define p_i. The sum of al the ponderation factors is equal to 1.
- K_i and K_r are the quantitative values of the decision criteria for the i-th alternative and the reference system. They can be referred, for example, to the production time (t_{0i}, t_{0r}), product cost (C_i, C_r), mechanical performances, quality (L_i, L_r), system flexibility (F_i, F_r), environmental impacts (E_i, E_r), etc.

The reference scenario is used as a benchmark to evaluate the performances of the other systems and it is characterized by an Index I_r equal to 1. In the case of production systems, it can represent a traditional process previously used by the company or by a competitor and the production of a defined number of parts. If multiple options have to be compared and no previous system is known, the reference system can be chosen between one of these; then, if no alternative gets an index value lower than one, the reference scenario is also the best choice according to the considered criteria.

Evaluation of the decision criteria.

The value related to the environmental sustainability decision criteria can be calculated by means of the standardised methodology of Life Cycle Assessment. LCA is an iterative approach constituted by 4 phases defined by the ISO standard 14040 and 14044 [6,11]. It allows to quantify the environmental impacts of a product or a process according to several impact indicators (e.g. Global Warming Potential, damage to Human Health, ect.) and considering all the aspects of their life cycle. The standard procedure phases are: goal and scope definition, in which the focus of the analysis, the functional unit, the goal and the system boundaries are defined; Life Cycle Inventory, where the inputs and outputs of the system are identified and directly or indirectly quantified; Life Cycle Impact Assessment, in which the inputs and outputs are translated into potential environmental impacts according to selected indicators. Dedicated software are used to automatically carry out this phase; finally, the LCIA results are critically reviewed and criticalities and improvement possibilities are identified. E_i and E_r can be retrieved from the LCIA results by considering an impact indicator that is representative of the studied system. LCA can be paired with the Life Cycle Costing analysis, an economic tool used to evaluate the cost incurred by a functional unit throughout its life cycle. LCC can also be used to calculate the economic criteria indicator (C_i, C_r) of the performance index.

The production time expressed in seconds can be used as a decision criteria value; it can be directly measured during the production of the components or calculated by estimating the process time, the inspection time, the movement time and the queue time.

The reciprocal of the load at break of a component could be used as a decision criteria value related to the quality of the scenario. In this way, if the mechanical properties of the component increase, the value of the index of performance decreases. More in general, if a feature of the product or the process should be maximized, it is possible to use its reciprocal as a decision criteria value. Further criteria and assessment methodologies could be introduced in the model to respond to the designers requirements.

Ponderation decision matrix.

The design requirements that affect the production process can be translated into values depending on the evaluation that is associated with each aspect by the producer.

This type of evaluation has the function of assigning a value on a scale from 1 to 5 depending on the importance or weight that one wishes to assign to each factor that contributes to the generation of the performance index. The matrix thus generated, an example of which is shown in Table 1, is called Ponderation Decision Matrix (PDM) and allows values to be assigned for the calculation of the weighting factors p_i, shown in the previous section. The p_i calculation is done through the ratio of the value assigned to the specific parameter in the PDM, divided by the sum of the values assigned to all decision criteria.

Table 1. Ponderation Decision Matrix.

Decision Criteria	**Weight 1**	**Weight 2**	**Weight 3**	**Weight 4**	**Weight 5**	**p_i**
Mechanical Properties		**X**				2/14 = **0.14**
Environmental Sustainability				**X**		4/14 = **0.29**
Costs			**X**			3/14 = **0.21**
Production Time					**X**	5/14 = **0.36**
TOT	**0**	**2**	**3**	**4**	**5**	**1.00** / **14**

Case study: 3D printing of composite isogrid structure.

The case study analyzed in this work refers to an additive manufacturing production system for CFRP components. In particular, isogrid structures, generated by particular geometric configurations, have been realized through FFF technology and reported in Fig. 1.

The isogrid structures were designed by means of a CAD software by choosing rib width, rib thickness, cell height, global length and global width of 3, 8, 18, 106 and 80 mm, respectively, and then were exported as an .STL file for the creation of a .GCODE by the slicing software. The geometric construction parameters mentioned before are shown in Fig. 1.

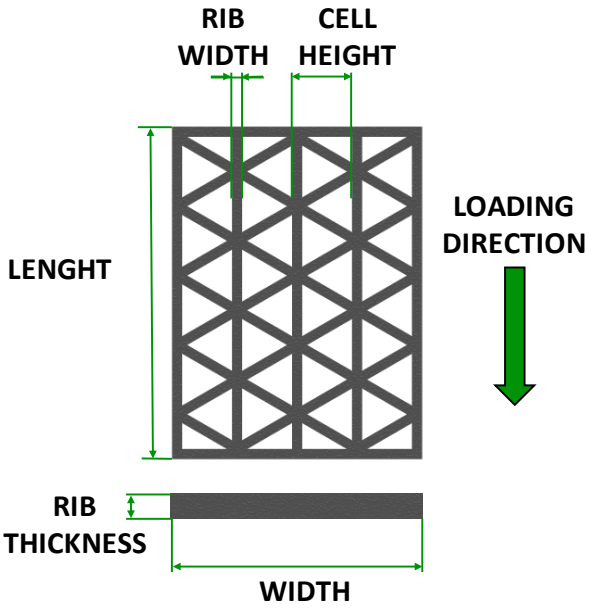

Fig. 1. Geometrical parameters of an isogrid structure.

The composite material used in this study, defined as Carbon PA, consists of a polyamide 6 reinforced with short (about 25 microns in length) carbon fibers at 20% in weight. According to the material datasheet, Carbon PA is characterized by an elastic modulus of 15.5 GPa and a ultimate tensile strength equal to 138 MPa, as also shown by authors in [9]. The material is supplied by Roboze S.P.A. in the form of a 1.75 mm diameter filament, suitable for processing through the Fused Filament Fabrication technique (FFF). The Roboze One+400 3D printer, equipped with FFF technology and supplied by Roboze Spa, was used for the additive manufacturing process, with the aim of realizing isogrid structures.

As the material is highly susceptible to moisture absorption, which causes a significant decrease in mechanical properties, Carbon PA was subjected to a drying process for about 4 h at the temperature of 120°C before the printing process. Moreover, during the printing phase, the material was maintained at 70°C in order to avoid moisture adsorption improving printing quality, reducing void formation. Main printing parameters for the realization of isogrid structures in CarbonPA through FFF technology are reported in Table 2.

Table 2. Main printing parameters.

Process Parameter	
Extruder Temperature	260°C
Bed Temperature	110°C
Infill Density	100%
Layer thickness	0.15 mm
Nozzle Diameter	0.4 mm
Nominal Printing Speed	50 mm/s
Infill Type	Linear
Raster angle	0°

With these process parameters, the effective printing time for the realization of each isogrid structure detected at the end of printing equals to 2.15 hours [7]. 3 on 6 printed isogrids were subjected to another drying process in the oven for 4 hours at 120°C to remove the moisture absorbed during and after printing, before being tested under compression load.

The mechanical performance of the as-printed and dried isogrid structures was calculated by subjecting them to compression tests with an MTS 810 universal testing machine under displacement control at a speed of 0.5 mm/min. The acquisition system connected to the machine's load cell made it possible to record the compressive load values associated with the relative displacement. The maximum load values in kN were then derived from each test.

Case study: Life Cycle Analyses.

The LCA methodology was employed to quantify the environmental impacts of the 3D printed isogrid structures. As for the mechanical test, two different scenarios were considered: the as printed isogrid structure (Scenario 1) and the one subjected to the drying process (Scenario 2). The goal of the study is to quantify and compare the impacts of the two scenarios with particular focus on the drying heat treatment of the printed structure. In fact, the LCA results are then to be used to calculate the multi objective performance index to determine whether or not the heat treatment represents a process improvement. Global Warming Potential (GWP, expressed in kg CO_2 eq) was selected as the environmental impact value of the performance index decision criteria. This impact indicator is widely used in literature LCA for production processes of composite parts and it is well representative of their environmental behaviour [12,13].

The functional unit is therefore defined as the 3D printing of a carbon fiber reinforced polyamide isogrid structure with defined dimensions (see paragraph 0). Considering the focus of the case study on the manufacturing process, a “cradle to gate” approach was used, and the following production phases were included: materials production (PA and short carbon fibers), transport, filament drying and temperature control during the printing, 3D printing process and isogrid post drying (only for Scenario 2). The use and End of Life phases were excluded from the analysis.

The Life Cycle Inventory phase is based on a previous work of the authors [14]. Primary data were retrieved from direct measurements during the production processes; this includes the energy consumptions of the machines and the weight of the components. Considering the composition of the filament defined in the datasheet (80% polyamide, 20% carbon fibers), the quantity of each constituent was calculated. Polyamide and electric energy impacts were retrieved from the Ecoinvent database while CF impacts were modelled according to Khalil et al [15]. Impacts related to the production of the machines used for the production and postprocessing were not included as their useful life is much longer than the time horizon considered in this study and they would have led to negligible contribution.

LCIA results were calculated by using the SimaPro software, equipped by default with the Ecoinvent commercial database. The environmental impacts analysis was paired with an economic assessment (LCC) that considered the same functional unit and the same scenarios. The cost associated with each structure was calculated considering all direct and depreciation costs and by considering appropriate allocation procedures.

Material cost was calculated considering the purchase price (120 €/kg) of the filament and the weight of the components (41.25 g). Energy costs were calculated considering the measured consumptions (1.366 kWh) and the cost per kWh. Machines depreciation was calculated considering their purchase price, their use time for the considered scenarios, their service life (expressed in hours) and their maintenance costs. Labour and design time were measured (0.3 h and 0.5 h respectively) and multiplied by the hourly staff cost (30 €/h for laboratory operator and 35€/h for designer) to evaluate personnel contribution to the total cost. Direct measurements of

time required for the production phases were also employed to calculate the total production time required for the two scenarios (4.45h for the first scenario and 6.55 h for the second one).

Results and Discussion

Fig. 2 shows the mean load vs. displacement curves of the dried and as-printed isogird structures tested under compressive load. It can be seen that there is a significant increase in performance when the material is subjected to a drying cycle prior to testing. The percentage increase in performance is equivalent to approximately 23%.

The average values of the maximum load measured for as-printed and dried isogrid structures are 13.08 kN and 16.08 kN, respectively.

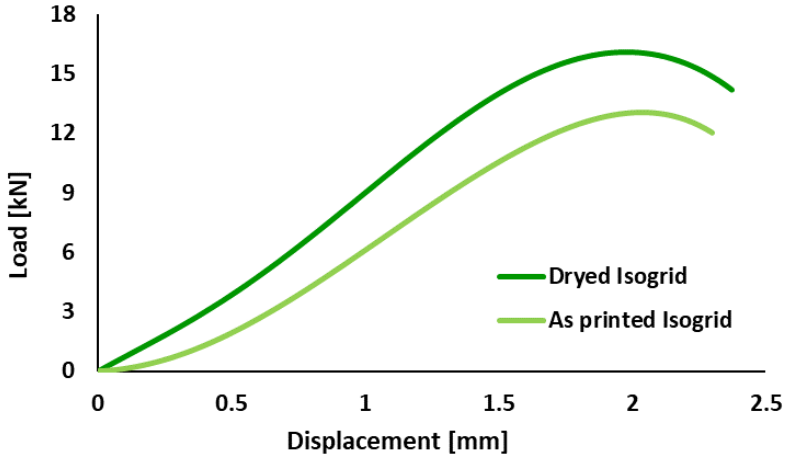

Fig. 2. Load vs. displacement curves of dried and as-printed isogrid structures.

Fig. 3 (a) presents the results of the LCA analysis in terms of Global Warming Potential. The two scenarios are the same with the exception of the structure drying process that is only present in Scenario 2. The as-printed isogrid structure showed environmental impacts about 20% lower than those of the heat treated parts (1.20 kg CO2 eq vs 1.46 kg CO2 eq). This is due to the electric energy production and consumption of the isogrid drying process.

Indeed, most of the production phases that include an electric energy consumption resulted in relevant environmental impacts; this also includes the filament initial drying (0.26 kg CO2 eq) and the filament temperature control during the printing phase (0.26 kg CO2 eq). This is due to the fact that the Italian energy mix is mainly composed of non-renewable sources. Improving the sustainability of the energy use could strongly reduce the overall impacts of the scenarios (e.g. by using renewable distributed energy sources).

The 3D printer has very low energy requirements for the stepper motors control and the nozzle heating and therefore resulted in low impact (0.05 kg CO2 eq). The most impactful phase is represented by the raw material (0.6 kg CO2 eq, between 41% and 50% of the total impacts, depending on the scenario); this is a common finding in many LCA literature studies focused on CFRP and it is attributed to the high-energy requirements of the matrixes and carbon fibers production.

Fig. 3 (b) reports the results of the economic assessment analysis for the two scenarios. As for the LCA, Scenario 2 is the best alternative with a total cost of 23.00 € while Scenario 1 has a total cost of 19.90€.

The main difference between the two scenarios is represented by the labour cost required in Scenario 2 for the post processing of the isogrid structure. Labor is also the most expensive cost item in both the alternatives. In 3D printing, labor is almost independent from the components

dimensions (and so the raw materials and machines use costs); hence, for small parts labor can be a major cost even if the process is highly automated.

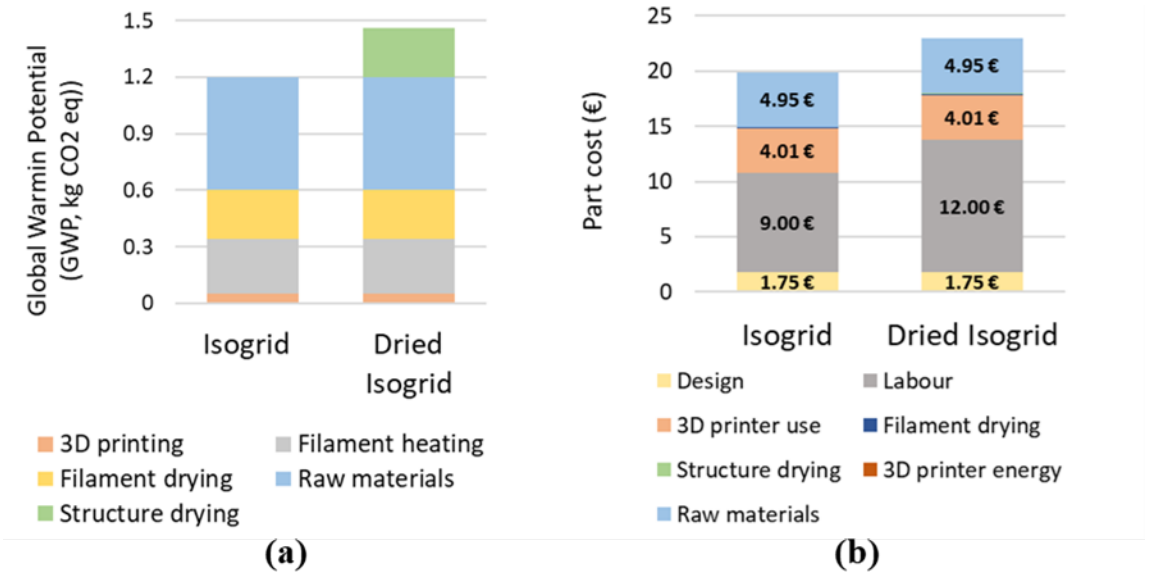

Fig. 3. LCA results in terms of GWP (a) and cost analysis results (b) for the two considered scenarios.

The depreciation costs of the oven for the heat treatment and the drying system are basically negligible due to their low purchase prices. Differently from the environmental assessment, the energy use has low relevance (about 1% of the total costs). Table 3 presents the production time of the different phases and the total manufacturing time of the two scenarios. The printing phase is the most time consuming, closely followed by the structure and filament drying. Overall, the post-printing heating treatment determines an increase in production time of about 50%.

Table 3. Production time for the two scenarios.

Production time		
Filament drying	2	h
Printing time	2.15	h
Printing setup	0.2	h
Part removal	0.1	h
Structure drying	2.1	h
Scenario 1	4.45	h
Scenario 2	6.55	h

Scenario 1 was selected as the reference scenario and the performance index of Scenario 2 was calculated accordingly. In line with the model, Scenario 1 index is equal to 1; Scenario 2 index is equal to 1.22 (Table 4), which means that it performed 22% worse than the baseline process according to the sum of decision criteria. The drying process allows to improve by 23% the decision criteria related to the mechanical properties. However, it lowers the performance of the system according to every other indicator, as it is time consuming, expensive and with high electrical energy requirement. The weight factors used for this case study are appropriate for low cost products with modest mechanical performances requirements (e.g. aesthetic components) and for which the sustainability is a major concern (e.g. for green labelled parts).

It is evident how the weight values are crucial for a correct use of the performance index and should be carefully identified in accordance with the company vision and the specific case study.

For example, considering the present case study, if the environmental sustainability criteria is not taken into account (weight factor equal to zero), the production time and cost relevance weight are lowered to 2 and 1 respectively, and the mechanical properties factor is set equal to 5, Scenario 2 becomes the best alternative with an index score equal to 0.98. That would be the case of structural components

This remarks the importance of a proper choice of the weighting factors and also the flexibility of the model. In fact, it can be a useful decision tool in almost every industrial sector for every set of decision criteria that the stakeholders wish to include in their evaluation process.

Table 4. Performance indexes for the two scenarios.

	Weight	Weighting factor	Scenario 1	Scenario 2
Mechanical properties	2	0.14	13.08 kN	16.08 kN
Environmental sustainability	4	0.29	1.2 kg CO2 eq	1.46 kg CO2 eq
Cost	3	0.21	19.9 €	23 €
Production time	5	0.36	4.55 h	6.55 h
Performance Index			1	1.22

Summary

In this paper, a new multi criteria decision model for industrial products and processes was proposed. The mathematical model provides a simple and effective tool to compare different alternatives and to select the best one according to several decision criteria. The tool can also be employed to optimize a base scenario by evaluating a multicriteria performance index as a function of defined variables.

The model was employed to compare “as printed” and “dried” 3D printed composite isogrid structure. Four different criteria were assessed: mechanical performances by means of compression tests, economic and environmental sustainability by means of LCA and LCC analyses and production times. The main results can be summarized as follows:

- On average, the drying process improves the compression resistance of the isogrid structures by 23% but it has negative effects for the other three decision criteria.
- The weighting factors can be calculated by means of the ponderation decision matrix considering the company vision and the analysed scenarios.
- The value of the performance index is strongly influenced by the weighting factors associated with each decision criteria. The best alternative can change depending on these factors and, therefore, on the company goals. For this reason, the model is suitable for a large variety of industrial components and decision criteria.

Future work could be focused on different applications of the proposed model to further validate it and to provide reference values for multicriteria decision processes.

Keywords: Aluminum Alloys, Recycling, Friction Stir Consolidation, Compression Test

Abstract. Friction stir consolidation (FSC) is a solid-state recycling method that directly converts machining scraps into semifinished billets. This process has been proven to be a more energy efficient and environmentally friendly technique compared to remelting based conventional recycling methods. During FSC, machining chips are transformed into a solid billet by the stirring action and friction heat of the rotating tool. Due to process mechanics, especially temperature gradient and strain rate, billets have shown different hardness values and grain size distribution across their sections. Therefore, in this research, miniaturized upsetting samples are extracted from the FSC billet. The purpose of minimizing the sample size is to get the local properties of a particular position. The intensive characterization was performed with future goals to find a more accurate numerical modelling and ultimately assign FSC billet to a potential industrial application.

Introduction

The current global demand for aluminum is 100 million tonnes per year [1]. The accelerating consumption, due to its growing application in lightweight transport, packaging, construction, and electronic industries, is putting immense pressure on industries to increase the production rate. However, per 1 ton of aluminum production from the primary source, 12-16 tons of greenhouse gas (GHG) are produced, which have severe adverse environmental impacts [2]. Besides, aluminum production from ores is also energy-intensive, leading to 13 Exa joules of energy consumption, and is therefore responsible for almost 1% of total global energy consumption [3].

Interestingly, aluminum is an infinitely recyclable material [3]. In Europe, almost 35 % of the aluminum demand is met by recycling aluminum scraps [4]. The conventional recycling route involves re-melting the metal, and thus it skips many of the complex steps of aluminum extraction from the primary source. Furthermore, recycling is highly energy efficient, requiring 5% of the energy compared to obtain aluminum from the primary bauxite source. Thus, recycling can shift aluminum's energy and carbon balance sustainability towards much greater sustainability.

The conventional recycling method has further limitations, especially during the recycling aluminum machining chips. The chip has a high surface-to-volume ratio and is highly oxidation prone, causing permanent material loss during the melting process. They cause adverse environmental impact, high cost, and significant permanent material loss [5]. Looking to the proportion, the machining scraps constitute almost 17% of the total scraps [6]. Therefore, the researchers turned to solid-state recycling (SSR) techniques. SSR are those methods that transform metal scraps directly into finished or semi-finished billet through mechanical means such as high pressure, friction, rotational speed, and force [7]. Recently, SSR processes have been analyzed as a potential alternative for recycling machining scraps.

Various SRR methods have been introduced for recycling metal chips based on the process mechanics and properties of desired product [8-10]. In fact, by omitting the melting phase, permanent losses mainly due to oxidation are avoided. Duflou et al. [5] have proved that equal channel angular pressing and spark plasma sintering outperform conventional remelting-based routes from the environmental impact perspective. Baffari et al. [11] proved the energy efficiency of friction stir extrusion.

Recently FSC has proved to be one of the environment recycling techniques compared to conventional remelting [12]. This technology has attracted many researchers as it proved its potential beyond the concept of recycling toward upcycling method [13]. FSC has two main steps: compaction and consolidation. During compaction, chips or powder are pressed in a hollow die chamber by applying a specific load through a cylindrical tool. Then compacted materials are further pressed and stirred through the tool's downward force and rotational speed during the consolidation phase [14]. So far, researchers numerically modelled [15] FSC process, identified the key process parameters [12] and proved its environmental efficiency with respect to conventional remelting.

A typical FSC, due to process mechanics such as different temperatures and strain rate distribution, is characterized by variation in mechanical properties along the radial and longitudinal direction of the billet [13, 14]. Previously, this variation was validated by Vickers's hardness test and grain size distribution analysis [16]. It is also crucial to analyze the effect of process mechanics on other important properties such as mechanical strength, fracture strength, and ductility. These mechanical properties can be obtained through tensile tension or compression test. However, due to variation in properties across the FSC billet section, miniaturized samples were extracted from the billet section. Interestingly, the miniaturization of the sample leads to homogenization and thus gives details of local properties. The concept of miniaturized samples for upsetting test, previously implemented by Hetz et al. [17] for sheet metal, was applied to the FSC billet. The broader objective is to find a more accurate solution for the numerical modelling of the FSC process and find the potential industrial application.

Material and methods

Material and process set-up.

As-received material was a 20x20 mm squared bar of AA 2011-T3. The bar was reduced into chips by a milling operation. The machining scraps were kept submerged in acetone for 15 minutes for efficient cleaning. An input chip mass of 15g was loaded in the cylindrical die with a nominal diameter of 25.4 mm and compacted at 5 kN force through an H13 steel cylindrical tool with a 25 mm diameter. The die and pressing tool were integrated with ESAB-LEGIO (Fig. 1), a dedicated friction stir welding machine. The chips compaction was an important step in order to avoid spilling out chips during consolidation. Finally, chips were transformed into a cylindrical billet by applying the rotating tool at 1500 rpm and 20 kN load for a processing time of 30 seconds. The selected process parameters in the current investigation were based on previous studies [13,16] as promising conditions for manufacturing sound billet.

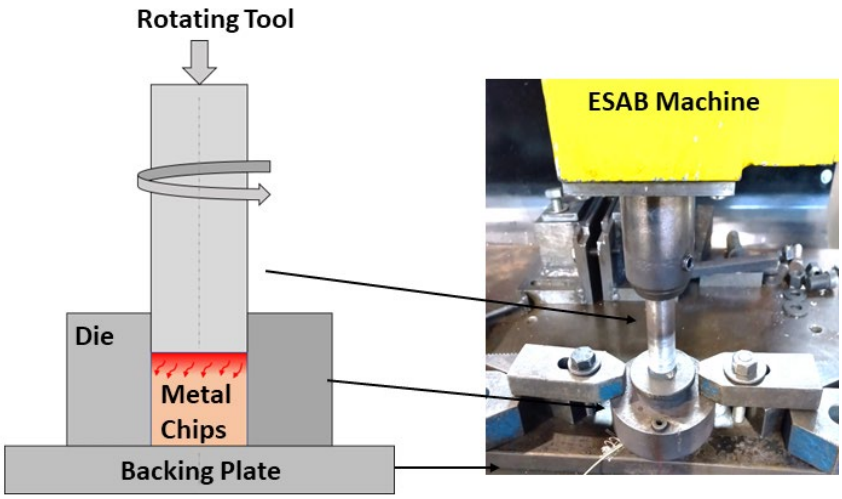

Fig. 1. Experimental setup of FSC.

Measured outputs.

After FSC consolidated step, the obtained billets had an average height and a diameter of 10 mm and 25 mm, respectively. First, the top and bottom surfaces of the FSC cylindrical billet were well polished to get a very flat surface. Then slices were cut (perpendicular to the cylindrical axis of the billet) from the top, middle, and bottom sections with a thickness of 1.5 mm and a diameter equal to the original billet diameter, as shown in Fig. 2 (right). From each disc slice, five miniaturized cylindrical upsetting samples were extracted that had a height (h) of 1.5 mm (slice thickness) and a diameter (d) of 1 mm through micro-EDM on an SX-200-HPM (Sarix SA). One sample (x1) was extracted from the center (r=0) and the remaining four samples (x2, x3, x4, and x5) were extracted at r=10 mm from the center of the billet. Upsetting tests were performed at a strain rate of 0.5%/s with upsetting sample dimensions given in Fig. 3. The height-to-diameter ratio (1.5) of the upsetting was selected based on the equation [17].

$$1 \leq \frac{h}{d} \leq 2 \tag{1}$$

According to this Eq. 1, a higher ratio exceeding the maximum limit leads to the buckling of the upsetting sample, which is considered a premature failure. On the other hand, a lower ratio emphasizes the effect of the frictional coefficient. Besides, Dionol ST V 1725-2 (MKU-Chemie GmbH) lubricant was applied to minimize friction.

Results and Discussion

True-stress strain of FSC billet.

This section gives details information about the true strain-strain curves of the FSC 2011-T3 billet. It also provides evidence of how far true stress-strain graphs agree with the hardness distribution profile across the FSC billet section that the authors investigated in their previous research [13,16]. Further, a comparison was also made between the true stress-strain curve FSC recycled billet and as received AA 2011-T3 bar.

On the top slice (Fig.4), the central sample (x1) showed higher strength compared to the remaining upsetting samples (x2 to x5). The flow curves of the remaining four were found almost aligned with each other. The reason was samples x2 to x5 were extracted from the same height (top slice) and same radial distance (r=10 mm). Interestingly, the variation in properties is enabled by FSC process mechanics, i.e., different strain rate and temperature distributions across the billet section, as reported by Tang et al. [14]. Although, a detailed analysis has not been performed so far, it is quite clear that the die wall and back plate serve as heat sinks, reducing the temperature. Due to this, chips close to the die wall and back plate don't receive sufficient heat input and deformation to be fully recrystallized, but some bonding is, however, achieved.

Likewise, the top slice flow curves, almost the same trend was found for the middle slice. The central specimen showed higher strength than the other samples, with the exception that the x2 graph was not aligned with the x3, x4, and x5 curves. This deviation of the x2 graph was unexpected, as x2 was extracted from the same radial distance (r=10 mm) and the same height (middle slice). Therefore, this misalignment could be an error that occurred while manufacturing the samples.

For the bottom slice, almost uniform flow curves were found for all samples. It is well evident that the strength of the material varies both in the radial and longitudinal direction of the billet. Further, the top part of the billet shows higher strength than the bottom part, and along the radial direction the central part is stronger than the region near the external surface. Also, along the radial direction, the difference in true stress-strain curves between the samples at the center (x1) and the other samples (x2 to x5) is higher for the top slice, then difference diminishes at the middle slices, and finally, all curves are aligned with each other for the bottom slice. For better understanding,

the trend of true stress-strain curves is discussed in terms of hardness distribution in the following section.

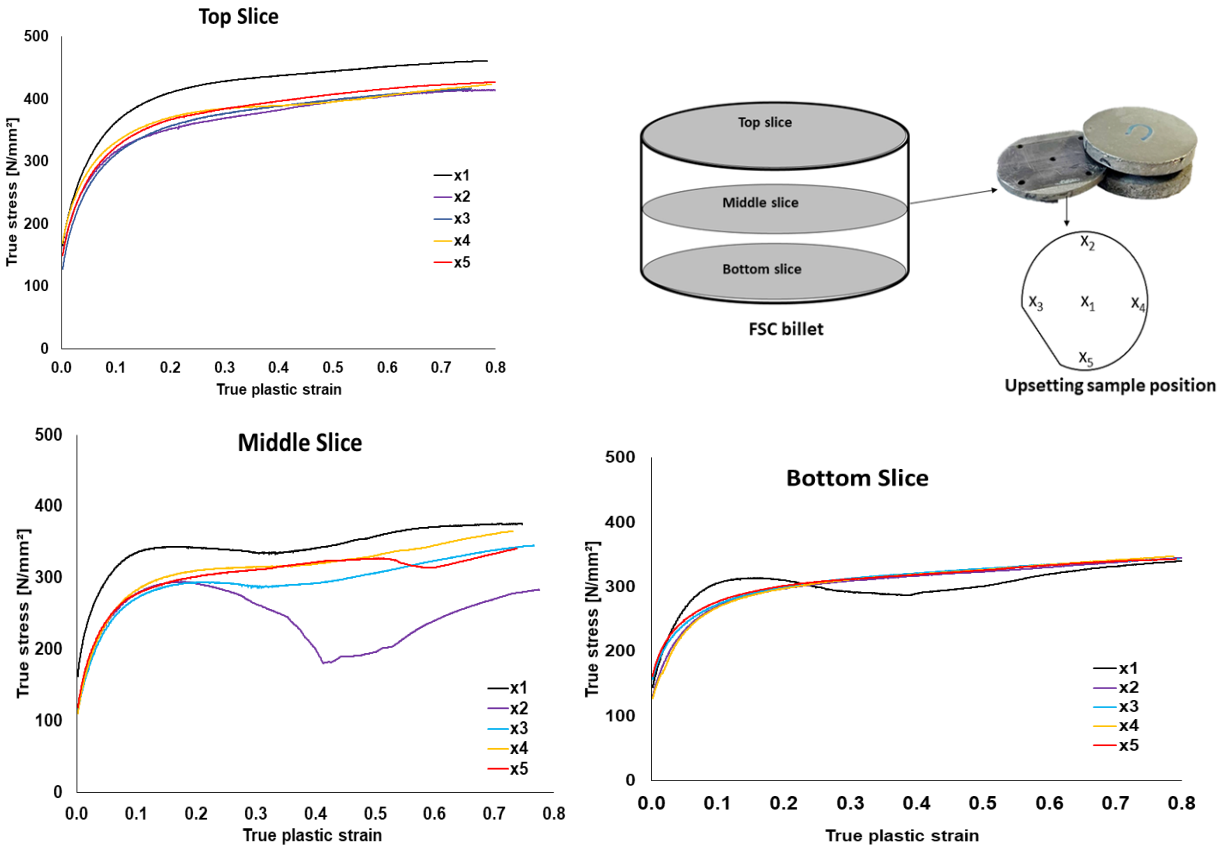

Fig. 4. True stress-strain curves for top, middle and bottom slices of FSC billet.

Comparison FSC billet true strain-strain and hardness trend.

Interestingly, the trend of true strain-strain profile was found very consistent with the hardness distribution trend. The hardness measurements were performed on the same material, AA 2011-T3, manufactured under the same process configuration as mentioned previous section. For hardness, a load of 49 N was applied for 15 seconds as dwell time.

As in Fig.5 (right side), on the top surface, the hardness value is higher, but variation in the radial direction is also very high. Similarly, in Fig.5 (left) the true stress-strain curves showed the material has good strength at the top (x1, x2, and x3), but the difference in material strength between x1 and x2/x3 is higher. It should be noted that x1 is an upsetting sample at the center (r=0), and x2 and x3 are at the left and right sides, respectively, of x1. Besides, x2 and x3 are at equidistance (r=10 mm) from x1.

Again in Fig.5 (right), the mid of the billet section shows a minor variation in hardness value along the radial direction. A similar relationship can be found for the flow curves of middle slice y1 and y2/y3 in Fig.5 (left).

For the bottom section, a lower but uniform hardness value can be noticed. Likewise, lower strengths but alignment of curves were noticed for the true stress-strain graphs of the bottom section (z1, z2, and z3).

It is quite clear that the true stress-strain curves followed the trend of hardness distribution. Overall, the central, and top zones show higher strength and higher hardness values in comparison

to the part near the external surface and bottom section, where relatively low hardness values were noticed.

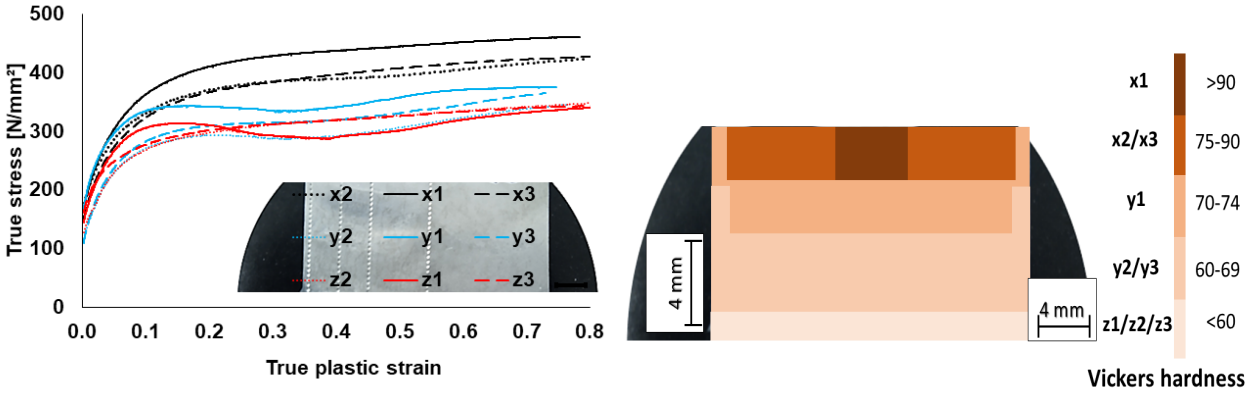

Fig. 5. Comparison between true stress-strain curves profiles and hardness distribution across FSC billet.

Comparison of true strain-strain profile of FSC billet and as-received material.

For the sake of better understanding, the true stress-strain curve of the as-received bar of AA 2011-T3 was compared with flow curves of specimens that were extracted from the center of the top (x1), middle (y1), and bottom (z1) slices of FSC billet section as shown in Fig. 6. Interestingly, the strength of the top layer of FSC billet was higher, middle slice's was comparable, and bottom slice strength was lower than as-received material. The variation in strength was previously also observed in the hardness profile. So, it is well evident that this phenomenon was enabled by FSC process mechanics [13,14, 16]. Dynamics recrystallization and full consolidation occur at the top surface, making the top surface superior to the as-received material.

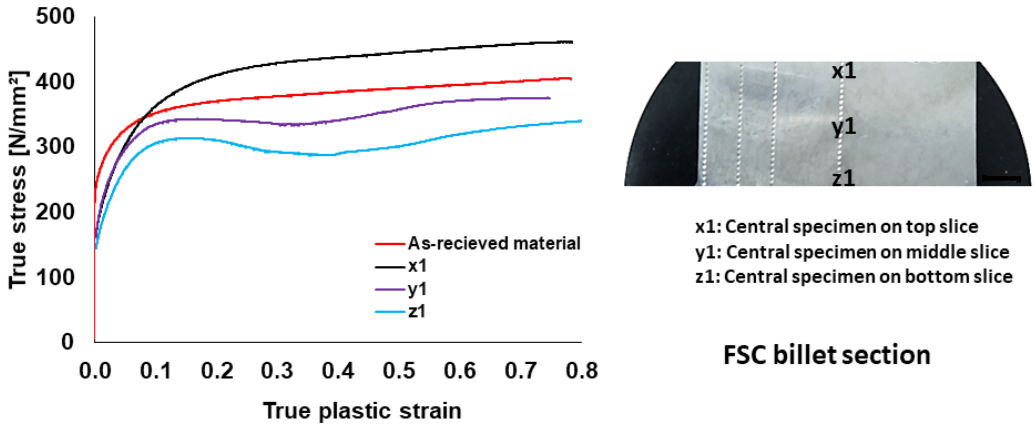

Fig. 6. Comparison of true stress-strain curve between as-received material and different section of FSC billet.

Summary

Based on the previous discussion, the following can be concluded.

1. The strength of FSC billet decreases both along billet advancing direction and radial direction.
2. The strength of top section is higher than strength of bottom section. Similarly, higher strength was found along the central part (r=0) compared to the strength of region near the external surface.
3. The flow curves were found in good agreement with the hardness trend across the billet section. It means that hardness is a good indicator for predicting FSC billet strength.

4. The region where the billet shows a higher hardness value also shows higher strength, and similar results were also valid for the zone of lower hardness value that showed lower strength.

It has been proved that the FSC process causes variations in the mechanical properties of the billet. The authors proved that multi-step FSC processes [16] implementation allows billet with more uniform mechanical and microstructural properties to be obtained. Further development will focus on the here presented characterization of multiple-step FSCed samples. The authors, in their previous studies [18], analyzed the performance of FSCed billets by conducting forging tests, and further developments are still in progress in terms of the double cup extrusion test. Also, an accurate numerical model will be developed in order to provide clarity on the process mechanics and to understand the actual factor causing the sample heterogeneity.

Keywords: Mechatronic Straightening Machine, Self-Learning Disturbance Compensation, Punch-Bending Process

Abstract. To increase the sustainability of forming processes such as punch bending, homogenization of the processed semi-finished product is an essential step in the manufacturing process. High-strength wire materials are usually available as strip material before being further processed in a forming process. For storage and transport, the material is coiled onto coils and transported to the customer. During the coiling process, residual stresses and plastic deformation are introduced into the wire. Thus, the final product quality is also influenced by the geometry of the coil. Straightening machines are used in production lines to compensate for these. Once a straightening machine has been set up, the settings for the roll positions are usually not changed. As a result, there is no reaction to material fluctuations, which means that the components to be produced do not meet the dimensional accuracy requirements. This leads to an increase in the rejection rate in manufacturing processes. To reduce the rejection rate, it is necessary to enable dynamic and flexible infeed of the straightening rollers. In this context, an innovative control concept with disturbance compensation was developed for the straightening process. The disturbance compensation uses a disturbance model that predicts the change in bending curvature over the coil radius. With this prediction, the straightening machine can be adjusted specifically. The roller positions are adjusted by a subordinate position control. The additional feedback from measured geometric product properties from the following punching-bending process enables the straightening machine to be adjusted even in the case of unforeseen fluctuations in the material properties. In this way, it is possible to react to any material fluctuations as required. This novel, demand-oriented adjustment of the straightening machine is expected to result in a high increase in the efficiency of the production process and a reduction of the rejection rate.

Introduction

Semi-finished products made of high-strength flat wire are usually transported to the customer on coils and further processed in downstream processes such as punch-bending. Transport and storage on coils induce pre-curvatures and residual stresses in the semi-finished product, which fluctuate over the coil length during uncoiling. These fluctuations in the semi-finished product have a negative effect on component quality in the downstream processes. In order to compensate for the variable curvature of the incoming straightening material, straightening machines with a large number of straightening rolls are used [1].

To reduce the number of straightening rollers, the fluctuations of the material properties must be known, which is generally not the case. The fluctuations can only be identified with great effort and at the earliest in the straightening result [2]. In addition, online correction of the roller positions in the straightening process is necessary. The rollers of the currently used straightening machines

Content from this work may be used under the terms of the Creative Commons Attribution 3.0 license. Any further distribution of this work must maintain attribution to the author(s) and the title of the work, journal citation and DOI. Published under license by Materials Research Forum LLC.

are adjusted manually or by motor. After the initial positioning, however, the rollers usually remain in the same position during the entire production process for a coil. To keep the straightening result constant under these conditions, it is not possible to reduce the number of straightening rollers. With a high number of straightening rollers, the number of alternate bending operations and the accumulated deformation of the material due to the straightening process increase. This leads to a reduction in the strength properties of the material like yield strength, tensile strength, and elongation at fracture [3].

This paper presents an innovative straightening process in which the straightening roller positions are adjusted online. For this purpose, deterministic disturbance variables in the straightening process are estimated. During the straightening process, the straightening result is evaluated based on measurement data and, if necessary, adjustments of the roll positions are derived. The use of intelligent straightening processes offers great potential for making manufacturing processes more sustainable and resource-saving.

State of the Art

In recent years, several approaches have already been investigated to determine the appropriate roller setting for the straightening process. These approaches can be divided into two categories: These are, on the one hand, the numerical approaches, which use FE models to simulatively determine the roller settings. On the other hand, experimental approaches are investigated with the use of different measurement methods.

The numerical approaches are based on FE simulations and often require a high computational effort. An example of this is the work in [4, 5]. The aim is pursued to reduce the residual stresses in the straightened material. The used optimization algorithms rely on a high number of simulations. In [6], an approach is presented in which the settings of all bending triangles in a FE model are adjusted via a sub-routine. Here, the focus was placed on the analysis of the bending line in the straightening machine.

To reduce the simulation effort, a control loop was implemented in an FE simulation in [7]. Within the FE model, the position of the upper edge of the sheet metal at the end of the straightening process was used as the measured variable for determining the residual curvature. The position specification of the second last roller is used as the control variable.

This approach is also used in [2], where a concept for the automated adjustment of a five-roller straightening machine is presented. Based on a force measurement during the closing of the first bending triangle, the material parameters necessary to determine the roller positions are identified. Through a previously conducted simulative parameter study, the appropriate roller positions are known for a variety of different straightening material properties.

This work is continued in [8]. The main difference to [2] is its online capability. This makes it possible to detect changes in the yield strength and pre-curvature of the metal sheet and readjust the roller position accordingly. The disadvantage of these approaches is always a high simulation effort, and the data is only valid for one specific machine configuration.

In addition to numerical approaches, experimental approaches should also be mentioned. In [9], a way to set up a straightening machine for flat wire is presented. Via an offline curvature measurement, the pre-curvature is automatically detected, and possible roller configurations are suggested to the operator via an experimentally created database. A concept for controlling straightening machines during operation is developed in [10]. In order to adjust the position of the rollers, the curvature of the sheet metal is measured behind the straightening machine by distance sensors. An experimental validation of the concept was not carried out. Another concept for an online control is presented in [11]. In this work, the straightening rolls are also adjusted by a control algorithm based on a curvature measurement behind the straightening machine. The residual curvature is continuously determined with a specially developed curvature sensor. However, according to the authors, the curvature measurement is the weak point and does not provide reliable

results because the curvature is overlaid by other process forces. Another online approach is presented in [12]. Here, mechanical material properties of the material under study are estimated. However, straightened material is assumed for the estimation.

An approach to control a leveling process based on the magnetic properties is presented in [13]. The magnetic properties are investigated considering the Barkhausen effect in connection with the residual stresses present in the material. The authors noted that with this type of measurement, the residual stress distribution is not sufficiently accurate, so no implementation of the concept was made. In [14, 15 and 16] an innovative setup of a straightening system is presented, which has an eddy current measurement system. Its measurement results can be correlated to variable material properties.

As a conclusion of this chapter, on the one hand the listed works require either a high simulation effort or preliminary tests with a special test configuration of straightening machine and semi-finished product. On the other hand, the detection of state variables of the semi-finished product is not sufficiently robust to implement a dynamic roller adjustment for a good straightening result. However, these are the requirements for a robust and efficient straightening process in order to reduce the rejection rate in downstream processes. For the application of a process, a low simulation and parameterization effort as well as an efficient transferability to other wire types is desirable. A control approach should also ensure the adjustment of the straightening rollers in the process to be able to react to fluctuating wire properties. For this purpose, a robust and reliable measurement of state variables of the wire must be ensured. Based on these requirements, the control approach presented in this paper was developed.

System Description and Control Architecture

The dynamic adjustment of the straightening rollers during the manufacturing process is desirable in order to be able to react to fluctuating material properties of the semi-finished product. Particular focus is placed on the development of a robust and efficient method that does not require time-consuming or resource-intensive preliminary tests and is suitable for industrial use. To develop such an approach, this paper considers the system shown in Fig. 1

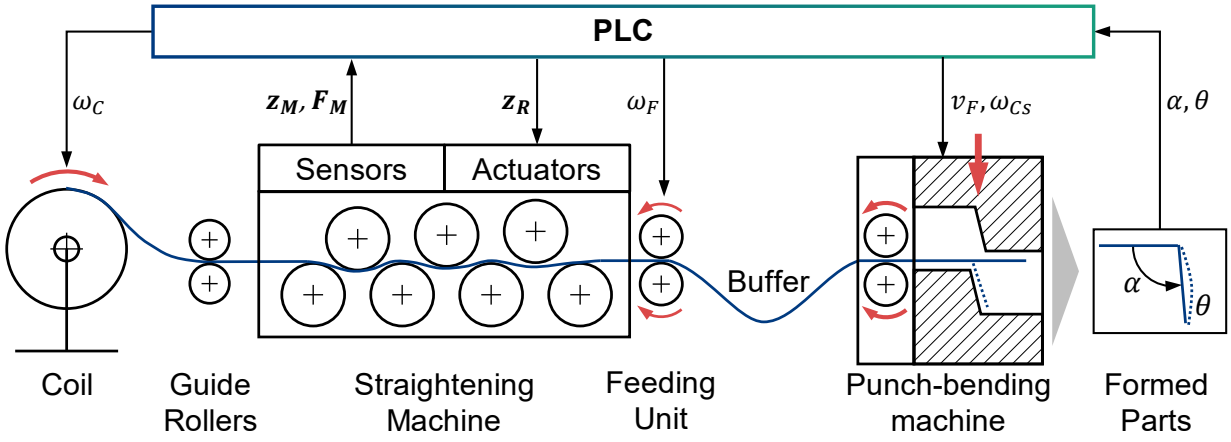

Fig. 1. Schematic representation of the entire manufacturing process.

Materials Research Proceedings 28 (2023) 2007-2016 https://doi.org/10.21741/9781644902479-216

The semi-finished product is uncoiled from a coil and fed to the straightening process via guide rollers. This is equipped with sensors to determine the roller positions $z_M = [z_{1,M}, z_{2,M}, z_{3,M}]^T$ and the straightening forces $F_M = [F_{1,M}, F_{2,M}, F_{3,M}]^T$ on these rollers. The semi-finished product is pulled through the straightening machine by a feeding unit. This is followed by a material buffer to make the transition from the continuous straightening process to the discontinuous punch-bending process. The punch-bending machine has a feeding unit and a punch unit. In this process, an L-shaped component is produced. The bending angle α and the straightness θ of the leg are recorded via a camera. A PLC controls all drives and processes the sensor data. The determining variables for the process speed are the coil speed ω_C upstream of the straightening machine, the feeding speed ω_F of the feeding unit downstream of the straightening machine, the feeding speed v_F at the punch-bending machine, and the cam disk speed ω_{CS} of the punch-bending machine.

The aim of the control approach presented here is the dynamic specification of the reference positions z_R for the straightening rollers. On the one hand, this should keep the quality of the straightening process reproducible at a high level. On the other hand, it should be possible to react to fluctuations in the material properties with a dynamic adjustment of the straightening rollers in the process. The fluctuations in the material properties are interpreted as disturbance variables and can be divided into two categories: deterministic and stochastic disturbance variables. In this approach, the change in pre-curvature over the coil radius is considered as a deterministic disturbance variable. Stochastic disturbances are, for example, width and thickness variations or the material composition.

Accordingly, the developed control approach is also divided into two parts. The feedforward control estimates and compensates for the change in pre-curvature with the aid of disturbance compensation. The feedback control is provided to correct the estimated roller positions in order to react to stochastic disturbances. The structure of the control approach is shown in Fig. 2 and is based on the two-degree-of-freedom structure (cf. [17]).

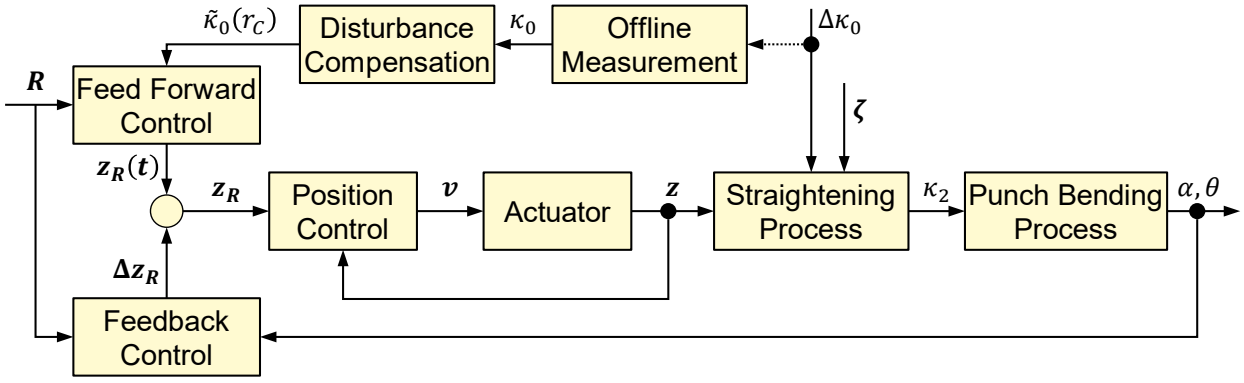

Fig. 2. Scheme of the control structure.

The vector R contains the setpoints for feedforward and feedback control:

$$R = [\kappa_{2,R},\ \alpha_R,\ \theta_R]^T \tag{1}$$

The variable $\kappa_{2,R}$ describes the reference value for the residual curvature of the flat wire behind the straightening machine. Corresponding, α_R and θ_R are the reference values for the characteristics of the component to be produced. Based on the reference specification, the feedforward control specifies a reference trajectory $z_R(t) = [z_{1,R}(t),\ z_{2,R}(t),\ z_{3,R}(t)]^T$ for the three movable straightening rollers. This is corrected by the closed loop control during the running

process by Δz_R, so that the final reference vector z_R is provided for the subordinate position control of the straightening rollers. These are controlled and act as manipulated variables on the flat wire in the first part of the controlled system, the forming process in the straightening machine. As deterministic disturbance variable, the change of the pre-curvature $\Delta\kappa_0$ influences the straightening process. The totality of all stochastic disturbances is summarized in the vector $\boldsymbol{\zeta}$. This includes, for example, variations in width, thickness, or material composition. With a residual curvature κ_2, the flat wire is fed to the punch-bending process, which represents the second part of the controlled system. In this, an L-shaped component is formed, which is characterized by the quantities α and θ (see Fig. 2). These quantities are measurable and can be fed to the control system as measured values.

The change of the pre-curvature $\Delta\kappa_0$ cannot be measured directly during the running process since it is overlaid by process-related tensile forces. This also applies to the residual curvature κ_2 behind the straightening machine. For this reason, only a measurement of the initial curvature κ_0 before starting the production process when inserting a new coil is possible via offline measurement. The initial curvature is fed to the disturbance model in the disturbance compensation. The disturbance compensation estimates the further variation of the curvature $\tilde{\kappa}_0$ over the coil radius r_C. In the feedforward control, a reference trajectory of the straightening roller positions as a function of time $z_R(t)$ is calculated. The exact operation of the disturbance compensation is presented in the following section. The algorithm of the feedback control is part of future work and will therefore not be considered further in detail.

Disturbance Compensation

After a flat wire has been produced in a rolling mill, it is coiled onto a coil for storage and transport purposes. The deformation of the wire on the coil does not immediately generate plastic deformation. Due to effects such as aging, hardening and also thermal influences a straightened coiled flat wire will again show curvature when it is uncoiled. With the right choice for the position of the straightening rollers, this pre-curvature can be compensated. However, the pre-curvature varies with the radius. The radius decreases continuously with the uncoiling of the flat wire and thus the pre-curvature of the wire increases (see Fig. 3 (a)). This requires a continuous adjustment of the straightening roller positions. To determine the roll positions, the pre-curvature must be known exactly. However, this cannot be measured continuously during the process, as this would require stopping the process and unraveling the wire. Therefore, the goal of the disturbance compensation is to estimate the pre-curvature $\tilde{\kappa}_0$ of the flat wire over the radius r_C.

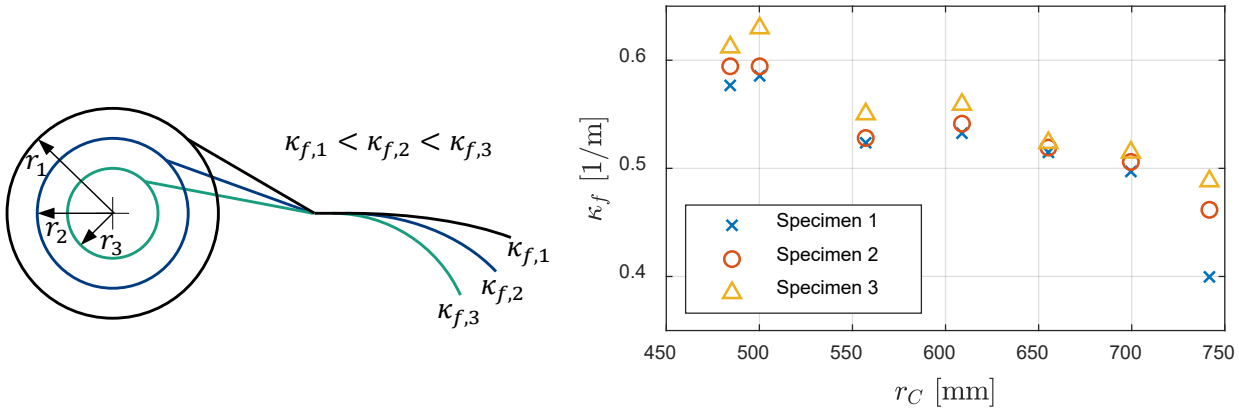

Fig. 3. Trajectory of the pre-curvature over the coil radius: (a) Schematic (left) and (b) measured (right).

Due to the mechanical material properties of steel, the wire springs back when it is uncoiled from the coil. This can be observed especially with wire made of high-strength spring steel. Thus, the curvature κ_f of the wire after uncoiling in the tension-free situation is not identical with the curvature κ_C of the wire in the forced position on the coil. To describe the dimension of this relationship, the springback ratio τ is defined:

$$\tau = \frac{\kappa_f}{\kappa_C} \tag{2}$$

The curvature κ_C during storage can be determined as the reciprocal of r_C. Thus, to calculate the spring-up ratio, it is necessary to measure the curvature of a wire segment in the tension-free state and to determine the coil radius on which the wire segment was stored. The springback ratio is an important parameter for the disturbance model, which will be presented in the following.

The change in pre-curvature during uncoiling a coil can only be measured destructively if specimens are taken from the different coil radii. The result of such an experiment is shown in Fig. 3 (b). The measurement shown was taken on a flat wire (material 1.4310) with a thickness of 0.5 mm and a width of 6.5 mm. The coil had an inner radius of 480 mm and an outer radius of 742 mm.

There is a wide range of factors that influence the trend. Both a fluctuating material composition and cross-section variations as well as the storage time and environmental influences such as temperature and air humidity during storage are to be mentioned here. Added to this are the tension conditions during coiling and the deformation history of the semi-finished product. Other influences such as anelasticity or hardening can be added. All these influencing factors are neither known nor individually measurable by the user who wants to process the semi-finished product into a product. For this reason, the disturbance model is initially kept intentionally simple. A linear relationship between the pre-curvature and the stock radius is assumed. Considering Fig. 3 (b), this is quite reasonable. Thus, the estimate $\tilde{\kappa}_0$ of the curvature over the coil radius r_C can be described with the disturbance model

$$\tilde{\kappa}_0(r_C) = m \cdot r_C + n \tag{3}$$

The parameters m and n describe the gradient and location of the linear function. On the one hand, this approach is particularly robust with respect to the large number of influencing factors and, on the other hand, it is straightforward to parameterize, which is advantageous in view of the limited data available when inserting a new coil. It is necessary to find at least two data points P_o at the outer and P_i at the inner of the coil, which give the information about the pre-curvature value and the corresponding coil radius.

The procedure for determining the two data points is shown in Fig. 4. The inner and outer coil radius $r_{C,i}$ and $r_{C,o}$ are geometrical parameters of the coil and therefore known. For the first data point P_o, the pre-curvature $\kappa_{0,o}$ can be measured using the offline measurement (see Fig. 2) after inserting a new coil. The pre-curvature $\kappa_{0,i}$ for the second data point P_i can only be measured when the coil has been completely uncoiled. Therefore, it is predicted using two sources of information. The first one is the springback ratio from Eq. 2. This can be calculated with the outer data point P_o. Assuming that the springback ratio is approximately constant over the coil radius, Eq. 2 can be transformed to κ_f and the pre-curvature at the coil inside can be predicted. The second source of data is a data base in which the curvature values of the previous coils are stored. Thus, the prediction $\tilde{\kappa}_{0,i,j}$ for the pre-curvature at the coil inside of the j-th coil can be calculated to:

$$\tilde{\kappa}_{0,i,j} = \varepsilon \cdot \tau_j \cdot r_{C,i} + (1 - \varepsilon) \cdot K_{0,i} \tag{4}$$

Here, ε indicates how much trust is placed in the estimation via the springback ratio. The value for ε can be set between 0 and 1. The closer ε is to 1, the more confidence is placed in the estimate of the springback ratio. $K_{0,i}$ indicates the moving average of the measured pre-curvature $\kappa_{0,i}$ of the previously processed coils:

$$K_{0,i} = \frac{1}{n}\sum_{k=1}^{n} \kappa_{0,i,(j-k)} \tag{5}$$

In it, n indicates the number of previously processed coils to be considered in the estimation. For the first coil, only the spring-back ratio is available for the estimation.

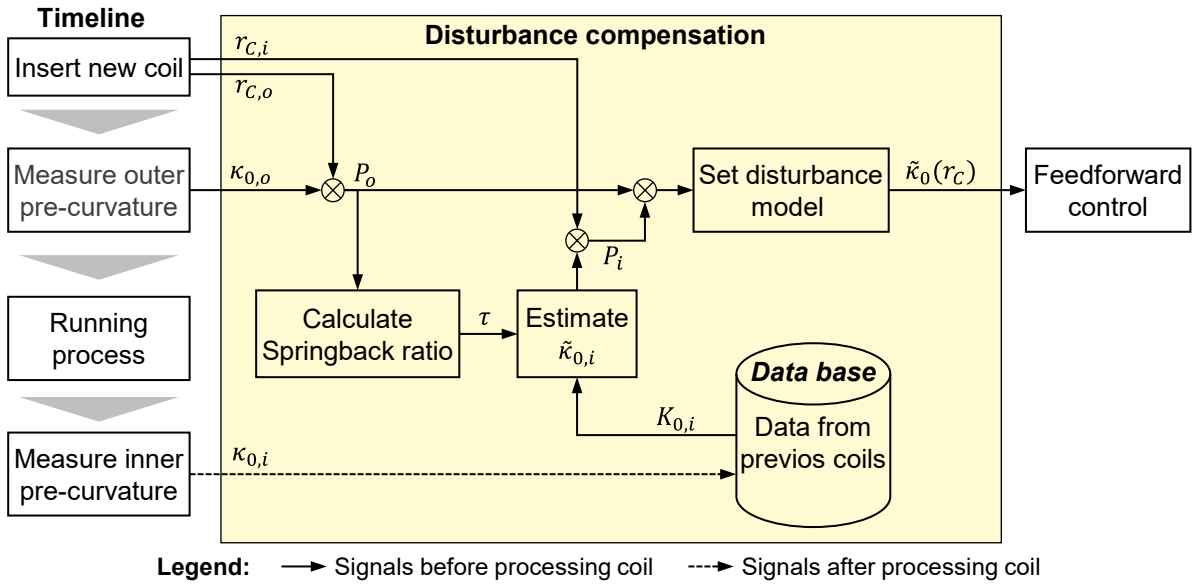

Fig. 4. Working principle of the disturbance compensation algorithm.

In the feedforward control, a nominal trajectory for the straightening rollers can now be determined based on a plant model of the straightening machine, so that the predicted pre-curvature trajectory is compensated over the radius. In combination with the process speed and the coil geometry, the feedforward control specifies a time-based reference trajectory for the positions of the straightening rollers.

This procedure takes into account the properties of the coil to be processed. At the same time, the material behavior on a coil is learned over several coils and the prediction is continuously improved. The more precise the prediction, the higher the straightening quality and the fewer straightening rollers have to be used. Thus, in addition to a high straightening quality, the number of straightening rollers is also reduced and thus the material is straightened more carefully and in line with requirements. As a result, the strength values are maintained and the overbending is reduced.

In order to show how the estimation algorithm works, it was carried out on three samples as an example. A flat wire made of the material 1.4310 and with the dimensions 6.5 mm x 0.5 mm (width and thickness) was considered. The coil had a diameter of 480 mm inside and 742 mm outside. The result is shown in Table 1. The measured pre-curvature $\kappa_{0,o}$ at the outer coil radius and the calculated springback ratio τ are listed in the second and third column. Subsequently, two estimates have been calculated. The first one is the estimate $\tilde{\kappa}_{0,i,1}$ calculated using only the springback ratio. The second estimate $\tilde{\kappa}_{0,i,2}$ was calculated using Eq. 4. For this purpose, $\varepsilon = 0.333$ was chosen. This means that the deflection ratio is trusted to be 33.3 % and the measured values of the previous

coils to be 66.7 %. The value was chosen because the estimate about the springback ratio on the first coil was a bit too high. This trend is confirmed on the other two specimens. Thus, for further coils, the trust ratio can be further adjusted in favor of the curvature values of previous coils. In the last column, the measurement of the pre-curvature $\kappa_{0,i}$ at the inner coil radius is shown for comparison.

Table 1. Result of the estimation algorithm ($\tilde{\boldsymbol{\kappa}}_{\mathbf{0},\boldsymbol{i},\mathbf{1}}$ corresponds to estimate only based on $\boldsymbol{\tau}$; $\tilde{\boldsymbol{\kappa}}_{\mathbf{0},\boldsymbol{i},\mathbf{2}}$ corresponds to the estimation according to equation 4 with $\boldsymbol{\varepsilon} = \mathbf{0.333}$).

#	$\kappa_{0,o}$ [1/m]	τ [-]	$\tilde{\kappa}_{0,i,1}$ [1/m]	$\tilde{\kappa}_{0,i,2}$ [1/m]	$\kappa_{0,i}$ [1/m]
Specimen 1	0.3996	0.2965	0.6177	-	0.5767
Specimen 2	0.4882	0.3622	0.7547	0.6360	0.5944
Specimen 3	0.4617	0.3426	0.7137	0.6282	0.6120

With these calculations, a trajectory for the straightening rollers can now be determined. In the case of specimen 3, the straightening machine would be set for a constant pre-curvature of 0.4882 1/m in a conventional straightening process. With the presented algorithm, a continuous change in pre-curvature from 0.4882 1/m to 0.6282 1/m is considered. This matches the actual change of the pre-curvature to 0.6120 1/m much better than assuming a constant progression. This shows the great advantage of the algorithm. With the estimation of the trajectory of the pre-curvature, the straightening rollers can be continuously adjusted during the running process. The small estimation error is acceptable in any case and is compensated by the feedback control. A static persistence of the straightening rollers in one position over the entire straightening process produces a considerably lower straightening quality and therefore requires a higher number of straightening rollers to compensate for this.

Summary

This paper presents a novel control concept for a manufacturing process consisting of a straightening machine and a punch-bending machine. The concept presented enables the straightening rollers to be readjusted during the manufacturing process. In this way, a novel possibility is created to be able to react to fluctuations in the material properties. Both deterministic and stochastic material fluctuations are addressed. With the help of the learning disturbance compensation, the deterministic change of the pre-curvature over the coil radius is estimated and compensated. Thus, over the entire manufacturing process, the estimation can be continuously improved, and the material behavior learned. Other stochastic material variations can be compensated via online measurement in the punch-bending process.

This method opens up completely new possibilities for an efficient and resource-saving manufacturing process. Compared to conventional levelers, the number of leveling rolls can be reduced. In addition, overbending can be avoided by straightening the semi-finished product as required, which preserves the strength properties of the material. This increases the sustainability of the forming processes in two key aspects: On the one hand, it is possible to react to material fluctuations and adjust the position of the straightening rollers. This leads to a reduction in the rejection rate of the manufacturing process. On the other hand, components can be designed slimmer and lighter by preserving the strength properties of high-strength steels. This results in a high potential for lightweight constructions with high strength steel. The combination of both aspects at the same time in one manufacturing process contributes significantly to a responsible and careful use of resources. At the present time, a potential of up to 8.5% in material savings is estimated. A detailed validation of this control concept is pending in the next research work.

Keywords: Biodegradable Polymers, Sustainable Packaging, Life Cycle Assessment

Abstract. The packaging industry is a significant contributor to the plastic pollution burdening our environment. One main issue with plastics is that they are designed to be durable, and so they persevere in the environment even after they have fulfilled their use. This study aims to analyse the potential benefits of switching to biodegradable and biobased polymers in the cosmetic packaging industry to lessen their environmental impact once disposed of. This assessment commenced with a sustainable material selection process to shortlist a set of viable biodegradable candidate materials (polylactic acid and wood plastic composites), for cosmetic compacts and then comparing them to acrylonitrile butadiene styrene as the benchmark material for this application. The functional, environmental and cost implications of such a change were quantified to validate the suitability of using biodegradable polymers. Functionally, polylactic acid and acrylonitrile butadiene styrene only passed the testing conducted making wood plastic composites an unviable option. wood plastic composites and polylactic acid were found to cost 40-53 per cent more than acrylonitrile butadiene styrene. In terms of the environmental impact, polylactic acid and wood plastic composites reduced the lifecycle impact by 18-30 per cent and the end-of-life impact by 26-42 per cent. The results obtained suggest great potential in shifting to such an alternative.

Introduction

People have become more aware of their impact on the environment, allowing sustainability to shape the way current businesses make long term decisions. This paradigm shift to sustainability is mainly brought about by consumer demand and legislation. Society demands that organisations become responsible corporate citizens and puts their money behind these demands. Therefore, businesses must shift to sustainable practices to remain competitive in today's market [1]. In the cosmetics industry, customers are seeking more eco-friendly products, this is substantiated by a projected natural and organic cosmetic market growth from €11.42 billion in 2021 to €17.35 billion by 2027 [2]. Moreover, fossil-based polymers are made from fossil fuels, a finite resource which is projected to run out by 2042 [3]. One benefit of using such materials is their relatively cheaper cost due to their popularity in the market. However, this will soon change, as the introduction of new regulations to cut down manufacturers' dependence on fossil fuels will lead to higher costs. In 2019, the global plastic production and incineration carbon footprint was estimated to be 850 Mt of CO_2. Such emissions could reach 1,340 Mt by 2030 and gradually increase to 2,800 Mt by 2050 [4]. By noting the accelerated growth of the bioplastic market, going from 2.11 million tonnes in 2018 to a projected 2.62 million tonnes in 2023, it is safe to assume that costs will be reduced as time progresses [5]. Therefore, it is imperative to explore alternative materials with lower carbon footprints throughout their whole life cycle.

A study conducted by Cinelli et al. commented on the unfeasibility of reusing or recycling cosmetic packages due to issues with post-use packaging collection and cleaning of residue contamination. Therefore, attaining a full circular economy proves to be challenging for the cosmetic packaging industry. They also commented on the vitality of considering the functional

requirements of the cosmetic packaging when opting for a biodegradable alternative [6]. Various researchers discussed renewable materials such as PLA and WPC as being suitable candidates for cosmetic packaging due to their decent mechanical properties and affordable cost [7, 8]. Sebastião et al. took a Life Cycle Engineering cradle-to-grave approach to biodegradable material selection. When selecting a biodegradable polymer alternative, they evaluated each candidate material's environmental, financial, and functional benefits, correlating the three through a ternary diagram. Furthermore, by creating a Multi-Attribute Decision-Making process, Sebastião et al. could analyse the performance of the materials by correlating their mechanical properties with the product requirements. The environmental and economic effects were then defined using life cycle analysis (LCA) and life cycle costing methodologies. Finally, the suitability of biodegradable materials was determined, confirming that PLA was well suited for their application [9]. One limitation in this approach is the lack of consideration of biodegradability at EoL; moreover, a more detailed decision matrix would have corresponded to a more inclusive analysis.

After reviewing various literature in this field, the goals of this study were set to select and compare different biodegradable polymers suitable for the cosmetic packaging industry, from functional, environmental, and cost perspectives. Thus, concluding whether biodegradable materials are superior to fossil-based non-biodegradable materials in the cosmetic packaging industry.

Method and Materials

The method followed throughout this study is summarized in Fig. 1. The product definition was the first step in which the case study part for this assessment was selected by following the recommendations of the industrial partner of this study (Toly Products Ltd). The *infinity round compact* made from Acrylonitrile Butadiene Styrene (ABS) material, as seen in Fig. 2, was chosen having a production volume of 2 million compacts per year. In this assessment the term compact will be used to refer to the cosmetic packaging made up of the base and lid excluding any stainless-steel pins, mirrors or powder inserts.

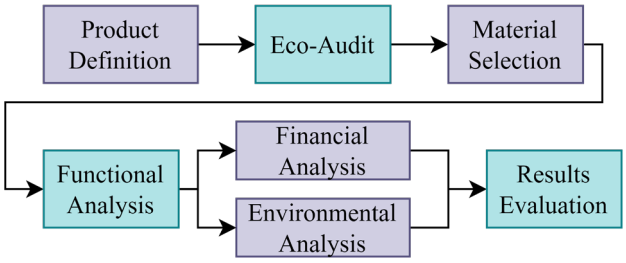

Fig. 1. Method Summary.

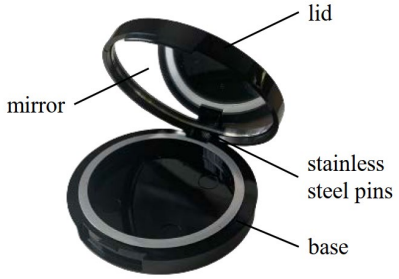

Fig. 2. Case Study Part.

Ansys Granta EduPack 2020 was used to conduct an 'eco-audit' on the case study part. This was used to establish the baseline energy and carbon footprints of the ABS compact at each life stage as shown in Fig. 3. This, together with the design requirements set by the industrial partner were used to create a translation table (Table 1) following the Ashby methodology [10]. By using the relative penalty function method, five materials were shortlisted: Polylactic acid (PLA), PLA with 30% natural fiber, PLA impact modified, Polyhydroxyalkanoates (PHA), Polycaprolactone (PCL) and wood plastic composites (WPC). The Ansys Granta EduPack synthesiser tool was used to create a material made of non-fibrous wood particles and PLA. This allowed for the inclusion of WPC in the assessment by incorporating it in the decision matrix constructed to rank the materials. The direct rating method was used to assign a unique weighting to each criterion in the decision matrix. Three main categories were highlighted and given equal importance: (i) *functional* (flexural strength, impact strength, density, and mould shrinkage), (ii) *financial* (cost), and (iii) *environmental* (biodegradability and carbon footprint). The ranking resulted in WPC placing first,

followed by the datum ABS and then PLA placing third. ABS HI121H, PLA 4043D and WPC Sulapac Universal grades were procured.

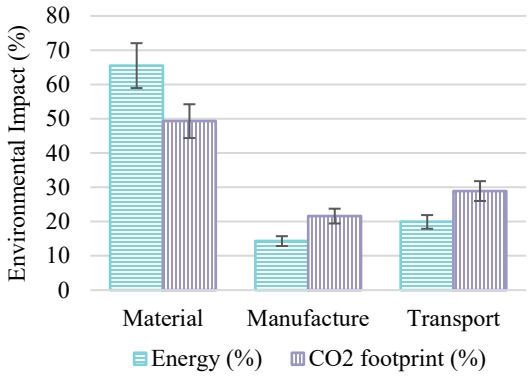

Fig. 3. Eco-Audit results for the Case Study Part.

Table 1. Material selection constraints and objectives.

Constraints	Geometrical: Radius; Thickness; Width Functional: 1. Must be biodegradable 2. Must be injection mouldable 3. Must support a flexural strength of F *[78MPa]* 4. The shrink rate must be like S *[0.4-0.7%]*
Objectives	1. Minimise Carbon Footprint 2. Minimise Embodied Energy 3. Maximise Impact Strength 4. Minimise Density 5. Minimise Cost

A thermal analysis using identiPol QA2 was performed on the materials to understand how their properties change with temperature. Three samples of ABS, PLA and WPC were run to build a database of these materials to be analysed by plotting Tan Delta and Stiffness vs Temperature plots. This equipment also allows the user to identify the contents of the tested material by running a quality index score test (QIS). Since WPC Sulapac Universal is a commercial material, this test was run to compare it to PLA due to an assumption that PLA was used as the biodegradable polymer matrix to which wood fibers were added. Therefore, ten samples of PLA were run through the identiPol QA2 to create a PLA reference dataset that could then be compared with WPC Sulapac Universal. Then, a score was generated between 0 and 10, 0 implying no match and 10 corresponding to a perfect match allowing the user to assume the composition of the material.

In terms of the quality analysis the standard procedure followed by the industrial partner to validate the compact's quality was adhered to. For the package integrity testing, an open-close cyclic test was performed, for which 400 open and close cycles were simulated. After 100 cycles, the compacts were checked to confirm whether the pins remained in the hinge. Furthermore, a drop test was performed on the compacts in which, five compacts were dropped with the compact base parallel and perpendicular to the ground from a height of one meter. The Mecmesin MultiTest 2.5dv force gauge was used to carry out the hinge break test, to determine the minimum force required to break the hinge, and a clip open test to determine the maximum force required to open the compacts' clip.

For the cost assessment the Part Cost Estimator tool available in Ansys Granta EduPack was used to allow for a cost comparison between the different materials. The tool required a series of cost and feature-related input data, from which it could estimate the manufacturing cost for one compact made from the different materials selected.

For the environmental assessment, a four step Life Cycle Assessment as shown in Fig. 4 (following ISO 14040:2006) using SimaPro 9.2 was used. Ecoinvent v3.3 was used for the inventory and impact assessment stages [11]. Furthermore, ReCiPe2016 (Hierarchist) was used as the impact assessment method to convert the life cycle inventories to a list of harmonised impact scores on a midpoint and endpoint level.

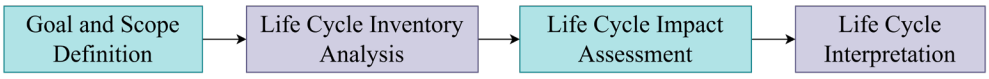

Fig. 4. LCA methodology.

The goals of the environmental LCA were as follows:

- Analyse and compare the impacts of the whole lifecycle of a PLA and WPC compact to those of an ABS compact.
- Compare the effects of different End-of-Life (EoL) scenarios i.e. (i) industrial composting, (ii) landfill, (iii) incineration, and (iv) recycling, for ABS, PLA and WPC compacts.

As for the scope of this assessment, the LCA was conducted for the base and lid of the compact, disregarding any pins and aluminium pans. Furthermore, a cradle-to-grave assessment was followed, neglecting the use and transportation phases. The use phase was ignored as the compact is a static object and thus consumes no energy or resources during its use phase. The transportation phase was also disregarded as it was assumed that similar routes would be followed by all three materials, thus having no significant influence on the overall environmental impact, given their relatively similar densities. Additionally, the functional unit, which is a quantified description of the system's performance was taken to be *2 million Infinity* Round Compacts. During the life cycle inventory assessment stage, the necessary inputs and outputs to evaluate the life cycle impacts of the compact were realised as highlighted in Table 2. The PLA and ABS readily available in SimaPro were selected for the raw material production phase. For WPC, the material was synthesised by first reviewing the material patent as in [12] and then relating this with the thermal analysis QIS test results. By noting that WPC Sulapac scored an 8 compared to PLA, it was assumed that it comprises 80% PLA and 20% wood fibers. As for the manufacturing phase, the injection moulding process was considered for all materials. For the EoL phase, landfilling, incineration, recycling, and industrial composting were considered. In Ecoinvent v3.3, there was no EoL scenario for industrial composting which was considered as an EoL scenario for the biodegradable polymers; thus, this was created by assuming that when the biodegradable compact is placed in an industrial composting facility, it transforms into carbon dioxide, water and humus as stated by NatureWorks in [13].

Table 2. Mass of raw material used per component.

Raw Material	Component	Volume (cm^3)	Density (g/cm^3)	Mass (g)
ABS	Lid	9.543	1.05	10.020
	Base	12.733		13.370
PLA	Lid	9.543	1.35	12.883
	Base	12.733		17.190
WPC	Lid	9.543	1.26	12.024
	Base	12.733		16.044

Following this, two assessments were conducted, (i) an EoL assessment and (ii) a Life Cycle assessment. For the latter, the EoL scenario considered was a mix of all scenarios. This was done as the probability of all the compacts ending up in the same waste disposal environment is highly unlikely as this depends on a series of factors such as the geographical location and product material. Therefore, the method adopted by Moretti et al. in [14] was implemented to model a complete life cycle of the compacts. For ABS, it was assumed that 30% was recycled, 39% was incinerated, and 31% was landfilled; for WPC and PLA, it was assumed that 15% was industrial composted, 15% was recycled, 39% was incinerated, and 31% was landfilled.

The results were interpreted by following the ReCiPe 2016 impact assessment method. This method follows a cause-and-effect pathway that allows for assessing the relationship between the inventories and their potential impacts. This addresses various environmental concerns at the midpoint level and then combines them into three endpoint categories, (in terms of damage to

Human Health, Ecosystems, and Resource Availability) allowing for a detailed and generalised assessment. The results obtained were then interpreted by first noting the impacts on the whole life cycle by switching from ABS to PLA and WPC, together with the effect of different EoL scenarios chosen. As highlighted in ISO 14040:2006, this phase must include the identification of significant issues highlighted throughout the assessment and an evaluation of the study itself [15]. This was done by first reviewing the life cycle inventory to confirm that the methods and data applied across the different materials were consistent and ensuring that long term emissions were considered in all scenarios.

Results and Discussion

Following the series of analyses conducted, the results were analysed to generate a comprehensive understanding of the impacts on the functional, cost and environmental factors when switching to PLA and WPC from ABS for the cosmetic compact case.

Thermal Analysis. From the Tan Delta vs Temperature graph shown in Fig. 5, the material's viscous to elastic response ratio was analysed. From the Tan Delta values at room temperature obtained, PLA registered the most significant Tan Delta value of 0.05 ± 0.01, followed closely by WPC at 0.03 ± 0.01 and then ABS at 0.02 ± 0.01. These values could imply that PLA has the relatively best energy absorption at room temperature. However, one must acknowledge that this is not related to the material's impact strength; thus, further functional testing is required to confirm such an assumption.

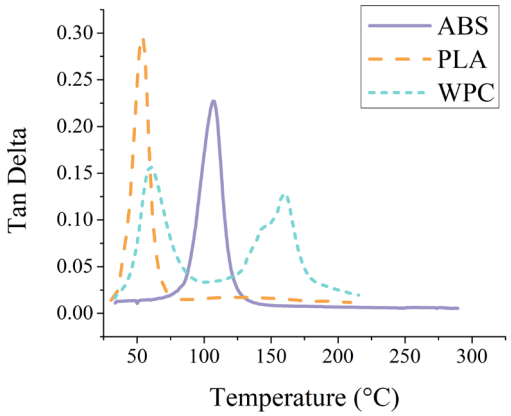

Fig. 5. Tan Delta vs. Temperature (˚C).

Furthermore, by noting the glass transition temperatures of the materials, ABS was the most thermally stable material, followed by PLA and WPC, which are relatively similar. The onset glass transition temperature for both PLA and WPC was initiated at approximately 40˚C, relatively close to room temperature. Therefore, when both compacts are used at temperatures above 40˚C (such as when the cosmetic compact is left in a car in summer), their structural integrity may not be upheld, and the compacts may warp or shrink depending on how excessive the temperatures are.

Table 3 summarises all thermal analysis results. ABS is an amorphous material, so no melting temperature was measured for this material. Furthermore, although PLA is a semicrystalline polymer, it behaved amorphously as no melting point was recorded. This is firstly due to its low crystallisation rate and secondly due to a relatively high cooling rate during the preparation of the testing samples. Therefore, the melting temperature of PLA listed in Table 3 was taken from its datasheet instead [16]. When comparing the WPC to PLA it was observed that the crystallisation rate increased for WPC, due to the presence of the wood particles, thus, resulting in a higher melting point.

Table 3. Thermal analysis results (Mean ± St. Deviation).

Material	Tan Delta at Room Temperature	Glass Transition Temperature (˚C)	Melting Temperature (˚C)
ABS	0.02 ± 0.01	108.50 ± 5.78	NA
PLA	0.05 ± 0.01	61.47 ± 2.25	145-160 [16]
WPC	0.03 ± 0.01	57.77 ± 1.85	187.77 ± 2.32

Quality Analysis. The results from the quality tests conducted were as seen in Fig. 6-9. Considering the overall performance of all three materials, PLA and ABS passed all tests, making PLA a viable biodegradable material for this case study part. WPC, on the other hand, while being visually attractive, was functionally inadequate. Throughout all the tests, the WPC compact was repeatedly failing from the hinge as a result of a low-quality weld line which was formed here, leading to the premature failure of the compact. It was assumed that the wood powder portion of WPC hindered the proper mixing of the two PLA melt flow fronts during injection moulding.

The injection moulded compacts were produced, having a relatively smooth surface finish. The PLA compact had a slight yellow tint which was not as attractive as the others. This may be improved by adding a colorant or master batch to cancel out the yellow tint. Furthermore, the PLA compact had visible streaks along the base, close to the injection point, as seen in Figure 6. These could be due to the low mobility of the polymer and could be avoided by increasing the melt temperature and back pressure during the injection moulding process as well as by adding a colorant. In all cases, there were no pronounced defects on the compact surfaces and all in all, they had a good surface finish.

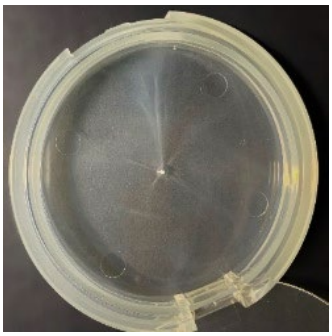

Fig. 6. Streaks along PLA base.

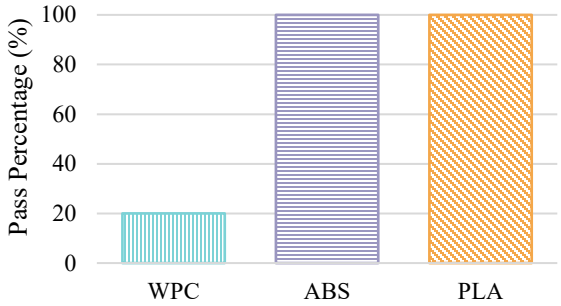

Fig. 7. Drop Test.

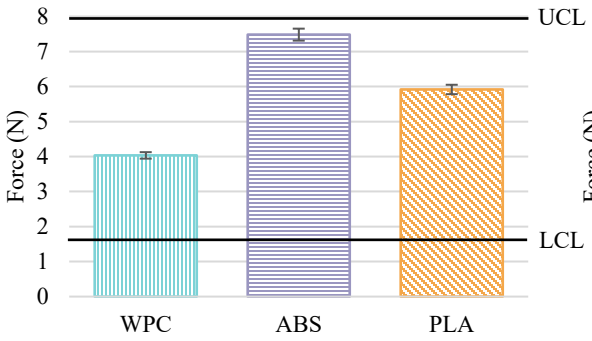

Fig. 8. Clip Opening Test (UCL = 8N, LCL =1.5N).

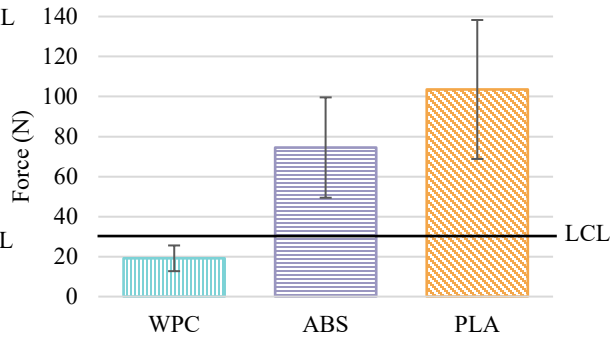

Fig. 9. Hinge Break Test (LCL = 26.5 N).

Cost Assessment. The cost per compact of ABS was €0.15, WPC was €0.21, and PLA was €0.23. The first observation was that biodegradable alternatives cost 40-53% more than ABS. This may be attributed to ABS's relatively more significant market presence. WPC and PLA compacts cost relatively alike, having only a 9% difference between them, which may seem minuscule, however, considering the yearly production of two million compacts, this difference will sum up to 40,000 EUR/yr. This distinction in price may be mainly attributed to the discrepancy in material cost rather than processing related costs.

Environmental Analysis. During the environmental assessment, three endpoint indicators were examined to obtain an understanding of the impact in terms of the effect on human health, resource availability and the ecosystem. To then generate a more in-depth assessment, the midpoint categories were used, allowing for a detailed understanding of the generated impact.

Life Cycle Assessment. After modelling the whole life cycle of the compacts, the relationship as seen in Fig. 10 was obtained by considering the total weighted impact of the three endpoint categories, which is the summation of the impact of the three endpoints. ABS had the overall highest environmental impact throughout its lifecycle. Opting for a WPC compact was found to correspond to a 35.2% reduction in life cycle environmental impact when compared to an ABS compact. Alternatively, opting for a PLA compact would lower the environmental impacts of the whole life cycle by 19.5%. During the material production phase, PLA generated the relatively most significant impact, 23.3% higher than that of ABS. WPC, however, generated relatively the same impact as ABS material production. Therefore, one may conclude that by increasing the content of wood powder in the PLA matrix for WPC, the impact during this life phase may be reduced. Moreover, for the manufacturing phase the biodegradable materials generated a more significant impact on the environment than ABS. The injection moulding of the PLA compact generated a 16.3% higher environmental impact than ABS, and WPC generated a 17.8% higher impact than ABS. This distinction corresponds to the relatively higher energy required and carbon footprint linked to the injection moulding of WPC and PLA [10].

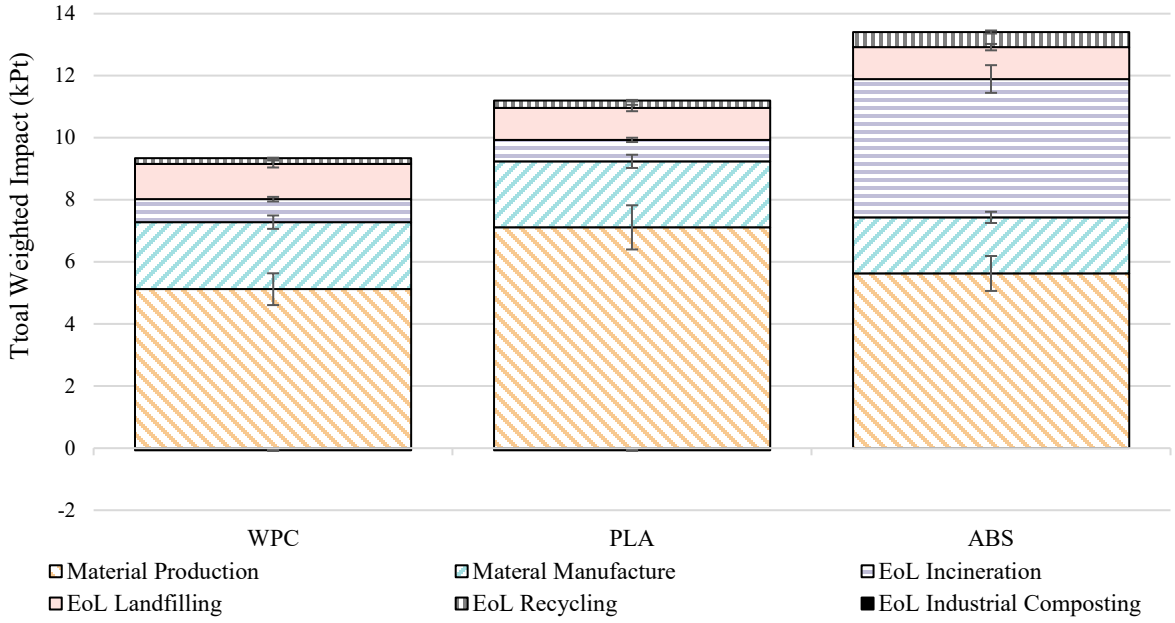

Fig. 10. Total weighted impact of the compact life cycle.

End-of-Life Assessment. In this assessment the EoL scenario was analysed by generating a total weighted impact score of the three endpoints as seen in Fig. 11. This allowed for the complete visualisation of the environmental impact of each EoL scenario.

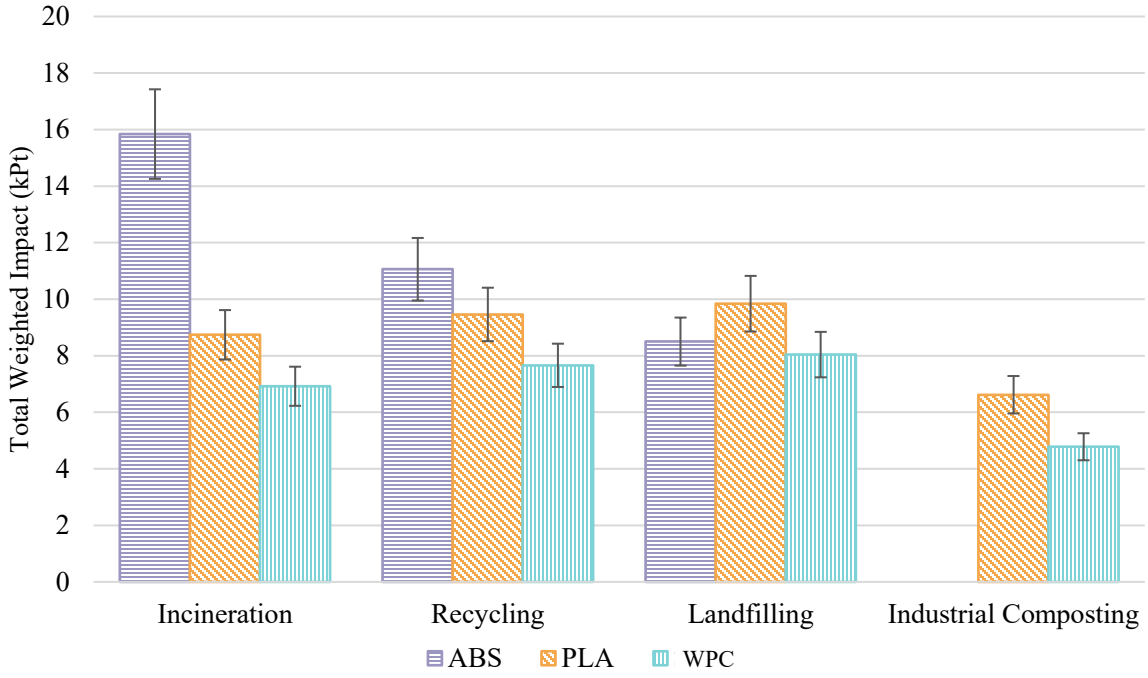
If one were to assume that the compacts would be incinerated at EoL, opting for PLA would generate a 57.8% smaller environmental impact than ABS and WPC would generate a 78.4% smaller impact than ABS. This distinction could be linked to the carbon dioxide given off during incineration, corresponding to 314,000 kg CO_2 eq for ABS, which was found to be 62.2% more than PLA and 82.9% more than WPC. Additionally, ABS contributed to the emission of 49,600 kg CO_2 eq of methane, which was significantly much more than that of PLA and WPC.

In terms of recycling and landfilling the variation in the results is not as significant as with incineration. With recycling, opting for PLA would reduce the environmental impact by 15.6% and opting for WPC would reduce the impact by 36.3% than ABS. From a midpoint analysis, recycling ABS ranked relatively high, as a substantial amount of waste was being generated, which

in turn was ending up being incinerated. Furthermore, in terms of carbon dioxide emissions during recycling, ABS was found to emit 155,000 kg CO_2 eq, which was 37.5% higher than PLA and 76.2% higher than WPC.

When considering landfilling as an EoL option, PLA generated the most significant impact, while ABS and WPC had relatively the same overall impact. The 14.6% difference between PLA and WPC and the 20.1% difference between PLA and ABS may be attributed to the higher biogenic methane gas emissions of biodegradable materials when landfilled. When a biodegradable material is placed in a landfilling facility, it undergoes anaerobic digestion due to the lack of oxygen, resulting in the emission of excessive biogenic methane gas [17]. When landfilling WPC and PLA, more than 650 kg/year of biogenic methane gas would be given off than when landfilling ABS.

In terms of the industrial composting scenario, the impacts of both WPC and PLA were the lowest out of all other scenarios. The 32.3% difference in environmental impact between the two may be attributed to the 20% wood fibres considered in the WPC material. In fact, one common trend across all EoL scenarios is the relatively lower impact of WPC to PLA which is linked to the wood fibre in the PLA matrix. Therefore, it may be assumed that by increasing the wood content, the environmental impact may be reduced.



Summary

The target objectives of this study were met as the evaluation of using biodegradable materials in the cosmetic industry was made in terms of the functional, cost and environmental categories. Following this assessment, PLA was recommended as a viable biodegradable alternative to ABS, as it generated a 19.5% lower life cycle environmental impact to ABS and when considering the EoL scenarios for PLA, it generated a 57.8% lesser environmental impact during incineration which is the most likely EoL scenario for cosmetic packaging [6]. Furthermore, PLA was recommended as it passed all functional tests carried out at the industrial partner, at times performing better than ABS, the datum material of this study. The downside of using PLA is that it costs 53% more than ABS. However, this distinction is projected to decrease once biodegradable polymers establish themselves more on the polymer market. Also, by considering the ever-increasing costs of the fossil-based polymers, ABS may no longer be a viable option in the near

future. One must mention that WPC was not recommended as the biodegradable alternative to ABS simply because of its failure to pass the quality functional tests. Had WPC passed the hinge break test, and the drop tests it would have been a relatively better material than PLA in terms of both cost and environmental impact, and so should not be completely disregarded for its application in the cosmetics packaging industry. The results of WPC break test can significantly be improved simply by positioning the weld line away from the hinge area, which in turn can be accomplished by changing the position of the injection gate.

Keywords: Thin-Film Sensor, Cold Forging, Cyclic Simulation

Abstract. Data acquisition and data analysis to gain a better process understanding are one of the most promising trends in manufacturing technology. Especially in cold forging processes, data acquisition close to the deformation zone seems challenging due to the high surface pressure. Thus far, process parameters such as die temperature are mainly measured with state-of-the-art sensors, including standard thermocouples, which are integrated into the tooling system. The application of thin-film sensors has been tested in hot forging processes for local die temperature measurement. However, the process conditions regarding tribology and tool load in cold forging are even more difficult. In this contribution, the use of thin-film sensors, applied on a cold forging punch for cup backward extrusion, is subjected. The aim is to investigate the applicability of such thin-film sensors in cold forging with special emphasis on temperature measurement in cyclic forming processes. The thin-film sensor system and its manufacturing procedure by vacuum coating technology combined with microstructuring are described. With these thin-film sensors the cup backward cold extrusion of steel billets was investigated experimentally. Cyclic tool heating simulations with thermal parameter variations were performed as a reference to experimental results.

Introduction

Cold forging has a long and established history and is still one of the most cost- and energy-efficient technologies to produce metallic components on a large scale for fasteners industry and automotive drive train systems. Besides the high process productivity and the low energy consumption, the parts show increased yield strength as a consequence of strain hardening during cold forming. Scientific process investigations in cold forging technology are usually conducted under stationary conditions, neglecting effects such as cyclic tool heating, which is inevitably a part of industrial processes. Process instabilities can cause scrap and may lead to unplanned downtimes of the whole process. In recent times, process digitization and process monitoring became one of the most promising trends in manufacturing technology to identify such process instabilities [1]. One decisive parameter for both dimension of the forged component and the tribological system of the process is the thermal condition of the tooling system. Especially during

transient ramp-up phase, temperature may increase a lot. To study the influence of tool heating on part dimensions, correct model boundaries are most important for a good prediction.
Fundamental investigations on elastic tool deformation considering both thermal expansion and mechanical compression were presented by Kuzman [2], who found a linear correlation between the normal pressure applied on a punch and its compression under different thermal conditions. The higher the temperature, the more the thermal expansion compensates the elastic compression of the punch due to mechanical loads. Numerical studies on die heating during process ramp-up in cold forging were shown by Qin et al. [3]. Tool heating was investigated with special emphasis on the characterization of ramp-up duration, until the die temperature reaches a steady state. Müller et al. [4] first investigated thoroughly the effect of temperature increase on friction conditions. In sliding friction tests could be shown, that a temperature increase ($\Delta T = 125$ K) during process ramp-up yields in friction coefficient decrease of up to 45 % for several lubricants such as molybdenum disulphide, polymer and soap. Furthermore, adhesion can be one limiting parameter under certain tribological loads and temperatures. Thus, it is important to be aware of the resulting temperature during the forming process close to the deformation zone - or even better, in the interface between tool and workpiece.

For the measurement of process data in the interface between two bodies, the use of thin-film sensors has been studied for different applications in manufacturing engineering [5]. A thin layer of a certain material featuring specific properties is applied on a surface layer, that insulates the sensory layer from the substrate material. Materials such as chromium are used to create thin-film sensors with a specific shape to allow measurement of the electrical resistance during changing external loads. Such sensors have been successfully applied in machining processes for temperature measurement of cutting inserts right on the rake face [6] as well as in grinding processes [7]. Novel application methods for the thin-film layer were studied in [8] and [9]. The application of thin-film thermocouples in surface textures of carbide tools was investigated in [10]. First applications in metal forming technology were shown in [11], where thin-film sensors were applied on hot forging tools to measure the die temperature in the interface between tool and workpiece during deformation. The wear resistance of the sensors, however, was limited.
In this publication, a first application example of thin-film sensors for temperature measurement on a punch surface in cup backward cold extrusion of steel cans is subjected. Especially the high tribological loads regarding normal pressure, sliding velocity, surface expansion and temperature prevailing in cold forging seem challenging for the application of such sensor systems. Wireless data acquisition is tested to gain real-time data during the experiments using an amplifier and data acquisition unit mounted to the press. The results show, that punch temperature profiles could be recorded, using the thin-film sensor system. Cyclic process simulations, considering the forming process itself, the ejection process and transfer time were performed using QForm UK 10.2.2 software. Parameter variations in cyclic simulations showed the main influencing factors during the die heating process within 250 forming cycles.

Experimental Setup and Process Simulation

System description.
For the investigation of the developed thin-film sensors in cold forging technology, a lab-scale cup backward extrusion process, consisting of a mechanical knuckle-joint press and a data acquisition system, was set up (see Fig. 1). The cup backward extrusion punch was chosen for the application of the thin-film sensors. An embedded system was connected to the press for data acquisition and transfer to a processing system via Bluetooth Low Energy (BLE). The thin-film layer system was designed according to the tribological loads applied to the tool surface, such as normal pressure, relative velocity, temperature and surface expansion, which were gained by numerical simulation. Data visualization and analysis was maintained by a data processing unit.

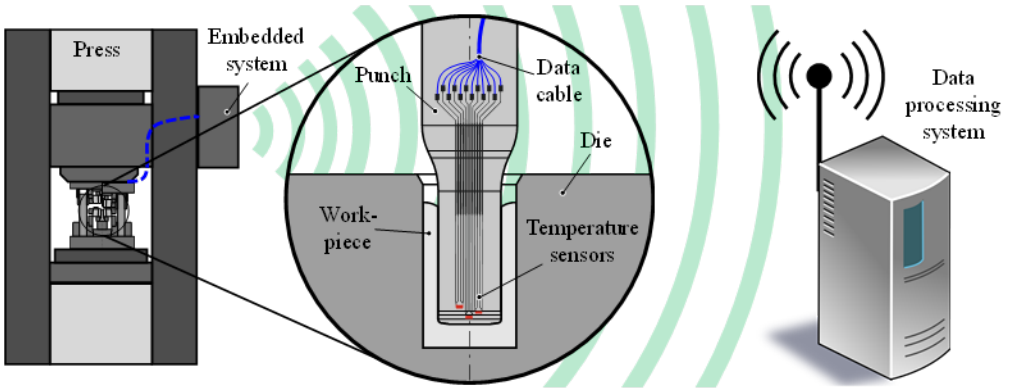

Fig. 1. Procedure for temperature measurement with thin-film sensors and data acquisition.

Thin-film sensor system.

The thin-film sensor system subjected here could be directly applied to the surface of a forging tool and consisted of three different functional layers. These layers were applied to the polished surface of the punch by means of physical vapor deposition (PVD) and plasma-enhanced chemical vapor deposition (PECVD) process. To realize sufficient electrical insulation in the required temperature range between the tool and the sensor structures, an aluminum oxide layer (Al_2O_3) was homogeneously deposited with a thickness of approx. 5 µm. An electrically conductive chromium layer with a thickness of 0.2 µm was chosen for the sensor layer. Due to the positive temperature coefficient (PTC) of chromium, the material was suitable as a temperature sensor, since an increasing temperature led to an increase in electrical resistance. The structuring of the metallic layer was achieved by a combination of photolithography and chemical wet etching. As shown in Fig. 2 a), a final layer of amorphous hydrogenated carbon (SICON®) was applied on top of the structured sensor layer for electrical insulation and wear resistance.

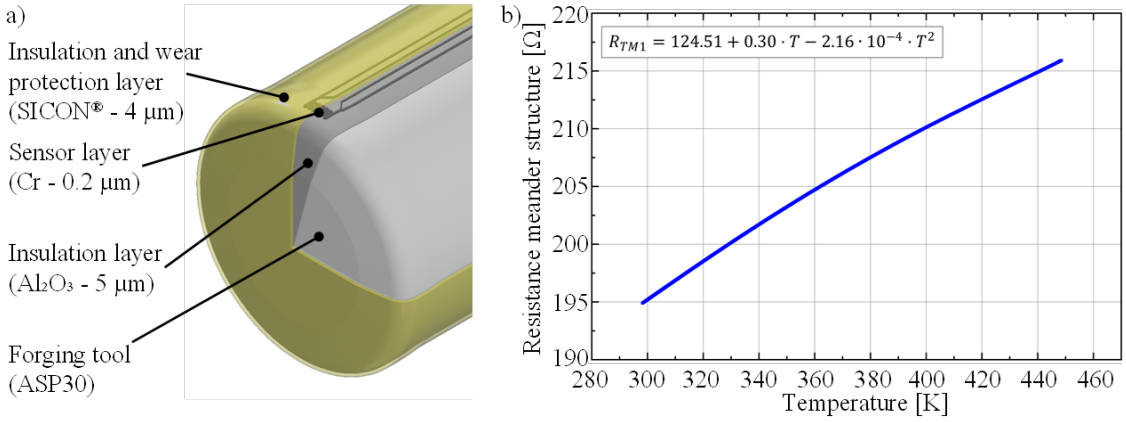

Fig. 2. a) Thin-film sensor on cold forging punch, b) temperature-resistance characterization.

The temperature sensors were conceived in a meandric design that enables a high spatial resolution of the measurement while keeping the sensor resistance in an optimal range for the measurement system. Due to the low resistance of the conductor paths, 4-wire sensing was used, enabling resistance measurements without an influence of the leads. To determine the characteristic curve for each sensor, the thermoresistive behavior was analyzed. For that purpose, the punch was heated up to 180°C in a furnace and cooled down to ambient temperature. A Pt100 reference sensor was positioned on the surface close to the sensor structure. As shown in Fig. 2 b), the dependence between resistance and temperature is approximately linear. To achieve higher accuracy, the measured values were fitted with a quadratic function.

Data acquisition system.

An embedded data acquisition unit was developed to collect the temperature data directly within the press in close distance to the sensory punch to suppress noise. The system is depicted in Fig. 3 a) featuring the sensory punch itself (1), the acquisition unit (2) and the data processing system (3).

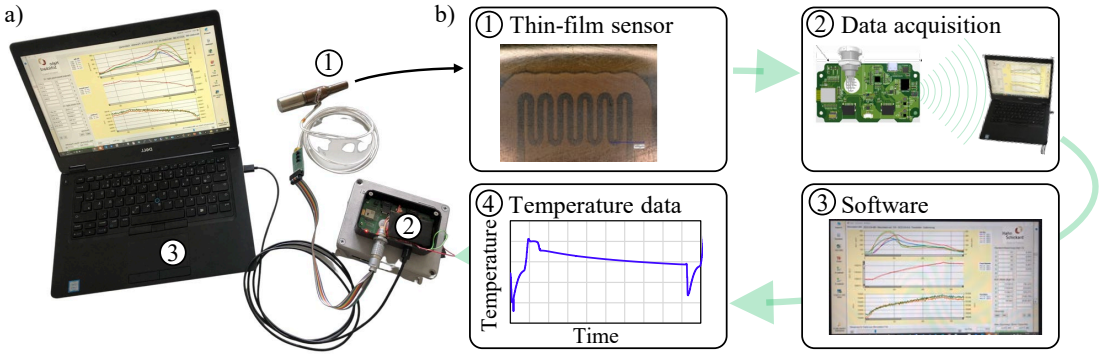

Fig. 3. a) Embedded data acquisition unit and b) process flow for temperature measurement.

The data acquisition process is shown in Fig. 3 b). A variation of the measured physical quantity, here punch temperature, led to a variation of the electrical resistance of the meandric thin-film sensor structure, which was measured by the data acquisition unit. This was achieved by sourcing a known current through the sensor and measuring the voltage drop across the sensor. To compensate the voltage drop over the wires, the sensor was connected with four wires. The known current in the range of 2 mA was flowing through two of them. The 4-point measurement method was used for the punch temperature sensor, as the sensor resistance was in the range of about 230 Ω. The main board included the power management unit, the USB- and BLE-interface for data exchange and the direct interface to the thin-film sensor via the analog frontend. To guarantee a good radio transmission, a polymer case surrounded the main board. Texas Instruments ADS131 analog to digital converter (ADC) was used within the embedded system. In the first stage, the embedded system sent raw digital data to a graphical user interface (GUI) running on a personal computer. The data was processed outside the embedded system. The digital value was transformed to the sensor resistance using the following Eq. 1.

$$R_{Sensor} = \frac{ADC_{value}}{ADC_{max}} \frac{U_{ref}}{I_{Sensor}} \quad (1)$$

where U_{ref} is the reference voltage of the ADC, I_{Sensor} is the known current trough the sensor, ADC_{value} is the measured ADC-Value of the ADC and ADC_{max} is the maximal ADC value of the ADC. Then, using the calibration curve of the sensor in Fig. 2 b), the resistance was transformed into the temperature signal.

Investigation of Tool Heating

Experimental investigations.

Cyclic tool heating was investigated experimentally based on an automated cold forging process. For the experiments, steel billets from DIN C15 (AISI 1015) were prepared by cropping and upsetting (d = 22.2 mm, l = 22.1 mm). A usual lubrication system, consisting of a phosphate conversion layer with soap lubricant (5 g/m^2) was applied to the billets. The cyclic cold forging experiments were performed on a mechanical knuckle joint press MAY MKN2-600/14 (F_{max} = 6,000 kN), equipped with a gripper automation system featuring 6.5 strokes per minute, see Fig. 4 a. Process subjected here was cup backward extrusion. The billet and a cross section of the cold extruded cup are shown in Fig. 4 b).

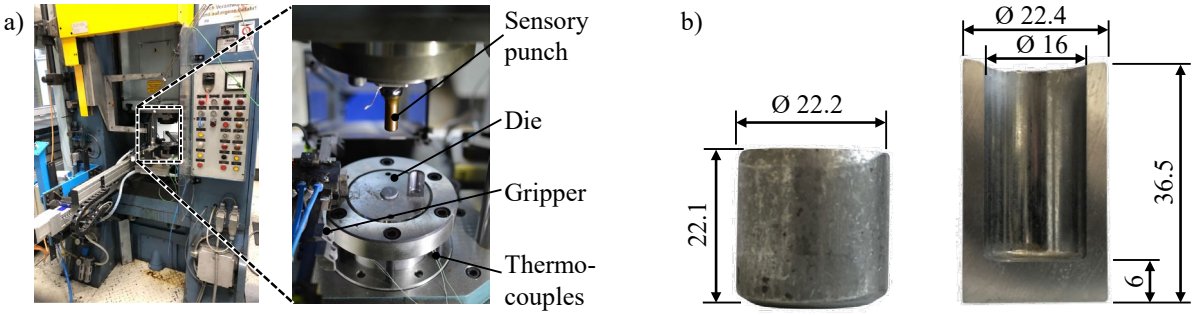

Fig. 4. Experimental setup for temperature measurement in punch and die during cyclic cold forging a) press and tool set, b) workpiece.

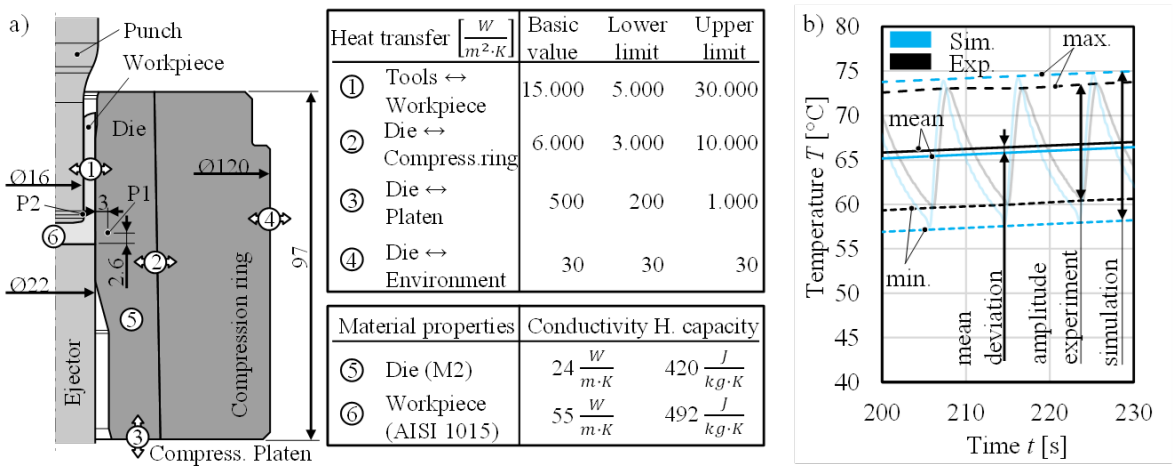
The average strain for this process was $\varepsilon_A = (d_a^2-d_i^2)/d_a^2 = 0.48$. During the experiments, process data such as ram stroke and punch load were recorded. As a central part of the investigation, thermal conditions of both die and punch were measured. For the application of thermocouples inside the forming die, a deep hole ($d = 0.9$ mm, $l/d = 50$) was manufactured by electrical discharge machining. The position and depth of the hole were chosen in such a way, that its ground was close to the inside die surface and close to the deformation zone during cup backward extrusion. The punch temperature acquisition was performed using the thin-film sensor and equipment described in 2.3 according to Fig. 2. The cyclic forging experiment was started at ambient temperature (28°C). A maximum of up to 250 cycles in one batch was performed with an average cycle time of 9.25 s.

Numerical investigations.

Punch diameter $d = 16$ mm was used to simulate the forming process of cups with an outer diameter $D = 22.4$ mm. Initial billet height was $h_0 = 22.1$ mm and final bottom height $h_1 = 6$ mm (see Fig. 4 b). Finite element code QForm UK 10.2.2 was used to create an axisymmetric process model with a plastic workpiece and rigid tools. Initial workpiece temperature was set to $T = 28$ °C and mixed friction model with a friction factor $m = 0.12$ and a friction coefficient $\mu = 0.05$ was used for contact definition between workpiece and tools. Decisive for the tool heating simulation were the heat transfer coefficients applied to the interface between the objects (see Fig. 5), such as heat transfer between workpiece and tools (including punch, ejector and die), heat transfer between die and compression ring / compression plates as well as heat transfer between die and environment, considering heat convection. Regarding the material properties, literature values for conductivity and heat capacity of M2 tool steel and AISI 1015 workpiece material were used. A full factorial design of experiments was set up for parameter identification according to the upper and lower limits depicted in Fig. 5. All parameter combinations were performed for 250 forming cycles. For analysis of the most suitable parameter combination, the temperature profiles of simulation variants and experiment were compared. The maximum temperature T_{max}, minimum temperature T_{min} and mean temperature $T_{mean} = (T_{max}+T_{min})/2$ were calculated for each cycle as shown in Fig. 5 b). For the simulated 250 forming cycles, an average value of the deviations in minimum, maximum and mean temperature between experiment and simulations was calculated for identification of the most suitable parameter set within the last third of the subjected number of strokes.



Heat transfer $\left[\frac{W}{m^2 \cdot K}\right]$	Basic value	Lower limit	Upper limit
① Tools ↔ Workpiece	15.000	5.000	30.000
② Die ↔ Compress.ring	6.000	3.000	10.000
③ Die ↔ Platen	500	200	1.000
④ Die ↔ Environment	30	30	30

Material properties	Conductivity	H. capacity
⑤ Die (M2)	$24 \frac{W}{m \cdot K}$	$420 \frac{J}{kg \cdot K}$
⑥ Workpiece (AISI 1015)	$55 \frac{W}{m \cdot K}$	$492 \frac{J}{kg \cdot K}$

Fig. 5. a) Simulation model for cyclic tool heating, b) analysis of heating curves.

Flow stress data for C15 steel was gained from compression tests at the Institute for Metal Forming Technology at the University of Stuttgart. The characterization tests were conducted on a thermomechanical testing system Gleeble 3800 C in a temperature range of 20°C ≤ T ≤ 200°C with strain rates of 0.1 s^{-1} ≤ $\dot{\varphi}$ ≤10 s^{-1}. Die and punch temperature were analyzed in the same area as measured by the thermocouples and the temperature meander, respectively (see Fig. 5 a). Using the cyclic heating simulation module in QForm UK 10.2.2, the whole process chain, consisting of forming operation, return stroke, ejection and transfer time, was modeled to gain representative results for thermal analysis. Mean cycle time in experiments was 9.25 s with a deviation of ± 0.6 %.

Results and Discussion

Experimental results.

The experimental investigations showed, that the embedded system and the wireless communication with the data processing system allowed to record the process data with a sampling rate of 60 Hz. For the punch temperature measurement, a maximum of 22 forming cycles were performed and for the die temperature measurement, 250 cycles were investigated. First surface scratches of the punch coating layer were detected in the area of the punch land after 22 cycles. The sensory structure considered here was not damaged, as it was located in the relief area of the punch. The experimental results for die heating (thermocouple at point P1, see Fig. 5 a) and punch heating (meander structure at point P2) are depicted in Fig. 6 for the second forming cycle of a continuous experiment. During forming process (1→2) with a duration of 1 s, heat was transferred to the tools and resulted in a die temperature increase. Due to the elastic compression of the punch, the measured resistance and thus the calculated temperature decreased in the first 0.2 s of the forming process. Possible reason for that behavior is a temporarily short-circuit between the sensory chromium layer and the punch substrate or the workpiece due to insufficient insulation under combined thermal and mechanical loads. As the heat transfer to the punch increased and the punch load decreased towards the end of the forming process, the calculated punch temperature significantly increased and reached its maximum. Elastic deformation of the workpiece as a consequence of residual stresses led to frictional heat and frictional forces during retraction of punch (2→3). This is why die temperature increased further, where the calculated punch temperature decreased due to the resulting axial and radial loads. During ejection process (3→4) and transfer time, both die and punch temperature decreased due to heat transfer to the surrounding objects and heat convection to the environment. For further analysis of the experimental punch heating profile, the areas with a significant influence of mechanical loads on the measured

resistance and temperature profile respectively, were neglected. Assuming, that the thin-film sensor measured the temperature without force influence only right after retraction of punch (2→3), a simplified linear segment between (A) and (B), as depicted in Fig. 6 a), was inserted. Due to the neglected thermal influence between (2→3), the temperature at point B was assumed as a lower bound estimation of the maximum cycle temperature.

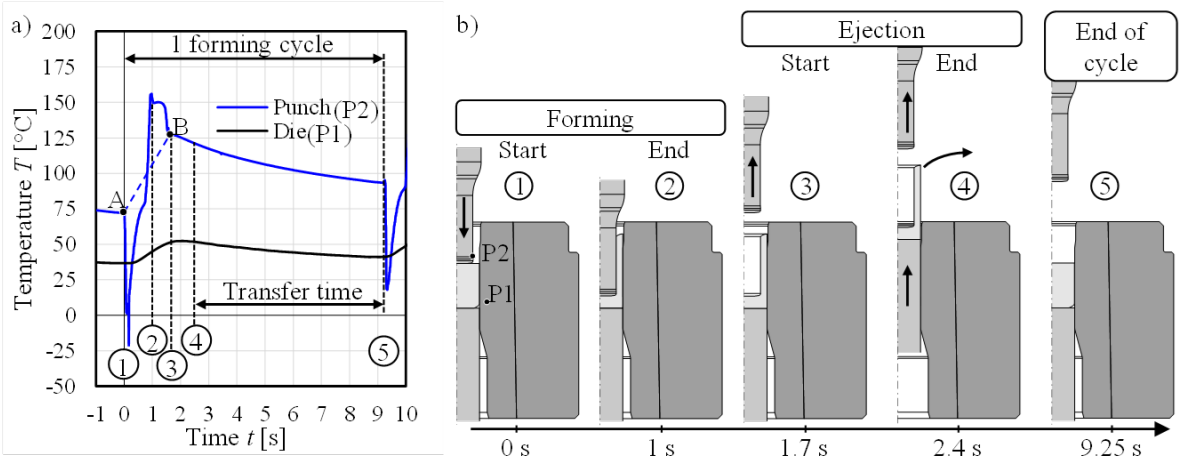


Fig. 6. a) Experimental tool heating profiles for one cycle; b) referring cold forging process.

The temperature profile for one forming cycle in Fig. 6 a) was extracted from a cyclic forming experiment depicted in Fig. 7. The diagram shows both punch and die heating during the first 22 forming cycles of the cold forging process. The punch temperature profile was simplified as described above by neglecting the influence of elastic punch deformation. Minimum, maximum and mean values of die and punch temperature profile were calculated as described in Fig. 5 b). Comparing the profiles after 22 strokes, the mean value of punch temperature is around 2.6 times higher than die temperature. The measurement position of punch temperature was close to the deformation zone, where frictional heat was generated.

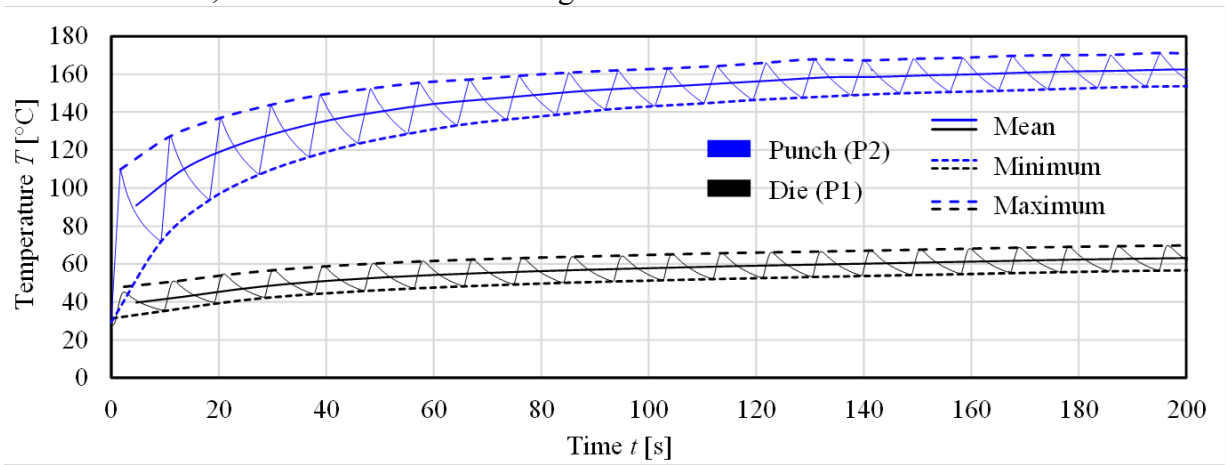

Fig. 7. Comparison of experimental punch and die heating profiles during 22 forming cycles.

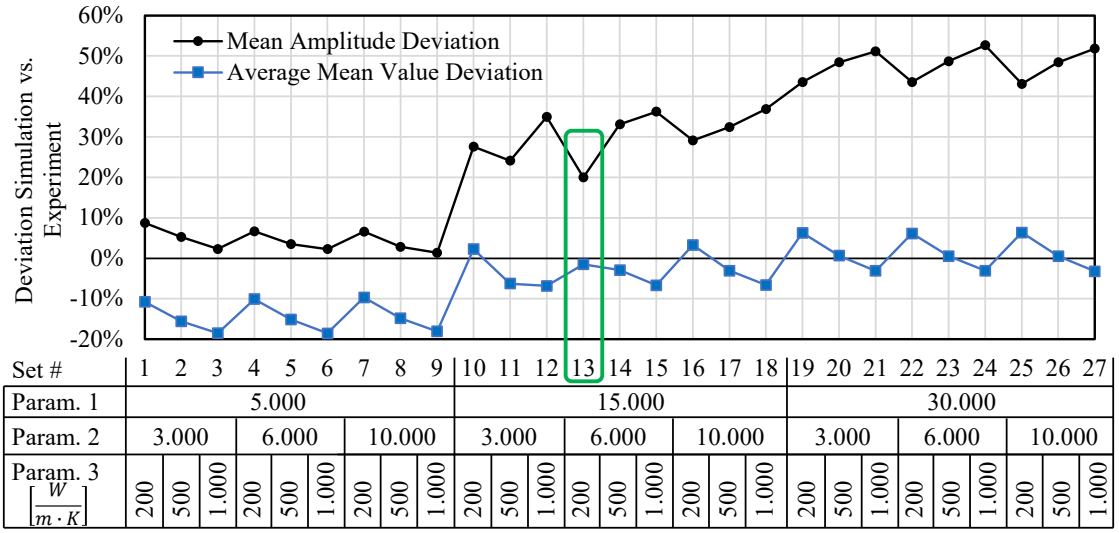
While the die temperature amplitude showed a decrease of about 20 % within 22 strokes, the amplitude decrease in punch temperature was about 70 %. Starting from an initial temperature of 28°C, the punch temperature showed a significant increase within the first strokes and a significant decrease during transfer time, where heat convection to the environment was predominant. As the temperature was measured with the thin-film sensor on the punch surface, such effects were even more visible.

Simulation results.

The fitting between full-factorial numerical parameter variations and experiments was analyzed by means of the die heating profile. For each forming cycle, the difference in mean value and amplitude between simulation and experiment was calculated according to Fig. 5 b). For an overall comparison of the parameter variations, the average of both mean value difference and amplitude difference within the last third of the subjected 250 strokes (no. 166-250) was quantified. Fig. 8 shows the magnitudes of both parameters as relative values, referred to the experimental result, for all 27 parameter sets. The sampling of each parameter set, consisting of heat transfer coefficient between workpiece and tools (parameter 1), between die and compression ring (parameter 2) and between die and compression platen (parameter 3) according to Fig. 5 is given below the diagram. The results show, that parameters 1 and 3 were the most decisive for both mean value and amplitude deviation. An increase of the heat transfer coefficient between tool and workpiece decreased the mean value deviation, but in the same way led to a higher amplitude deviation. An increasing heat transfer between die and compression platens (parameter 3) yielded in decreasing mean values of the heating profiles. The thermal field within the die showed after 50 strokes temperatures in the interface between die and compression ring of about 60°C and in the lower area of the die, close to the compression plate, around 40°C. It can be assumed, that both parameters 2 and 3 showed low effect due to the limited die heating prevailing within 50 forming cycles. With increasing number of strokes, the thermal field propagates in the die, which is why the heat transfer between die and adjacent objects becomes more important as shown in Fig. 8.



Set #	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	20	21	22	23	24	25	26	27

Fig. 8. Deviation of cyclic die heating profiles between simulation and experiment as mean values for stroke no. 166-250 for a full factorial parameter study with 27 parameter sets.

For best fit between simulation and experimental results within the subjected strokes no. 166-250, the mean value deviation was the most important factor for the correct prediction of the heating profile. Parameter set no. 13, as highlighted in Fig. 8, was the most suitable for describing the experimental heating profile with a little mean value deviation (-1.5 %) in combination with an amplitude deviation of 20 %. The numerical die heating result for parameter set no. 13 is shown in Fig. 9 in comparison with the experimental results.

The simulation profile showed due to the little mean value difference a good agreement with the tendency of the experimental die heating profile, thus the amplitude difference was about 22 %. Parameter set no. 13 was used to track also the punch temperature profile as a reference to the experimental results for 22 forming cycles. The maximum value of the experimental punch heating profile was well represented by the cyclic simulation result, whereas the amplitude was

overestimated by two times in simulations. The large deviation in punch heating amplitude may arise from the assumptions described in Fig. 6 a). According to this, higher maximum temperature values of each stroke should appear considering the complex interaction between elastic and thermal deformation of the punch. Furthermore, the punch was modelled as a monolithic body, which does not include the thermal properties of the thin-film layer system on the punch surface.

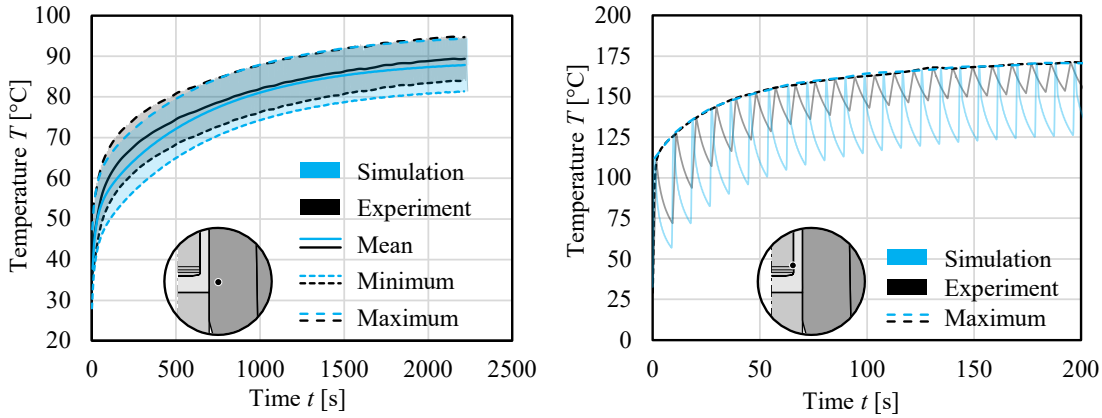

Fig. 9. Comparison of cyclic tool heating in simulation and experiment: a) die, b) punch.

Summary

In this contribution, the application of a thin-film sensor system on a cup backward extrusion punch in cold forging of C15 steel for temperature measurement close to the deformation zone was subjected. Punch heating during cold forging process was analyzed in experiments using the novel sensory structure in combination with the developed data acquisition unit featuring wireless data transfer. For calibration of simulation model, die temperature close to the deformation zone was measured with thermocouples inside the die. Numerical parameter variations were performed to gain suitable heat transfer coefficients for die heating and to use this data for punch heating simulation. The investigations showed, that the application of the thin-film sensor for temperature measurement on a cold forging punch close to the deformation zone is possible considering the prevailing tribological loads during 22 cyclic experiments. The developed embedded system allowed resistance measurement of the applied thin-film meander structure and wireless data transfer via Bluetooth Low Energy, where the actual punch temperature values were calculated based on calibration curves. The thin-film sensors for temperature measurement on the punch surface were due to the physics of the measuring principle force sensitive. A simplified punch temperature profile could be gained by neglecting the area of the process, where the punch was under mechanical load and thus yielded in a lower-bound estimation of the maximum temperature during deformation. The cup backward extrusion process could be modelled using the cyclic tool heating module in QForm UK 10.2.2 considering the whole process chain over a duration of 250 strokes. Parameter variations showed, that the heat transfer coefficients to adjacent objects, such as compression platens underneath the die, become more important for a correct prediction of the heating profile with increasing number of forming cycles. The analysis of mean amplitude deviation and average mean value deviation between measured and simulated die heating profile is a suitable method to find a best-fit parameter set. Using the most suitable parameter set of the die heating investigation also for the punch heating investigation yielded in an underestimation of the measured punch temperature profile, where maximum values were in good agreement.

In future investigations, the calibration of force influence on the measured resistance signal of the thin-film sensor should be considered for a precise estimation of the maximum temperatures during forming process. Furthermore, for both die and punch, more temperature measurement points should be investigated to make proof of the identified heat transfer parameters.

Keywords: Reverse Flow Forming, Cryo Forming, α'-Martensite, Closed-Loop Control

Abstract. Workpiece property-control permits the application-oriented and time-efficient production of components. In reverse flow forming, for example, a control of the microstructure profile is not yet part of the state of the art, in contrast to the geometry control. This is, due to several reasons, particularly challenging when forming seamless tubes made of metastable austenitic stainless AISI 304L steel. Inducing mechanical and/or thermal energy can cause a phase transformation from austenite to martensite within this steel. The resulting α'-martensite has different mechanical and micromagnetic properties, which can be advantageous depending on the application. For purposes of local property control, the resulting α'-martensite content should be measured and controlled online during the forming process. This paper presents results from the usage of a custom developed cryo-system and different application strategies to use liquid nitrogen as a coolant for local enhancement of the forming-temperature depending α'-martensite content.

Introduction

With growing customer demands the requirements on materials, tools and processes within manufacturing companies are increasing accordingly [1]. Therefore, one of the main objectives of production and manufacturing technology is the reproducible production of (complex) defect-free components. The control of local workpiece properties (e.g. microstructure profile), satisfying customer needs while meeting requirements, has gained more and more importance. This still constitutes a challenge in reverse flow forming, since the process is affected by a large number of influencing factors e.g. tool and machine behavior, properties of the semi-finished product like eccentricity as well as the chemical composition and is therefore hard to predict [2]. A promising approach in this context is an according closed-loop process control. Extensive experimental investigations were carried out in regard to a better control of the α'-martensite content in austenitic stainless steel (AISI 304L) tubes during thermomechanical reverse flow forming. The focus of the investigations was the use of temperature as a control variable to influence local transformation behavior. Since cooling favors the phase transformation (austenite → α'-martensite) liquid nitrogen was applied through a custom developed cryogenic nozzle to maximize the cooling effect and therefore the α'-martensite formation. As part of the cryogenic reverse flow forming different process strategies (timing of cooling during the process) and different cooling strategies (varying cooling areas to produce axial and axial-angular graded α'-martensite areas) were investigated. Local property control e.g. wall thickness and α'-martensite offers an advantage in product labeling. This method can be utilized for a unique, invisible and novel product identification comparable to an invisible QR code. The local manipulation of the α'-martensite content, while maintaining the external dimensions, generates an individual and invisible microstructure profile, making the products tamper-proof. Previous and current work has shown, that two strategies can

be differentiated to decouple the geometry and the product properties. The first strategy employs a multi-stage process that utilizes process parameters such as the feed rate and infeed, which has been demonstrated to be effective in earlier research. Our previous investigations have shown a correlation between the selection of these parameters and the α'-martensite content, while maintaining the external dimensions [3]. The second strategy is part of current work and involves thermomechanical forming, which locally affects the formation of α'-martensite in a single-stage process through the active manipulation of temperature (cooling/heating). To locally grade properties such as the α'-martensite content, it is necessary to differentiate between grading directions. One approach to improve the properties of the tube is through axial grading, where the martensite content is varied along the length of the tube. While previous research has shown success in this method [3], current efforts aim to enhance the technique by also controlling the α'-martensite content in the angular/circumferential direction. For this, rapid cooling methods or periodic/cyclic local cooling or heating must be implemented during the tube forming process, as the tubes need to reach varying temperature profiles in both the length and angular direction as they rotate. However, precise control of these properties remains a challenge and is yet to be established as a common practice. The ongoing research endeavors to develop new techniques and methods to overcome these challenges and achieve the desired level of local property control. The α'-martensite contents for local grading of the microstructure profile and the creation of an invisible labeling of the components must be distinctly detectable for the sensors to be used. The differences of the martensitic and non-martensitic ranges must be well above the measurement uncertainty of the measuring instrument. For these investigations the feritscope FMP30 from Helmut Fischer was used with a measuring accuracy of approx. ±1 %.

Principles and Material

Flow forming as an incremental process offers various advantages in terms of flexibility and efficiency [4]. Based on a defined wall thickness reduction within tubular components the process allows the production of parts with an excellent shape and dimensional accuracy as well as prime surface qualities [5]. Components that meet such high standards and offer the above-mentioned advantages can be used to produce, among others, components for the aerospace industry. Here, precision and lightweight play an essential role, which is covered by flow forming. Just to name a few application examples: drive shafts for jet engines and helicopters are flow formed components [6]. In principle, the rotating tube is set backlash-free on a rotating mandrel and is typically deformed by a multiple roller tool arrangement generating the necessary deformation forces for the wall thickness reduction. The roller tools can be moved in radial and axial direction, reducing the outer diameter of the tube and thus generating an elongation. In reverse flow forming, the material flows in the opposite direction to the roller tool movement [7], as demonstrated in Fig. 1. This process is the focus of this paper.

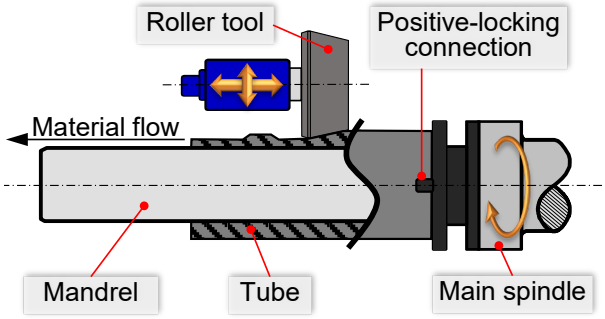

Fig. 1. Reverse flow forming principle.

The stainless steel AISI 304L (X2CrNi18-9, 1.4307), which is used as semi-finished material for the seamless tubes, is austenitic. Containing a metastable austenitic phase, a phase transformation from austenite to α'-martensite could occur strain- or temperature-induced [8]. The α'-martensite, nucleating at the intersections of the shear bands, has different mechanical and micromagnetic properties and can be detected offline (e.g. Feritscope) or online via micromagnetic sensor equipment (e.g. 3MA-II) like addressed in previous papers [9,10,11]. Besides the mentioned influencing factors, the α'-martensite formation is also dependent of the chemical composition and the austenite grain size of the semi-finished product [12,13]. Depending on the chemical composition of the material batch the potential for α'-martensite formation can significantly vary. The used material batch offers a qualitatively low potential for α'-martensite formation, since fractions of austenite stabilizing elements like nickel are relatively high [14]. Comparisons with different material batches show for the same process parameter combinations variations in resulting α'-martensite content between approx. 10 % and 85 %. This aspect again emphasizes the need for property control. For material batches with low potential for α'-martensite formation, more deformation and/or lower (cryogenic) forming temperatures must be achieved to reach similar α'-martensite contents. Since the semi-finished tubes with an outer diameter of 80 mm are seamless, they contain an eccentricity and therefore slight deviations from the nominal wall thickness of 4 mm.

Machine and Experimental Setup

All experiments were carried out on a PLB 400 spinning machine from Leifeld Metal Spinning GmbH (Ahlen, Germany) with a drive power of 11 kW and a maximum achievable spindle speed of 950 rpm. The hydraulically driven cross support equipped with two machining axes, was developed at LUF at Paderborn University and is capable of generating a maximum force of 35 kN on each of its axes (X/Y-axis). By default, the operating pressure of the external hydraulic system amounts 80 bar and can be increased up to 120 bar, when required. Additionally, a universal tool holder allows the attachment of a variety of tools or tool systems. For the investigations, a single-roller tool configuration was used to provide enough space for the sensor equipment, which will be applied for online-measurement purposes, which was presented in previous publications of the authors and is not the focus of this paper. The roller has an attack angle of $\alpha = 12°$, a transition radius of $R = 2$ mm and an exit angle of $\beta = 5°$. For the external dimensions, a rolling diameter of 155 mm and a roller width of 46.5 mm can be measured. In the process, a solid counter holder with two ball-bearing counter rollers is used to support the mandrel. A cryogenic cooling system was developed for the experiments and placed on the machine bed. It contains a liquid nitrogen tank, a flexible stainless steel tube for the liquid nitrogen, pneumatic tubes, a set of valves and a two-component cryogenic nozzle that bundles the liquid nitrogen and transports it with compressed air surrounding it. The cryogenic nozzle was mounted in a distance of 8 mm from the specimen, which was to be deformed. For temperature monitoring an infrared camera (Infratech VarioCam head HiRes 640) was used. Fig. 2 shows the machine and experimental setup.

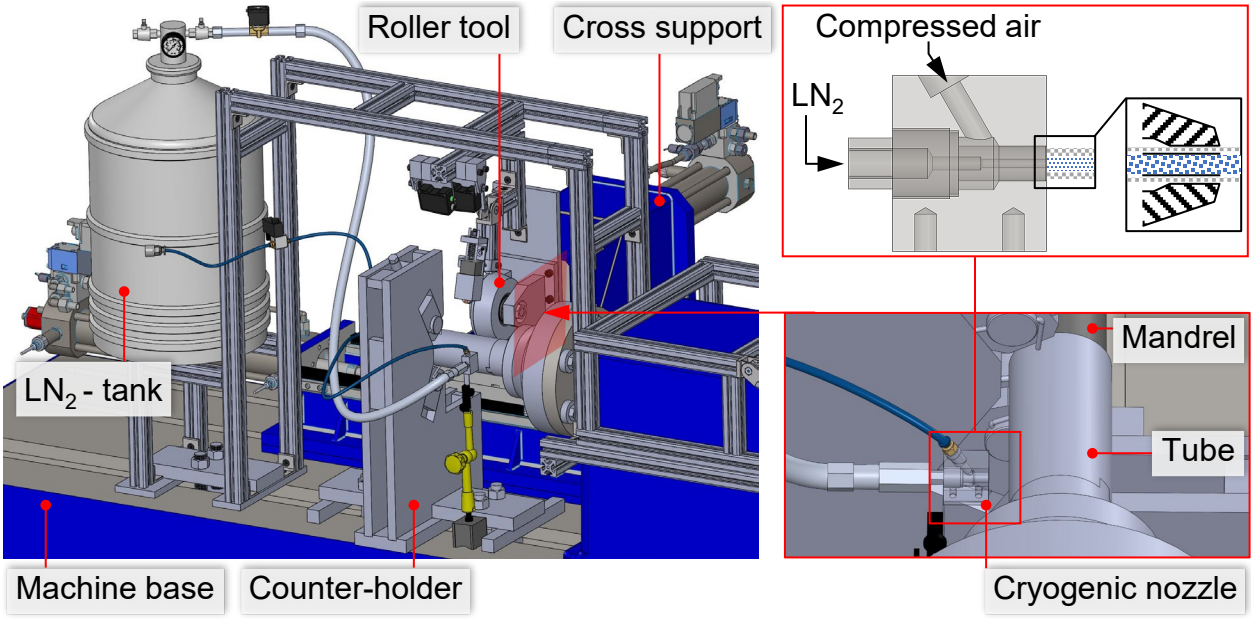

Fig. 2. Machine and experimental setup as 3D-model.

Experiments with three different cooling strategies were conducted. In the first experimental cooling strategy, the tube was rotated and simultaneously shock-cooled for a certain period of time prior to forming. Due to the stationary positioning of the cryogenic nozzle, this resulted in an axial section on the tube which was cooled down circumferentially (ring-shaped cooling prior to forming). The second experimental set-up was performed in analogy to the first strategy, with the difference that the shock cooling was conducted simultaneously to the flow forming (ring-shaped cooling while forming). In the third experimental set-up the aim was to create a spot that was shock-cooled before forming, which is why the rotation was switched off during the cooling of the component. (spot cooling prior to forming). For all three cooling strategies a radial infeed of 2 mm, a feed rate of 0.1 mm/s and a rotational speed of 5 rpm was selected. Fig. 3 shows the initial state of the specimens and the deformed specimens on which the cooled areas are highlighted in red.

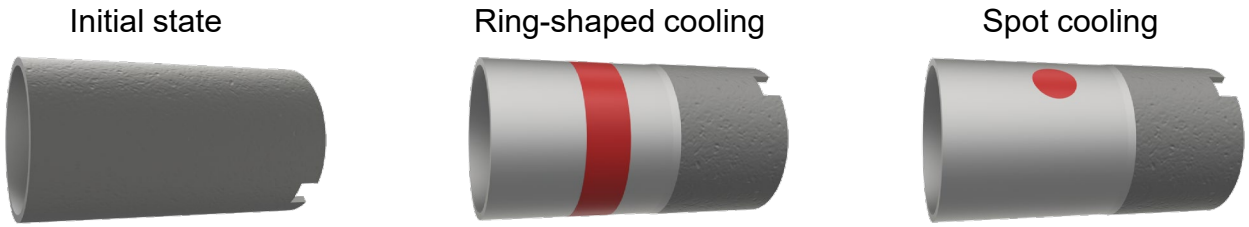

Fig. 3. Cryogenic deformed areas on specimens (highlighted in red).

Results and Discussion

For the first cooling strategy (ring-shaped cooling prior to forming) the tube, with an initial temperature of 16°C, was cooled down with the liquid nitrogen in the ring-shaped area for approx. 200 s to -8°C using a rotational speed of 5 rpm. Then the reverse flow forming process was initiated. The time span between the cooling of the tube and the deformation of the ring-shaped cooled area was approx. 115 s and the initial pressure of the liquid nitrogen tank was at 0.5 bar.

For the second cooling strategy (ring-shaped cooling while forming) the tube had an initial temperature of 17°C and was also cooled down to -8°C in the ring-shaped area using the liquid nitrogen. In this case, the forming process was started before cooling. Only after reaching the tube section to be cooled, the cooling was started and sustained for approx. 200 s, also at an initial

pressure of 0.5 bar. At a feed rate of 0.1 mm/s, an axial tube section of 20 mm was thus formed with active cooling. Fig. 4 shows the actual setup for the second cooling strategy.

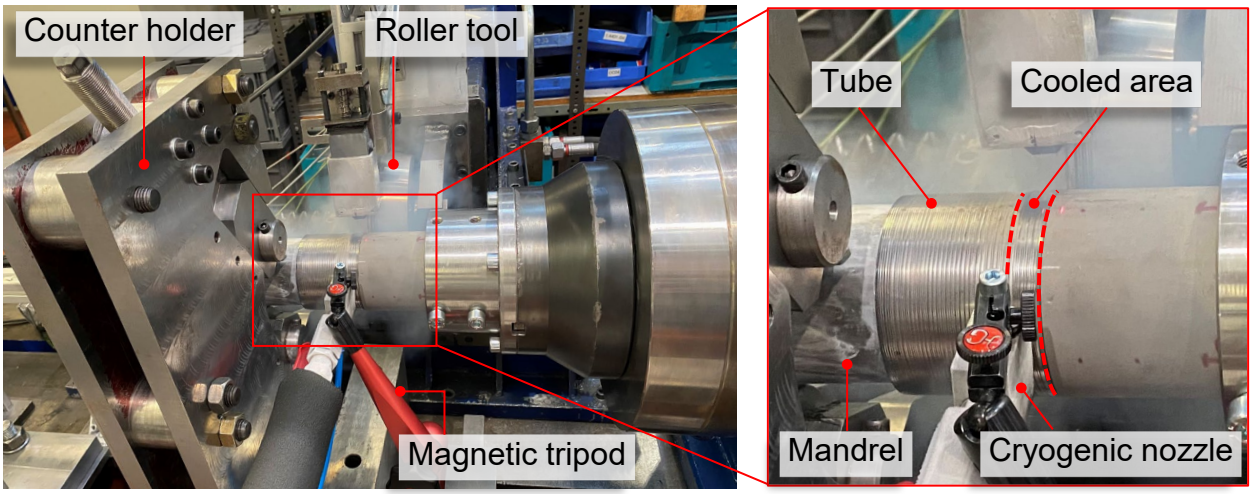

Fig. 4. Ring-shaped cooling while forming (second cooling strategy).

The third cooling strategy (spot cooling prior to forming) included a tube with an initial temperature of 15°C. After the reverse flow forming process was initiated prior to cooling, the axial feed and the rotation of the mandrel was switched off while forming was taking place. The system was switched off so that the area, in this case a circular spot, could be cooled down for approx. 130 s until the surface of the tube was frozen, again with a liquid nitrogen tank pressure of 0.5 bar. The infrared camera was not able to measure the temperature in the spot since it displayed a temperature of -273.15°C, which corresponds to absolute zero with 0 K. Then the cooling process was stopped and the reverse flow forming process was restarted to form the cooled spot as well as the rest of the tube. Here, the cooling process was not sustained while forming, since the rotation would again result in the cooling of a ring-shaped area. Fig. 5 shows the actual setup for the cooling strategy.

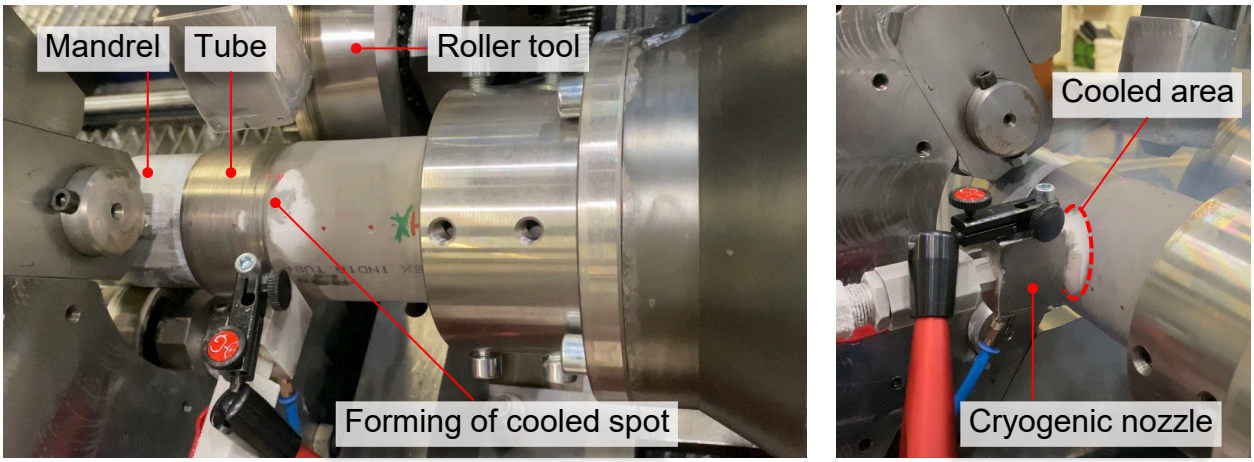

Fig. 5. Spot cooling prior to forming (experiment 3).

The resulting tubes were investigated through measurements with a Feritscope (FMP 30, Helmut Fischer) using the magnetic induction method, a micromagnetic sensor (3MA-II, Fraunhofer IZFP) based on magnetic Barkhausen noise (MBN) effect, eddy current analysis (Modulus r - 200 kHz) and hardness tests (HV3). The measurements were used to localize and

quantify the α'-martensite content, which correlates with the underlying measured variables such as the maximum amplitude of the MBN profile (Mmax) [15,16]. Fig. 6 shows the measurement results with the Feritscope, where cooled areas show higher α'-martensite contents. Four measuring circles with identical distances of 22 mm were used for the measurements. For this purpose, the measuring circles were divided into 30°-sections. The result for the second cooling strategy shows the highest α'-martensite content with a maximum of approx. 17 vol.-%, which is comparatively low due to the chemical composition of this specific material batch, which contains high proportions of austenite-stabilizing elements. This result can also be explained by the fact that the component was deformed during cooling and therefore could not warm up towards room temperature before deformation, in contrast to the first cooling strategy. Also, the coolant flow continuously dissipates the forming heat. In addition to measuring circle 2 where the cooling was mainly carried out, an increased α'-martensite content can be observed in measuring circle 1. This is due to the fact that this section adjacent to measuring circle 2 was also cooled during the cooling of measuring circle 2. Since there is little time between the cooling of measuring circle 2 and the forming of measuring circle 1, this result is also reasonable. The ups and downs for the α'-martensite measurement in the measuring circle 2 are due to pulsation of the liquid nitrogen. As a result of the evaporation of the liquid nitrogen, due to the comparatively warm hose, liquid nitrogen and a gas mixture alternately escape from the nozzle. This leads to inhomogeneous cooling of the rotating tube section. The first cooling strategy shows the same effect due to pulsation of the liquid nitrogen. The α'-martensite content is also lower than for cooling strategy 2, which is due to the time span between the cooling of and the deformation of the ring-shaped cooled area. For the cooling strategy 3 only one large peak for the α'-martensite content is visible, since only one spot was cooled down. An increase in α'-martensite content for areas close to the spot is due to thermal conduction to the adjacent area.

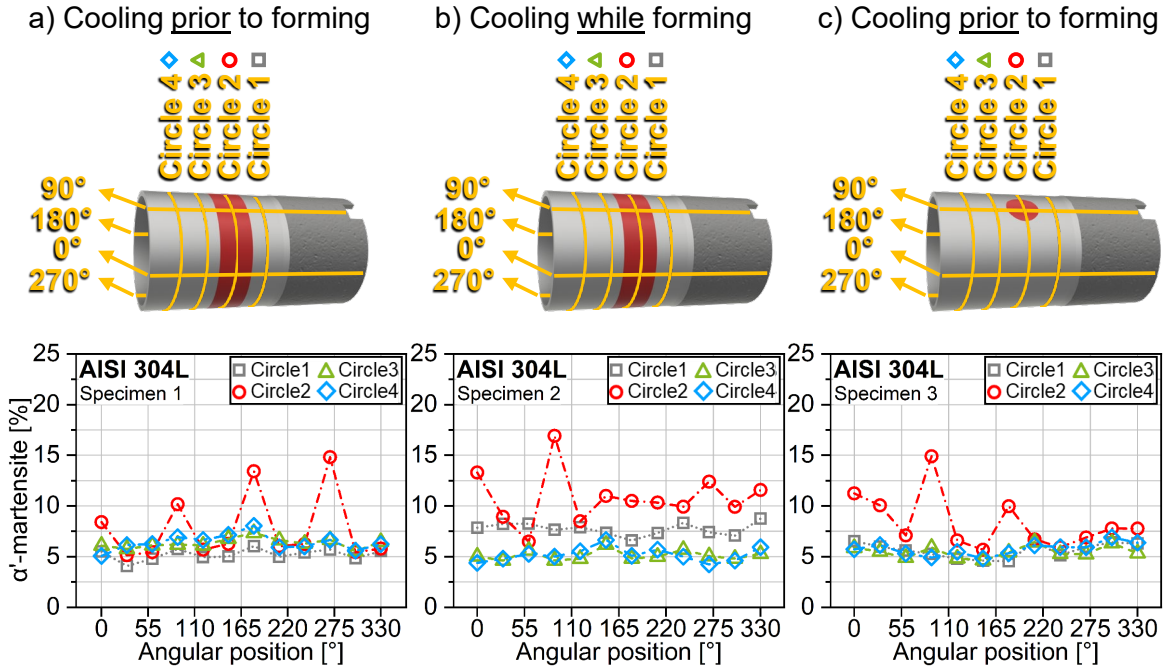

Fig. 6. Feritscope measurement results for the three applied cooling strategies.

The measurements with magnetic Barkhausen noise (MBN) effect performed with the 3MA-II, shown in Fig. 7, also display higher values for measuring circle 2, which is located in the cooled areas. Similar to the previous measurements with the Feritscope, areas adjacent to measuring circle 2 also have slightly higher values, as they have been co-cooled.

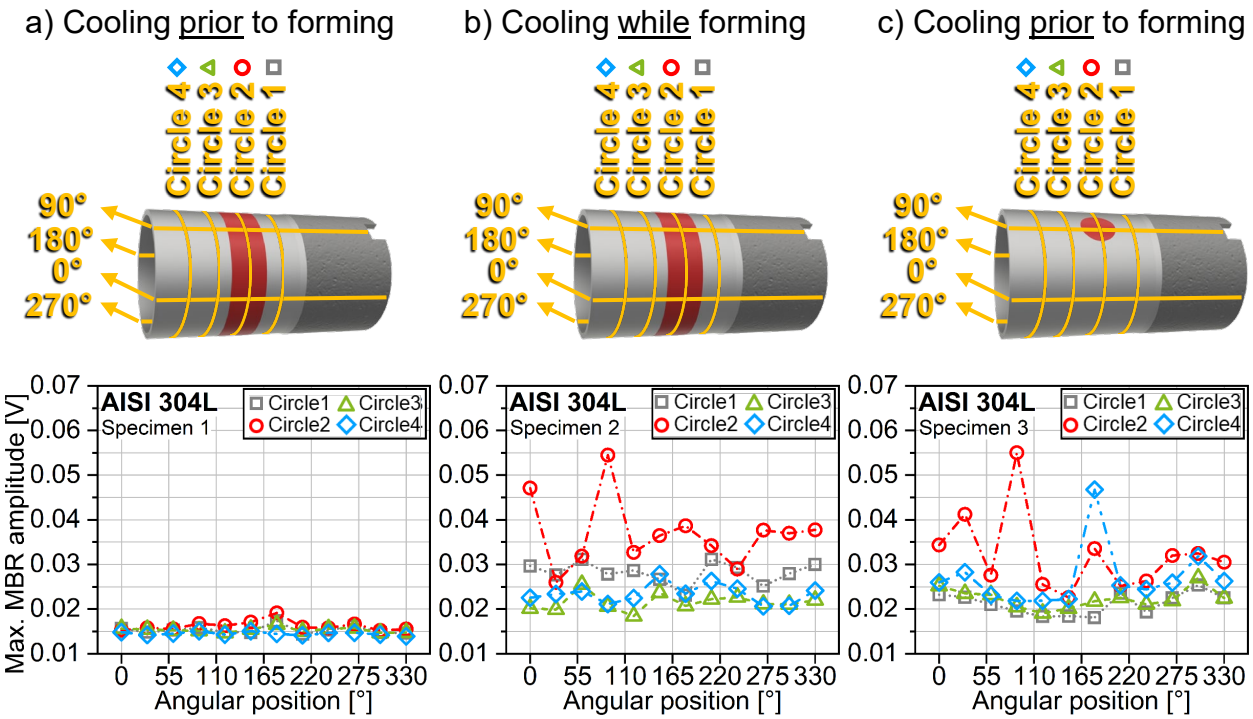

Fig. 7. 3MA-II measurement results for the three applied cooling strategies.

Other than expected, here the values for the measurements regarding cooling strategy 1 show low magnitudes for measuring circle 2. This might be due to the fact that the areas with martensitic microstructure might be smaller in terms of area than in cooling strategy 2, for example. However, it may also be caused by disturbance influences such as the incorrect alignment of the measuring head to the workpiece.

Eddy current analysis was used as a further non-destructive characterization technique. The changes of conductivity and permeability of the material due to the phase transformation from austenite into α'-martensite can be detected by means of the parameter "modulus r". This parameter is computed from real and imaginary parts of the impedance vector corresponding to each deformation state with respect to a point considered as the initial condition (unformed metastable austenite). The measurements, shown in Fig. 8, indicate a strong similarity to the measurements with the Feritscope. Here, the correlation of the measuring variable with the α'-martensite is also visible. The comparison of the measured α'-martensite contents with the Feritscope in Fig. 6 shows in cooling strategy 1 there are higher magnitudes for the parameter "modulus r" for lower α'-martensite contents, which could be due to a superposition of effects triggered by other variables influencing "modulus r".

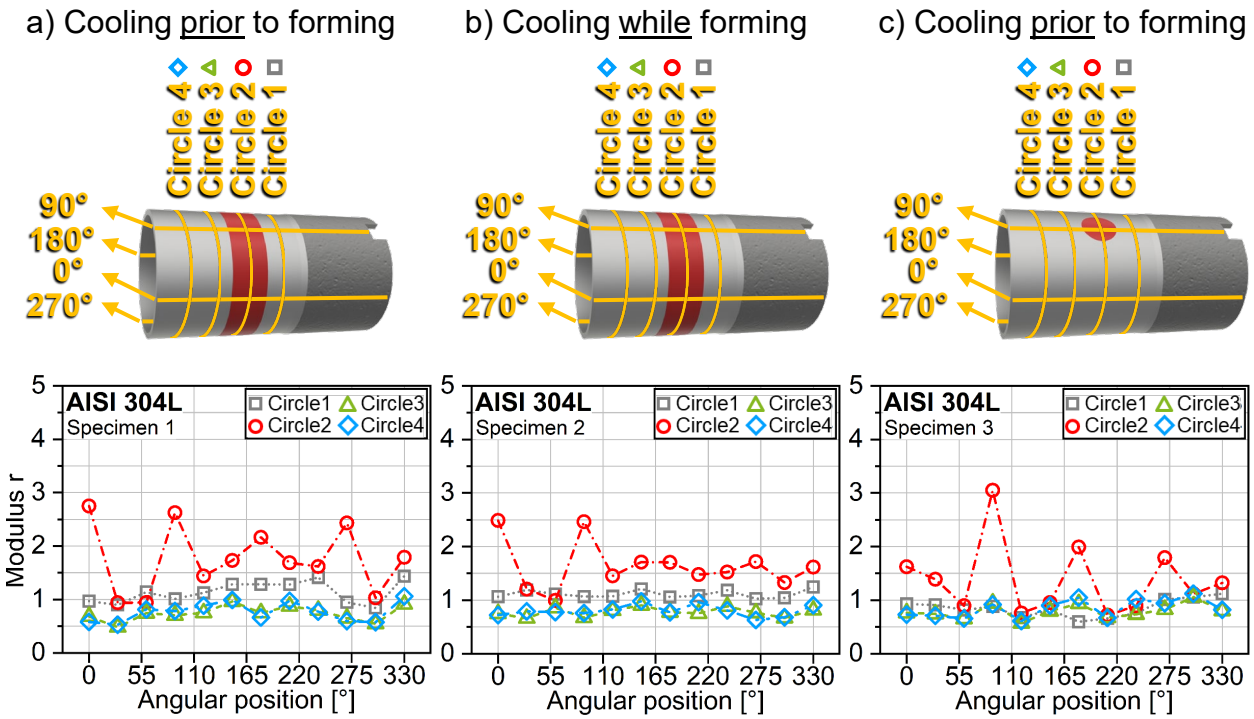

Fig. 8. Eddy current analysis for the three applied cooling strategies.

A comparison of the results from the hardness tests (HV3) in Fig. 9 show the same correlation with the α'-martensite content. The hardness increases with higher magnitudes of α'-martensite. As can be seen, for example, from the measurements for cooling strategy 3, the highest value for hardness results here, although the α'-martensite content is higher for cooling strategy 2 (compare Fig. 6). This is due to the influence by the work hardening, which can be quite different.

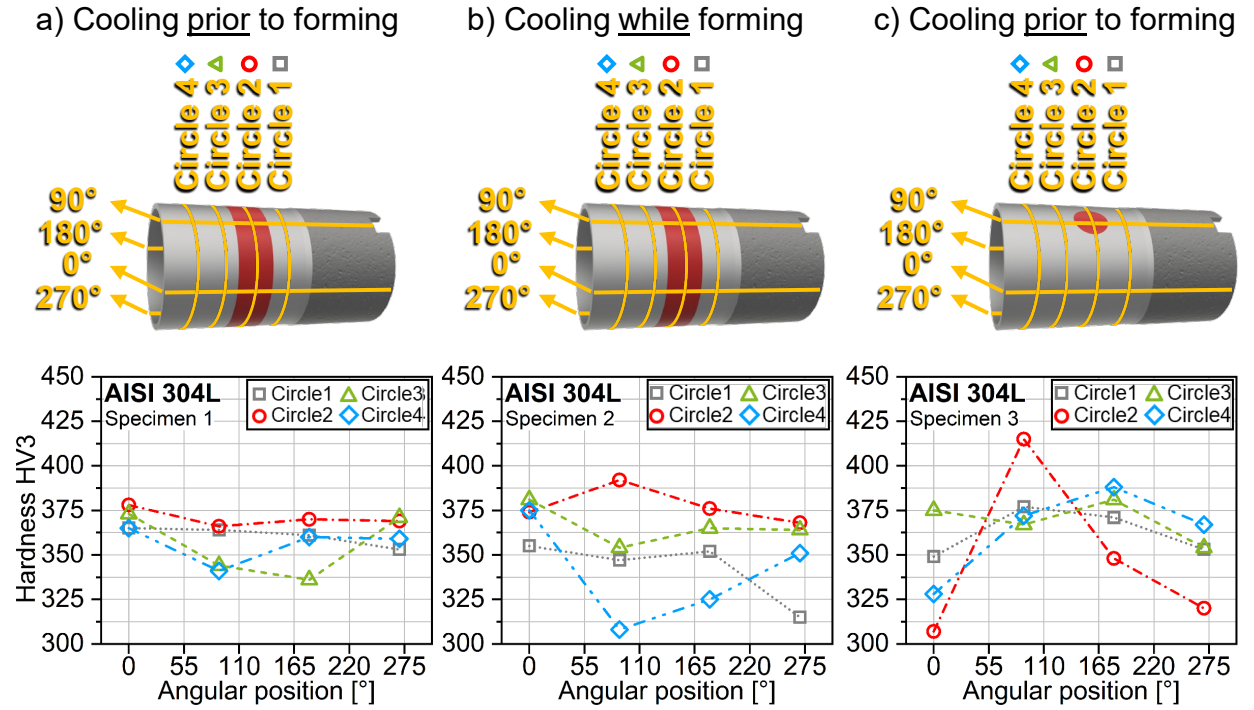

Fig. 9. Hardness tests (HV3) for the three applied cooling strategies.

Investigations of the wall thickness (compare Fig. 10) did not show any influence caused by the martensitic microstructure. The wall thickness increase in feed direction of the roller tool is caused due to material-pile-up in feed direction.

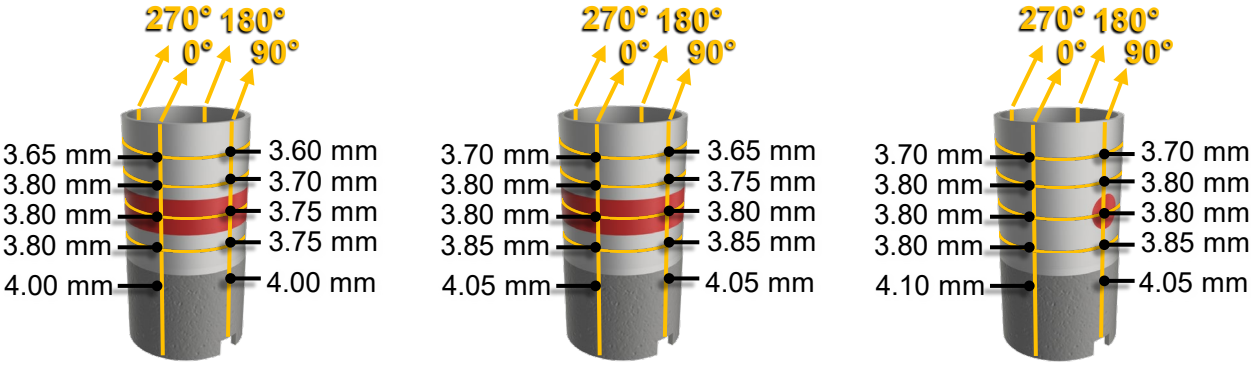

Fig. 10. Wall thicknesses resulting from the three applied cooling strategies.

The EBSD results in Fig. 11 show the microstructure of the cryogenic flow formed areas. The phase mappings display a qualitative distribution of austenite (blue) and α'-martensite (red) phases. The inverse pole figure (IPF) shows the grain orientation of the microstructure. The pictures of the areas deformed at room temperature conditions, indicate almost no transformation of the microstructure, which remains predominantly austenite (blue color in the phase mapping). This correlates well with the micromagnetic measurements on these areas, where almost no α'-martensite was detected. On the cryogenic flow formed area the dark lines in both pictures correspond to shear bands, which are a characteristic of the phase transformation during plastic deformation of metastable austenite. The intersection points of these shear bands are energetically favored nucleation points of the α'-martensite (red color in the phase mapping), which is shown on the red colored areas of the phase mapping.

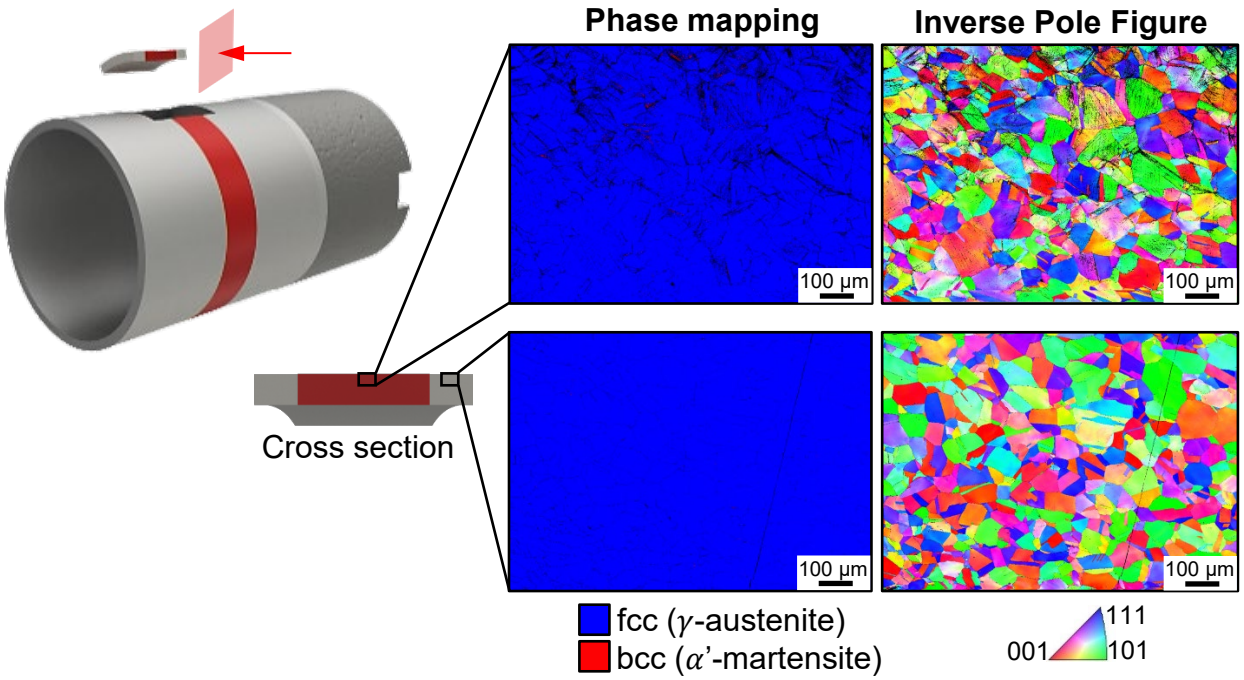

Fig. 11. EBSD results of the microstructure of the cryogenic flow formed area: phase mapping and inverse pole figure (IPF).

A higher quantity of shear bands and nucleation points of α'-martensite is present close to the outer surface, where the cryogenic deformation occurs. On the deeper areas, the deformation decreases which is evidenced in a lower quantity of shear bands and α'-martensite.

Summary

The results from the investigation show that the cryo system is useful for the invisible local enhancement of the α'-martensite content. The cryogenic nozzle is capable of focusing the liquid nitrogen surrounded by compressed air to form a cooling jet. As a result from the investigation of the different cooling strategies, cooling during forming was found to be the most effective method for maximizing the α'-martensite content. The investigations also show that the material batch of the tube used allows comparatively little α'-martensite formation due to its chemical composition, which contains high proportions of austenite-stabilizing elements. The investigations have also shown that automation of the cooling, i.e. inclusion of the cooling strategy in the process control, appears to be useful. Currently, to cool a spot, as with cooling strategy 3, both process stop and shock cooling were performed manually. In the future, the cryogenic system is to be further developed so that position-dependent (depending on the axial position of the roller tool) and angle-dependent (angular position of the tube to be formed) cooling is controlled automatically. This enables the automated production of so-called 2D-gradations (axially and angularly graded structures) similar to cooling strategy 3. For this purpose, an absolute encoder has been implemented within the forming machine, via which the angular position of the tube can also be incorporated into the control system. Furthermore, electromagnetic valves are currently being implemented in the control system in order to automate the release of the liquid nitrogen and the compressed air. The planned design of the cryogenic system is shown in Fig. 12.

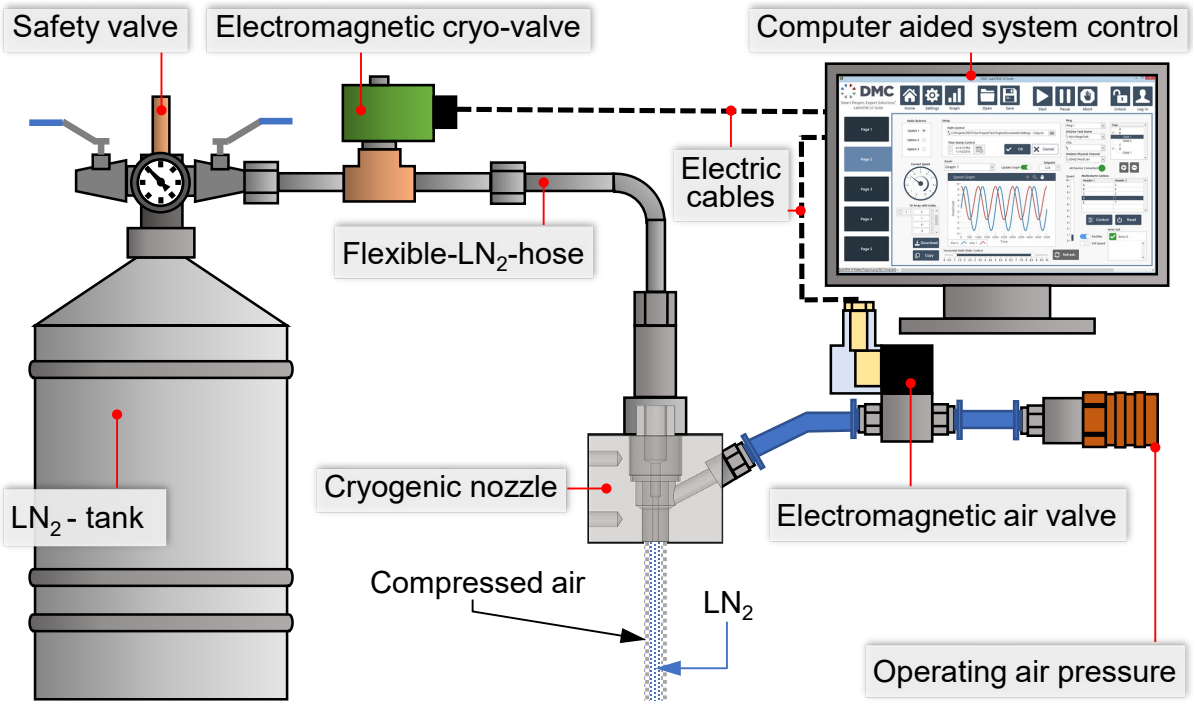

Fig. 12. Planned cryogenic system design.

With regard to thermomechanical forming, ongoing work is currently being conducted on an induction system which is to be used for purposely lowering the α'-martensite content locally through heating. In this way, for example, the co-cooling of adjacent tube sections can be prevented, which can improve the grading sharpness in the axial and angular direction. The

sharpness of local gradients in the grading process depends on various factors, including the geometry of the roller tool determining the contact area (e.g. transition radius and the attack angle of the roller), the achievable temperature differences in the areas being formed, the thermal conductivity of the material, the duration between cooling and forming. These factors, along with the constraints of the forming machine, such as achievable process parameters and actor dynamic, affect the formation of α' martensite and the distinction between different areas. Contact with warm tools and resulting process heat can decrease the temperature differences crucial for grading sharpness. These aspects are currently being investigated and will be quantified in future work.

Keywords: Flow Forming, Graded Structures, Control Strategy, Closed-Loop Property Control

Abstract. Climate change, rare resources and industrial transformation processes lead to a rising demand of multi-complex lightweight forming parts, especially in aerospace and automotive sectors. In these industries, flow forming is often used to produce cylindrical forming parts by reducing the wall thickness of tubular semifinished parts, e.g. for the production of hydraulic cylinders or gear shafts. The complexity and functionality of flow forming workpieces could be significantly increased by locally graded microstructure and geometry structures. This enables customized complex hardness distributions at wear surfaces or magnetic QR codes for a unique, tamper-proof product identification. The production of those complex, 2D (axial and angular) graded forming parts currently depicts a great challenge for the process and requires new solutions and strategies. Hence, this paper proposes a novel control strategy that includes online measurements from an absolute encoder to determine the angular workpiece position. Workpieces of AISI 304L stainless steel with 2D-graded structures are successfully manufactured using this new strategy and analyzed regarding the possible accuracy and resolution of the gradation. At this point, a dependency of the gradations on the sensor and actuator dynamics, accuracy and geometry could be noted. It is further evaluated how the control strategy could be extended by an observer-based closed-loop property control approach to enhance the accuracy of the suggested strategy.

Introduction

Current developments and transformation processes like climate change, the transition to electric vehicles and the rising scarcity of resources depict a great challenge for products as well as for production processes. Especially in the automotive, aerospace and railway industry, there is therefore a rising demand for high strength, lightweight forming parts [1]. Furthermore, product counterfeiting is a serious problem in several industrial fields. A locally graded microstructure distribution on the surface of a forming part could be a feasible new solution for both cases. This could be e.g. an invisible, magnetic QR code for unique product identification against counterfeiting or a locally restricted hardness distribution at wear surfaces that allows reducing the wall thickness of the components.

To produce those customized parts, there is a need of flexible forming processes that allow individual product shapes or product features by function integration in small batches. At this point, classical die based-forming processes like deep drawing are rather at a disadvantage since the product shape is defined by the product-specific tool design. Thus, incremental forming

processes with mobile, universal tools like in the flow forming process are preferred in this case [2]. Flow forming is already used in the automotive and aerospace industry to produce cylindrical forming parts by reducing the wall thickness of tubular semifinished parts, e.g. for the production of hydraulic and pneumatic cylinders or gear shafts [3]. According to current knowledge, angular graded microstructure profiles have not yet been added to the products like an invisible QR code that represents additional functionality.

The process-integrated manufacturing of those novel graded parts requires special control strategies and information of the angular workpiece position during the whole process. For this purpose, a new control strategy is subsequently proposed in this paper that includes the sensor feedback of an absolute encoder to coordinate the actuator motion. Thus, it is possible to produce flow forming parts with locally restricted forming areas. These forming areas - in contrast to the workpiece area outside - incorporate a martensitic microstructure which is caused by deformation in terms of a strain-induced phase transformation. In the following, the special axial and angular restricted areas with a different microstructure are called 2D gradation. Each gradation produced by the proposed control strategy features a certain local accuracy which is further analyzed in this paper. Building on this, a closed-loop property control can be prospectively designed to enhance the accuracy of the gradations and simultaneously adjust geometric and material properties, so that the created QR code will be manufactured invisible.

Setup

Process and material.

This paper focusses on backward flow forming on a single roller flow forming machine. The investigations were performed with seamless tubes of stainless steel. The semifinished parts own a length of $L = 120$ mm, an outer diameter of $d_O = 80$ mm and a nominal wall thickness of $w = 4$ mm. The tubes are manufactured according DIN1127. Thus, the tubes feature an angular wall thickness eccentricity due to fabrication tolerances, with a deviation between maximum and minimum value of up to 15% [4]. The tube material is AISI 304L (X2CrNi18-9, 1.4307) which is a metastable austenitic stainless steel. By plastic deformation of this steel, a strain-induced phase transformation from austenite to α'-martensite can occur [5, 6] that influences the workpiece properties like the hardness and the micromagnetic properties. The process and material were already used in previous publications of the authors. Thus, it is referred to [7, 8] for additional information.

Machine and sensor concept.

The experiments were executed on a PLB 400 single roller spinning machine originally manufactured by Leifeld Metal Spinning GmbH (Ahlen, Germany) and later modified. The current setup is shown in Fig. 1 and was previously published in [7]. Here, the roller (entry angle $\alpha = 12°$, transition radius $R = 2$ mm, exit angle $\beta = 5°$) is mounted on a hydraulic actuated cross support that can be moved position-controlled in axial (x) and radial (y) direction for forming the workpiece. The specimen is positioned on a mandrel that is set into rotation by a spindle with an electric drive motor. The mandrel is also supported by two stationary rollers in opposite direction to the tool to compensate the high forming forces and to avoid mandrel deflection.

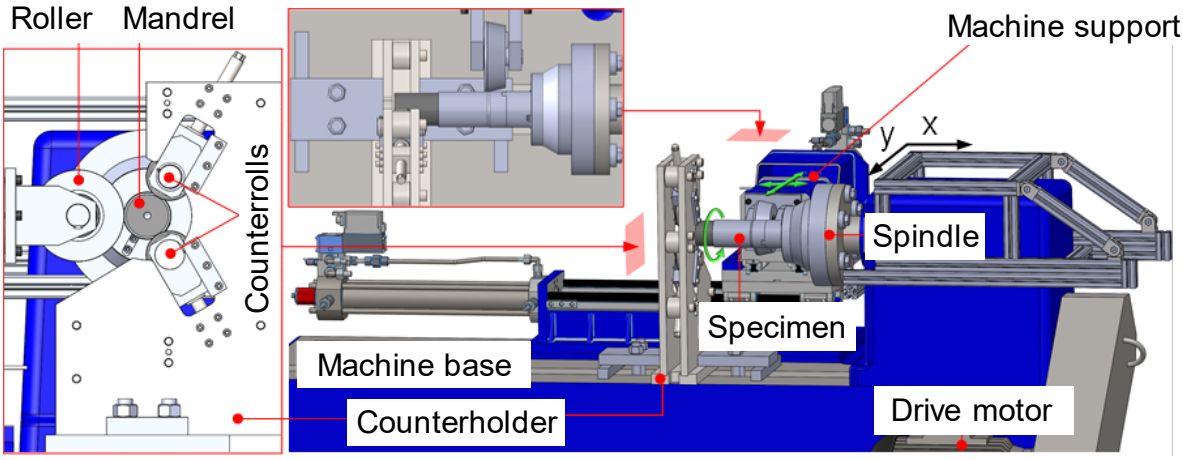

Fig. 1. Machine setup.

The machine setup includes an additional sensor system for angular gradations and property control purposes (see Fig. 2). An absolute encoder Hengstler Acuro AC58 is mounted at the end of the spindle shaft for the determination of the angular workpiece position and of the rotational speed. The sensor is specified with a resolution of 12 bit and 2048 incremental pulses in the single turn mode. The machine also contains a laser distance measuring system for measuring the resulting wall thickness reduction online during the forming process. Two laser sensors OM70 by Baumer Electric are connected to the machine support moving axially along the workpiece. One of the sensors points perpendicularly near of the forming zone with an angular offset of 90°, but no axial offset. The second sensor is positioned with an additional axial offset of 5 mm in front of the forming zone. While the first sensor is measuring the formed area, the latter measures the unformed. It is thus possible to calculate the resulting wall thickness reduction from the differential signal of both sensors. The sensor system also contains a micromagnetic 3MA-II sensor that is out of the focus of this paper (see [8] for additional information about the sensor concept).

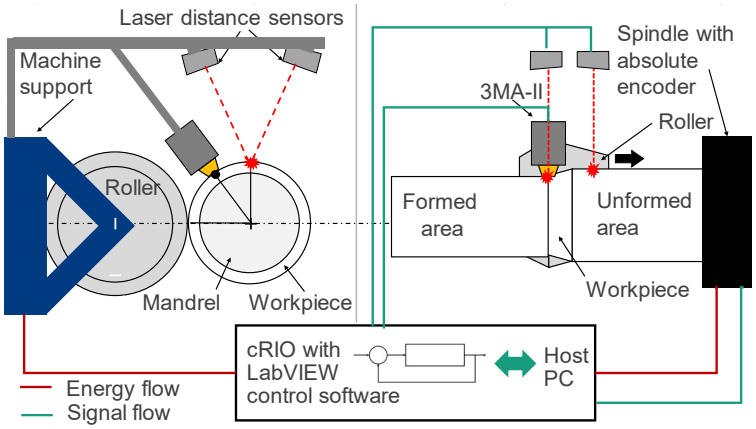

Fig. 2. Sensor concept (scheme).

Machine control architecture and control strategy.

The flow forming machine is equipped with a NI compactRIO real-time controller (cRIO 9035). On the controller, the overall machine control is executed including the position closed-loop control of the two hydraulic actuators and the control of the spindle motor. The additional sensor system is also connected to the cRIO controller (see [8] for further details). The absolute encoder transmits the measured rotational position and speed digitally using the BiSS-C protocol to a

special encoder module (SEA 9521) of the cRIO. The control on the cRIO is programmed in the LabVIEW development environment. It is a free programmable, CNC-orientated control software that was developed in [9] and [10] and extended in [8] for property control issues. In the control program, the toolpath is defined by

$$P = \begin{bmatrix} x_1 & y_1 & f_{x,1} & f_{y,1} & \theta_1 & n_1 \\ \vdots & \vdots & \vdots & \vdots & \vdots & \vdots \\ x_M & y_M & f_{x,M} & f_{y,M} & \theta_M & n_M \end{bmatrix} \quad (1)$$

Each row corresponds to a block of a conventional NC program. In each block, the desired final tool position in axial direction x and in radial direction y is defined, and in addition the feed in both directions for the tool movement (f_x and f_y) until reaching the specified final position. Those values act as an input to the internal position control of the machine support. The program is added in this paper by two additional columns for the rotational speed n and the desired angular position of the mandrel θ. Here, a transition to the next block (with new desired values for x_i, y_i, $f_{x,i}$ and $f_{y,i}$) is enforced when the measured value θ_{mes} amounts approximately θ_i. Since the absolute encoder delivers the measurement values with a certain accuracy and the rotation of the mandrel takes places continuously without stopping at θ_i, it is thus necessary to utilize a threshold value ε for defining the transition condition:

$$|\theta_{mes} - \theta_i| < \varepsilon \quad (2)$$

Procedure

Effective resolution of the absolute encoder within the control system.

For defining a suitable threshold value, the effective resolution of the absolute encoder within the setup is determined at first. It generally depends on the nominal resolution of the encoder itself and the signal sampling of the control system. For this purpose, the time signal of the absolute encoder is analyzed at different rotational speeds from 3 to 50 rpm. By comparing the measured angle values between two consecutive sample values, the effective angular resolution $\Delta\boldsymbol{\theta}$ is determined (see Fig. 3).

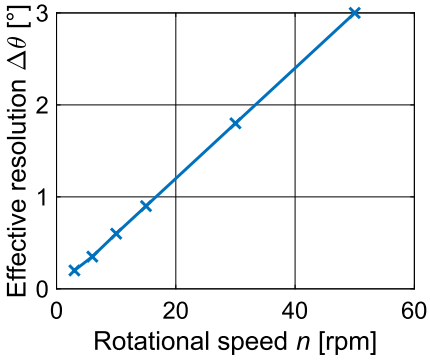

Fig. 3. Working principle of the forming control for angular parts.

The effective resolution $\Delta\theta$ significantly depends on the rotational speed n. It varies between 0.2° at the lowest speed and 3° at the highest. This effect is caused by the sampling time of the control system $t_{sample} = 0.01$ s. Since the nominal sensor resolution amounts $\Delta\theta_{nom} = \frac{360°}{2^{12}} = 0.088°$ and is much higher, the sampling effect is clearly dominating regarding the resolution. From the effective resolution, a suitable threshold value for the control can be defined since the threshold

should be greater (or equal at minimum) than the effect. In the worst case, the resolution is 3° in the experiments. Thus, the threshold value ε for the control is determined to ±3° in this paper.

Determination of the desired values (control strategy).

To produce axial and angular graded surface elements of 45°, 90° and 180° on the tube, an angle-dependent control strategy must be defined. In this paper, a rectangular strategy for the desired control values is proposed that alternates the actuator position in radial direction between a position near above the tube surface and a second position that corresponds to a desired infeed depth (see Fig. 4). The switching point of the desired value is

$$i \cdot \Delta\theta_{grad,des} \quad \text{for } i = 0 \ldots \frac{360°}{\Delta\theta_{grad,des}} \tag{3}$$

e.g. 0°, 90°, 270°, where $\Delta\theta_{grad,des}$ is the desired gradation angle. The sequence is repeated for several revolutions. Concurrently, an axial feed movement is defined. Thus, a gradation area occurs on the workpiece surface through the superposition of rotation and axial feed.

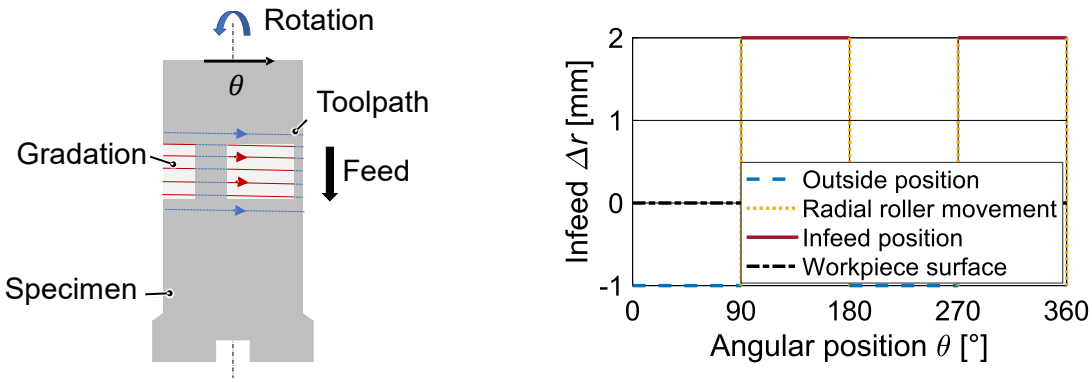

Fig. 4. Control strategy for 90°-gradations - desired actuator toolpath.

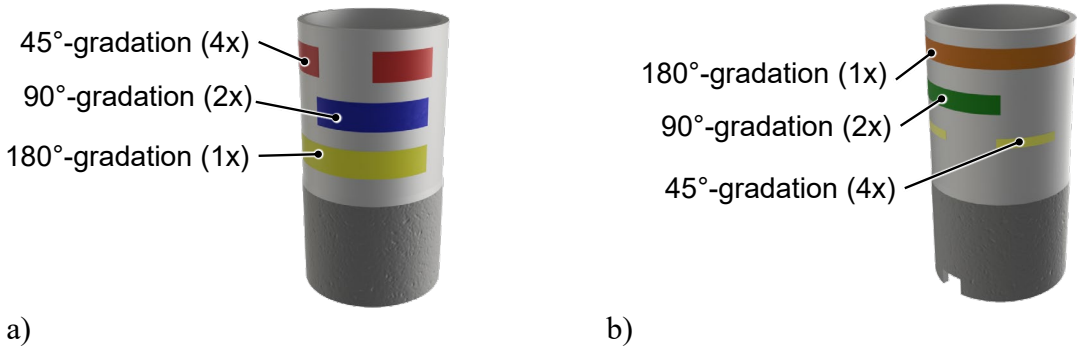
Experimental investigation by forming graded structures.

Two geometric gradation structures were investigated on specimens with the novel control strategy to validify the strategy and to analyze the accuracy of the produced gradations. Both specimens include three annular areas where gradations are placed. In the first area, a single gradation with $\Delta\theta_{grad,des} = 180°$ is placed, two 90°-gradations in the second and four 45°-gradations in the third (see Fig. 5).



a) b)

Fig. 5. Specimen 1 (a) and specimen 2 (b) with graded structures.

Both specimens differ in the axial width of the gradations. In specimen 1, the axial width of each gradation is equal while the width is varying in specimen 2 by contrast. Here, the width is defined

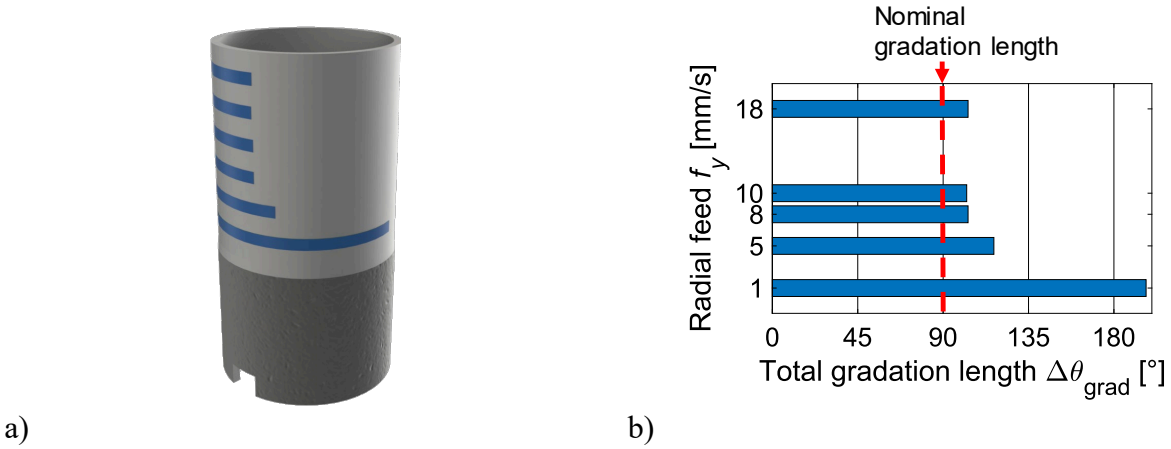
by the number of rotations during the production of the specimen: 8 rotations for 180°-gradations, 4 rotations for 90°-gradations and 2 rotations for 45°-gradations. Thus, the width declines the shorter the gradation angle in this specimen.

Both experiments were performed with an axial feed of 0.1 mm/s according to former flow forming experiments of the authors in [7]. The rotational speed was defined by 5 rpm and the radial feed was set to 10 mm/s. The radial feed value f_y was determined after preliminary investigations (specimen type 3). Here, f_y was varied between 1 and 18 mm/s by a constant rotational speed of 5 rpm and a constant nominal gradation length (desired gradation angle) of 90°. This experiment was carried out without axial feed and only by performing a single rotation.

Results

Investigation on the radial feed.

At first, a specimen type 3 (produced with different radial feeds) was evaluated regarding the total length of the gradation. Since the gradations depict local areas with a reduced wall thickness and a gleaming, it was possible to evaluate the graded areas using a flexible measuring tape.



a) b)

Fig. 6. Influence of the radial feed/infeed velocity on the total angular gradation length: specimen (a) and results (b).

It can be seen from Fig. 6 that the total gradation length differs in every case from the desired nominal length of 90°, which is defined by the control. At a radial feed of 1 mm/s, the measured length amounts more than 180°. The total gradation length is significantly reduced by increasing the feed from 1 mm/s up to 8 mm/s. This is due to the shorter time the actuator takes until reaching the desired infeed position (see Fig. 8a). For infeed velocities of more than 8 mm/s, the total gradation length converges to approx. 103° despite of the faster actuator. This effect is probably caused by the contact area between roller and workpiece. Hence, the oversize of 13° cannot be compensated by a higher actuator dynamic. Additionally, a strong vibration occurs at the counter holder of the machine for radial feeds of more than 10 mm/s. The following experiments on different nominal gradation lengths are thus performed with a radial feed of 10 mm/s.

Local resolution and accuracy of the gradations.

Both specimens with different nominal gradation lengths (specimen 1 and 2) were analyzed regarding the gradation geometry and length. Hence, it is possible to exactly determine the resolution/accuracy of the gradations and to obtain a correlation between the resulting and nominal gradation length, which is the input to the control.

On specimen 2, the gradation width was also varied. Thus, there are gradations of a single rotation (single turn gradation) and of multiple rotations (multi turn gradation). A single turn gradation consists of three regions in axial and angular direction (see Fig. 7). In angular direction,

the gradation consists of three areas: a full width main area and two transition areas at the beginning and the end where the width increases or declines. Therefore, two different lengths of gradation could be distinguished: the inner length of the full width area and the total angular length of the gradation (full width area length + transition area length) that was already used as a measure in the preliminary investigation. The shape of the transition areas is mainly influenced by the roller geometry since the wall thickness is not constant in the axial direction of the whole gradation. There are two inclined surfaces in axial direction at the beginning and at the end of the gradation with a declining/increasing wall thickness. The inclined surfaces (entry and exit region) are caused by the entry and exit angle of the roller while the deepest point of the gradation corresponds to the nose region of the roller [11]. In the transition areas, the width of the entry and exit region decreases/increases to/from zero while the nose region exists on the whole length of the gradation.

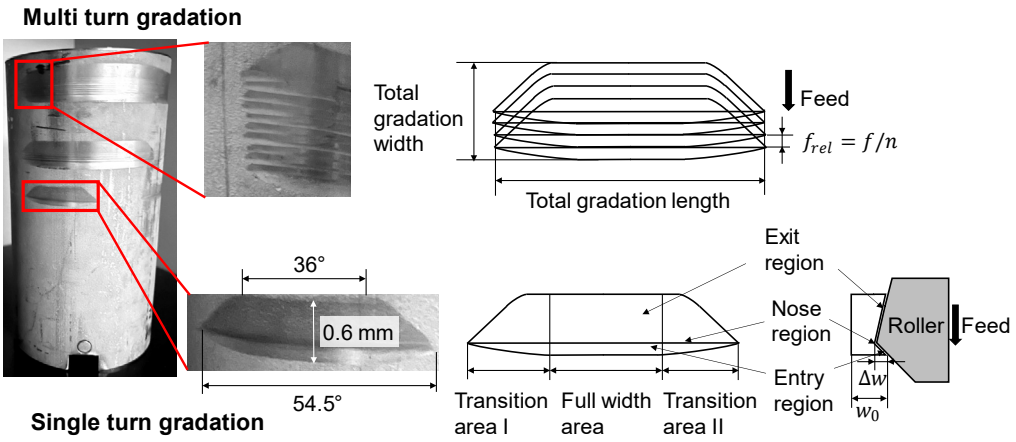


Fig. 7. Geometry of the gradations.

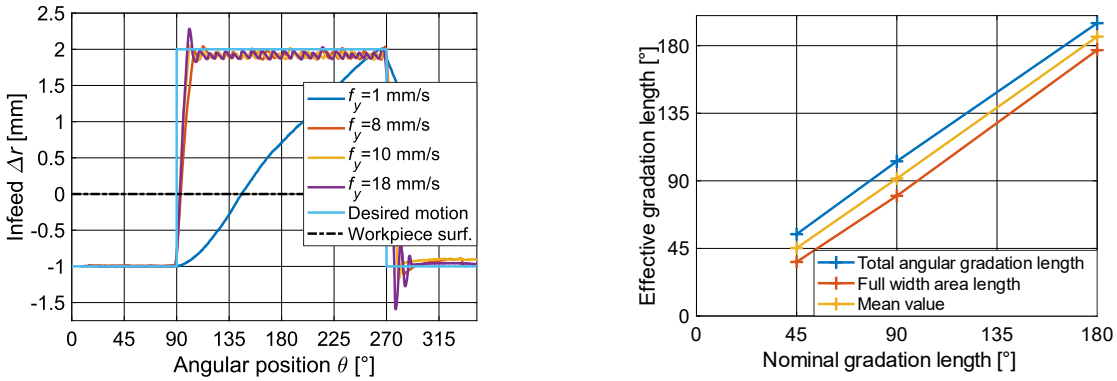
On the multi turn gradations (90° and 180°), the entry and exit region is rarely visible. This is due each multi turn gradation consists of a superposition of single turn gradations that are axially displaced by the related feed f_{rel} in axial direction. Through the axial feed, the entry and exit area are repeatedly shifted by the nose radius of the roller. The entry and exit region thus exist only on the two axial edges of the gradation. Hence, the full width area can only be measured at the edges while the length of the plan area inside the gradation corresponds to the total gradation length.
The results of the length measurement are summarized in Fig. 8b taking the example of specimen 2, but generally the results for specimen 1 are similar. In each case, the total angular gradation length exceeds the desired value of 45°, 90° or 180° (nominal gradation length) by approx. 15 – 25°, like in the results from the preliminary investigations. The precise value might vary between the gradations due to the accuracy of the switching condition (ε-condition, see section 2) up to ±3°. The full width area length amounts approximately 18° less than the total angular length of the gradation in every case. It can be seen that the mean value of the total angular length and the full width area length is approximately (with the accuracy of ±3°) equal to the nominal gradation length from the control. There are principally two reasons for the existence of the transition areas at the edges of the full width area: the actuator dynamics and the roller geometry. In case of the 90°-gradations, the actuator takes 2° until entering the workpiece surface and additional 7° until reaching the desired infeed of 2 mm (see Fig. 8a). Exactly 90° after starting the motion, the actuator is leaving the workpiece (with the same duration as entering but vice versa). This obviously leads to an angular displacement of the gradations of $2 \cdot 2°$ and to the elongation of the gradations due to the transition areas by $2 \cdot 9°$. Otherwise, it has been seen from the preliminary investigations that a higher actuator dynamic of more than $f_y = 10$ mm/s does not influence the total length of the gradations anymore. In this case, also the roller geometry in

circumferential direction leads to the transition area. This is due to the contact area between tube and roller that corresponds to an intersection of a cone (roller) and a cylinder (tube, see [11] for further information regarding the contact geometry).



a) b)

Fig. 8. Influence of the radial feed/infeed velocity on the effective angular gradation length: a) measured actuator dynamics, b) measured gradation length.

By conclusion from the investigations on accuracy, the resulting gradation geometry is mainly influenced by the transition areas at the left and right edge of the gradation. Using the correlation from Fig. 8b, it could be possible to adjust the nominal gradation length in the control to receive a full width area length or total gradation length that matches to a desired value. But in every case, there will be a fuzziness of the gradation due to the physics of the actuator and roller geometry. In this context, also the minimal dimension of a gradation with the current machine setup (process parameter, controller, infeed, and roller geometry) can be derived. Here, the minimal angular length is 18° since the angular gradation length minimally amounts to the length of both transition areas. The minimal axial width corresponds to the width of a single turn gradation, namely the width of the entry, nose and exit region. In the experiment with an infeed of 2 mm, the minimal width amounts approximately 0.6 mm. Generally, it also depends on the wall thickness reduction since the contact area between roller and tube differs.

Wall thickness reduction of the gradations.

The gradations were also investigated regarding the resulting wall thickness reduction. Therefor, a caliper Kroeplin D4R50 (resolution: 0.05 mm) was used. The measured average wall thickness inside the gradations of specimen 1 amounts 3.74 mm, and in specimen 2 the wall thickness is 3.78 mm. The average initial wall thickness also differs between both specimens (3.95 mm for specimen 1 and 4.03 mm for specimen 2). The resulting wall thickness reduction is thus 0.21 mm (specimen 1) and 0.25 mm (specimen 2) which is nearly the same regarding the accuracy of the caliper. Hence, a deviation between the infeed of the roller (2 mm) and the thickness reduction is observed. This effect is essentially caused by undesired machine behavior, e.g. the flexibility of the support and the mandrel, and was already detected during previous investigations at the same machine (see [7] for example). The detailed results for each gradation are shown in Fig. 9. In angular direction, the wall thickness slightly differs between each gradation and moreover inside of them. This effect is caused by the eccentricity of the semifinished parts.

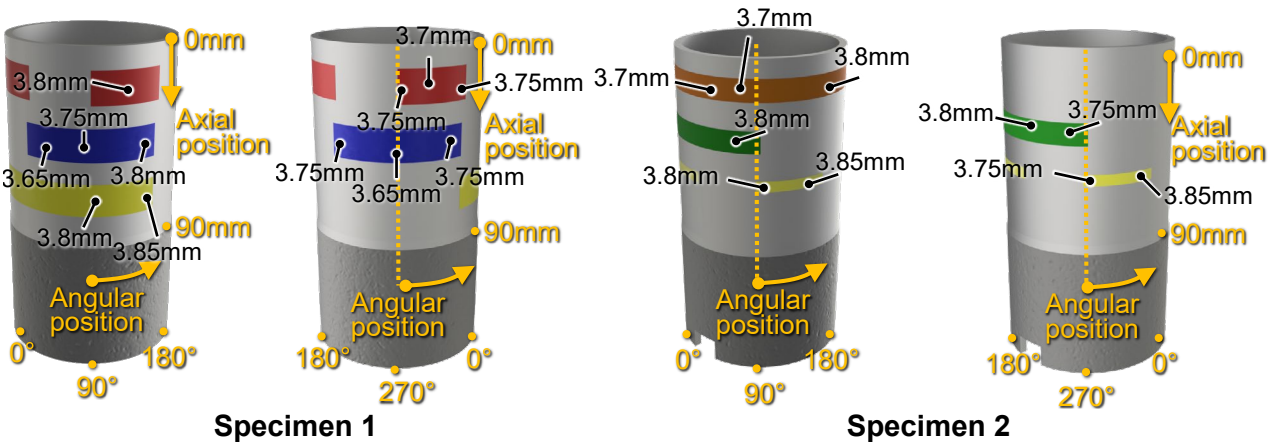


Fig. 9. Measured wall thickness inside the gradations.

α'-martensite formation inside the gradations.

A deformation-induced α'-martensite formation inside the gradations was expected due to metastable austenitic semifinished parts and the wall thickness reduction inside the gradations. For this purpose, the specimens were also analyzed by Feritscope FMP30 (Helmut Fischer GmbH, Sindelfingen, Germany) to detect the volume fraction of the α'-martensitic phase. The results (see Fig. 10) were measured at intervals of 5 mm in axial and 12° in angular direction.

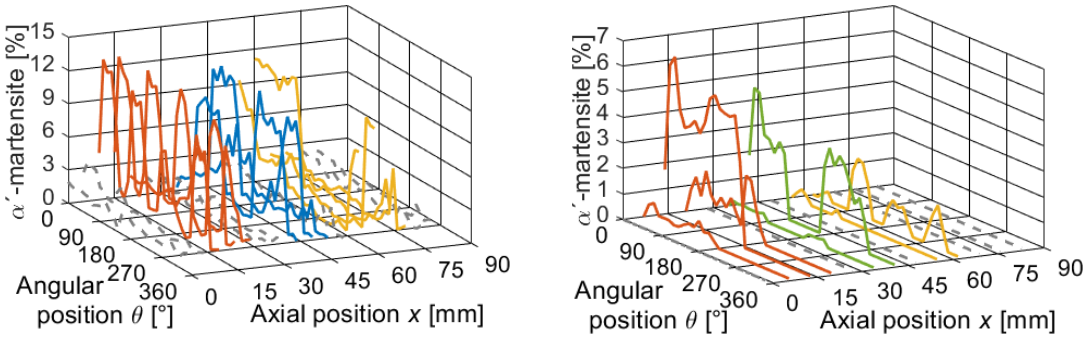

Fig. 10. Measured α'-martensite volume fraction of specimen 1 (left) and specimen 2 (right).

In each gradation of specimen 1, an α'-martensite volume fraction of approximately 11% was measured. In the non-deformed areas by contrast, the α'-martensite amounts less than 3%. Thus, a clearly graded α'-martensitic structure could be identified. On the axial edge of each gradation, the peak value of the α'-martensite measurement is on a lower level (e.g. 5% for the 90°-gradations). This effect could be influenced by the sensor spot that measures inside and outside the gradation at the edge. In angular direction, there is also a gradient of the measured amount of α'-martensite. At the beginning of the gradation (inside transition area I), the α'-martensite amount is lower than at the middle (full width area), where a maximum is reached, and decreases again until the gradation end (transition area II). This is because the contact conditions between tool and workpiece are optimal at the center. However, while forming the gradations, a forming force gradient is created over the material until the optimal contact conditions are reached (at the beginning) or released (at the end), which is reflected in the angular α'-martensite gradient.

Online measurements of the wall thickness reduction during forming.

Regarding a future use in a property control for 2D gradations, the measurements of the two laser distance sensors were also recorded during the production of the two specimens. Sensor 1 was placed on the same axial position as the forming tool, but with an angular displacement. Here,

the distances between the two sensors and the workpiece arise when the support starts infeeding at $t = 98.5$ s/$\varphi = 182°$ (see Fig. 11). Similarly, the distances decline with a distinct downshift at $t = 104.9$ s/$\varphi = 360°$ while the support moves back into the starting position. Both distance shifts are similar, so no wall thickness reduction is detected during the support motion. Wall thickness reduction is firstly measured with a temporal delay of 3.3 s to the actuator signal starting at $t = 101.8$ s/$\varphi = 275°$ and ending at $t = 108.2$ s/$\varphi = 90.5°$. This temporal delay is caused by the angular displacement between sensor and forming zone that amounts approximately 90°. The signal difference of both laser distance sensors amounts approximately 0.3 mm which corresponds roughly to the manually measured wall thickness reduction values.

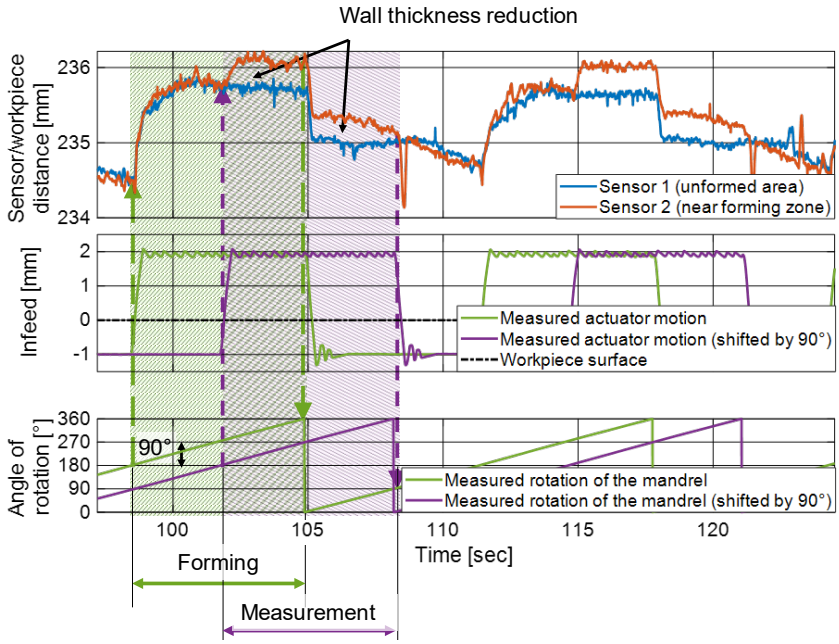

Fig. 11. Influence of the actuator movement and angular sensor displacement on the online wall thickness measurement (forming and measurement of the gradation).

Summary

In this paper, a novel control strategy for the flow forming process was presented. Here, flow forming was enabled to more complex, 2D (axial and angular) graded structures on the specimen surface like a QR code by integrating an absolute encoder into the control. This encoder-based control strategy was successfully validated by the experimental manufacturing of locally graded forming parts. The resolution and accuracy of these gradations in angular direction significantly depend on the actuator dynamics, namely the infeed velocity/feed in radial direction. Above a certain critical velocity, the effect of the actuator dynamic decreases. In this case, the imprint of the roller geometry on the specimen (contact area) becomes the dominating effect. The result is that the gradations own a greater total angular length than the actuator feeds in. In axial direction, the gradation edges were also influenced by the roller geometry. For this reason, a minimal gradation dimension of 0.6 mm in axial and of 18° in angular direction was concluded from the experiments. Thus, a required line thickness of 0.5 to 4 mm for a QR code could be almost realized. In angular direction, structures of 4° to 40° were required since multiple gradations should be circumferentially placed for a QR code. For this purpose, different roller geometries will be evaluated in further investigation to enhance the accuracy due a dependence on the roller radius is assumed. Besides the dimensional accuracy in angular and axial direction, the specimens were also investigated regarding the wall thickness reduction in radial direction. Here, a significant deviation between infeed and thickness reduction was noticed. Nevertheless, the wall thickness reduction

also leads to an α'-martensite formation and thus to a locally graded α'-martensite structure on the specimen. The resulting magnetic properties of the α'-martensite structure will be analyzed in future research.

The presented control strategy could be further extended by a closed-loop control of the wall thickness reduction to compensate the deviation of the reduction. Concurrently, it would be favorable to adjust the α'-martensite volume fraction by a closed-loop property control to a defined value (see Fig. 12).

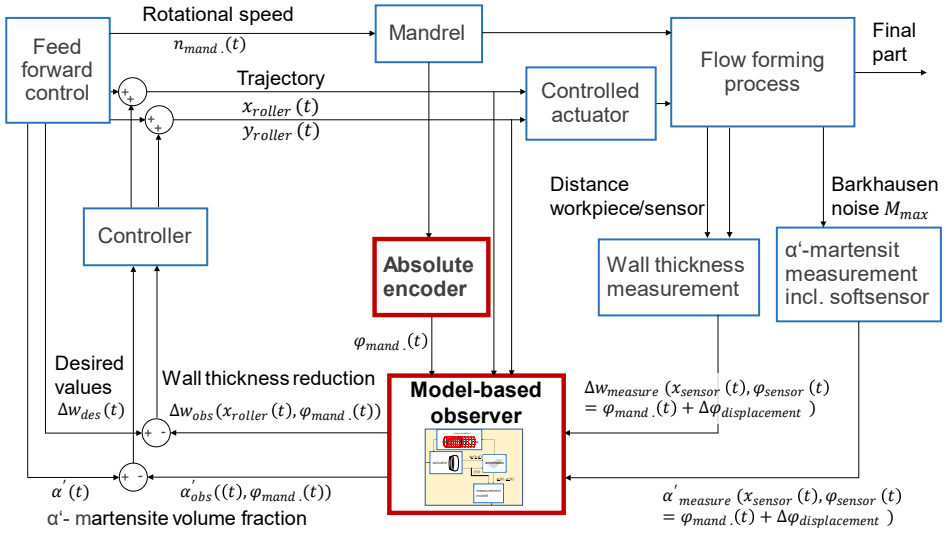

Fig. 12. Concept of a closed-loop property control structure with a model-based observer.

As seen from the measurements of the laser distance sensors, such a closed-loop control for 2D gradations is difficult since the forming result is detected with a spatial and temporal displacement. Therefore, it is not possible to simply compare the measured value to the desired. A possible solution to overcome this challenge is to include a model-based observer into the closed-loop control structure (see Fig. 12). The observer could allocate the measured values to the correct location within a model of the specimen surface and output the wall thickness and the α'-martensite fraction at the actual actuator position. Thus, it would be possible to correctly determine the control error and enhance the process accuracy by applying a closed-loop property control to the process.

Keywords: Open-Die Forging, Reinforcement Learning, Process Optimization, Grain Size

Abstract. The open-die forging process can produce large workpieces with excellent material properties that can be used for heavy-duty applications like turbine shafts. The mechanical properties result from the microstructure, which in turn directly results from the process route. Since in open-die forging processes commonly hundreds of unique forming operations are carried out, numerous process routes lead to the same final geometry but produce different microstructures. This is why the prior design of an optimal pass schedule is essential to ensure good mechanical properties of open-die forgings. In the past reinforcement learning (RL) was already used to design optimized pass schedules for open-die forging that achieve the desired geometry, utilize the available press force, and reduce the number of passes. Furthermore, the design of a single pass schedule only took a few seconds which creates opportunities for the use of RL in control systems e.g. for the microstructure. This is why in this publication an existing RL algorithm is extended so that microstructure can be included in the optimization. Within this process, a microstructure model is integrated into the RL algorithm and the reward function (defines the goal of the training process) was extended in two steps to also rate the achieved average grain size continuously dependent on the temperature of the workpiece. In addition, the RL implementation was changed to ensure the production of the desired final geometry leading to a decrease in the complexity of the optimization problem. Thus, both an improvement of the designed pass schedules and a significant reduction of the training time of the RL algorithm was achieved.

Introduction

Open-die forging is a bulk metal forming process that offers the possibility to produce large mostly longitudinally oriented workpieces while removing casting defects from the component. This includes the closing of casting voids and the transformation of an unfavorable microstructure that can result from casting into a fine homogeneous one. Therefore, open-die forgings exhibit excellent mechanical properties and are often used for heavy duty applications like turbine shafts. During the forging process, the workpiece is incrementally formed using simple tools. Therefore, the final geometry of the component results from the sequence of forming operations, which can comprise up to several hundred individual strokes. This leads to an infinite number of different forging processes, which all result in the same final geometry, but can differ significantly in terms of the microstructure produced, the energy required, or the process duration.

To ensure efficient processes and high component quality in open-die forging targeted process design and, in the long term, process control are of great importance. An optimized process design, considering the microstructure produced, can be achieved e.g. via finite element (FE) simulations coupled with a microstructure model. Since FE simulations of open-die forging processes often require long computing times, a fast design or the control of forging processes is not possible using this approach. In the industry forging processes are until today often designed based on experience

or using simple models describing e.g. the geometry development. In addition, commercial software to design pass schedules, such as the program "ForgeBase®" from SMS group GmbH [1] or "easy2forge" from Dr. Fister GmbH [2], are available. Although these programs can quickly design (in some instance optimum) pass schedules for various ingot geometries, considering e.g. plant boundaries, the microstructure generated is not yet included in the design. Overall, a need for new possibilities for rapid design of optimum pass schedules as well as targeted process control arises, whereby besides geometry further workpiece parameters such as grain size are included.

In this publication, a novel approach for the design of optimized open-die forging processes using the machine learning method reinforcement learning (RL) is presented. RL algorithms as well as deep reinforcement learning (DRL) approaches have been successfully applied in various manufacturing applications including metal forming for different process design and control tasks [3,4]. Gamal et al. [5] trained a deep deterministic policy gradient algorithm to control the roll gap in bar and wire hot rolling using real plant measurement data. Dornheim et al. [6] used a RL approach coupled to a FE-simulation of the process to optimize the blank holder force in sheet metal deep drawing. Scheiderer et al. [7] used a soft actor critic algorithm to design an optimal pass schedule for heavy plate rolling that produces a desired grain size.

Since RL algorithms learn and store general rules for optimal behavior in different situations, after a successful training process they can determine solutions for individual problems in a very short time. In addition, (deep) neural networks can be used to store the knowledge learned during the training process, which can map even highly nonlinear correlations that are often present in open-die forging e.g. due to the incremental forming. For this reason, a double deep q-learning (DDQL) algorithm for the optimized design of open-die forging processes was developed in [8]. The algorithm is capable of designing pass schedules that achieve the desired final geometry while making use of the available press force and reducing the number of passes. Since the design of one optimized pass schedule via RL took only 2-4 seconds, the potential of RL for process planning and control has already been demonstrated. Since microstructure has a great influence on the mechanical properties of a forging, in this publication, a microstructure model is incorporated into the existing DRL algorithm to enable consideration of the produced grain size in the design of optimized pass schedules for open-die forging.

Previous Reinforcement Learning in Open-Die Forging

The machine learning approach RL is similar to human trial-and-error learning [3]. In an industrial open-die forging plant, this learning procedure runs unconsciously. Both press and manipulator operators select process parameters such as height reduction or bite ratio on a daily basis, interacting with their environment the open-die forge. In addition, they receive subsequent feedback on the part quality, e.g. good part or scrap, and thus with time learn how different materials and workpiece geometries are forged optimally (cf. Fig. 1, left).

Throughout its training process, the RL algorithm implemented in [8] undergoes the same learning process. Here, a so-called RL agent (cf. Fig. 1, center) interacts with its environment by selecting actions that correspond to process parameters such as bite ratio or height reduction (cf. Fig 1, middle). In contrast to a plant operator, who learns directly from the real forging process, the RL agent uses a virtual forging environment (cf. Fig. 1, right). This incorporates fast process models that can calculate the change in key workpiece properties such as geometry [9], temperature [10], and equivalent strain (in the core fiber) [11] as well the process duration and press force. Since it is often necessary to design several thousands of pass schedules in a RL training process as well as analyzing them concerning the material and process properties achieved, using a real forging plant for training is not feasible. This is due to risks for operators and machines as well as considerable costs incurred from the material used, wear, and the occupancy of staff and plants.

The virtual forging environment uses the process parameters selected by the agent to adjust the current state of the workpiece, including its geometry, temperature, and equivalent strain (in core fiber). An evaluation of this action selection according to a so-called reward function follows. The reward function assigns a scalar reward to each process parameter selection of the algorithm considering the current ingot state and hence, defines the goal of the RL training process. Afterwards, the agent uses the rewards and the information on the state change to adapt its action selection rules stored in a neural network (cf. Fig 1).

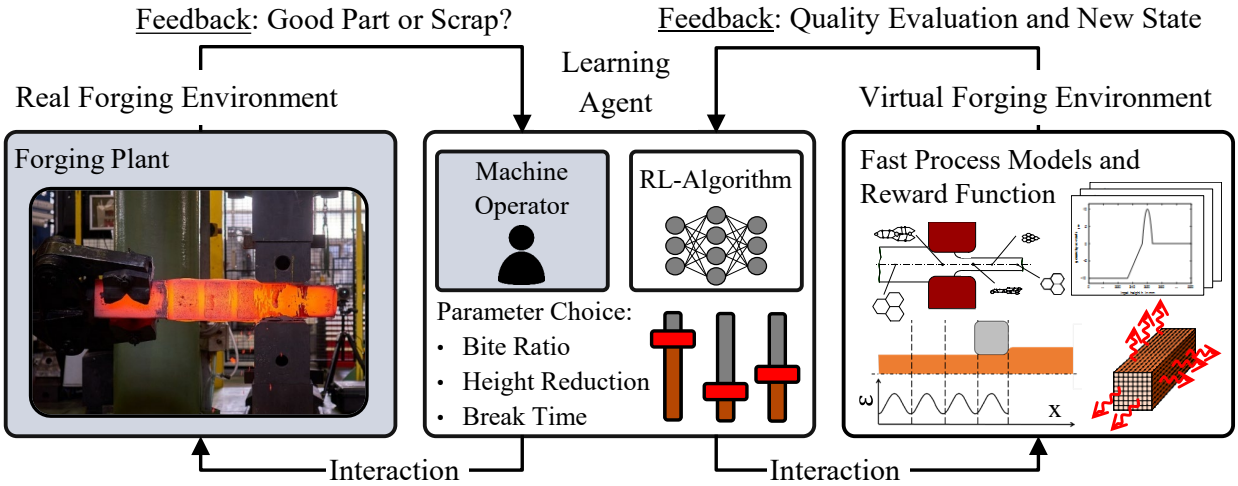

Fig. 1. Graphical representation of the trial-and-error learning procedure; left: human plant operator; right: RL algorithm.

In the given implementation, the RL agent learns how to design efficient forging processes. The goal includes not only to produce the desired final geometry but also to minimize the number of passes and to make the best possible use of the available press force. At the same time, process and plant limits such as the maximum force of the press are considered in the pass schedule design. For this reason, 80 % of the maximum press force is set as the nominal value, which, when adhered to, provides the maximum reward for the algorithm. In contrast, the reward function produces a penalty if the press force limit is exceeded. A detailed description of the implementation as well as the training process of the RL algorithm can be found in [8].

Description of the Use Case

To ensure good mechanical properties in open-die forged components while forging efficiently a targeted adjustment of the microstructure is essential. The RL algorithms presented throughout this publication are all trained to design pass schedules considering forging ingots made of 1.4301 steel (AISI 304), with a starting temperature of 1100°C and an initial grain size of 200 µm. The initial ingots have square initial cross-sections with edge lengths between 180 mm and 220 mm and are drawn out to final cross-sections with edge lengths between 100 mm and 140 mm. The initial length of the forging ingots is 500 mm. In the end, the trained RL algorithms should be able to give optimal pass schedules in seconds for various combinations of initial and final ingot geometries within the above-mentioned ranges. This would enable the use of RL-algorithms not only for fast offline design but also for online process adaption in order to control forging processes.

In a first step, the existing RL algorithm for efficient forging (no consideration of grain size) is trained without modifications. Afterwards, 400 different pass schedules with uniformly distributed combinations of initial and target geometry were designed using the RL agent. A semi-empirical microstructure model [12] was used to analyze the produced grain size along the core fiber of each pass schedule. This creates a comparative measure to rank the effectiveness of the later discussed

changes that account for grain size in the optimized pass schedule design. Fig. 2 shows the consolidated results using a heat map. Here, each box represents a pass schedule whose associated initial and target workpiece geometry can be read on the x and y axes, respectively. The coloration of the box represents the average austenitic grain size achieved in the core fiber of the workpiece at the end of the forging.

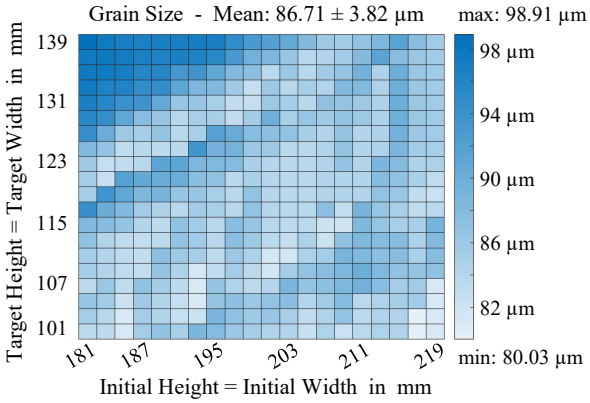

Fig. 2. Heatmap showing the produced average grain sizes of 400 different pass schedules designed by RL without a specific grain size reward.

The generated average grain sizes vary between 80.03 µm and 98.91 µm with a standard deviation of 3.82 µm. Averaged over the 400 pass schedules, the mean average grain size is 86.71 µm. Furthermore, averaged comparative values for the deviation from the target geometry (± 0.23 %), the average number of passes (6.15), and the utilization of the press force (± 5.02 %) are calculated and listed in Table 1.

Extension of the Previous RL Implementation

To enable the RL algorithm (cf. Fig. 1) to consider the production of a specific grain size in the process design, the existing implementation was extended in three steps. The first step consists of the implementation of a microstructure model developed by Karhausen et al [12] into the environment of the algorithm. The model uses semi-empirical equations to estimate recrystallization and grain growth, as well as a substructure modeling to determine the change in austenite grain size during forging. The model input is time-resolved data of temperature and equivalent strain along the core fiber that is already available in the environment of the RL algorithm.

In the second step, the previous reward function (cf. [8]) consisting of a weighted sum of the single rewards for force utilization and geometry, was complemented by an additional term R_{GS} to evaluate the generated mean austenitic grain size in the core fiber at the end of each process (cf. Fig. 3). As shown in Fig. 2, the mean average grain size produced by the previous algorithm was 86.71 ± 3.82 µm with a minimum grain size of 80.03 µm. To force the adapted RL agent to change its pass schedule design pattern for each combination of initial and target geometry, a target grain size of 70 µm, as well as a permissible maximum deviation of ± 10 µm, was chosen. This ensures that the new target grain size does not overlap with the previous grain size spectrum of the efficient forging use case (cf. Fig. 2).

To reflect this, a grain size reward function R_{GS} was designed, which is evaluated only once at the end of each pass schedule and hence, is referred to as a sparse reward. The reward R_{GS} divides into three characteristic sections depending on the mean grain size (cf. Fig. 3). The first section covers the permissible target grain size region of 70 ± 10 µm. Here, the reward increases parabolically and reaches its maximum at the exact target grain size. Outside the permissible grain size range, the reward drops linearly with increasing deviation from the target grain size in section two until it remains constant at its minimum in section three. This lower limit of the reward is called reward clipping. It prevents large gradients from occurring in the training process of the RL algorithm, which can increase the training stability.

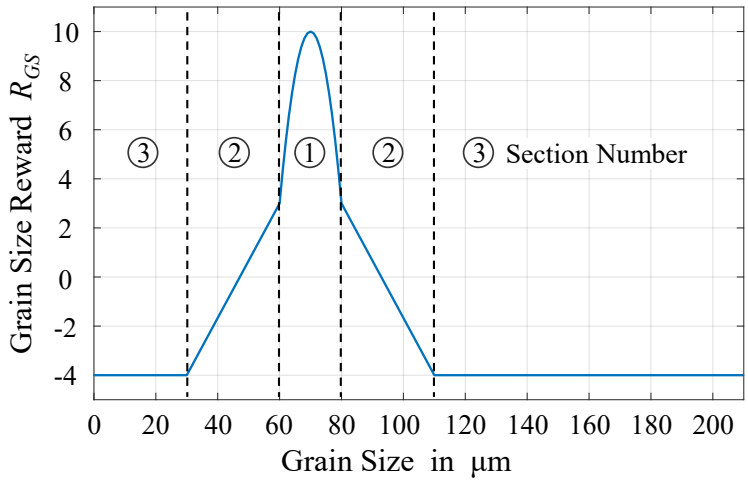

Fig. 3. Graphical representation of the sparse grain size reward R_{GS}.

Finally, the action selection of the algorithm, which previously consisted of height reduction (3% - 30%) and bite ratio (0.3 – 0.9), was extended by the selection of a break time between 0 and 120 seconds before every second pass. This enables the algorithm to influence the microstructure significantly more throughout the forming process. Now, depending on the current ingot state, the RL can e.g. lower the workpiece temperature by cooling or give material-physical processes such as static recrystallization or grain growth the necessary time to complete.

Training of the RL Algorithm – Sparse Grain Size Reward

After the RL algorithm was extended and the use case was defined, a new training process with 100,000 iterations was carried out. This corresponds to 100,000 designed pass schedules that are analyzed concerning their final workpiece properties by the environment using fast process models. The training process took about eight days on four cores of an Intel® Xeon® E5-2667 v3 processor with the algorithm successfully converging against high rewards.

To classify the quality of the generated pass schedules, again 400 different pass schedules were designed using the trained RL agent and then analyzed concerning their achieved grain sizes. Subsequently, averaging was used to generate comparable process parameters such as a mean number of passes or an averaged deviation from the target geometry. On average, the grain size over all 400 pass schedules is 70.99 ± 3.58 µm (cf. Fig. 4) and thus close to the desired target value of 70 µm. In comparison to the previous RL algorithm for efficient forging, the mean grain size decreased significantly throughout all 400 pass schedules (cf. Fig. 2) while the standard deviation remained almost the same. Moreover, nearly all processes produce a grain size within the permissible range between 60 µm and 80 µm. Only a small cluster of five pass schedules (cf. Fig. 4, red frame) exceeds the permissible maximum value of 80 µm with a maximum grain size of 82.05 µm for the combination of an initial height of 189 mm and a final height of 139 mm.

In addition to the new optimization goal of generating a defined grain size, the agent also successfully took into account the objectives for efficient open-die forging. The average number of passes was reduced to 5.9 while the designed pass schedules use the available press force well. This is underlined by a small average deviation of 6.1 % from the target press force, whereby the maximum press force is not exceeded in any pass schedule. In general, the designed pass schedules lead to the desired target geometry well resulting in an average deviation of 0.31% between generated and desired final height. Nevertheless, one of the 400 pass schedules (initial height = 213 mm and target height = 137 mm) failed on the permissible final height range (target height ± 1%) with a deviation of -1.02 % from the target geometry.

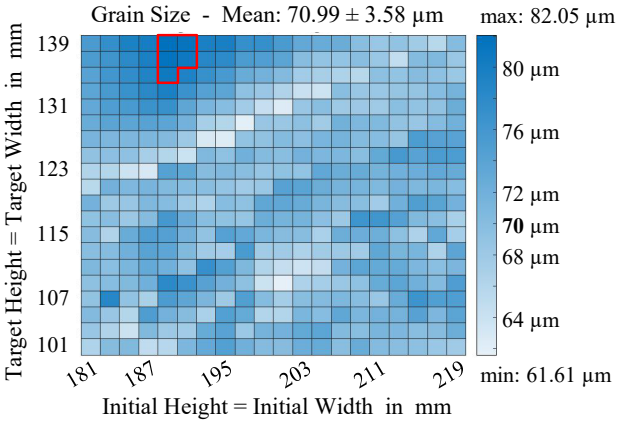

Fig. 4. Heatmap showing the produced average grain sizes of 400 different pass schedules designed by RL with a sparse grain size reward (cf. Fig. 3).

The pass schedules failing slightly on complying with the target grain size and target geometry ranges indicate that the algorithm might not have converged to its full extent yet. One reason for this slow and incomplete convergence could be the increased complexity of the optimization problem. Furthermore, an unclear formulation of the optimization goals within the reward function can result in bad convergence as well as the observed grain sizes outside of the desired range. A longer training process might improve the result quality but due to the already high training duration of several days, it is not a feasible solution. Instead of longer training durations, the following chapter aims at two different approaches to increase the efficiency of the training process: Reducing the complexity of the optimization problem and improving the reward function.

Reduction of Complexity

The first change to the implementation of the RL algorithm aims at reducing the complexity of the optimization problem to be solved. Until now, the algorithm has had to balance four optimization objectives (set final geometry, minimize number of passes, utilize press force, set grain size) and satisfy all of them simultaneously. So far, the final geometry resulted from the selected height reductions and bite ratios, considering the occurring spread. Since the desired final cross section is known upfront and fast process models can predict the geometry change during forging, from now on the desired final geometry is directly ensured in the implementation of the RL environment. As soon as the algorithm selects a combination of height reduction and bite ratio that causes the final height of the workpiece to fall below the desired final height, a correction of the last two passes happens. Here, the height reduction is inversely lowered by backwards calculation of the geometry model ensuring the exact production of the target geometry. The bite ratio and break time selected by the algorithm remain unchanged during this adjustment. This change to the implementation removes one of the four optimization objectives, so that the complexity of the optimization problem decreases significantly, which should lead to improved convergence in the training process. Since hereafter, the desired geometry is always produced perfectly, the associated reward calculated after the last pass is invalid and removed from the reward function.

Furthermore, a restriction of the number of actions selectable by the agent decreases the complexity even further. The discrete action choice of the used RL (double deep Q-learning) agent is based on the estimation of the value $Q(s,a)$ for all possible action choices a in the current state s. The Q value represents a measure of the total reward expected for the remaining process, which the agent tries to maximize. Therefore, the agent always chooses the actions with the highest Q-value, promising the highest total reward gained. So far, the RL agent can choose bite ratios between 0.3 and 0.9 in increments of 0.05, and height reductions between 3% and 30% in increments of 1%. In combination with break times, which the algorithm is allowed to choose between 0 s and 120 s in 30 s increments, 1820 combinations of action choices are possible in each state of the forging. Hence, before every action choice 1820 Q-values need to be calculated, leading to the conclusion that in the current implementation increasing discretization of actions leads to

slower action choices and hence to higher training durations. Furthermore, the algorithm must estimate the value *Q(s,a)* for all combinations of state *s* (state of the forging ingot) and action *a* (combination of process parameters) and store it in the neural network. This mapping becomes more difficult as the number of combinations increases. This is why the step size of the action choices bite ratio (0.3 : 0.05 : 0.9 → 0.3 : 0.1 : 0.9) and height reduction (3% : 1% : 30% → 3% : 3% : 30%) were reduced. Through this adjustment, the number of possible actions per state decreases from 1820 to 350 representing another significant reduction in complexity.

Adaption of the Reward Function

Besides the high complexity of the optimization problem, the design of the reward function can be a reason for the slow convergence behavior as well as the miss of the desired grain size range. The definition of the reward function is one of the most important issues in RL, because the reward function does not only influence the achieved result, here e.g. the quality of the generated pass schedules, but also the training process itself. A well-defined reward function contributes to accelerating the convergence of RL algorithms and leads to more stable training processes. It is known that compared to sparse rewards, continuous reward functions promote the convergence of RL algorithms and lead to better training results. In the present context of pass schedule design, a sparse reward corresponds to feedback that is given only once per pass schedule after the last pass, whereas a continuous reward is calculated after every second pass. The current reward function already includes continuous rewards for utilizing the available press force and for minimizing the number of passes, but producing a specific grain size is only rated sparsely (cf. Fig. 3). It is hardly possible to describe the microstructure evolution during open-die forging processes inversely due to the incremental forming and interaction of various material physical effects like recrystallization and grain growth. For this reason, there is no feasible benchmark for the continuous evaluation of the ingot state over the process to achieve a desired grain size at the end of the process.

To overcome this hurdle, a new temperature-dependent continuous reward of the grain size is introduced, which should help the algorithm to reliably achieve the desired final grain size across all combinations of initial and target geometry. This reward structure is based on the assumption that the algorithm can only influence the microstructure as long as the ingot is sufficiently hot. As the workpiece cools during forging, processes such as recrystallization and grain growth are increasingly restricted, and hence, the influence of the agent on the microstructure decreases. This insight enables the creation of a new reward function $R_{GS,C}$ for rating the grain size continuously throughout the pass schedule. A downward-opening parabola whose maximum occurs at the target grain size forms the basis of this function. As can be seen in Fig. 5, on the one hand, the minimum reward is lowered with falling temperatures. On the other hand, the parabola is unilaterally stretched in the direction of larger grain sizes with raising temperatures. Both effects described, apply linearly between 900°C and 1100°C and represent the decreasing influence on the grain size (cf. Fig. 5). Outside this temperature range the reward $R_{GS,C}$ remains constant. The new continuous grain size reward only complements the existing sparse grain size reward. Hence, at the end of a pass schedule still a grain size reward inspired by Fig. 3 is calculated. It is to be noted that $R_{GS,C}$ is deliberately defined as negative. The punishment granted for each pass indirectly represents the goal to also minimize the number of passes, since higher amounts of passes lead to more grain size evaluations resulting in a higher overall punishment.

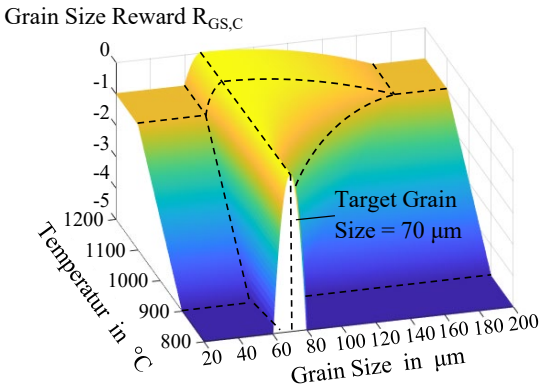

Fig. 5. Graphical representation of the continuous reward function for the grain size $R_{GS,C}$.

Retraining of the adapted RL algorithm – Continuous Grain Size Reward

To be able to assess the influence of the adjustments made, the adapted RL algorithm had to be retrained once again. This training process comprised 50,000 iterations that equal 50,000 designed and analyzed pass schedules, and took only 24 hours on four cores of an Intel® Xeon® E-2236 processor. Again, 400 different pass schedules were designed using the trained RL algorithm and the achieved mean austenitic grain sizes are summarized in Fig. 6.

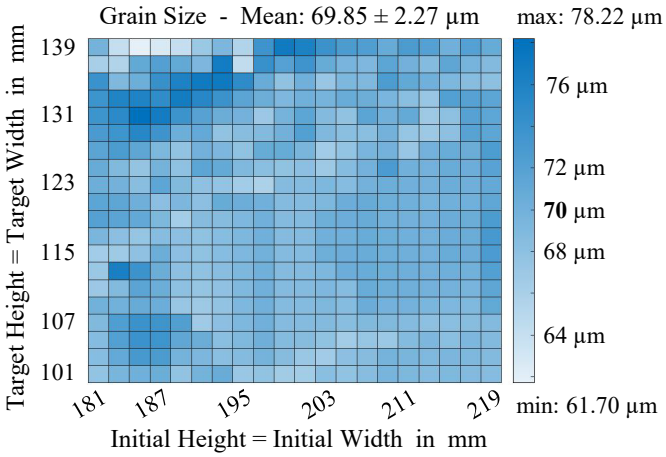

Fig. 6. Heatmap showing the produced average grain sizes of 400 different pass schedules designed by RL with a continuous grain size reward.

Averaged over all 400 pass schedules, the adapted RL algorithm produces a mean grain size of 69.85µm, which is very close to the target grain size of 70µm. The standard deviation results in 2.27µm while none of the 400 pass schedules produces a grain size outside the desired range. In addition, the algorithm continues to meet the goals of efficient open-die forging with an average number of passes of 5.55 and an average deviation of 5.5% between the predicted and nominal press force. At the same time, plant limits such as the maximum press force are observed in all pass schedules. Compared to the previous results from the RL algorithms with no and with sparse grain size rewards (cf. Table 1), a significant improvement in the quality of the designed forging processes was achieved.

Table 1. Summary of the pass schedule quality of all three RL algorithms.

RL algorithm	no GS reward	sparse GS reward	continuous GS reward
Average grain size [µm]	86.71 ± 3.82	70.99 ± 3.58	69.85 ± 2.27
Average number of passes	6.15	5.88	5.55
Avg. deviation nominal Force [%]	5.02	6.13	5.53
Avg. deviation from final height [%]	0.23	0.31	0

In general, the latest RL algorithm shows similar process design patterns compared to its predecessor with sparse grain size reward. Whenever possible, large height reductions are applied to reduce the number of passes. At the same time, break times and bite ratios are selected interdependently so that the press force is utilized well and the desired grain size is achieved. The greatest behavior change is present in the area in which the maximum permissible grain size of 80 µm was previously exceeded (see Fig. 4, red frame). Here, the adapted RL algorithm applies six passes instead of four while concentrating deformation in passes three and four. This leads to a different recrystallization timing, which shifts the final grain size into the desired range.

The significant improvement in the quality of the designed pass schedules, combined with the drastic reduction of the training duration from eight days to 24 hours, demonstrate the feasibility of RL for the design of optimized pass schedules in open-die forging with consideration of microstructure. After the training process, the design of one optimized pass schedule only takes about four seconds. This short calculation time enables the use of RL for the control of open-die forging processes when combined with a suitable process monitoring system (cf. [13]). If deviations from the target process route happen that would lead to e.g. an undesired change in final grain size, the monitoring system can detect those. Subsequently, a RL algorithm could be used to calculate a new optimized pass schedule in real time, starting from the intermediate state of the process and continuing to produce the desired final grain size. To achieve this, further changes to the RL algorithm are necessary, so that it can cope with sensor noise present in the real forging environment as well as a wider range of input states of the forging ingots.

Summary

In this publication, an existing RL algorithm for the design of efficient open-die forging processes was extended to successfully consider microstructure in the process design. In a first extension, a sparse grain size reward was introduced into the RL algorithm leading to an improved microstructure. The average grain size of 70.99 ± 3.58 µm was significantly closer to the target value of 70 µm compared to the original implementation (86.71 ± 3.82 µm). The goals of efficient open-die forging (produce target geometry, use available press force, reduce number of passes) were also met, although slightly worse than before (cf. Table 1). Since individual pass schedules still missed the desired range for the grain size as well as the target geometry, a new continuous reward structure depending on the ingot temperature was added in a second extension. Besides that, the complexity of the underlying optimization problem was reduced so that the RL algorithm is now able to design optimized pass schedules for all combinations of initial and target geometry. On average, the mean austenitic grain size after the forging resulted in 69.85 ± 2.27 µm while all designed pass schedules complied with the specified grain size limits. In addition, the adherence to the optimization objectives of efficient forging also improved, underlining the great potential of utilizing process knowledge for the improvement of reinforcement learning applications. Besides the raise of result quality the duration of the training process decreased from eight to one day and the design of individual optimized pass schedules still takes just a few seconds. This highlights not only the possibility to use RL for the fast design of optimized pass schedules, but also the potential to use RL for the control of open-die forging processes.

Outlook

In the future, forging experiments on the open-die forging press of the Institute of Metal Forming (IBF) as well as microstructure analysis are planned to validate the presented RL approach. In addition, after the extension, the algorithm is still able to design individual optimized pass schedules in a few seconds. This offers the potential to extend the RL algorithm from designing processes in advance to control open-die forgings with regard to microstructure. To achieve this, the RL has to be extended so that deviations from a nominal process, such as interruptions or varying initial temperatures, can be included in the training process and hence, be reacted to.

Keywords: Sheet-Metal Forming, Material Properties, Property Monitoring, NDT

Abstract. Material properties can vary both along a sheet-metal coil and from coil to coil despite tight tolerances influencing the process stability of sheet-metal processes and the part quality, which leads to rejects and machine downtime [1]. This significantly affect the economic efficiency of the process. Monitoring fluctuations in material characteristics at regular intervals along sheet-metal coils is enabled directly by non-destructive testing (NDT) before the process offering conclusions on the material properties. Another material monitoring technique arises from monitoring process conditions of the upstream processes, e.g., cold rolling, leading indirectly to insights on material properties. In this work, a systematic literature review (SLR) [2] is conducted to investigate recent approaches for material monitoring and for the utilization of resulting material data for optimizing different sheet-metal forming processes. Existing approaches for different sheet-metal forming processes are critically appraised. Based on the SLR research gaps are revealed and research opportunities, e.g., arising from a potential transfer of existing solutions between different forming processes and recent advances in data-driven methods, are identified.

Introduction

Despite tight tolerances, variations in material properties along a sheet-metal coil or between different batches of the same material have been shown to occur during sheet-metal production [3]. These material fluctuations lead to defects such as burr formation or dishing behavior in shearing processes and to defects such as spring back in bending or forming operations [4]. Thus, fluctuating material properties result in rejects, robustness problems and downtime of sheet-metal forming processes. Typically, material properties are only measured at the beginning and at the end of coils. This makes it difficult to draw conclusions about the material quality in the event of defects.

With the rise of the digital transformation in manufacturing to the Industry 4.0 the concept of the Internet of Production is gaining more importance [5]. In an Internet of Production all process-characterizing information about a production process is available for the realization of real-time process control and decision support. In the case of material variation that means the information about the material properties along the coil needs to be available to achieve full transparency, to adapt the process to changes in material properties and in case of workpiece defects to provide data for effective troubleshooting.

One solution to this problem is to measure or monitor the material characteristics along the sheet-metal coil before the sheet-metal process with the help of non-destructive testing (NDT). Already in 1994, Engel et al. demonstrated the potentials of NDT for sheet-metal processes [6]. Nowadays NDT allows drawing direct conclusions about material properties, such as tensile

strength or elongation at break, and can be performed inline at regular intervals along the coil as it is being processed [7].

Besides NDT, another approach to material monitoring arises from monitoring process conditions of the upstream processes of sheet-metal forming processes, e.g., hot rolling [8], leading indirectly to insights on material properties. The use of cross-process data fundamentally enables the identification of quality-relevant parameters in the process chain and thus, the optimization of the process itself or of the subsequent process in the process chain. The sharing of information along the process chain is one of the main goals of an Internet of Production.

Since a lot of research is already done in this field, this paper methodologically researches the approaches to handle fluctuating material properties for the usage in an Internet of Production. The two presented approaches of monitoring material properties along sheet-metal coils lead to following research questions:

RQ1. How can fluctuating material properties be directly measured by NDT?
RQ2. How can fluctuating material properties be indirectly measured by monitoring the upstream process?
RQ3. How is the knowledge of fluctuating material properties along the coil utilized to optimize sheet-metal processes?

To answer these questions a systematic literature review (SLR) is conducted. First, the research methodology is described in section 2 and after that in section 3,4 and 5 the research questions are discussed chronological based on the results of the SLR. In section 6, research gaps in the field of material monitoring are identified.

Research Methodology

The research methodology of the conducted SLR is based on the research methodology from Xiao and Watson [2]. It consists of three stages planning, conducting and reporting with different steps (Fig 1). The problem formulation is already described in section 1 in the form of three research questions.

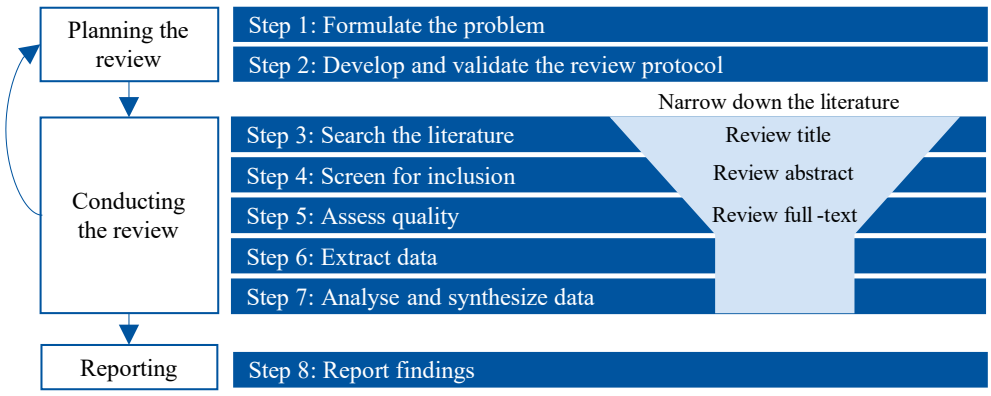

Fig. 1. Methodology of the SLR (adapted from [2]).

Based on these research questions, topics for keywords were selected (see Table 1). The first keyword topic focusses on “mechanical properties” and “material variations” ensuring that the retrieved literature contains these or synonyms of these terms. In addition, the literature search is intentionally limited to publications on sheet-metal forming, in particular, common sheet-metal forming or shearing technologies and the most important upstream processes for the production of sheet-metal coils. Here common sheet-metal forming processes were chosen. The last keyword topic focuses on different monitoring and utilization methods of known material properties based on the fact that known material characteristics are used for control or data-driven analysis.

Table 1. Keywords of the conducted SLR.

Material Properties		Sheet Metal Forming		Processes		Utilization
material variation **OR** material fluctuations **OR** material variability **OR** material scatter **OR** mechanical properties **OR** material properties **OR** steel strip properties **OR** sheet metal properties **OR** material characteristics **OR** material measurements	**AND**	sheet metal forming **OR** metal forming **OR** forming technology **OR** sheet metal separation **OR** strip steel **OR** steel sheets **OR** sheet metal **OR** sheet material **OR** steel strip **OR** cold rolled strip **OR** coil	**AND**	normal cutting **OR** shear cutting **OR** shearing **OR** blanking **OR** punching **OR** fine blanking **OR** fineblanking **OR**	**AND**	optimization **OR** monitoring **OR**
						NDE **OR** NDT **OR** non-destructive testing **OR** non-destructive evaluation **OR** non-destructive examination **OR** nondestructive testing **OR** nondestructive evaluation **OR** nondestructive examination **OR** eddy current **OR**
				stamping **OR** deep drawing **OR** car body part **OR** bending **OR**		closed loop control **OR** control materials **OR** feedback control **OR** feedforward control **OR** online control **OR** offline control **OR**

With these keywords 355 publications were found in the database Scopus. Scopus only considers peer-reviewed papers, books, and conference papers. Duplicates and publications that were not in English or older than from the year 2000 were removed. Based on the research questions the publications were examined by their title and abstract. Then a backward/forward search was conducted. An overview of the conducted SLR is given in Fig. 2.

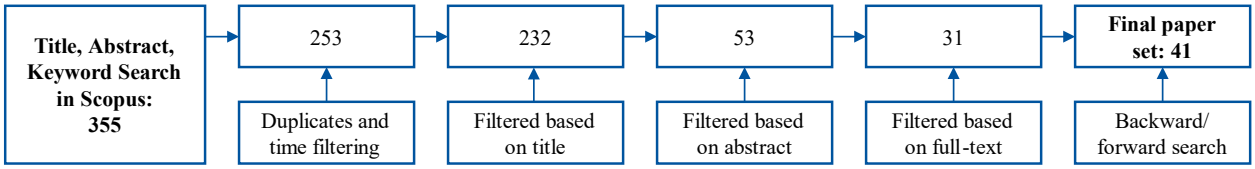

Fig. 2. Review process of the conducted SLR.

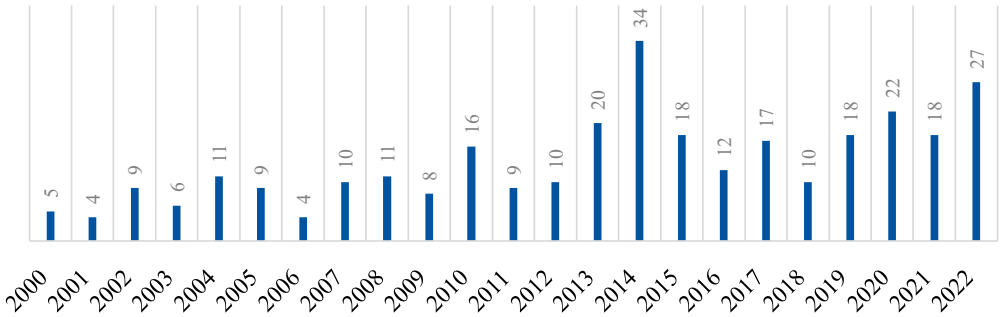

Fig. 3. Publication per year.

A first analysis of the publications per year shows that the topic of monitoring fluctuating material properties for optimizing sheet-metal forming processes became increasingly important until 2014 and after 2014 the importance remained, leading to the assumption that this topic is still relevant and will be relevant in the future.

To give a first overview of the results, Fig. 4 shows the number of publications found in the SLR after filtering for duplicates and time for different keyword topics displayed in the rows of column 3 of Table 1. It is evident that the topic of material variation is addressed primarily for the upstream processes, hot rolling, cold rolling, and roller levelling and for the sheet-metal forming processes stamping, deep drawing and bending. There are not many publications regarding sheet-metal separation processes.

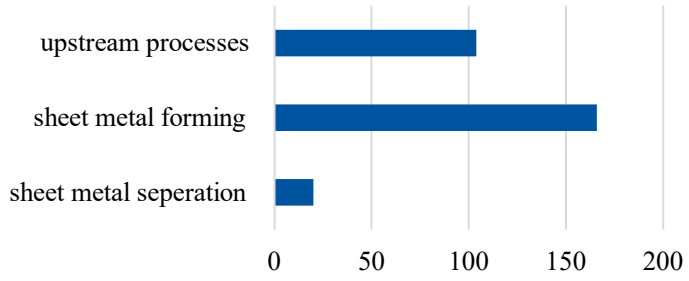

Fig. 4. Publication regarding different processes.

In the following three sections the research questions will be discussed based on the outcome of the SLR. A summary of the cited publications is given in Table 2.

Non-Destructive Testing in Sheet-Metal Forming (RQ1)

Non-destructive testing methods are suitable for measuring the material properties at regular intervals along the coil before the sheet-metal forming process. The operating principles of non-destructive testing methods include ultrasonic testing, X-ray examinations and electromagnetic methods. In sheet-metal forming, electromagnetic methods are commonly used because there is a correlation between the mechanical and electromagnetic properties of sheet-metal since the microstructure is influencing both. Several scientific publications study how signals from various electromagnetic sensors correlate with material properties.

For instance, Magnetic Barkhausen noise was used to measure hot-stamped high strength steel [9] and cold-rolled steel strips [10,11] in a lab setting. These measurements were used to predict different material properties, e.g., yield strength. Unterberg et al. distinguish whether material specimen were extracted from the start, the middle, or the end of a sheet-metal coil using a machine learning algorithm with magnetic Barkhausen noise as input data [12]. However, magnetic Barkhausen noise has not yet been used for inline monitoring.

Commonly used sensors for in-line measurements of sheet-metal material include, eddy current sensors (eddy current method), the 3MA sensor (micromagnetic, multiparametric microstructure and stress analysis), and the IMPOC sensor (magnetic inductive method). For each of these sensors, it has been shown that the sensor signals are related to the mechanical properties. Various publications report successfully using 3MA sensor for inline sheet-metal monitoring and predicting tensile strength, yield strength, residual stress, and hardness of the material along a coil with a regression based on 3MA data [13-15]. Heingärtner used multidimensional regression based on eddy current data to calculate the material parameters tensile strength, yield strength, uniform strain, and elongation at break in inline production [7]. Moreover, Lee et al. tested different machine learning algorithms to predict the yield stress and the uniform elongation based on 6 features of eddy current signals and achieved a high accuracy [16]. Zoesch et al. were able to detect cracks and thinning of material during deep drawing with two sensors (eddy current, 3MA) [17]. The IMPOC sensor was used to predict mechanical parameters such as tensile strength and yield strength [18] as well as to find uniformity in material properties along coils [19].

Indirect Measurements of Material Properties (RQ2)

The monitoring of processes that produce sheet-metal represents an alternative strategy to directly measuring the material in sheet-metal forming processes. The inline monitoring of sheet-metal producing processes not only facilitates the optimization of these processes itself, but also of downstream sheet-metal forming processes.

Table 2. Summary of the publication conducted in the SLR.

Research Question	Processes/Sensors	Literature
Fluctuating material properties	Sheet-metal forming in general	[1,3,4,20]
RQ1	Magnetic barkhausen noise	[9-12]
	Eddy current	[6,7,16,17]
	3MA	[13-15]
	IMPOC	[18,19]
RQ2	Hot rolling	[8,21-23]
	Cold rolling	[24]
	Roller levelling	[25-27]
	Stamping	[28]
RQ3	Stamping	[29-31]
	Deep drawing	[32-40]
	Bending	[41-43]

For the process of hot rolling, it was already shown in 2005 that it is possible to predict different mechanical properties such as yield strength of hot rolled steel coils based on data including process data such as coiling temperature and chemical factors with an artificial neural network. However, approximately 21% of the predicted yield strength values deviated more than ±15 MPA from the true value [23]. Chen and Fan showed in 2021 that based on the input data rolling temperature, curling temperature and the chemical composition of the material the material properties tensile strength, compression and elongation can be predicted by different regression models with an coefficient of determination of over 99% [8]. In [21] similar results were presented. In addition, electromagnetic monitoring was used in a hot strip mill to monitor the phase transformation and to extract the data of austenite transformation. Based on this data the hot rolling process was optimized in an offline control system [22]. Cuznar and Glavan investigated the data-driven optimization of the cold rolling process. The developed models enabled optimal cold rolling parametrization and real-time monitoring [24].

The roller levelling process was monitored by Nikula and Leiviskä using acceleration measurements. They utilized these measurements to predict the properties yield strength, width and thickness of the processed steel along the coil [27]. Magro et al. investigated an approach to predict the yield stress after the tension levelling process and to adapt the initial process parameters according to an analytical model [26]. Grüber and Hirt proposed a semi-analytical model that calculates the levelling force and determines in an inverse approach the material data [25].

In another approach, times series signals from force sensors of the stamping process as an upstream process are evaluated and used to predict the tensile strength, yield strength and elongation at break of the processed material [28].

Utilization of the Knowledge of Fluctuating Material Properties (RQ3)

Fluctuating material properties create uncertainties for downstream sheet-metal forming processes. These uncertainties influence the process stability, the process outcome and hence the product properties [20]. Thus, material fluctuations must be included in the process parameterization to increase the stability of the process or when adapting the process with different control strategies to optimize the process outcome.

For a stamping process, variations of material were measured with non-destructive testing and different motions for a servo-press were evaluated [29]. The data of this experiments were then evaluated using Bayesian logistic regression resulting in a model that determines motion profiles for a servo-press based on material characteristics [31]. Maretta and Di Lorenzo proposed a method were meta-models and Monte Carlo simulation were combined to analyze the influence of coil-to-

coil material variations on thinning and spring back to enhance the robustness of a stamping process [30].

A method for knowledge-based control of a deep drawing process was proposed by Fischer et al., combining feedforward control based on inline material measurements from an eddy current sensor and feedback control based on inline measurements of draw-in [36]. Another approach to minimize the influence of material variation by feedback control was presented by the same author [37]. Heingärtner et al. implemented an intelligent control system using numeric simulations and material data acquired by eddy current, process settings and draw-in measurements to optimize the manufacturing of kitchen sinks and tested it on a production site [38].

Endelt distinguishes between non-repetitive uncertainties and repetitive uncertainties in sheet-metal forming. While non-repetitive uncertainties are for example variance in sheet thickness and uneven lubrication. The repetitive uncertainties are for example changes in material properties, tool wear and tool temperature, which lead to process downtimes [33]. To handle these uncertainties Endelt and Danckert proposed a control strategy with an inner loop reducing the current draw-in error of the produced part and an outer loop based on a iterative learning control scheme handling the repetitive uncertainties and transfer information to optimize the draw-in flange from the produced part to the next part [35]. Endelt tested also a similar approach of iterative learning control algorithms on two benchmark problems [34]. Furthermore, Endelt develop the control strategy based on an inner loop and an outer loop further by adding numerical simulations to reduce the draw-in error [33]. A numerical study for a deep drawing process, where material fluctuations were included through a sensitivity analysis, and a proof of concept for a new control strategy by adapting the blank position was conducted by Briesenick et al. [32].

Based on various material data such as IMPOC signals and oil levels recorded in a stamping plant, van Stein implemented an anomaly detection algorithm in a car body stamping process to detect outliers in material properties along steel coils [39]. On the same press shop, Purr examined various data sources in a press shop from various measuring systems also IMPOC signals with the aim of detecting fluctuations in the process. The result shows that the material fluctuations have a strong influence on the quality of the car body components [40].

In bending, material variations lead to spring back and thus, control strategies have been developed. A summary of these strategies is given in [20]. In this systematic literature review the focus was on the fluctuations of material properties. In [41] the authors used finite element simulation to identify a spring back compensation strategy. It was shown that this compensation strategy is able to reduce spring back under varying material properties and sheet thickness. Lafon et al. modelled different uncertainties, especially material properties to find a robust optimization procedure for a draw bending process [42]. The effect of yield strength variation and part dislocation was studied by Waheed et al. to optimize bending force and residual stresses [43]. It was found that the yield strength has a major effect on bending force and residual stresses.

Identified Research Gaps

The SLR revealed existing scientific studies, which already apply different NDT methods to obtain insights about material properties at regular intervals along sheet-metal coils in-line at the shop floor. Nevertheless, only few studies investigate in-line monitoring of material properties in relation to the parametrization of sheet-metal forming processes and the outcoming part quality at industrial scale. The investigation of non-destructive material measurements along coils offers the quantification of influences originating from the material and enables profound data-driven evaluation based on a high amount of available data to realize decision support and real-time control. Furthermore, NDT has been used to predict material properties by using features of raw signals but further investigation of correlations between specific signal properties of the raw signals and specific material properties provide an opportunity to derive new insights into potentially underlying cause-and-effect relationships.

Although existing publications already report that knowledge of material properties was obtained by monitoring upstream processes, in particular hot rolling, cold rolling, roller levelling and stamping, it is at best used to optimize the same process but there is no publication using these insights to optimize the subsequent sheet-metal forming processes. Compared to NDT, the approach to monitoring upstream processes usually requires cross-company collaboration, which, combined with the heterogeneity of the different process data, further complicates this approach. However, research on other manufacturing technologies suggests, that a holistic optimization of process sequences not only offers economic but also ecological advantages [44]. A holistic approach in sheet-metal processing requires to overcome existing data silos and to share data across processes in the sense of an Internet of Production [45].

Another opportunity arises from the combination of the two material monitoring approaches to obtain larger data sets, facilitating the use of data-driven methods to adjust the sheet-metal process to ensure to enable a high-quality process outcome despite fluctuating material properties. Data-driven methods for process optimization and control in sheet metal processing offer the potential to learn complex, unknown interdependencies along process sequences. This leads not only to the optimization of the sheet metal forming process and the quality of the resulting part, but also to the adaptation of upstream processes to specified material requirements based on the previously established dependencies between varying material properties and process parameterization.

In addition, research is mainly limited to sheet metal forming processes, whereas the influence of material variations and a corresponding process optimization has not yet been investigated for sheet metal shearing processes. Hence, there is an opportunity to transfer the solutions presented from sheet metal forming to shearing processes.

Summary

A systematic literature review was conducted showing that there are two different approaches to monitoring fluctuating material properties along coils. It has been shown that non-destructive testing is used successfully inline to measure material properties. Moreover, various methods to monitor material properties in the upstreaming processes hot rolling, cold rolling, roller levelling and stamping were pointed out. The knowledge of material properties along a coil is already used to optimize stamping and deep drawing processes based on different control strategies and research considers fluctuating material properties to optimize different bending processes.

In addition, research gaps were identified: 1) The utilization of knowledge of material properties along coils in relation to the parametrization of sheet-metal forming processes and the outcoming part quality on an industrial scale needs to be investigated in more detail. 2) Further cross-process data exchange is required to research the optimization of downstream processes when fluctuations in material properties occur. 3) The investigation of material variations in sheet-metal shearing processes is still an open topic.

Keywords: Property Control, Forming, Punch-Hole-Rolling, Sheet-Bulk Metal Forming

Abstract. Process controls are getting increasingly more common in forming. Nevertheless, they are not suitable to achieve consistent quality when dealing with varying process disturbances. Differing properties of the raw material and other external influences like temperature variations and vibrations make it hard to achieve the tightly specified tolerances needed in today's production environment. Product property controls represent a solution for these difficulties and create the opportunity to integrate additional functionality into the product and the process. In this project, the implementation of a multivariable product property control is investigated using the example of a recently developed process, called punch-hole-rolling. It is targeted to control product properties such as the collar height and the hardness on the inner surface. It has been shown in previous publications that it is possible to control the collar height in 1.0338 by carefully choosing suitable process parameters. In recent works the possibility was presented to control the hardness by changing the same parameters, using the TRIP steel 1.4301. The publication at hand aims at proving the feasibility of the multivariable product property control by reviewing the previous results for 1.4301 and proving that it is possible to control the collar height and the hardness on the inside of the collar simultaneously. Further, a concept is presented for the implementation of such a control.

Introduction

In recent years resources have become increasingly scarce. In 2022, steel prices in northern Europe and especially Germany spiked at two times the rate it had, just three years ago [1,2]. Simultaneously, the price of energy has almost tripled in the same time period [1]. Furthermore, environmental protection is becoming increasingly more important as new legislation for example in Germany proves [3]. Reducing the material and energy consumption is an easy way to improve the human impact on nature. Given the current circumstances it is obvious that this also brings major economic benefits. Simply reducing the consumption is not an option in most industries, however, as this would lead directly to a proportionate reduction in production, which is neither economically viable nor desirable. Therefore, other solutions need to be found. One option is to switch from production processes which are less material and energy efficient to those that are more efficient. Here, forming processes have great advantages compared to cutting processes. They have a higher material utilization and use less energy on average [4]. Nevertheless, there are many products, which can not be produced by forming. Either the geometry cannot be formed or the products require tolerances, which cannot be produced by conventional forming processes. A

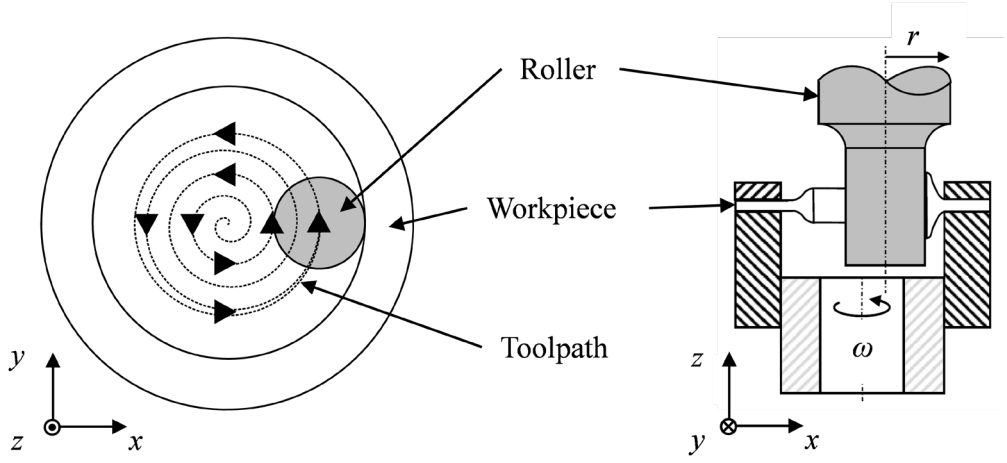
great example for this type of products are bearing seats. Due to the great advantages of forming processes it is senseful to develop new processes to overcome these challenges. In the case of bearing seats, punch-hole-rolling is a proposed solution, which is a recently developed forming process that is presented in more detail in the following chapter. Another option to increase the resource efficiency of production processes is to reduce the proportion of parts that have to be scrapped. Fluctuations in the material can easily lead to product properties out of specification, especially in forming processes. Controls enable the compensation of disturbances, but conventional process controls in forming are not able to detect the specific deviations, and many conventional processes do not have the degrees of freedom to counteract them. In their work, Allwood et al. presented product property controls in combination with suitable processes as a solution for these problems [5]. With this technology it is also conceivable to control more than one property at a time and further enhance the advantages of forming processes.

Punch-hole-rolling.

Punch-hole-rolling is a process, which was recently developed at the Institute for Production Engineering and Forming Machines (PtU) at the Technical University of Darmstadt in cooperation with the Institute for Applied Materials (IAM) at the Karlsruhe Institute of Technology. It is a forming process which is best specified as sheet-bulk metal forming, according to the definition by Merklein et al. [6]. Additionally, the process is an incremental forming process. Knoll et al. classified the process as pressure forming due to the acting stresses and as a rolling process due to the main tooling used [7]. Punch-hole-rolling consists of two separate steps. The first step is the punching step in which the starting hole is generated. Unlike the name may suggest, the starting hole does not have to be punched. Previous tests showed that drilling is a suitable alternative. The two steps of the process also do not have to be performed directly after another. The second step is hole-rolling. In this step, the roller is inserted into the hole in the workpiece, which was created by the first operation. After that, the tool performs a spiral movement, in which the material of the sheet metal is pushed outwards and to the top and bottom. This movement enlarges the hole, simultaneously forming a collar on both faces of the metal sheet. Ideally both sides of the collar are mirrored copies of each other. In Fig. 1 the punch-hole-rolling process is pictured. On the left side of the figure, the process is shown from the top and the spiral movement of the roller is marked. On the right side of the figure, the process is shown from the front. The sectional view of the workpiece allows to see the forming of the collar. On the right-hand side of the workpiece the collar is pictured almost in the final stage, while the left-hand side shows it shortly after the process started.



Fig, 1. Sketch of the punch-hole-rolling process, including the relevant process parameters [8].

The process can be influenced by changing the starting hole diameter in relation to the diameter of the finished product, the radial feed rate and the rotational speed. With these process parameters the two product properties of interest, collar height and hardness on the inner surface of the collar, can be influenced. The specific relations will be discussed in the subsequent chapters. In Fig. **2** the setup for performing the punch-hole-rolling process is shown. A conventional lathe is used for this purpose. Therefore, the sheet metal is mounted on the main spindle. The starting hole is drilled in this position with the tailstock. For rolling a tool, designed for this use, is fitted to the cross slide. The tool has a roller, which can freely rotate, additionally two sensors for measuring the process forces are integrated. A linear sensor from Burster is used to measure the radial movement. Due to the one-sided bearing of the roller in this setup, the process forces are limited significantly. Additionally, the deflection often leads to an asymmetrical collar. Therefore, a new tool is built [8]. Nevertheless, all tests for the publication at hand were performed with the setup on the conventional lathe.

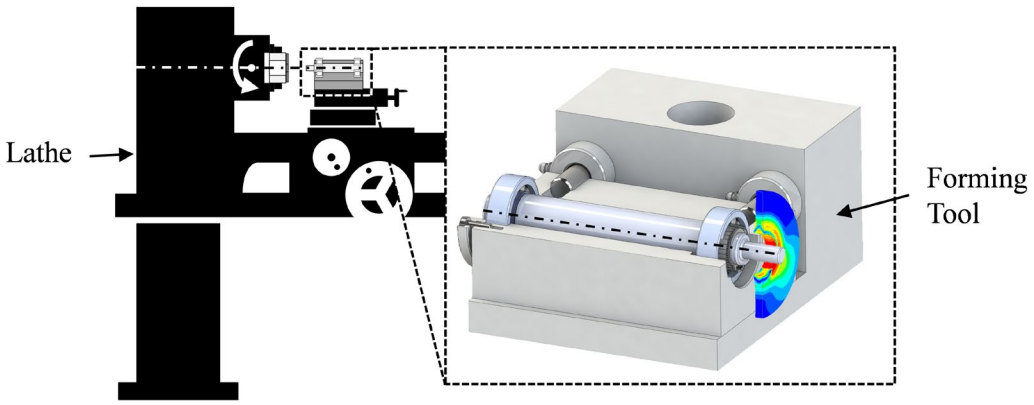


Fig. 2. Punch-hole-rolling setup on a conventional lathe cf. [7].

The final product of punch-hole-rolling is a hole with a collar on both sides of a metal sheet. Pure forming processes which produce similar geometries are collar forming and friction drilling. Compared to these two processes, punch-hole-rolling has three distinct advantages for the use case of forming bearing seats. Punch-hole-rolling produces a double-sided collar; Therefore, the bearing center and the sheet center can be aligned to enhance the force transfer from the bearing to the housing. Additionally, the incremental nature of the process allows for production of the small tolerances required for bearings. Furthermore, the process has multiple degrees of freedom, that can be used to control the material properties.

Characteristic of the Collar Height in Punch-Hole-Rolling

By varying the process parameters in punch-hole-rolling a few different product states can be produced. One of the product properties, that can be influenced is the height of the collar. The height depends strongly on the difference between the initial diameter and the final diameter of the hole in the product, but can be adjusted in a smaller range during the process.

Collar height in DC04.

In [7], tests were performed on DC04 to characterize the forming of the collar and, especially the development of the collar height in more detail. The collar height was found to increase approximately linearly with the change in radius. In [9], it was additionally found that changing the radial feed rate of the process leads to a change in the gradient of the graph. Thereby, a higher feed rate leads to a lower gradient and thus to a lower collar height. Furthermore, it was concluded, that the rotational speed does not influence the collar height in a significant way. In Fig. 3**,** three graphs are shown that highlight the different relations between the collar height and the various

process parameters. In each graph, the collar height is plotted over the radius of the hole. The x-axis starts on the starting hole radius, for which 4 mm is chosen in most tests. The y-axis begins at a collar height of 2 mm, which equals the thickness of the sheet metal. Each graph consists of many datapoints, measured on different test pieces, which are hole-rolled to various radii and measured offline. Therefore, steps in the graphs can occur due to variations in the process. On the left side of Fig. 3, the trends of collar height for three different rotational speeds and two different feed rates are depicted. As stated by Mühl et al., the difference in rotational speeds is insignificant compared to the change in feed rate. On the right side of Fig. 3, the trends of collar height for four different feed rates are shown. As can be seen in the first graph, and as stated before, it is clear that the feed rate influences the collar height in a significant way. Nevertheless, the maximum spread of the collar height is quite small with less than 2 mm for a 6 mm widened radius. By changing the starting hole diameter, the collar height can be adjusted in a wider range. For demonstration, a fifth trend is added of test pieces with a starting hole radius of 5 mm. The trend runs parallel to the one with the same feed rate but with a smaller starting hole.

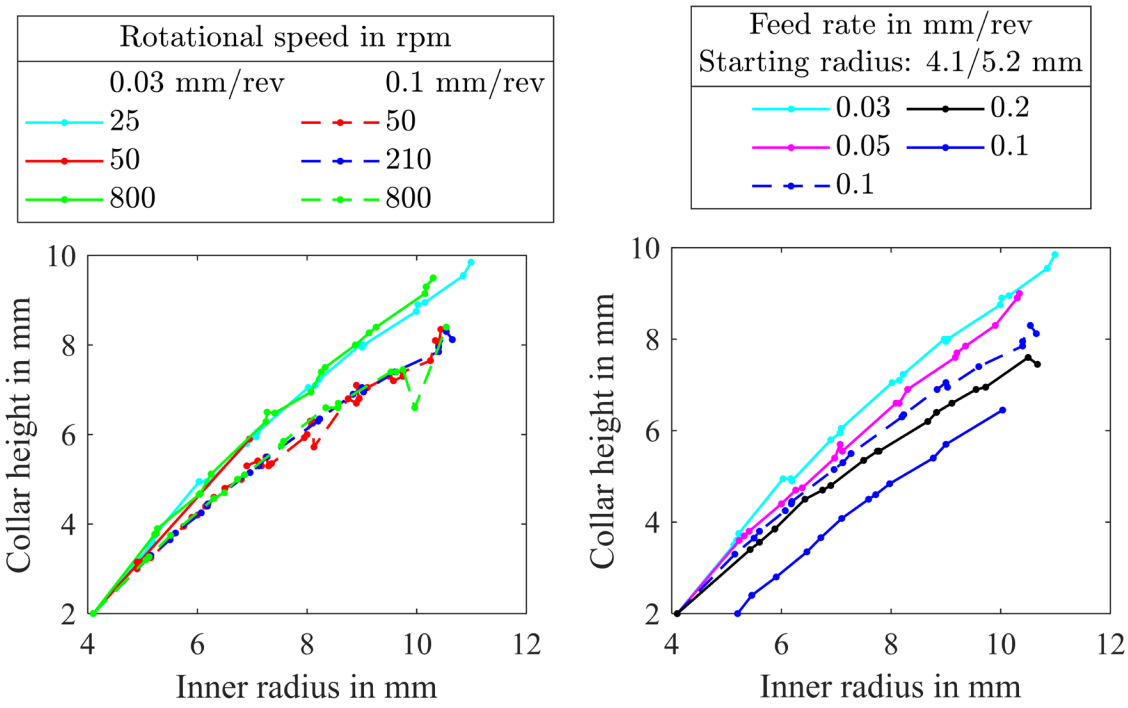

Fig. 3. Trend of the collar height over the inner radius in punch-hole-rolling in the material DC04 for varied process parameters left: for two different feed rates and three different rotational speeds each and right: for four different feed rates at rotational speeds between 25 and 210 rpm and for one varied starting diameter.

Collar height in 1.4301.

To identify the limits of the process and the current test setup, tests were also conducted with the stainless steel 1.4301. This steel has a significantly higher yield stress than the tested DC04. Additionally, this material is affected by the TRIP-effect, which is going to be used in the product property control. TRIP stands for transformation induced plasticity. The effect is the strain induced conversion to martensite. [10] Due to the higher hardness of martensite compared to the normal grain structure of the material, it is possible to change the hardness of the material in dependence of the martensite fraction. The influence of punch-hole-rolling on this product and material property will be discussed in more detail in the following chapter.

To evaluate the correlations between the process parameters and the collar height in 1.4301, the same tests as on DC04 are conducted. It is planned to determine if the same characteristics also can be seen in 1.4301. In Fig. 4, the trend for the collar height in 1.4301 is depicted. Due to the higher strain-hardening coefficient, the process force rises much faster than in DC04. Therefore, it is not possible to reach the same radii with the same force restriction. Additionally, a roller with a bigger diameter has to be used and the feed rate is highly restricted. As seen in Fig. 3, the feed rate has a significant influence on the collar height. Due to the limitations in choosing the process parameters, only a small variation can be achieved. In this case, feed rates of 0.03 mm/rev and 0.05 mm/rev are compared. Nevertheless, a similar trend as in DC04 can be observed. Even though the trend is noticeable, the difference between both parameters is quite small. To rule out measurement noise as a cause, another test is performed with 210 rpm instead of 25 rpm, which is expected not to differ significantly from the test with same feed rate. It can be observed that the trends for the two tests are quite similar and both show a significant difference to the test with the different feed rate. Therefore, it is assumed, that the collar height in 1.4301 has the same characteristics as in DC04. Nevertheless, it is necessary to conduct more tests with the planned, more advanced setup [8].

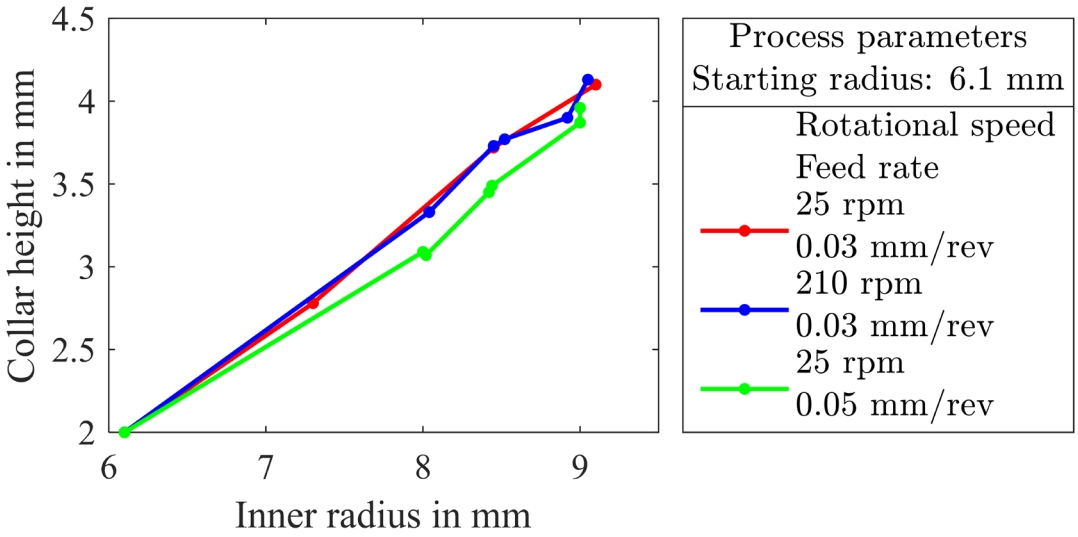

Fig. 4. Trend of the collar height over the inner radius in punch-hole-rolling in the material 1.4301 for varied process parameters.

Characteristic of the Hardness of the Inner Surface in Punch-Hole-Rolling

The second product property, which can be influenced by punch-hole-rolling is a non-geometric one. It is the hardness of the surface on the inside of the formed collar. The hardness is examined for two different materials with different effects for its hardening. The first is DC04, where the hardness increase was discovered and is explained by conventional cold hardening of the material due to the plastic deformation. In 1.4301, the TRIP effect leads to an increase in the martensite fraction and thus to a higher hardness of the material in general. Both characteristics are discussed in more detail in the following chapter.

Hardness in DC04.

In DC04, the hardening of the material due to punch-hole-rolling was measured for the first time. To determine the characteristics more closely in [9] specimens from the previous tests primarily concerning the collar height were examined in more detail. It was discovered that the hardness rises with increasing radius and thus deformation, but remains constant above a certain point. A correlation between the process parameters feed rate and rotational speed and hardness could not be observed. Therefore, the hardness in DC04 cannot be controlled with the punch-hole-

rolling process. It is suspected that the increase in hardness occurs due to cold hardening during the deformation of the material.

Hardness in 1.4301.

Due to the disadvantages with DC04, it is decided to use the stainless steel 1.4301 in future tests. As explained before, this steel is affected by the TRIP effect by which the grain structure of the material is transformed into martensite. This effect is strain induced. [10] In preliminary flat crush tests it was shown that the transformation depends on the plastic strain as well as the plastic strain rate. In punch-hole-rolling this leads to a dependence on all of the process parameters. The radial position of the roller in combination with the rotational speed determine the tangential speed between the roller and the material. In Fig. 5 the trend for the surface hardness over the inner radius is shown for two different sets of process parameters. To measure the hardness, the collar was cut and the slice embedded in epoxy. The hardness was measured by conventional means approximately 50 µm below the surface. It can be seen that the hardness generally increases with increasing inner radius and thus plastic strain. Additionally, the trend shows that the increase of hardness is reduced with higher forming rates. This also reflects the behavior observed in the preliminary tests and correlates with the lower measured martensite volume fractions of these samples.

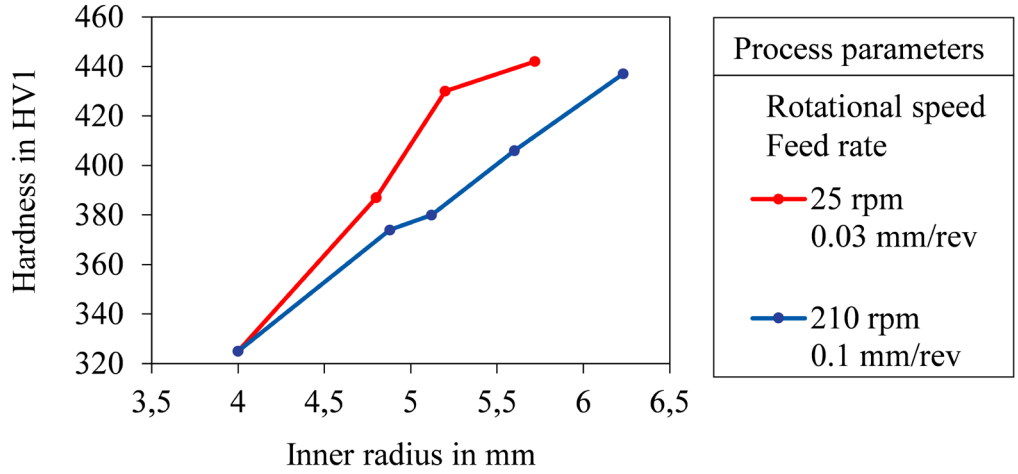

Fig. 5. Trend of surface hardness over the inner radius in punch-hole-rolling in the material 1.4301 for varied process parameters.

Barkhausen noise.

To be able to control the hardness of the material during the process, it is necessary to measure it first. This is especially challenging due to the needed real time capability of this sensor and the necessity to take the measurement without disturbing the forming process. As a suitable solution for this challenge, the Barkhausen noise analysis is identified. This analysis is based on the fact that in ferromagnetic materials the magnetic domains grow during magnetization and therefore the walls between the different domains are moved. Due to interactions of these domain walls with pinning sites such as material defects, sudden changes in the magnetization of the material occur. Measuring the magnetic flux density of the material during a cycle of magnetization and demagnetization results in the so called Barkhausen noise. Due to the interaction of the domain walls with the microstructure of the material the Barkhausen noise includes information about many different material properties. [11-14] In their paper, Mühl et al. showed that the hardness of the material after punch-hole-rolling can be correlated with the root mean square value of the Barkhausen noise signal. [9]. Furthermore Spies et al. have shown in their paper that this is also true for the amplitude of the signal and that it can also be correlated with the alpha martensite volume fraction and the plastic strain in 1.4301. Moreover, a concept was presented for the integration of the sensor into a future test rig. [8] All correlations were identified by taking offline

measurements and comparing them with the results of conventional measuring processes [8,9]. Using this data, the online Barkhausen noise measurements can be converted into the product properties of interest. All this taken together shows the theoretical feasibility of a magnetic Barkhausen noise sensor for the use in a process control for punch-hole-rolling.

Proof of the Feasibility of a Multivariable Product Property Control in Punch-Hole-Rolling

The previous chapters have shown, that the collar-height and hardness can be controlled individually in the material 1.4301. This includes proposing Barkhausen noise as a solution to the challenge of inline hardness measurements. The collar-height meanwhile could be measured by a 2D laser scanner. For a multivariable product property control it is nevertheless necessary to prove that this control can also be achieved simultaneously and independently from each other. Since the test setup is currently incapable of proving this experimentally, it is expedient to do so by a theoretical presentation of the proposed closed-loop control strategy instead. Therefore, the process is represented mathematically. In Equation 1 the dependencies of the product properties collar height and surface hardness are depicted. The height of the collar is dependent on the relative radius Δr and the feed rate $\dot{r}$. The starting radius is determined before the process starts, therefore it is not a variable that can be used. The product radius is demanded by the planned application. Therefore, the relative radius is also not variable. By solving the yet to be determined formula for the collar height for the feed rate, it is possible to determine the feed rate, necessary to achieve the desired collar height. The process is quite similar for the hardness, the only difference being that it also depends on the rotational speed. Due to the pre-determined feed rate the formula is solved for the necessary rotational speed.

$$\begin{bmatrix} h_{\mathrm{col}} \\ HV_{\mathrm{sur}} \end{bmatrix} = \begin{bmatrix} f_{\mathrm{hcol}}(\Delta r, \dot{r}) \\ f_{\mathrm{HVsur}}(\Delta r, \dot{r}, \omega) \end{bmatrix} \tag{1}$$

It is obvious that a poorly chosen start radius leads to not achievable numbers in the process parameters. Unachievable product properties will also lead to unrealistic process parameters. Therefore, the set of producible product parameters is finite. In addition, not all combinations of product properties can be reached, even though the properties can be simultaneously controlled in theory. To look into this in more detail, it is suitable to look at the properties that can be achieved with the given range for the forming parameters. Since the process varies a lot for different roller diameters and relative radii these will be defined for this example. The following numbers are valid for a roller diameter of 8 mm and a relative radius of 2 mm. The feed per revolution can be varied between 0.03 mm/rev and 2 mm/rev whilst the rotational speed can be varied between 25 rpm and 800 rpm. In Fig. 6, an approximation of the working area for this parameter set is shown. It should be noted that some of the depicted values are approximated an may change slightly with further research. Nevertheless, the diagram is suitable to get a quick overview. In the corners the extreme values of the possible parameter combinations are shown. The first number describes the rotational speed and the second one the feed per revolution. It can be noted that in the lower left corner two points correspond to another. This happens because the feed per revolution of 2 mm/rev is so high that no transformation to martensite is expected to occur even at the lowest rpm. The hardness of 300 HV1 matches the hardness of the base material. Due to cold hardening, this is nevertheless likely to increase to a limited extent.

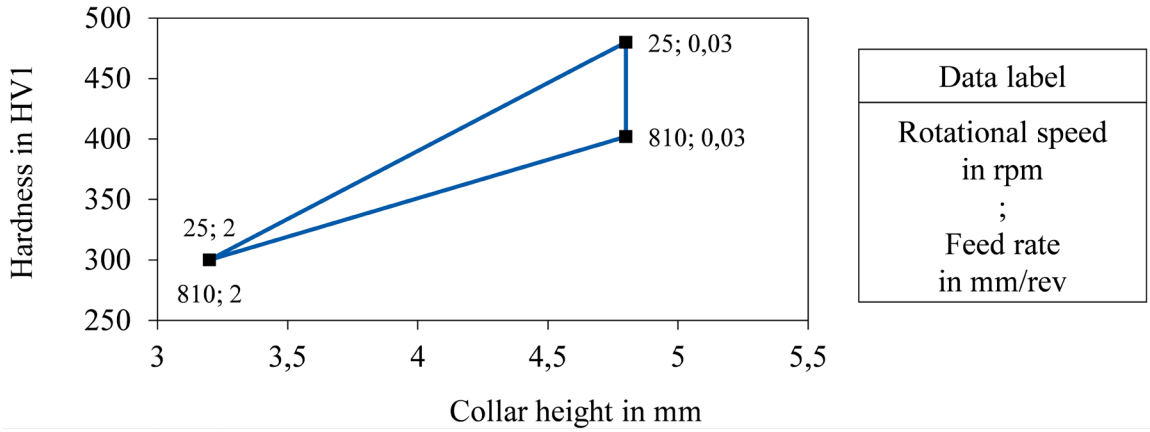

Fig. 6. Approximation of the achievable product properties, collar height and surface hardness for a given set of process parameters in the material 1.4301.

Concept for a Multivariable Product Property Control in Punch-Hole-Rolling

In order to control the process, the transfer behavior of the manipulated variables $\boldsymbol{u} = [\dot{r} \quad \omega]^T$ to the product properties to be controlled $\boldsymbol{x} = [h_{\mathrm{col}} \quad HV_{\mathrm{sur}}]^T$ is of essential importance. The relations described in Eq. 1 can be described using data-driven models of varying complexity. In this context, data-driven models have two elementary advantages. First, the complex relationships between manipulated and controlled variables do not need to be described by analytical models. Second, large parts of data-driven models are differentiable, which is especially useful for control engineering applications. If the functions f_{hcol} and f_{HVsur} presented in equation 1 are fitted via data-driven models and then derived with respect to the manipulated variables, formulas for the rates of change of the variables according to Eq. 2 follow.

$$\dot{\boldsymbol{x}} = \frac{\partial [f_{\mathrm{hcol}}(\boldsymbol{u}) \quad f_{\mathrm{HVsur}}(\boldsymbol{u})]}{\partial \boldsymbol{u}} \cdot \dot{\boldsymbol{u}} = \boldsymbol{J}(\boldsymbol{u}) \cdot \dot{\boldsymbol{u}} \tag{2}$$

The locally linearized inverse of the Jacobian matrix $\boldsymbol{J}(\boldsymbol{u})^{-1}$ can now be used to transform deviating-controlled variables $\boldsymbol{e}_x$ into velocity changes of the manipulated variables $\Delta\boldsymbol{u}$. Fig. 7 provides an overview of the proposed closed-loop control approach. The reference variable for the properties to be controlled is a time series whose final values are the final collar height and hardness. Deviations between the desired time series $\boldsymbol{x}_{\mathrm{des},t-1}$ and observed time series $\hat{\boldsymbol{x}}_{\mathrm{act},t-1}$ can be transformed into velocity changes of the manipulated variables $\Delta\boldsymbol{u}$ via the inverse Jacobian matrix $\boldsymbol{J}(\boldsymbol{u})^{-1}$ and carefully selected gain factors $k_{\mathrm{P},i}$ in the diagonal gain matrix $\boldsymbol{K}_{\mathrm{P}}$. The elements of the diagonal gain matrix thus weight the control deviations of the corresponding control variables x_i and lead to low control dynamics if chosen too low or to oscillations if chosen too high. These calculated velocity changes $\Delta\boldsymbol{u}$ can then be added to the manipulated variable $\boldsymbol{u}_{t-1}$ generated in the last cycle step of the control unit and lead to the manipulated variable $\boldsymbol{u}_t = \boldsymbol{u}_{t-1} + \Delta\boldsymbol{u}$ of the next cycle. In the punch hole rolling process, the implemented sensors are then used as input variables for an observer $\boldsymbol{f}_{\mathrm{obs}}$ that observes the product properties $\hat{\boldsymbol{x}}_{\mathrm{act}}$ from the sensor signals $\boldsymbol{s}$. In the observer, the correlations between recorded sensor signals and the controlled variables that have already been investigated in published papers (e.g. magnetic Barkhausen noise and hardness) are used to estimate the actual states of the controlled variables. [8, 9] These are then in turn used in the feedback loop of the control scheme to determine the control deviation.

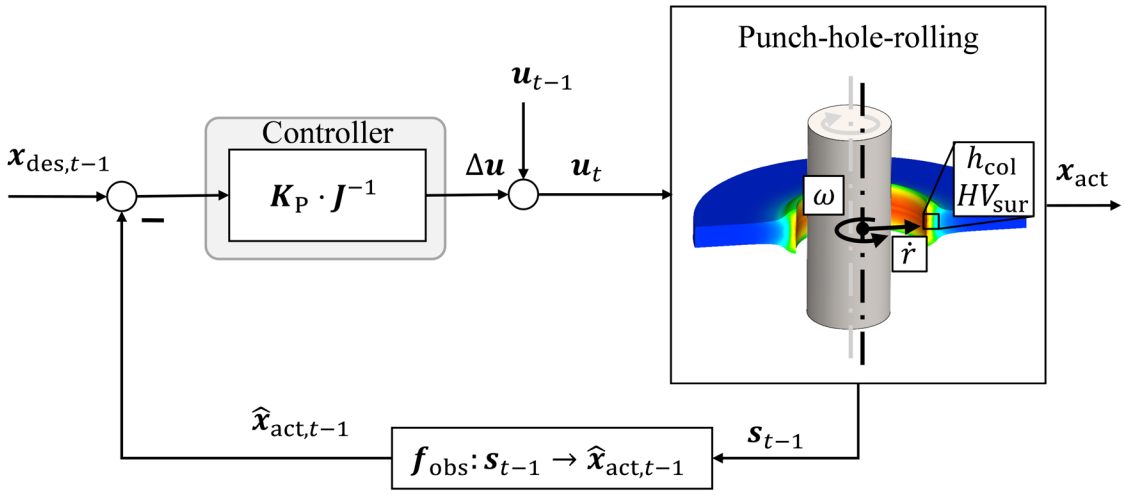

Fig. 7. Block Diagram of the proposed closed-loop control approach for punch-hole-rolling.

Summary

In this paper, the basic behavior of the material, formed by punch holing was presented. In particular, the changes of the product properties of interest, collar height and surface hardness on the inside of the collar during the process have been discussed. Subsequently, the possibility for a multivariable product property control in the punch-hole-rolling process was shown, supported by the data presented prior. Lastly, a concept for the control itself was established, considering the difficulty of controlling more than one property at a time, which are not completely independent of each other. It is planned to validate the theoretical possibility for the multivariable product property control presented in this paper in the near future by means of further tests. The upgraded test setup required for this is being built currently. It is also planned to implement the concept for the control scheme shown in the new test setup and to test and improve its suitability as well.

Keywords: Freeform Bending, FEM, Barkhausen Noise, Softsensor, Closed-Loop Control

Abstract. Freeform bending with a movable die makes it possible to bend complex structures and seamless radii without changing the bending tools. Currently, most research focuses on minimizing the geometrical deviations without considering the mechanical properties of the bent tubes. A previous work showed, that the geometry can be decoupled from the mechanical properties with non-tangential bending [1]. The implementation of a soft sensor based on ultrasonic contact impedance measurements (UCI) of the property-controlled freeform bending has also been examined [2], as well as a structure for closed-loop control based on material properties [3]. The present work deals with a micro-magnetic sensor and Barkhausen noise (BHN) and investigates its suitability for the closed-loop control. For this purpose, different processing routes for freeform-bent steel tubes are experimentally investigated by their characteristic BHN. In addition to an existing simulation model, a data basis for the impact of freeform bending parameters is built to extend the existing model of a property-based closed-loop control.

Introduction

Freeform bending with a movable die is a forming technology that allows the bending of complex three-dimensional tube geometries without changing the bending die. The accuracy of the bending process depends on the tolerances and fluctuations in the mechanical properties as well as the tolerances of the process (e.g., friction, etc.). These disturbances significantly influence the bent part. In addition, inadequate knowledge of the mechanical properties before and after the bending process can lead to deviations in downstream processes. This leads to the conclusion, that there is a need for closed-loop control based on the mechanical properties of the tube, to reduce failures as well as scrap and to improve the quality of freeform-bent parts.

Non-tangential bending allows the decoupling of the geometry and mechanical properties [1]. In order to control the mechanical properties during the freeform bending process, a suitable measuring system must be available in addition to the intervention in the kinematics of the bending die. This paper provides an experimental analysis of the influence of freeform bending process parameters on BHN for steel tubes. Therefore, different states of the steel tubes (unbent, bent,

unbent and annealed, annealed and bent) are measured with a micro-magnetic sensor and the BHN is analyzed. Furthermore, tubes formed with the new concept of non-tangential bending are under investigation. Ultimately, the results are compared to the numerical model to check the congruence between the numerical model and measurements on real bent tubes.

State of the Art

Freeform bending with a movable die is a process that has been investigated to a large extend. Most of the research focuses on improving the geometrical accuracy of the freeform-bent part, but only a few investigate the mechanical properties during the bending process. [4] showed that the manufacturing strategy of roll-formed tubes influences the material properties and the subsequent bending process. There have also been investigations that analyze the influence of different process parameters on the bending result in freeform bending using numerical simulations [5]. Numerical simulations are often used to get a better understanding of the freeform bending process. [6] showed two models for freeform bending with three and five degrees of freedom and a simulation model for rotary draw bending. Both round tubes and profiles were bent using these models. Another simulation model for freeform bending as the preform forming step of hydroforming was also investigated [7]. A simulation model is used to calculate the motion profile of the bending die to get better geometrical accuracy results while reducing scrap [8]. If only a 2D bending part is manufactured, the hole part can be described by the parameters radius and bending angle. In freeform bending there is a process-related, complex transition between straight tube segments and the area of constant curve curvature due to the particular motion profile of the bending die [9]. Accordingly, the specified bending radius is determined by means of regression only in the region of constant curve curvature [10]. The bending angle is calculated from the direction vectors of approximated straight lines at the beginning and end of the bent part. Automatic extraction of the bending line from discrete data and vice versa makes this analysis much faster and more efficient [11]. In terms of influencing factors, [12] conclude with numerical simulations and validation experiments that the yield strength affects the forming limit and wrinkling instability. The results also showed that friction and clamping pressure have a smaller impact on the forming limit compared to the axial propulsion speed and the gap between the tubes and bending die. The concept of [13] shows that a kinematic bending process can be controlled. A concept for both direct and indirect control of torque superposed spatial bending was presented in their work.

Different approaches are pursued to optimize the bending processes using the extended Kalman filter (EKF) in particular. On the one hand, it is used to predict the trajectory during freeform bending and thus to optimize the process and the process parameters [14]; on the other hand, the EKF is also used in the field of stress prediction and closed-loop control during freeform bending [1]. There have also been investigations into BHN measurements to analyze the residual stresses. BHN is affected by residual stresses to the same extent as it is by the microstructure, but a careful calibration process is necessary to get a good correlation between stresses and BHN [15]. BHN has also been installed in a broaching machine tool to conduct in-situ measurements during the orthogonal cutting process, and a correlation between the residual stress and the detected BHN signal was evaluated [16]. Another study showed that the reciprocal of the peak amplitude of the BHN has a linear relationship with the stresses [17]. Therefore, tensile tests with carburized SAE 9310 and 32CDV13 were applied. For low-frequency BHN measurements near the surface, it was shown that in case-carburized steel, the residual stresses change differently compared to the subsurface in response to the prior applied tensile or compressive stresses [18]. Although BHN has been the subject of numerous studies, the results are difficult to compare because most studies differ in terms of the material and samples used [19]. Therefore, it can be concluded that a better understanding of how different factors influence BHN is still needed.

As the state of the art indicates, BHN is suitable for measuring different specimens and a range of materials. In addition, it is also shown that freeform bending with its many degrees of freedom

is a suitable controllable process. Overall, the great need for closed-loop control based on the mechanical properties of the tube during freeform bending can clearly be seen.

Materials and Methods

This paper deals with the experimental analysis of the influence of residual stresses in the raw material on the geometry and BHN of freeform-bent steel tubes. The aim is to show that different stress states can be measured using a micro-magnetic sensor and analyzed using BHN. In addition, it will be shown that different stress states influence the resulting bent part. Due to the kinematic forming process and the associated many degrees of freedom, freeform bending with a movable die is particularly suitable for influencing the mechanical properties.

Freeform bending machine and tubular raw material. In this article, all experiments are performed using a 6-axis freeform bending machine with a movable die, built by J. Neu GmbH (Grünstadt). The machine has six degrees of freedom, of which three are translational and three are rotational. Fig. 1 shows the six degrees of freedom and all relevant parts of the freeform bending machine.

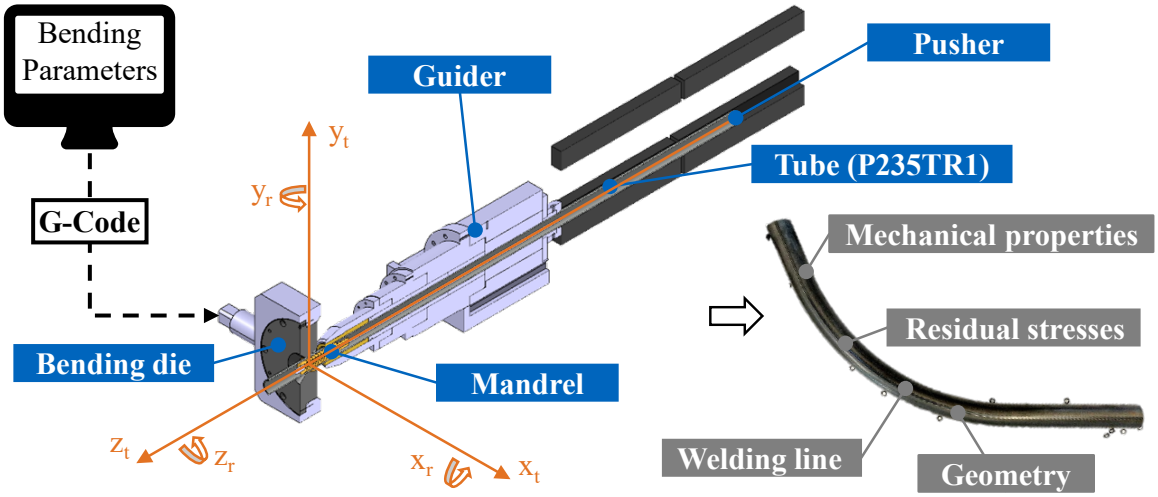

Fig. 1. Principal of freeform bending with movable die and the resulting bent part [1].

To produce a freeform-bent part, a round tube must first be inserted into the machine. The tube is then advanced along the z-axis at a constant speed. The tube is pushed over the bending mandrel and through the bending die. In addition to the feed, the die starts to move. The bending die can be deflected in the xy-plane and can rotate around all three axes (x-, y- and z-axis), performing the movements simultaneously. To bend a tube, as shown in Fig. **1**, the bending die is deflected and rotated to its maximum position, then stops and remains in the maximum deflected position until the bending angle is reached, and then returns to the starting position. This entire process occurs while the tube is being constantly advanced. The kinematic process can therefore be divided into three sections: the transition, the constant and return sections. For a more detailed understanding of the process, the authors refer to detailed studies of the freeform bending process [1-3, 7, 8].

For the experimental investigations in this paper, welded steel tubes made of P235 are used. The circular steel tubes have an outer diameter of 42.4 ± 0.5 mm, a thickness of 2.6 ± 0.3 mm and a length of 800 ± 2 mm with an evenly finished weld seam. The tubes are manufactured according to the international norms EN 10217-1 and EN 10219-1. The steel tubes have been used in other investigations and are already described in detail [1, 2, 20].

Analysis of bending geometry and Barkhausen noise signal. To analyze the geometry of the parts, a three-dimensional triangular surface mesh of the part is created by an optical measurement system with a handheld laser sensor. The bend angle is determined by fitting a cylinder at each

end of the tube and then measuring the angle between the two centerlines. To analyze the curvature, several sections are created along the longitudinal direction of the tube, and a circle is fitted through each section. The centers of all fitted circles are then connected, resulting in the centerline of the bent part. The curvature of the centerline is then calculated and evaluated. The curvature is divided into the same three sections as dictated by the kinematics of the bending tool (transition section, constant section and return section) and a non-bent section at the beginning and end of each tube.

To measure and analyze the BHN, a micro-magnetic sensor named *µmagnetic* in interaction with the software *Optimizer4D* from QASS GmbH (Wetter) is used. As BHN is a non-destructive testing method measurement method with high sampling rates, it is advantageous compared to other stress measurement methods, such as the hole drilling method. Since the BHN can be influenced by a gap between the sensor and workpiece, the sensor is placed directly on the tube to neglect this influence. To avoid short-circuiting or overdriving the BHN, a tape covers the sensor and, at the same time, minimizes the distance between the sensor and the tube. The sensor measures the inductive current, and the results are subsequently visualized using a Fourier transformation. The 3D landscape of the measurement signal consists of the axes frequency, time and amplitude. The process flow for the downstream signal processing of the BHN is shown in Fig. 2.

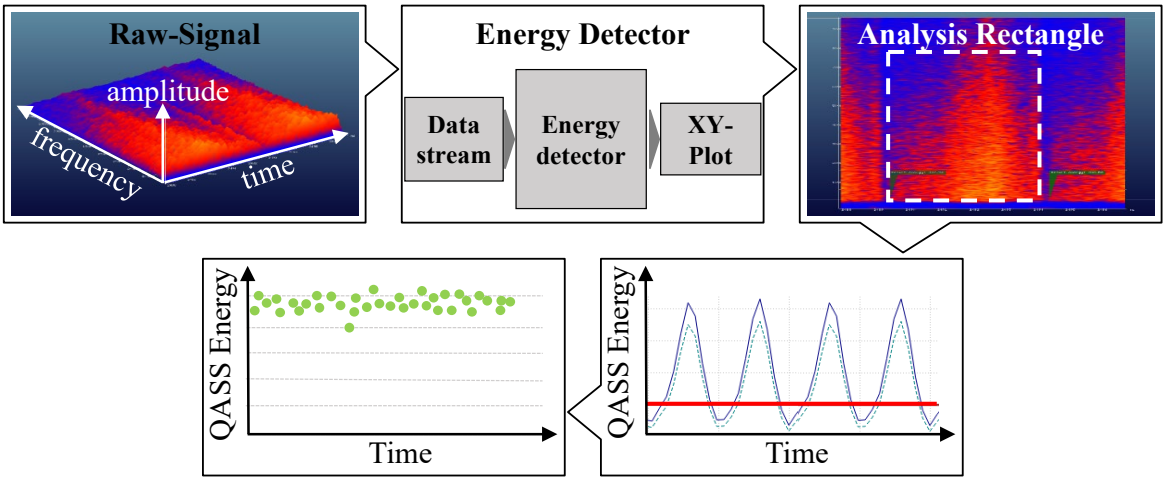

Fig. 2. Process flow for measuring and analyzing the MBH.

An analysis network with a so-called “energy detector” is used to analyze the Fourier-transformed BHN signal. It finds contiguous ranges of a certain minimum energy in a signal. The energy is calculated within a rectangular window (in time and frequency), which is successively shifted forward in time. Neighboring windows in which an energy threshold is exceeded are combined to form a pattern. This pattern is analyzed with respect to the mean value and standard deviation for each measurement point. To ensure a high penetration depth, an excitation frequency of 200 Hz and magnetizing voltage of 700 mV is set. At higher frequencies, the penetration depth is reduced. The *Optimizer4D* software offers an energy-related value in both the time and frequency axes, which is called QASS energy. This value cannot be expressed by the SI-unit system and is, therefore, given later on without a unit [16].

Strategy. The focus is on the influence of the stress state of the raw material in freeform bending and the suitability of the micro-magnetic sensor for inline measurement of property changes during freeform bending. Therefore, different conditions of the unbent tube are investigated, as well as freeform bending experiments with different starting conditions (see Fig. 3). With these experimental investigations and bending strategies, some research questions arise:

1. Can disturbances in the unbent raw material be measured with BHN and is there a difference compared to annealed raw material?
2. How does annealing influence freeform-bent tubes in terms of geometry and BHN?
3. Is it possible to measure a different BHN in non-tangential freeform-bent tubes?

This paper tries to find answers to these research questions by carrying out experimental investigations and micro-magnetic measurements on freeform-bent steel tubes.

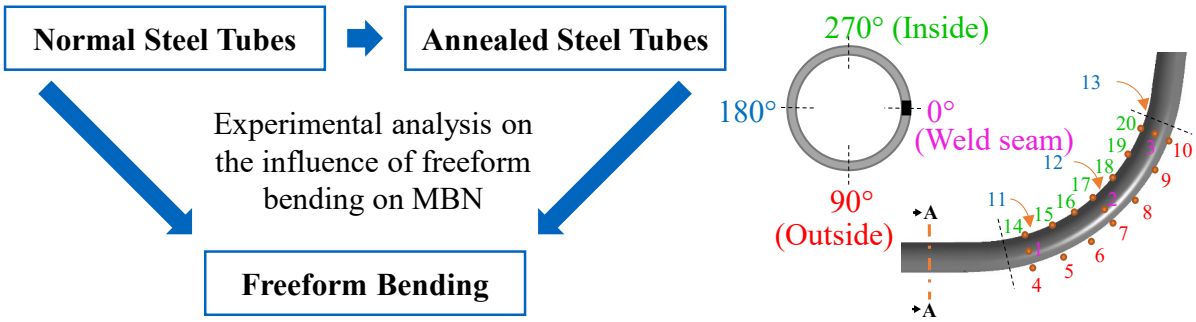

Fig. 3. Big picture and schematic depiction of measurement points on the unbent and bent part.

Experimental Investigations

This section describes the experimental investigations starting with residual stress annealing the unbent tubes, followed by the freeform bending process with a movable die, and the BHN measurement and analysis methods.

Residual stress annealing.

Residual stress annealing is used to minimize the residual stresses within the unbent tube. Table 1 shows the exact annealing parameters for the steel tubes made from P235. The annealing parameters were also part of other investigations with the same tubes [1].

Table 1. Residual stress annealing parameters for the experimental investigations.

Freeform bending and Barkhausen noise measurement. After the residual stress annealing, all tubes (normal and annealed) are bent with the freeform bending machine. Two different bending strategies are used. The first bending strategy includes five different part geometries (V01 - V05), where all result in a different curvature and bending angle. The second bending strategy includes seven different kinematics using the non-tangential bending technology [1]. This results in bent

parts with the same geometry but different residual stresses, according to [1]. The maximum deflection y_{max} and rotation φ_{max} of the bending die for all experiments are listed in Table 2.

Table 2. Freeform-bent parts with deflection and rotation of the bending die.

Name	**V01**	**V02**	**V03**	**V04**	**V05**

The unbent (normal and annealed) and the bent tubes are measured at several measuring points with the micro-magnetic sensor; see Fig. 3. There are three measuring points on the sides of the tube, with one side corresponding to the weld seam (0°). On the inside (270°) and outside (90°), there are seven measuring points each since this is where the tube records the greatest possible deformation. Please note that all measurement points are on the constant section of the bent tube.

Results and Discussion

At the beginning, the unbent raw material and the annealed raw material are investigated by micro-magnetic measurements, and additionally, the influence of the annealing process on the geometrical dimensions of the unbent tubes is analyzed. Subsequently, the results of unbent tubes with and without prior annealing are described and discussed in terms of geometry and BHN. A distinction is made between tangentially and non-tangentially bent tubes for the bent components.

Unbent raw material.

There are two different conditions of the unbent material: normal and annealed. The annealing process has been carried out with the parameters shown in Table 1. Optical measurement technology was used to measure the surface of the tube and then evaluate the outer diameter (D_{Out}) and inner diameter (D_{In}). In addition, measurements were carried out with the micro-magnetic sensor at the positions shown in Fig. 3. The results are shown in Fig. 5.

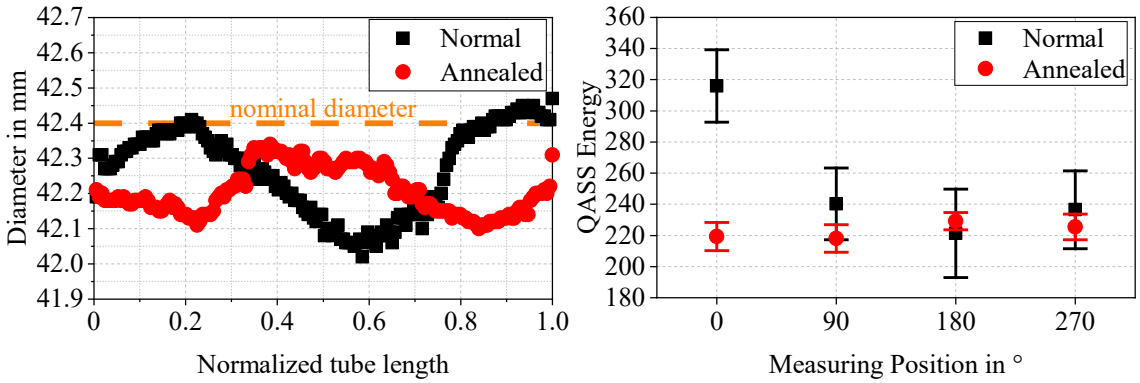

Fig. 5. Results for unbent tubes with and without residual stress annealing Left: Outer diameter, right: BHN.

For the outer diameter, it can be seen that all measurement points are within the desired tolerances (42.4±0.5 mm) for the normal and annealed tubes. The left side of Fig. 5 shows an example of a measured tube where the measuring points are distributed over the length. In addition, it appears that a trend reversal is occurring because of the annealing. At both ends, the normal tube

has a larger diameter than in the middle area, while the annealed tube shows the opposite trend. The deviation of the outer diameter is smaller after annealing compared to the normal material. The thickness of the material is within the tolerances (2.6±0.5 mm) for all measurement points. For geometrical tolerances, annealing has a positive impact due to the fact that the deviations become smaller.

On the right side of Fig. 5, the weld seam (0°) has a higher QASS energy level compared to the other measurement points for the normal tube. After annealing, the energy level of the weld seam decreases to approximately the same level as the other points. Because of the annealing process, the stresses throughout the tube were relieved, and the microstructure was affected. Fig. 4 shows significantly fewer grain boundaries in the annealed material, resulting in a lower QASS energy level. Overall, it can be stated that stress-relief annealing mainly affects the weld seam and results in a more homogeneous measurement signal with lower standard deviations.

Influence of bending process on BHN. Both unbent tube conditions (normal and annealed) are bent with the freeform bending machine and the exact same process parameters. The results are divided into the results for tangential bending (V01 - V05) and non-tangential bending (A01 - A07). The results are analyzed in comparison with numerical simulations based on a simulation model already described in [20].

In terms of geometry, it can be seen that the tubes made from the annealed material achieve higher constant curvature (equals smaller radii) than the non-annealed tubes, according to Fig. 6. This trend can be seen for all bent components V01 - V5 and A01 - A07. It can also be seen that for the non-tangential bent parts, approximately the same curvature results. This validates that constant curvature is possible for various non-tangential bending setups and builds the foundation for the following investigations. Since no differences were found in the geometric dimensions of the unbent annealed tube compared to the normal unbent tube, the differences in the curvature must be attributed either to the reduced stresses or the changed microstructure and the associated material properties after the annealing process.

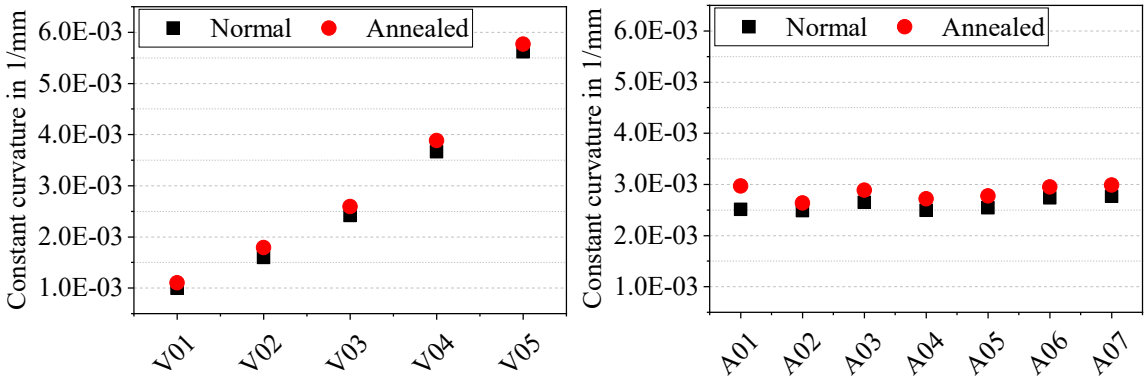

Fig. 6. Curvature of the freeform-bent parts made from normal and annealed straight tubes.

The results of the BHN analysis for the outside of the freeform-bent parts V01 - V05 and the non-tangential bent parts A01 - A07 with and without annealed raw material are shown in Fig. 7. The figure also shows the von Mises stresses determined by numerical simulations using the same measurement points as in the real bending investigations. In all tests and in the simulation, the results on the inside scatter strongly, which is why the evaluation concentrates only on the outside.

Fig. 7 shows that the BHN measurements for annealed tubes have greater fluctuations than the BHN results of normal tubes. A similar trend can be seen in the results of the annealed tubes and the simulation. With increasing curvature, the QASS energy level in the annealed tubes and the von Mises stresses determined in the simulation increase. This behavior is also to be expected due

to the bending process because the greatest strain occurs at the greatest curvature, which increases the stresses. The increase in the BHN can be explained by the fact that predominantly tensile stresses are expected on the outside of the bent tube, and these stresses increase the intensity of the BHN. Compressive stresses, on the other hand, reduce the intensity of the BHN. Only test V03 does not fit well with this trend. In contrast, this trend cannot be seen in the normal tubes. Here it seems like the QASS energy level decreases with increasing curvature. This allows the assumption that the stresses induced in the base material run counter to the stresses introduced by the freeform bending process. The fact that the results of the simulation fit better to the annealed tubes than to the normal tubes is because in the simulation, bending is done with a tube where the initial stress state is zero. The annealing reduces the stresses, and therefore the simulation corresponds more to these experiments.

In the following section, the results of non-tangential bending are examined in more detail. The quintessence of non-tangential bending is the introduction of different stress states at constant geometry. If we look at Fig. 7 together with Fig. 6, we can see exactly this relationship. Significant differences can be seen in both the simulations and the measured freeform-bent parts. On the outside, for example, the highest QASS energy level (A03) is more than 10% higher than the lowest (A01). In contrast to the previous results, a similar trend for the non-tangentially bent components can be seen between normally bent tubes and the simulation. The annealed tubes also fit with this trend, except for the outlier at A03. In the context of the BHN, the results show that as stresses decrease, the BHN also decreases, and as stresses increase, the BHN increases. Based on the results shown, it can be said that the sensor used and the BHN are suitable for measuring different stresses during freeform bending. However, in order to be able to use the sensor in a property-based control loop, a correlation of the BHN with the real stresses in the bent part must still be created. In addition, the magnetization parameters must be further refined in order to determine the various influences on freeform bending as much as possible, even in an inline measurement.

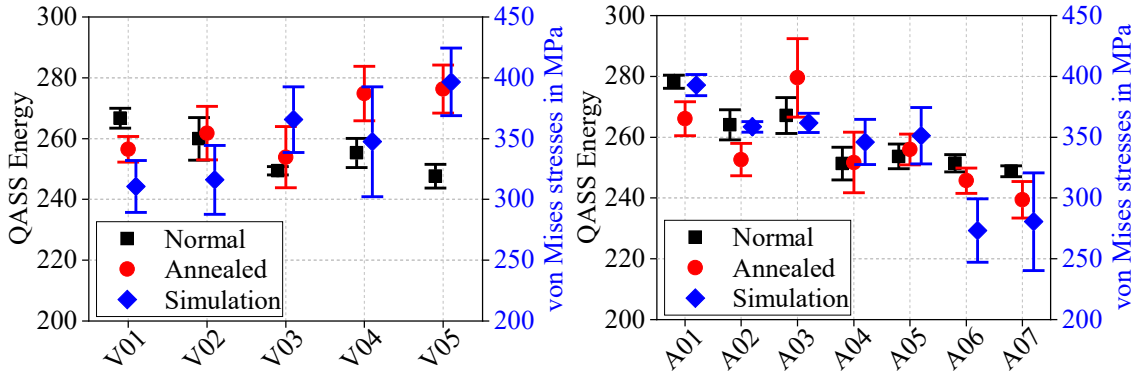

Fig. 7. Resulting BHN on the outside of freeform-bent tubes in comparison to von Mises stresses determined in numerical simulations. Left: tangential bending, right: non-tangential bending.

Summary

In the present work, the influence of different initial conditions in the tubes during freeform bending on the geometry and BHN was investigated. For this purpose, a series of tests were carried out with annealed and non-annealed tubes, which were then measured and evaluated with the micro-magnetic sensor. In addition, the results were compared with the results from the simulation. The following findings can be noted in relation to the research questions defined at the beginning of the study:

- Different QASS energy levels were found in the circumferential direction of the tube, with the weld seam significantly above the base material. The energy levels of the base material were all within a certain scatter band, which is reduced by annealing.

- In terms of geometry, it was found that the annealed tubes lead to smaller radii compared to non-annealed raw material. In terms of BHN, the annealed tubes showed better accordance with the simulation result and the presented theory.
- In non-tangential bending, it is possible to decouple the mechanical properties from the geometry. The differences in the non-tangentially bent tubes could be measured with BHN, showing a similar trend in the normal and annealed results as in the simulations.
- The micro-magnetic sensor can measure differences in freeform-bent parts, and the results are in good accordance with the simulation model. With these results, it can be said that the sensor can be used to measure BHN quickly and use the results in order to control the freeform bending process based on its properties.

For future work the parameters of the micro-magnetic sensor need to be optimized for the given steel tubes in order to measure more accurately. In addition, a correlation between the BHN and residual stresses is necessary to get a better understanding of the process and to control the bending process.

Keywords: Fine Blanking, High Manganese Steel, Strain Hardening, Twinning Induced Plasticity, Die Roll, Sheared Part Quality

Abstract. Fine blanking is a highly productive process for manufacturing of high accuracy sheet metal parts with functional surfaces. The specific process characteristic leads to high forming in the shear zone and an associated strain hardening of the sheared functional surfaces. Utilization of the process-immanent sheared surface hardening can reduce time and resources of downstream heat treatment processes such as case hardening. High Manganese Steels (HMnS) are characterized by a high strain hardening capacity due to the deformation mechanisms of twinning and transformation induced plasticity occurring during forming. As a result of high tensile strengths, HMnS are suitable as lightweight materials, but often exhibit a relatively low yield strength in terms of structural design features. One approach for increasing the strength values without changing the alloy design is a forming-induced strain hardening of the semi-finished sheet metal by means of upsetting. Therefore, this paper deals with an experimental investigation of the influence of pre-hardening on the blanked part properties during fine blanking of HMnS X40MnCrAlV19-2 LY (1.7401). For this purpose, sheet blanks were strain hardened by means of flat coining and subsequently fine blanked with an analog geometry representing tribologically stressed functional surfaces. Relevant functional surfaces were then analyzed by means of microhardness measurements with regard to the sheared surface hardening as well as characterized in terms of the quality-determining attributes die roll and clean-shear area. Due to the deformation mechanism of twinning, fine blanking of pre-hardened HMnS resulted in a combination of process-immanent high sheared surface hardening and increased yield strength with simultaneous optimal functional surface quality.

Introduction

The intrinsically driven economic resource efficiency [1] as well as the reduction of ecologically harmful emissions [2] force a continuous optimization of product development and the necessary manufacturing processes in the sheet metal processing industry. Particularly in the development of dynamically moving sheet metal workpieces, this results in the implementation of consistent lightweight design strategies for saving raw materials and emissions through lightweight material, shape and concept design [3]. Fine blanking is a process for the series production of geometrically complex sheet metal workpieces with high dimensional and shape accuracy combined with optimum material utilization [4]. Due to the high accuracy and quality of the sheared surface, fine blanking is a near-net-shape technology, e.g. for the manufacturing of gears or sprockets [5]. Process characteristics of fine blanking (cf. Fig. 1b and c) are three independently acting process forces (blanking, counter and vee-ring force), a small relative die clearance, a wedge-shaped vee-

ring as well as die edges prepared with a chamfer or radius [6]. During the shearing process, the vee-ring and counter force induce a high hydrostatic pressure in the shear zone [7]. The embossing of the vee-ring, the die edge preparation as well as a small die clearance favor the formation of additional compressive stresses [8]. The resulting superimposed compressive stress generates a plastic flow in the shear zone over the entire blanking path, which prevents tensile stresses and results in a smooth and tear-free sheared surface of high quality [9]. The load-bearing capacity of sheared functional surfaces is reduced by a die roll (cf. Fig. 1c), which is completely formed after 20 to 30% of the blanking path [10]. A large number of scientific studies have already investigated the factors influencing the clean-shear area and die roll during fine blanking and have shown comparable tendencies regarding the influence of process (e.g. vee-ring force), tool (e.g. die clearance) and workpiece parameters (e.g. material properties) [7].

In terms of process mechanics, a small die clearance with increasing blanking velocity from 10 to 70 mm/s causes a significant temperature increase of the shear zone during plastic flow as well as an increase of the blanking force [11]. The plastic flow of the sheet material in the shear zone basically leads to high deformation in the area in front of the die edge, which results in a significant increase in the dislocation density and thus in strain hardening of the sheared surface [12]. This process-immanent hardening in the near-surface area of fine blanked functional surfaces offers the potential to substitute a downstream heat treatment by using sheet materials with high strengths and strain hardening properties [8]. Regarding the use of lightweight materials, High Strength Steels (HSS) such as micro-alloyed fine grain steel S700MC (1.8974) are increasingly used for fine blanking [13]. However, as increasing strength is accompanied by a lower forming capacity [14], HSS are only suitable to a limited extent for forming sheet metal workpieces with spatially complex geometry. High Manganese Steels (HMnS) exhibit a superior combination of high strength and high formability [15] and thus offer the potential to address both lightweight material and shape design in sheet metal workpieces. HMnS are classified with a manganese content higher than 15 wt.% and characterized by a high strain hardening capacity during plastic deformation [16]. Forming of HMnS thus leads to a high strain hardening of the plasticized area, which is a result of the occurring secondary deformation mechanisms Twinning Induced Plasticity (TWIP) and Transformation Induced Plasticity (TRIP). With unchanging alloy design, the activation of different deformation mechanisms and thus the influence on the hardening behavior depends on the temperature [17], stress state [18] and strain rate [19]. The alloy design of a HMnS influences the magnitude of the stacking fault energy (SFE), which is used as a parameter to adjust the secondary deformation mechanism [16]. This enables the design of a specific deformation mechanism at a given temperature based on thermodynamic calculations of the SFE [20]. Despite the high strain hardening capacity, HMnS often exhibit low yield strength due to the soft austenitic matrix [17].

However, in order to exploit a lightweight and forming potential based on deformation mechanisms in fine blanking of HMnS, fundamental investigations are still lacking. Investigations on fine blanked sprockets made of non-alloy structural steel S275JR (SS400) have shown that these exhibit a higher wear resistance due to the sheared surface hardening than conventionally manufactured and heat-treated sprockets made of non-alloy quenched and tempered steel C50 (S50C) [21]. As a result of increased residual compressive stresses, fine blanked gears made of micro-alloyed fine grain steel S355MC (1.0976) showed a comparably high tooth root bending strength to low-alloy, heat-treated case-hardening steels [22]. Fine blanking of higher-strength Dual Phase (DP) steels DP600 [23] as well as DP780 and DP980 [24] offers potential for substitution of downstream heat treatment due to the strain hardening behavior, but also resulted in poor sheared surface quality with a tear-off height of more than 50% of the sheet thickness. Investigations on fine blanking of TRIP steel also revealed large tear-off heights of 40% of the sheet thickness at the sheared surfaces [25]. In a study on fine blanking of flat coined case-

hardening steel 16MnCr5 (1.7131), the die roll formation was reduced due to a forming-induced increase in the strength values [26].
In fine blanking of conventional steels, the sheared surface hardening has a positive effect on the behavior of tribologically stressed functional surfaces and thus shows potential for substituting heat treatment. The high deformation in the area in front of the die edge provides an ideal condition for utilizing the combination of high strain hardening and high formability during fine blanking of HMnS. Pre-hardening of the sheet material by means of upsetting represents a possible approach for influencing the strength values of HMnS. In order to achieve a combination of increased yield strength and high sheared surface hardening, fine blanking of pre-hardened HMnS was investigated in the present work. For this purpose, sheet metal blanks with various height reductions have been flat coined and fine blanked with a part geometry representing tribologically stressed functional surfaces. Depending on the part geometry, an analysis of the strain hardening as well as quality-determining attributes was then carried out.

Experimental Setup for Fine Blanking of Pre-Hardened HMnS

To investigate the influence of pre-hardened HMnS on the sheared part properties during fine blanking, sheet blanks made of hot-rolled X40MnCrAlV19-2 LY (1.7401) with the dimensions given in Fig. 1a were used. In order to evaluate the potential of mechanism-induced sheared surface hardening, additional sheet blanks of micro-alloyed fine grain steel S700MC (1.8974) have been fine blanked. Table 1 shows the yield strength $R_{\mathrm{p0.2}}$, ultimate tensile strength R_{m}, uniform elongation A_{G}, elongation at fracture A and initial hardness for the sheet materials.

Table 1. Characteristic values of the mechanical properties valid for room temperature T = 22°C

Material	$R_{\mathrm{p0.2}}$ [MPa]	R_{m} [MPa]	A_{G} [%]	A [%]	Initial hardness [HV0.1]
HMnS	407	843	50	A_{50} = 55	202 ±4
S700MC	780	865	9.5	A_{80} = 19.1	296 ±5

Fig. 1a and b show the schematic setup for fine blanking of pre-hardened HMnS. The pre-hardening of the sheet blanks was carried out in a tool for flat coining with two parallel ground upset plates. The tool-side adjustment of the height reductions Δs_i was carried out using spacers adapted to the target sheet thickness of s = 4.6 mm. In order to investigate two different pre-hardening stages of HMnS, sheet blanks have been surface ground on both sides to the initial sheet thicknesses $s_{\mathrm{I}i}$ specified in Fig. 1a. As a reference for the sheared part analysis, sheet blanks from both HMnS and S700MC were additionally surface ground to the target sheet thickness of s = 4.6 mm.

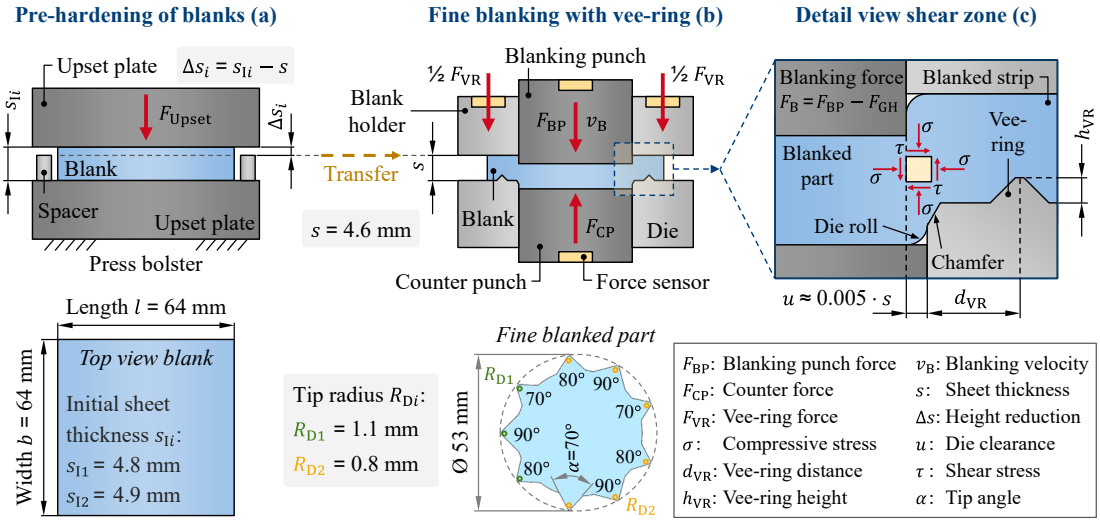

Fig. 1. Setup for pre-hardening (a) with subsequent fine blanking (b) and a detailed view of the shear zone (c).

Flat coining was carried out on a *Schuler HPX 400* hydraulic press with a ram velocity of 5 mm/s. After measuring the upset sheet blanks regarding the height reduction, the fine blanking tests were conducted on a servomechanical fine blanking press *Feintool XFT 2500 speed*. Fine blanking was performed with a modular designed single part producing tool (one part per stroke), which is instrumented with piezoelectric force sensors to measure the process forces. The sheared part geometry consisting of convex form elements with different tip angles α and tip radii R_{Di} represents an analogy application case for tribologically stressed functional surfaces. Acute angles with small radii are challenging (high difficulty level D) in terms of blanked part quality as well as punch edge load. To categorize the difficulty level, classification tables dependent on the sheet thickness and sheared part geometry (e.g. angles) are used according to [8], where $D = 1$ represents the lowest difficulty. The major geometric quantities of the sheared part are shown in Fig. 1b. The blanking punch and die were manufactured from *Böhler S390* powder metallurgical high speed steel with a hardness of 65 HRC and provided with the *Platit FeinAl* coating (AlCrN-based nanolayer coating) tailored to fine blanking. *Holifa VP1150/200* chlorine-free lubricant was used for the flat coining and fine blanking experiments. The process and tool parameters used for fine blanking are specified in Table 2.

Table 2. Process and tool parameters used for fine blanking.

Blanking velocity v_B	45 mm/s	**Die chamfer angle**	35°
Vee-ring force F_{VR}	620 kN	**Die chamfer height**	0.3 mm
Counter force F_{CP}	170 kN	**Vee-ring distance d_{VR}**	2.5 mm
Die clearance u	20 µm	**Vee-ring height h_{VR}**	0.7 mm

In order to investigate the mechanical properties and to evaluate the hardening behavior, tensile tests of the HMnS used were conducted at the *Steel Institute IEHK* according to DIN EN ISO 6892. The tensile tests were carried out at different temperatures using a *ZwickRoell Z250* tensile testing machine with a temperature chamber. The strain was measured in an open loop using *Zwick multiXtens*. Dynamic tensile tests were conducted at a strain rate of 10 /s using a servohydraulic 20kN *Roell-Amsler* high-speed (18m/s) tensile testing machine. The force was measured by a piezo

electric load cell and combined with strain gauges on the sample heads to obtain a smoothed signal [27]. The initial dimensions of the samples used had a thickness of 2mm, length of 15mm and width of 6mm. The analysis of the sheared surface hardening was carried out in dependence of the part geometry using the three convex form elements with the tip radius R_{D1} = 1.1 mm (Fig. 2a). For this purpose, samples at the corresponding tip angles α were separated out for each blanked part investigated in such a way that the separation line A-A is aligned normally to the functional surface. After metallographic preparation, microhardness measurements were conducted according to the scheme shown in Fig. 2.

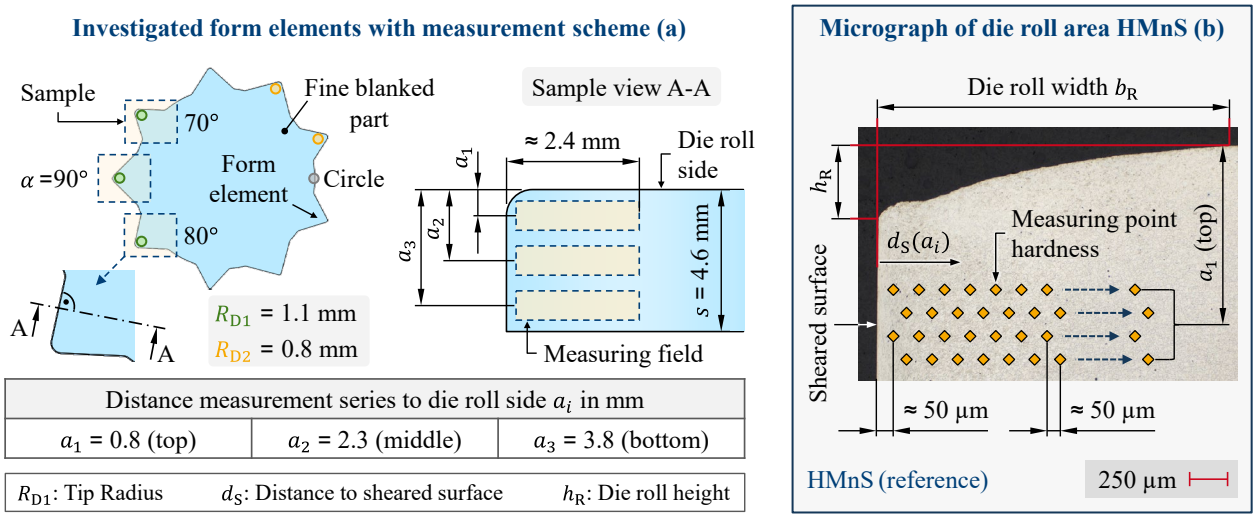

Fig. 2. Investigated form elements with measurement scheme (a) and a micrograph of the die roll area (b).

Since the sheared surface hardening depends on the blanking path, three measuring fields were investigated based on the distance to the die roll side a_i. Fig. 2b exemplarily shows a micrograph of the die roll area of HMnS at the position circle with the pattern of hardness indentations, which have horizontally as well as vertically an indentation distance of 100 µm to each other. The high strain hardening directly below the sheared surface enables the hardness measurement to start at a distance of 50 µm from it. To increase the resolution of the hardness profile, an associated series of measurements was carried out with an offset of half an indentation distance. In order to enable a smoothing of the hardness values by means of averaging, two of these patterns were measured for each measuring field. The microhardness measurements were done using a *Fischer* microhardness measuring system *Fischerscope HM2000* according to the force-indentation depth method with a holding time of 10 s. In this case, the Vickers hardness *HV* is determined by converting the plastic part of the universal hardness HU_{pl} based on DIN 50359-1 into HV_{pl}. In order to evaluate the quality-determining attributes of fine blanking, the die roll was measured and the functional surfaces were investigated regarding tear-off. To determine the die roll, the fine-blanked parts were polygonized using a *GOM ATOS Core 3D* scanner and a software-based target-actual comparison was conducted using a CAD model by means of *GOM Inspect Suite*. For this purpose, the height differences at the form elements marked with colored circles in Fig. 2a were measured in a 2D plot using sectional planes with an equidistant step size of 2.5 µm and evaluated script-based. For the investigation of the tear-off height, images of the functional surfaces were taken based on light optical microscopy (LOM) using a *Keyence VHX-5000* digital microscope and evaluated graphically. For each analyzed state regarding the pre-hardening of the HMnS as well as the additionally considered HSS S700MC, respectively two blanked parts were evaluated

and averaged for the hardness results. All other analysis results presented are based on the averaging of five blanked parts in each case.

Results Analysis

To evaluate the strain hardening behavior, Fig. 3a shows the calculated SFE of the investigated HMnS as a function of the temperature as well as the ranges of assumed secondary deformation mechanisms. The SFE was calculated based on a thermodynamic model using the chemical composition of X40MnCrAlV19-2 LY at a grain size of 30 µm [20]. Generally, a SFE below 18 to 20mJ/m^2 enables a TRIP effect and a higher SFE up to about 50mJ/m^2 results in a TWIP effect. [28]. Above an SFE of 45 to 50mJ/m^2, twinning is drastically reduced and dislocation slip (SLIP) is the preferred activated deformation mechanism [16]. For the HMnS investigated, the TWIP effect is assumed to occur in a temperature range of approx. -20 to 140°C.

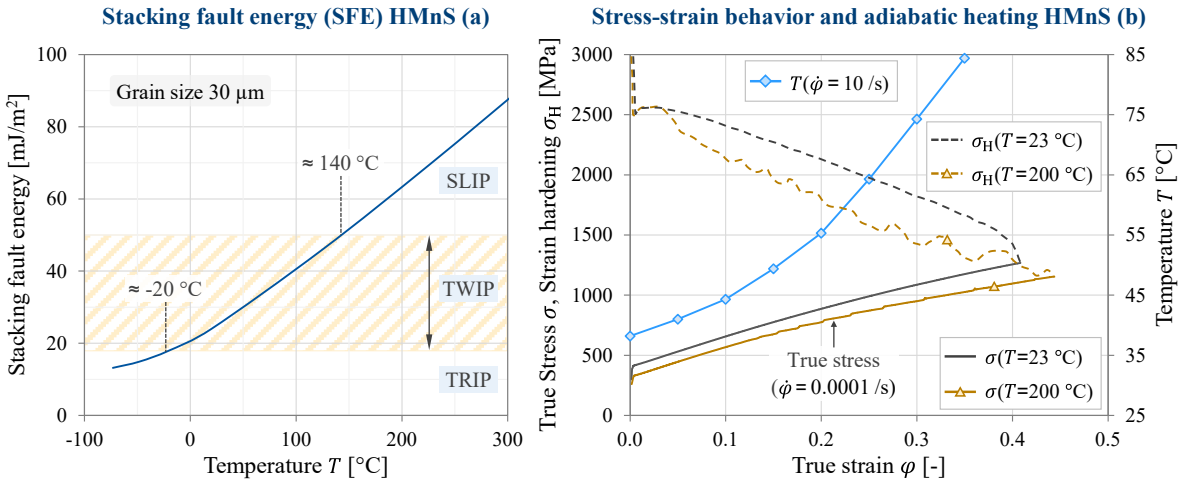

Fig. 3. Calculated SFE (a) and stress-strain behaviour (quasi-static) as well as adiabatic heating (dynamic) (b).

Fig. 3b shows the strain hardening behavior of HMnS based on true stress-strain and strain hardening curves determined from the tensile tests. The true stress-strain curves were determined for a temperature of 23 and 200°C with a strain rate of $\dot{\varphi}$ = 0.0001 /s. The corresponding strain hardening curves shown (dashed lines) result from the derivation of the respective stress-strain curves. An increase in temperature leads to a reduced flow stress in the stress-strain progression. Likewise, the corresponding strain hardening curve is significantly reduced with increasing temperature from a true strain of approx. $\varphi \approx 0.04$. Since the elastic strain of the tool elements in the force flow and the true strain of the sheet material in the shear zone are superimposed during fine blanking, the exact determination of the strain rate is challenging. Neglecting the elastic tool strain, the strain rate with regard to the investigated process parameters is about 10 /s during the shearing process. Fig. 3b additionally shows the temperature rise due to adiabatic heating measured by thermography during the dynamic tensile test for a strain rate of $\dot{\varphi}$ = 10 /s up to a true strain of $\varphi \approx 0.35$. The rising adiabatic heating as well as the reduction in strain hardening at higher temperature during the tensile tests indicate an increase in SFE (Fig. 3a) and thus an influence on the strain hardening behavior due to shearing of HMnS.

Based on the respective initial sheet thickness s_{1i}, the height reductions Δs_i were measured to determine the relative height reduction $\Delta h = \Delta s_i / s_{1i}$ of the upset sheet blanks. For the first pre-hardening stage, a height reduction Δs_1 = 0.2 mm with a deviation of ±0.012 mm was obtained, which corresponds to a relative height reduction of $\Delta h \approx 4.2\%$. With a deviation ±0.015 mm for Δs_2 = 0.3 mm, the relative height reduction for the second pre-hardening stage is $\Delta h \approx 6.1\%$. To

evaluate the process behavior during the shearing process, Fig. 4a shows the blanking force progression of the HMnS in the reference state (Δh = 0%) compared to HSS S700MC and exemplarily the specified vee-ring and counter force. Due to the sensor arrangement (cf. Fig. 1b), the blanking force F_B is determined by subtracting the counter force F_{CP} from the blanking punch force F_{BP}. In the fine blanking press used, the counter and vee-ring force are applied hydraulically and exhibit a subsiding oscillating curve over the shearing phase resulting from the closed loop control behavior. Both force curves are slightly above the set values after transient oscillation, but during the shearing phase the underlying settings are obtained on average.

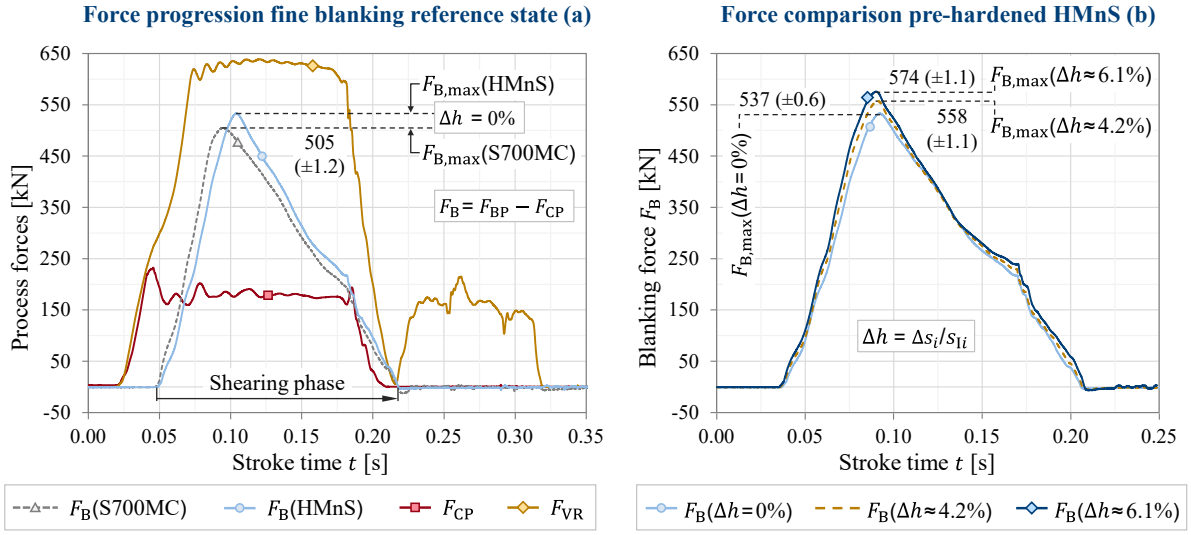

Fig. 4. Fine blanking forces of the reference state (a) and blanking force comparison of pre-hardened HMnS (b).

Despite almost equally high tensile strength compared to the HSS S700MC, an increased maximum blanking force $F_{B,max}$ of approx. 32 kN is observed for the reference state of the HMnS (Fig. 4a) due to the high hardening capacity. The slightly less steep increase in blanking force in the shearing phase is due to the forming behavior of HMnS reflected in the yield strength $R_{p0.2}$. In contrast, the comparison of pre-hardening stages shown in Fig. 4b indicates a more rapidly rising blanking force with increasing relative height reduction Δh, which can be explained by an increase of the yield strength. For the first pre-hardening stage (Δh = 4.2%), the maximum blanking force increases by 21 kN and for the second (Δh = 6.1%) by 37 kN compared to the reference state of HMnS. With less than 0.3%, the standard deviations of the maximum blanking force given in parentheses are to be considered as neglectable.

Fig. 5a shows the sheared surface hardening for fine blanked HMnS in the reference state (Δh = 0%) as well as for HSS S700MC with respect to the functional surface α = 80° for the measuring fields (cf. Fig. 2a) top (a_1) and bottom (a_3). As expected, the hardness values in the near-surface area ($d_S \leq 0.5$ mm) increase related to the die roll side with increasing blanking path (top to bottom). Due to the high strain hardening capacity, the HMnS is characterized in the near-surface area by a pronounced sheared surface hardening with an enormous hardness increase. Directly below the sheared surface, the hardness values of HMnS are approx. 140 HV higher than the values of S700MC for the top as well as the bottom measuring field. The plotted work hardening depth of the respective materials indicates the distance from the sheared surface where the bulk hardness is reached on average regarding the measuring field middle. With a value of about $d_S \approx 1.6$ mm, the HMnS in the reference state (Δh = 0%) achieves a work hardening depth more than twice as large as that of the micro-alloyed fine grain steel. According to DIN EN ISO

18203, the hardness value for determining the case hardening depth CHD is defined as 550 HV, and for determining the surface hardening depth SHD, limiting hardness values are specified based on the minimum surface hardness. For the measuring field bottom, the achieved sheared surface hardening of HMnS is accordingly comparable with a case hardening depth of CHD ≈ 0.15 mm and for a surface hardness ($d_S \approx 0$ mm) of 630 HV with a surface hardening depth of SHD ≈ 0.25 mm.

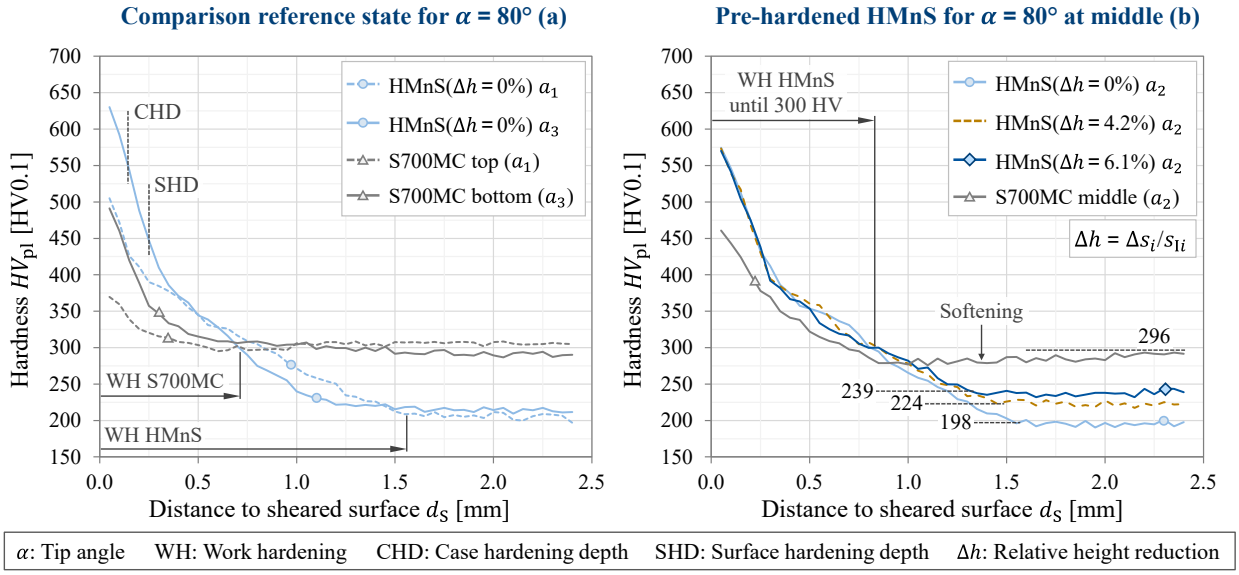

Fig. 5. Sheared surface hardening for tip angle α = 80° regarding the reference state (a) and pre-hardening (b).

Fig. 5b shows the hardening of the fine blanked functional surface α = 80° depending on the relative height reduction Δh carried out for pre-hardening of the HMnS in comparison to the HSS S700MC for the measuring field middle (a_2). The pre-hardening of the HMnS has no influence on the profile and the height of the sheared surface hardening in the near-surface area, but causes an increase in the bulk hardness, of which the averaged value is given for each hardness profile shown. The first pre-hardening stage (Δh = 4.2%) increases the bulk hardness by an average of 26 HV and the second (Δh = 6.1%) by an average of 43 HV, which in each case also suggests an increase in the yield strength. Compared to the measuring field middle, the hardness values for the reference state of the HMnS in the field bottom (Fig. 5a) are above the determined bulk hardness (~198 HV) after reaching the work hardening depth ($d_S \geq 1.6$ mm). One possible reason that the hardness values are on average 14 HV higher than the bulk hardness is a strain hardening due to the induced compressive stresses of the vee-ring and counter force at least in the area of the sheet surface close to the shear zone. The hardness profile for the S700MC in the measuring field middle (Fig. 5b) shows a slight softening with values about 20 HV lower than the bulk hardness (~296 HV) in the range of $d_S \approx 0.8$ to 2.2 mm. With increasing pre-hardening Δh, the achievable work hardening depth of the HMnS decreases (Fig. 5b). Based on a bulk hardness of 300 HV, a work hardening depth of at least $d_S \approx 0.8$ mm is to be expected for the measuring field middle with increasing pre-hardening of the HMnS.

The tip angle of the convex form elements also has no influence on the profile and height of the sheared surface hardening with respect to the investigated tip radius R_{D1} = 1.1 mm. Fig. 6a exemplarily shows the hardness profiles for pre-hardened HMnS (Δh = 6.1%) and S700MC for the measuring field middle (a_2) depending on the tip angle α. The achieved work hardening depth of the second pre-hardening stage of HMnS is about $d_S \approx 1.3$ mm. Regarding a comparison to case

and surface hardening, for the measuring field middle the hardening depths are CHD ≈ 0.1 mm and SHD ≈ 0.2 mm (surface hardness 570 HV). For all determined hardness profiles, the scatter of the averaged hardness values lies within a range of ±6.4 HV.

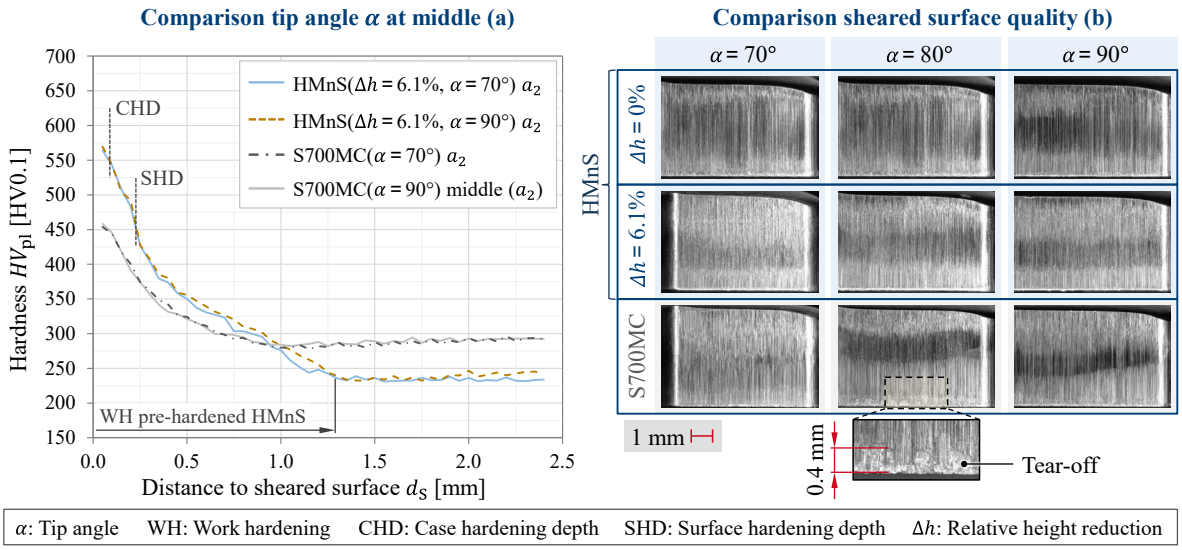

Fig. 6. Sheared surface hardening regarding the tip angle (a) and quality of the functional sheared surfaces (b).

The quality of the investigated functional surfaces is shown in Fig. 6b based on the LOM images for the reference state and the second pre-hardening stage of the HMnS compared to the HSS S700MC. Independent of the investigated tip angle α as well as the relative height reduction Δh, the fine blanked HMnS is characterized by a high sheared surface quality without tears and with tear-off heights below 0.05 mm. The micro-alloyed fine grain steel exhibits a comparably high sheared surface quality with minor tear-off heights of about 0.2 mm at α = 70° and 80° and a tear-off height of 0.4 mm at α = 90°.

For the analysis of the die roll formation, two tip angles with smaller tip radius (R_{D2} = 0.8 mm) were considered in addition to the form elements marked with R_{D1} in Fig. 2a. Fig. 7a shows the characteristics of the investigated fine blanked part and the sectional planes used to measure the die roll. The sectional planes are collinear to the respective angle bisector of the investigated tip angle α. In order to quantify the influence of pre-hardening on die roll formation during fine blanking of HMnS, relative reference values have been formed based on the values of the determined heights and widths. The relative die roll height difference Δh_{PH} indicates the relative reduction between the reference state (Δh = 0%) and the second pre-hardening stage (Δh = 6.1%) of the HMnS and is based on the minimal die roll height difference $\Delta h_{R,min}$ in each case for considering the variation range. The minimal die roll height difference was determined using the standard deviations calculated for the respective worst case (cf. Fig. 7b). The determination of the relative die roll width difference Δb_{PH} regarding the pre-hardening is based on an analogous approach to Δh_{PH}. The evaluation of the HMnS compared to the micro-alloyed fine grain steel is carried out on the basis of the relative die roll height difference Δh_{MF} as well as width difference Δb_{MF}. These reference values indicate the relative difference between the reference state of the HMnS and the HSS S700MC and were determined analogously to the procedure described before. The results of the die roll analysis are shown in Fig. 7b in dependence of the investigated form elements. The pre-hardening of the HMnS results in a reduction of the die roll at all form elements, which rises with increasing relative height reduction Δh. For the HMnS, the second pre-hardening stage results in reductions of about Δh_{PH} ≈ 7 to 11% in terms of the die roll height and about

$\Delta b_{PH} \approx 7$ to 14% in terms of the die roll width. Compared to the HSS S700MC, a larger die roll is formed for the reference state of the HMnS, which is characterized by approx. $\Delta h_{MF} \approx 30$ to 56% higher die roll heights and between $\Delta b_{MF} \approx 50$ to 60% higher die roll widths. For the second pre-hardening stage of HMnS, the relative difference values to S700MC are consequently lower.

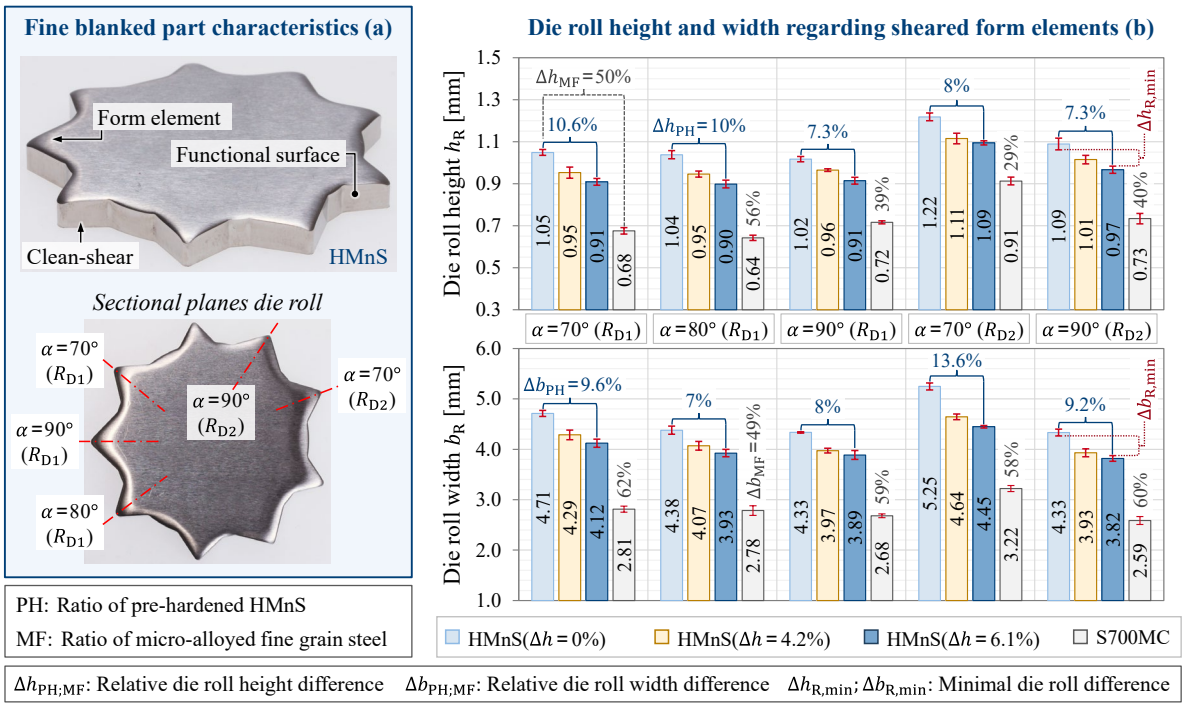

Fig. 7. Characteristics of the investigated fine blanked part (a) and comparison of die roll height width (b).

Regarding the comparison of related relative height reductions Δh of the HMnS, no influence of the tip angle α on the die roll height is observed in terms of the larger tip radius R_{D1} (Fig. 7b). In contrast, a slightly decreasing trend with increasing tip angle is detectable for the die roll width. With respect to the smaller tip radius R_{D2}, the comparison of the relative height reductions for HMnS shows a significant increase in die roll heights and widths with decreasing tip angle. For the S700MC, a comparable behavior to the HMnS is observed for both tip radii with regard to the influence of the tip angle on the die roll height and width.

Discussion and Conclusion on Fine Blanking of Pre-Hardened HMnS

The influence of pre-hardened HMnS X40MnCrAlV19-2 LY on the sheared surface hardening as well as the quality determining attributes during fine blanking was investigated. The process-immanent sheared surface hardening is described in the literature with a positive influence on the wear resistance as well as on the dynamic strengths of tribologically stressed functional surfaces and thus offers the potential to substitute a subsequent heat treatment after fine blanking. The investigated HMnS showed a good formability with high strain hardening during fine blanking, but with regard to the use as lightweight material also exhibits a low yield strength in relation to the tensile strength. In order to increase the strength values, HMnS sheet blanks were pre-hardened by means of flat coining and subsequently fine blanked with an analog geometry representing tribologically stressed functional surfaces (form elements). With almost the same tensile strength compared to the additionally fine blanked HSS S700MC, the hardening properties of HMnS lead to an increase in the maximum blanking force of 6.3% for the reference state and 13.7% for the second pre-hardening stage. Increased blanking forces cause especially at a high difficulty level D increased tool loads during fine blanking due to locally high stresses [24] and require the use of

appropriate tool materials regarding a sufficiently high tool life [13]. Compared to the reference state, the relative height reduction of the second pre-hardening stage (Δh = 6.1%) led to a steeper rise of the blanking force progression as well as to a 6.9% increase of the maximum blanking force. Forming-induced strain hardening generally results in an increase in yield as well as tensile strength due to dislocation accumulation and increased dislocation density [9]. This is reflected in the blanking force progression of the second pre-hardening stage of the HMnS, so that an increase in the strengths as well as in the yield strength ratio $R_{\mathrm{p0.2}}/R_{\mathrm{m}}$ can be assumed. The higher strength was also evident in a 20.7% increase in the bulk hardness for the second pre-hardening stage.
Based on the deformation mechanisms, the high strain hardening capacity of HMnS caused an enormous increase in hardness in the near-surface area ($d_S \leq 0.5$ mm) of the functional surfaces compared with HSS S700MC. Directly below the sheared surface, the hardness values increased with increasing blanking path from 500 HV (top) to 630 HV (bottom). Due to the process characteristics of fine blanking, the high deformation of the sheet material in the area in front of the die edge leads to heat dissipation. Based on results in the literature for shearing with a small die clearance [11], a temperature increase in the range of 170 to 210 °C is to be expected with increasing blanking path for the sheet thickness and blanking velocity investigated in this work. The tensile tests of HMnS showed a reduction of the strain hardening curve with a temperature increase in the quasi-static case and a significant increase in adiabatic heating with increasing true strain in the dynamic case. Regarding the calculated SFE of HMnS, the TWIP effect is assumed to be the dominant deformation mechanism for the high hardness increase of the sheared surface. However, due to the superposition of high true strain and high temperature rise with increasing blanking path, an influence on the strain hardening behavior in the shear zone as a result of reduced twinning cannot be excluded.

In terms of tribologically stressed functional surfaces, a non-uniform hardness distribution due to the hardening increase depending on the blanking path represents a disadvantage. One possibility to compensate for this hardness gradient is a strain hardening of the die roll side by means of a subsequent forming operation after fine blanking [8]. The pre-hardening state as well as the tip angle of the form elements had no influence on the hardness values in the near-surface area at the respective investigated position of the functional surface. An influence of local stresses due to the geometry of convex form elements on the sheared surface hardening is therefore not determinable. Based on the comparison to case and surface hardening, limit values of the achievable work hardening depth have been determined for the HMnS used as well as the process parameters applied, which allows a first evaluation of potential applications. Compared to the large tear-off heights during fine blanking of DP and TRIP steels described in previous studies, the investigated functional surfaces showed a high quality despite pre-hardening of the HMnS. The higher die roll of the form elements in comparison to S700MC is due to the lower yield strength ratio of HMnS [9]. The observed die roll reduction with increasing pre-hardening of the HMnS confirms the results of previous works [26].
The investigation on fine blanking of pre-hardened HMnS has shown that a combination of process-immanent high sheared surface hardening and increased yield strength with simultaneous optimal functional surface quality is achievable. Based on an appropriate adaptation of the heat treatment and the rolling process in semi-finished HMnS production [17], there is thus the potential to realize sufficiently high basic strengths with high sheared surface hardening for the implementation of lightweight design strategies by exploiting the deformation mechanisms during fine blanking. In summary, the following conclusions are to be derived:

1. Forming-induced pre-hardening in combination with fine blanking allows a targeted global or local increase in strength and thus an influence on the sheared part properties. The pre-hardening of the investigated HMnS increased the basic strength and reduced the die roll.

2. The superposition of high deformation and compressive stress in the shear zone enables an activation of the deformation mechanisms during fine blanking of HMnS. Compared to HSS S700MC, the investigated HMnS was characterized by a significantly increased sheared surface hardening due to the TWIP effect.
3. The achieved sheared surface hardness in the near-surface area was neither dependent on the pre-hardening state nor on the geometry of the sheared part. Due to the good formability of the investigated HMnS, the fine blanked functional surfaces showed a high sheared surface quality despite pre-hardening.
4. Semi-finished HMnS production designed for fine blanking offers the potential to realize application-specific sheared part properties in terms of high functional surface hardness, quality and basic strength by exploiting the deformation mechanisms.

Keywords: Skin-Pass Rolling, Friction Model, Property-Controlled Forming

Abstract. The surface roughness including average roughness (Ra) and peak number (RPc) after skin-pass rolling influences the strip's product properties, such as its friction coefficient in the subsequent sheet metal forming process. In order to both ensure an optimal tribological behavior and fulfill the process requirements of the following forming steps, predefined roughness combinations of Ra and RPc should be attained in skin-pass rolling. In this work, a preliminary friction model relating friction and combination of Ra and RPc is determined using flat die drawing tests for DC04 steel. The model is validated by deep drawing tests and embedded in a roughness control system for skin-pass rolling. To show a proof of concept for independent control of tribological properties from strip thickness, a simulation framework is implemented in Matlab/Simulink. The results indicate that the friction coefficient can be controlled between 0.0924 and 0.1003 for the considered test scenario (which is) characterized by a normal pressure of 75kN and a relative speed of 10mm/s.

Introduction and State of the Art

In modern industry, skin-pass rolling is used to adjust the strip's surface roughness by imprinting the work rolls' textured surface. Since skin-pass rolling is mostly the last rolling pass after conventional cold rolling, it influences the subsequent processes decisively by controlling the strip's surface quality. In accordance, correlations between the strip's roughness including average roughness (Ra) and peak number (RPc), and its tribological properties, i.e the friction coefficient, have been reported [1]. In sheet metal forming processes like deep drawing, friction is usually required to generate the necessary forming force and control the movement of the sheet within the dies [2]. At the same time, the friction coefficient significantly affects the springback, failure, minimal sheet thickness as well as the deviation of sheet thickness of the workpiece [3,4]. Under defined lubrication and deformation conditions, the sheet formability and cracking tendency also largely depends on the surface finish [5]. Hence, in skin-pass rolling a certain surface roughness shall be achieved in accordance with the subsequent forming condition for optimal tribological behavior to fulfill process requirements and avoid forming defects in the next process.

The friction coefficient primarily depends on the surface roughness, relative speed, normal pressure, and lubrication between the contact surfaces [2]. A common model is given by the Stribeck curve, which relates dynamic viscosity of the lubricants, relative speed, and normal pressure [6]. Three lubrication regimes can be identified from the Stribeck curve: boundary, mixed, and hydrodynamic lubrication, as shown in Fig. 1 (left). In the first two lubrication regimes asperity contact exists while in the third lubrication regime asperity contact can be neglected. Thus, there

is less wear regarding both contact surfaces for high Hersey numbers. It can also be observed that the friction coefficient is relatively higher in boundary lubrication and the initial stage of mixed lubrication. Noteworthy, there is no clear boundary of the three lubrication regimes. Since in sheet metal forming the friction is required and avoiding the wear between sheet and tool is not the primary objective, only friction with limited amount of lubricant, i.e. boundary and mixed lubrication, is considered in this work.

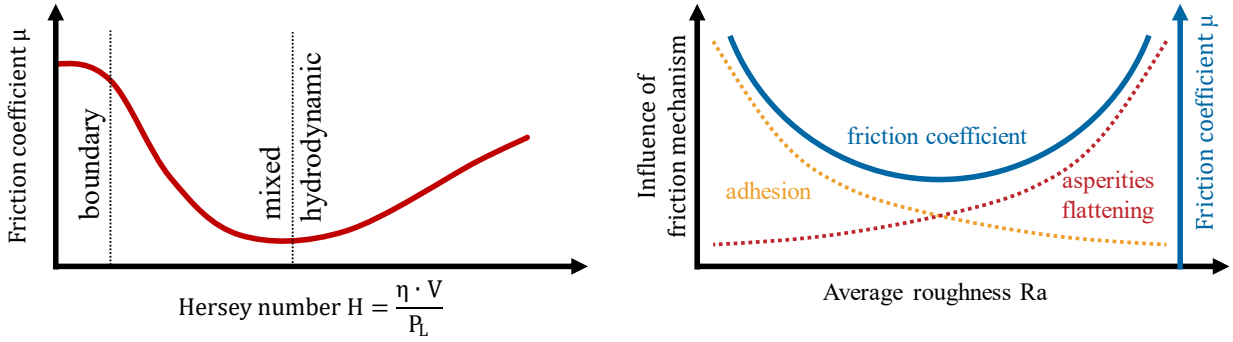

Fig. 1. Stribeck curve with the lubricant's dynamic viscosity η, relative speed V, and normal load per length PL (left); two mechanisms of influence of Ra on friction coefficient (right) [7] .

According to Stribeck curve the friction coefficient μ increases with lower relative speeds, higher normal pressures, and lower lubricant's viscosity in regions of boundary and mixed lubrication. However, some works [7,8] also show that a higher normal pressure causes lower friction in some pressure ranges and processes. The influence of surface roughness on friction has also been extensively studied in recent decades. Emmens et al. utilized flat die drawing tests and rotation friction tests to study the effect of surface roughness on friction for a deep drawing process with steel and aluminum [1,9]. Stribeck curves of specimens were determined for a surface roughness range from 0.1 µm to 3.08 µm. The result for steel indicates that a higher surface roughness regarding the maximal peak height (Rpm) causes a higher friction coefficient [1]. Here, the parameter Rpm is proportionally related to Ra. For aluminum the surface roughness shows a different influence on friction depending on the applied normal pressure. In case of lower normal pressure, the surface roughness has the same influence as for steel: higher Ra leads to a higher friction coefficient. However, when applying higher normal pressures, the friction coefficient drops slightly at first and then rises with a increasing Ra [9]. In another study, Zhou et al. investigated the influence of surface roughness on the friction coefficient by using a tribometer with a tool which moves reciprocally on the steel specimen surface[10]. The reciprocating frequencies were 2 Hz, 4 Hz, and 6 Hz and the specimen surface roughness (Ra) varied from 0.02 µm to 0.5 mm. The result reveals that below a testing frequency of 2 Hz a higher surface roughness causes a higher friction coefficient. For higher testing frequencies (4 and 6 Hz) the friction coefficient decreases at first and then increases again with increasing surface roughness. This non-linear behavior of the influence of roughness on friction coefficient (first decreasing and then increasing) is also observed by Lee [11] in flat die drawing tests and by Wihlborg [12] in bending under tension tests. This phenomenon can be explained as the interaction of two mechanisms, i.e., the adhesion between contacting asperities and the flattening of asperities, cf. Fig. 1 (right) [7]. With relatively lower surface roughness, the adhesion effect dominates while increasing roughness reduces the real area of contact and offers more lubricant pockets, therefore, friction coefficient decreases. With relatively higher surface roughness, the flattening effect dominates and asperities tend to be flattened by the normal load during the contact, which introduces more resistance for slide, and thus results in higher friction coefficient [7,13]. Because the decoupling of Ra and RPc is difficult in most roughening processes such as normal skin-pass

rolling, shot-blast texturing (SBT), or electric discharged texturing (EDT), there is only limited amount of works focusing on the influence of RPc on friction coefficient. In fact, both positive and negative correlations between RPc and the friction coefficient can be observed under different test conditions [14,15]. According to the aforementioned works, the effect of surface roughness on friction depends on test types, and multitude of different processes and lubrication conditions in different ranges of roughness. Due to this complexity, the type of friction test and its condition should be chosen carefully in accordance with the considered forming process.

In order to produce strips with a defined surface roughness in skin-pass rolling, the surface roughness of work rolls or the transfer ratio during imprinting should be adjusted. Because of the time and cost inefficiency of producing and changing rolls with different surface roughness, frequent change of work rolls should be avoided. Therefore, the adjustment of strip's surface roughness is usually achieved by changing the roughness transfer ratio, which is influenced by several process parameters. Kijima et al. [16,17] found that the peak pressure within the roll gap and work roll radius influence the roughness transfer ratio: Higher rolling forces lead to better roughness transfer as the peak pressure in the roll gap is higher, and a greater roll radius is favorable for roughness transfer due to higher peak pressure. The work of Çolak et al. [18] shows that in dry and lubricated condition higher rolling speeds and higher thickness reductions increase the rolling force and thus the transfer ratio. Furthermore, according to industrial practice lower strip tension in skin-pass rolling causes higher imprinting [19]. This effect was also investigated in preliminary work by Li et al. [20] and validated using multi-scale finite element (FE) simulations. Along with a higher thickness reduction, decreased strip tension causes higher average roll pressure and consequently increases the transfer ratio. The potential of changing the strip's surface roughness by varying strip tension was indicated in this work as well. The aforementioned process parameters, especially thickness reduction and strip tension, can be employed during skin-pass rolling for controlling the transfer ratio and adjusting the product's surface roughness, thus enabling automatic control.

Conventionally, a tandem rolling mill is used to control strip roughness during skin-pass rolling. It uses an allocation of the total height reduction between the two rolling stands to independently control the strip roughness from the strip thickness. Li et al. [21] used a tandem rolling mill together with a heuristic model to control the resulting strip roughness. The heuristic model employed here describes the correlation between the tactile measurement of the strip roughness with the process force, roll roughness, and roll radius. Overall, a roughness of (0.42 ± 0.05) µm could be ensured for 65 % of the material, in contrast to 15% in the uncontrolled case. The heuristic model of Bozhkov et al. [22] predicts the resulting strip roughness based on the average contact stress, roll radius and material strength. Here, experimental validation demonstrated that there was an average deviation between measured and predicted strip roughness of 7% with varying strip roughnesses between 1 µm and 2.5 µm over 170 km of strip.

Utilizing the strip tension to manipulate the imprinting represents an alternative method, first validated in [23]. The independent control of strip roughness and strip thickness with the use of strip tension has the advantage that no additional height reduction is necessary. However, it has the disadvantage that strip tensions of up to 40 % of the material yield strength are necessary to obtain a sufficiently large process window [23]. In preliminary work, the strip tension could be used together with the manipulation of the roll gap to vary the roughness of the strip by 0.3 µm with a height reduction of 5% and an initial strip thickness of 1 mm. However, due to the high measurement noise of the roughness measurement and the insufficiently high strip tension, this should only be considered as a proof-of-concept [23].

So far there is no publication on the process control of skin-pass rolling with regard to the strip's friction coefficient. As a preliminary trial, the task of this work is at first the determination of the friction coefficient of steel specimens with different surface roughness under test conditions, which

resemble a subsequent deep drawing process. The result is utilized to model the influence of Ra and RPc on the friction coefficient. The second task is including this friction model into a control system for skin-pass rolling with roughness control to ensure production of strips with desired tribological properties that meet the requirements of the subsequent forming process. A Matlab simulation framework is implemented based on process models validated in previous work. In particular, a model for predicting the rolling force according to Bland & Ford (1948) [24], a function for modeling the progressive roll stand deflection [25], and a heuristic function describing the imprinting of the rough work rolls are used [23]. Moreover, using the strip tension and tandem rolling as actuators, the two aforementioned concepts for roughness control in skin-pass rolling are combined in order to obtain the largest possible variation range of roughness and friction coefficient. A typical rolling test is presented in which the desired tribological property is varied while keeping a constant strip geometry.

Materials and Flat Die Drawing Test

In this study two steels, DC01 and DC04 are used. DC04 is primarily considered in the friction model and the considered deep drawing process. However, our DC04 strip is too narrow for the flat die drawing machine, and the amount of the wider DC04 plates we have is limited. Due to this geometric restriction, a similar material, DC01 is applied in friction tests. The result is compared to some additional friction tests with DC04 plate specimens to ensure the substitutability of DC01 for DC04 results.

The surface of test strips is treated by SBT to create different surface roughness. Roller leveling is used afterwards to ensure the flatness of specimens. The surface roughness Ra and RPc were measured using a mobile roughness measuring tool MarSurf PS1 by Mahr GmbH in accordance with DIN 4287. The Ra and RPc of the specimens are listed in Table 1. Note that #1 is not treated by SBT and as a result, shows both the lowest Ra and RPc values while in other specimens (#2 to #5) RPc decreases with a higher Ra.

Table 1. Specimens and parameters used in flat die drawing test.

Specimen	Material	Geometry [mm^3]	Ra [µm]	RPc [1/cm]	Normal pressure P [MPa]	Drawing speed V [mm/s]
#1	DC01	1*10*1000	1.02	66	10, 25, 50, 75	10
#2			1.55	171		
#3			2.14	146		
#4			2.96	125		
#5			3.46	105		5, 10, 50
#1-V	DC04	1*32*1000	1.04	72	50	10
#3-V			2.03	152		

As illustrated in Fig. 2, the friction parameter is determined using flat die drawing test with Tribometer 5000 by Raziol Zibulla & Sohn GmbH. The tool with a size of 200mm2 is made of steel 1.2379 with hardness of HRC 63. The DC01 specimens are tested with normal pressures of 10MPa, 25MPa, 50MPa, and 75MPa with a drawing speed of 10 mm/s to determine the influence of Ra, RPc, and normal pressure, see Table 1. For specimen #5 extra tests with varied drawing speeds of 5mm/s and 50mm/s are conducted to investigate according correlations. The tests with DC04 specimens (#1-V and #3-V) with a normal pressure of 50MPa and a drawing speed of 10mm/s are used as a comparison to the respective tests with DC01 (#1 and #3) to ensure that the result of DC01 can be generalized for DC04. The lubricant WISURA LS 710 by Fuchs Lubricants

Germany GmbH is applied while the lubrication condition for all tests in this work is controlled using a laboratory lubrication system by Raziol Zibulla & Sohn GmbH with a nozzle opening value of 35, nozzle height of 35mm, and oil pressure of 3 bar. Every test is repeated 4 times with fresh specimen. The results are then averaged for the subsequent analysis.

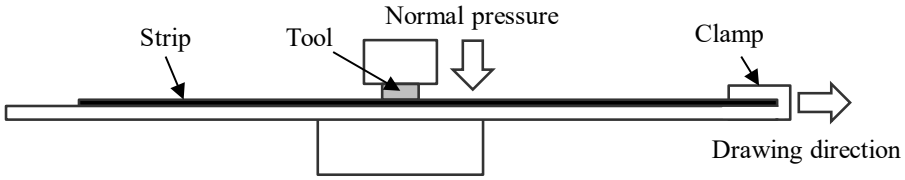

Fig. 2. Flat die drawing test.

The result of flat die drawing test for DC01 is depicted in Fig. 3. The influence of normal pressure P can be observed in Fig. 3 (left): Under this test condition a higher normal pressure causes a lower friction coefficient, which is also noticed in other works [7,8]. Because of the totally different Ra and RPc combinations of specimens the influences of Ra and RPc on friction coefficient are difficult to separate from each other, see Fig. 3 (middle, right). However, it can still be noticed that a descending tendency exists with higher Ra and lower RPc, if #1 is neglected due to the irregularity of its Ra and RPc combination. This influence of Ra can be explained with the domination of the adhesion mechanism: higher Ra decreases the real contact area, and thus, the friction coefficient [7,13]. Moreover, higher RPc results in narrower peaks and valleys on the contact surface, which then deforms easier due to the flattening effect [7]. Accordingly, the real contact area increases, the volume of lubricant pockets decreases and consequently higher friction coefficients result. It is also visible that the effect of Ra and RPc is more obvious with higher normal pressures: The maximal difference of friction coefficient at a normal pressure of 10 MPa is 0.0106, while the maximal difference of friction coefficient with a normal pressure of 75 MPa is 0.0231. This result of flat die drawing test is also plotted in 3D space, see Fig. 4 (left). Here, the different combinations of Ra and RPc of the specimens can be clearly identified.

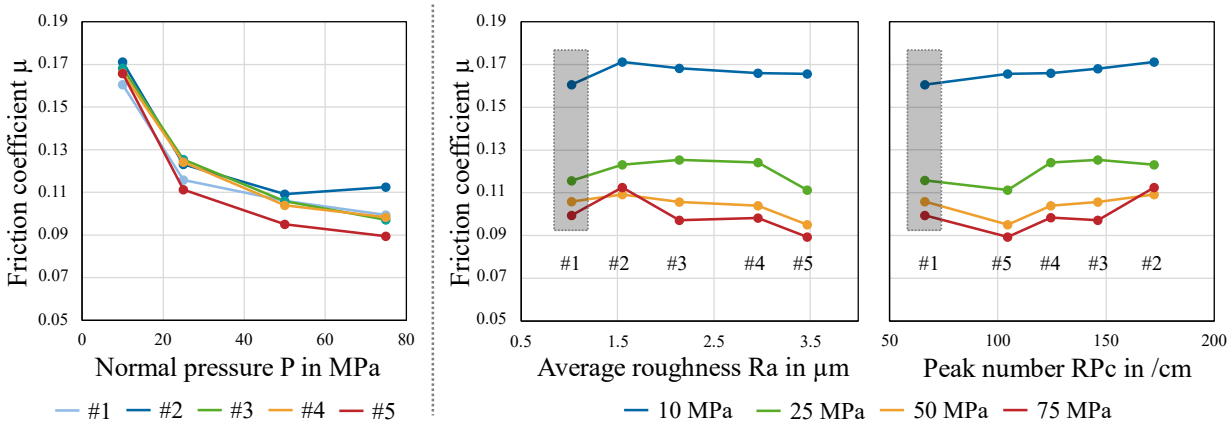

Fig. 3. Results of flat die drawing tests for DC01. The evolution of friction coefficient is illustrated over normal pressure P (left), average roughness Ra (middle), and peak number RPc (right).

Drawing speed is varied for test series #5 while a normal pressure of 50 MPa is applied. Fig. 4 (right) shows the minor influence of the drawing speed on friction under this test condition: Higher relative speeds lead to slightly lower friction coefficients, which is also observed in the Stribeck curve.

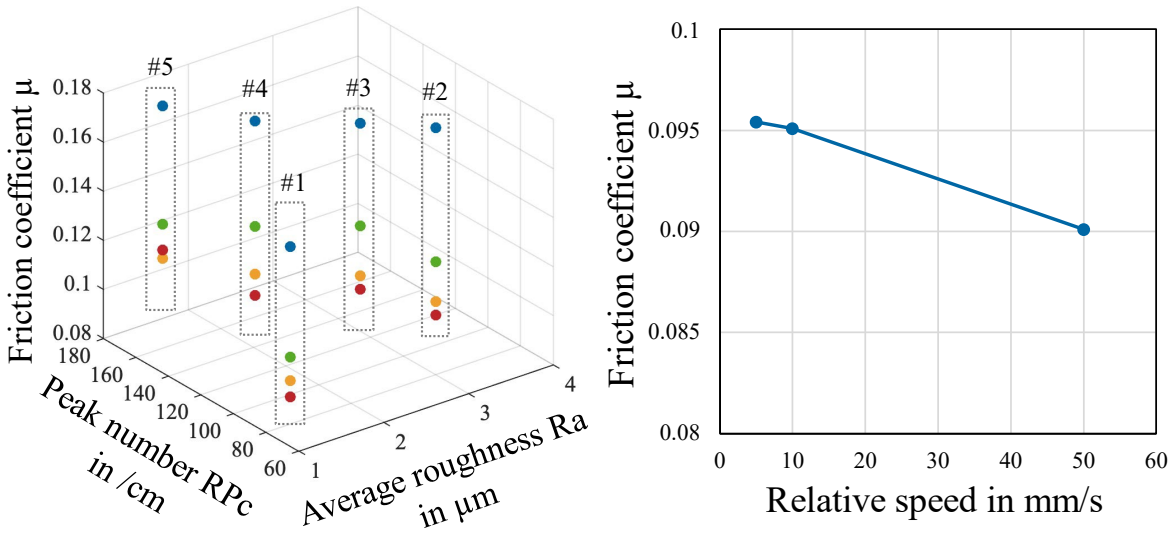

Fig. 4. Result of flat die drawing test for DC01 in 3D space (left); Influence of relative speed on friction coefficient (right).

Comparing the friction coefficients derived for DC04 and DC01, only small deviations are apparent, see Table 2. This result can also be supported by the similarity of the two steels' chemical compositions and mechanical properties. Therefore, the results obtained for DC01 can also be generalized for DC04, given the same test conditions.

Table 2. Comparison of the results of DC04 and DC01.

Specimen	Normal pressure P [MPa]	Drawing speed V [mm/s]	Friction coefficient μ[-]		Deviation [%]
			DC04	DC01	
#1-V (DC04) and #1 (DC01)	50	10	0.1058	0.1060	- 0.19
#3-V (DC04) and #3 (DC01)			0.1067	0.1057	0.95

Modeling of the Friction Coefficient

Based on the results of the flat strip drawing tests, a preliminary friction model considering the influence of normal pressure P, average roughness Ra, peak number RPc, and relative speed V is fitted using flat surfaces for different normal stresses, as shown in Fig. 5 (left). Accordingly, the friction coefficient μ is calculated as:

$$\mu = f(\mathrm{Ra}, \mathrm{RPc}, \mathrm{P}, \mathrm{V}) = (\mathrm{a} + \mathrm{b} * \mathrm{Ra} + \mathrm{c} * \mathrm{RPc}) * \mathrm{d} \quad (1)$$

where [b]= /µm and [c]=cm, and a and d are dimensionless. These fitting parameters a, b, c, and d mapping the normal pressure, Ra, RPc, and relative speed respectively. These fitting parameters are given by:

$$a = 1.987 * P^{-1.549} + 0.09679 \quad (2)$$

$$b = -0.0003376 * P^{0.763} + 0.001973 \quad (3)$$

$$c = 4.426 * 10^{-5} * P^3 - 5.358 * 10^{-8} * P^2 + 1.751 * 10^{-6} * P + 9.141 * 10^{-5} \quad (4)$$

$$d = 1 - 0.001038 * (V - 10) \quad (5)$$

with [Ra]= µm, [RPc]=/cm, [P]=MPa and [V]=mm/s. As extrapolation strategy, parameters b and c are fixed if the normal pressure is outside the measured data, i.e., lower than 10MPa and higher than 75MPa.

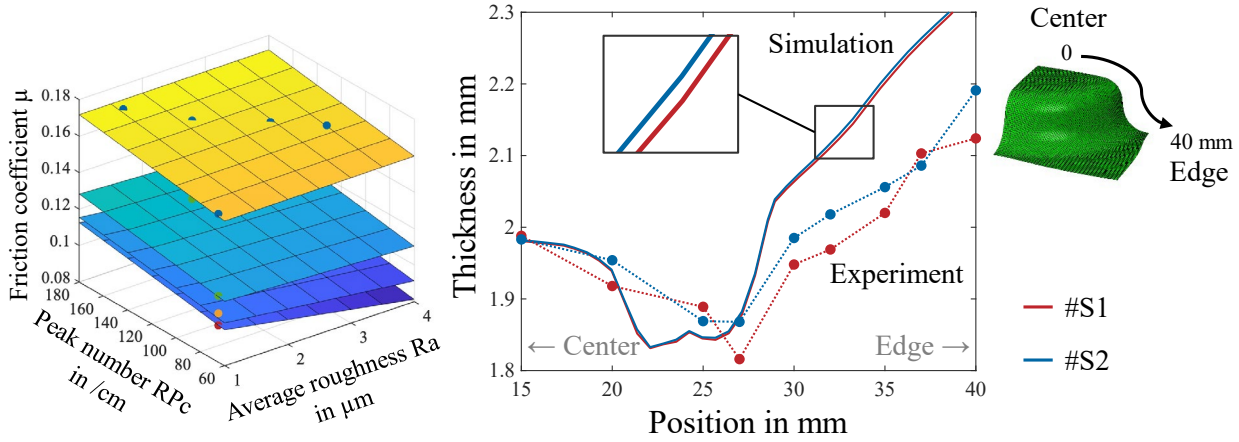

Fig. 5. Fitted friction model (left); Validation of the friction model (right).

With a maximal deviation of -5.77% the friction model shows a good agreement with the measured data and is sufficient to describe the friction behavior under the given conditions, see Table 3.

Table 3. Deviation of the fitted model from the measured data recorded at V = 10 mm/s.

Specimen	Deviation [%]			
	10 MPa	25 MPa	50 MPa	75 MPa
#1	-0.36	0.14	-5.43	-5.77
#2	0.04	2.68	2.99	3.62
#3	0.16	2.02	1.66	4.92
#4	1.57	4.13	1.86	3.78
#5	0.82	4.24	3.00	0.11

The friction model is also implemented in FE simulations using the user-subroutine FRIC_COEF with continuum shell elements in Abaqus/Standard 6.14. The results are validated with deep drawing (cupping) tests with tool speed of 5 mm/s, blankholder force of 60 kN, drawing depth of 15 mm, and punch diameter of 50 mm. As shown in Table 4 two DC04 plates with different surfaces are employed for validation. The corresponding experiment is conducted on a deep drawing press by Lauffer GmbH. After the experiment the thickness along the center line is measured using a thickness gauge by Mitutoyo with a precision of 0.01mm.

These measured thickness profiles are compared with the ones obtained from the simulation and presented in Fig. 5 (right). The results of simulation and experiment show the same tendency: from center to edge the thickness reduces at first, which is induced by large deformation in radial direction near the cup corner. Then the thickness increases significantly, which is caused by tangential material flow on the side and flange. On the edge of the specimens, the thickness of #S2 is higher than the thickness of #S1 due to the different initial surface roughnesses, which can also be observed in the simulation. The maximum relative deviations of #S1 and #S2 between simulation and experiment are 8.61% and 8.54%, respectively. This is due to the flattening of surface asperities on the edge, which is visible after the deep drawing experiments (see Fig. 6 left) and is not considered in the friction model. Another reason of this deviation is that the maximal normal stress in this deep drawing process is notably higher than for the flat die drawing tests.

Especially near the cup corner high normal stress is observed and it can cause poor extrapolation, cf. Fig. 6 (right). Moreover, the substitutability of the results of DC04 and DC01 can also be affected by the high normal stress. In addition, measurement errors stemming from the thickness gauge should also be considered.

Table 4. Specimens for deep drawing tests with their initial roughness.

Specimen	Material	Geometry [mm^3]	Ra [µm]	RPc [/cm]
#S1	DC04	2*80*80	2.92	130
#S2			4.44	99

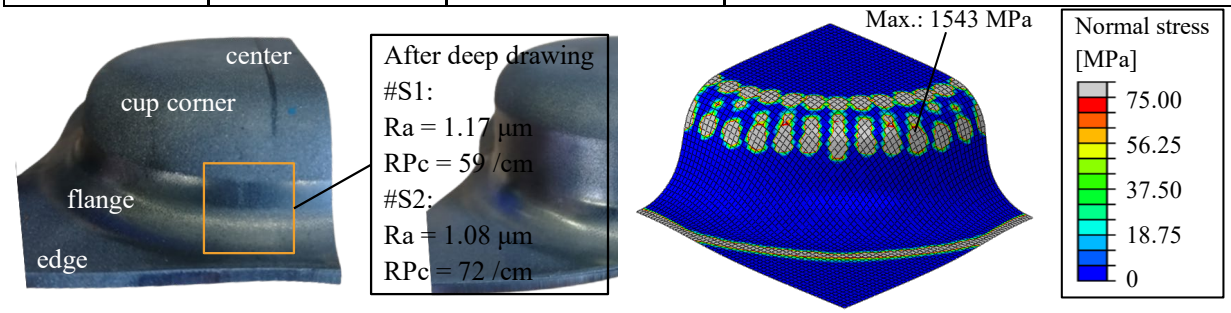

Fig. 6. Flattening of surface asperities after experiments (left); normal stress distribution in deep drawing (right).

Automatic Control of the Friction Coefficient

To show a proof of concept for independent control of tribological properties and strip thickness, a simulation framework is implemented in Matlab/Simulink. A tandem rolling mill with a quarto rolling stand with flat work rolls and a duo rolling stand with EDT work rolls with a Ra of 3 µm and RPc of 78 1/cm are modeled. In order to enlarge the process window, the control system is combining the roll gap actuation of a tandem rolling mill with the strip tension in the incoming and outgoing strip t_0 and t_2, respectively. The strip tension between the stands t_1 is kept constant in order to avoid cross-coupling of the two roll gaps. In order to keep the number of manipulated variables small, the strip tension at the entrance was set equal to the strip tension at the exit. This simplification had no negative impact on the possible process window of the control, since both actuators share a positive correlation with the friction coefficient.

The presented friction model as well as a cold rolling, roll stand deflection and imprinting model from prior work are embedded into the model-based optimal control system with a sampling time of 5 ms and a rolling speed of 100 m/s. The material under consideration is DC04 steel and a rolling speed of 50 m/min is selected, so that actuator speeds are well within in their respective admissible sets. Lubrication is neglected and the simulated process variables are superimposed by process and measurement noise according to a real tandem rolling mill from Bühler Redex GmbH with modified measurement setup [26]. The strip tension can be varied in the simulation between 150 N and 3000 N.

The simulative results are presented in Fig. 7. The actuator values are shown in the two lower diagrams. The roll gap heights of the two roll stands are shown at the bottom left and the strip tensions are shown at the bottom right. The diagram at the top left shows the initial strip thickness h_0, the strip thickness between the two roll stands h_1 and the strip thickness at the exit h_2 along its reference $h_{2,des}$. It can be seen that the outgoing strip thickness tracks the constant reference of 0.93 mm with minimal error (root mean squared error of 1.1 µm), despite of incoming strip thicknesses h_0 of (1 ± 0.008) mm, which reflects actual material tolerances present in DC04 steel. The measured and desired friction coefficient µ are shown in the diagram at the top right. Reference values between 0.093 and 0.101 are specified in 0.001 steps. The controller attains the

desired friction coefficients μ with exception of coefficients over 0.1 which prove infeasible due to the constraints on the strip tension and the minimal contact requirement of the second roll stand.

The feasible process window (friction coefficient as a function of the selected strip thickness h_2) for an exemplary sheet metal forming process with a normal pressure of 75kN, relative speed of 10 mm/s, and controlled lubrication condition is shown in Fig.8. Here, the maximum and minimum adjustable friction coefficient are shown as two enveloping lines. By increasing the total height reduction, the maximum of the friction coefficient can be significantly increased. For a height reduction of 7%, a friction coefficient between 0.0924 and 0.1003 can be set in the demonstrated process, which corresponds to a variation of 8.6%. Extending the actuators' working range would also increase the feasible process window.

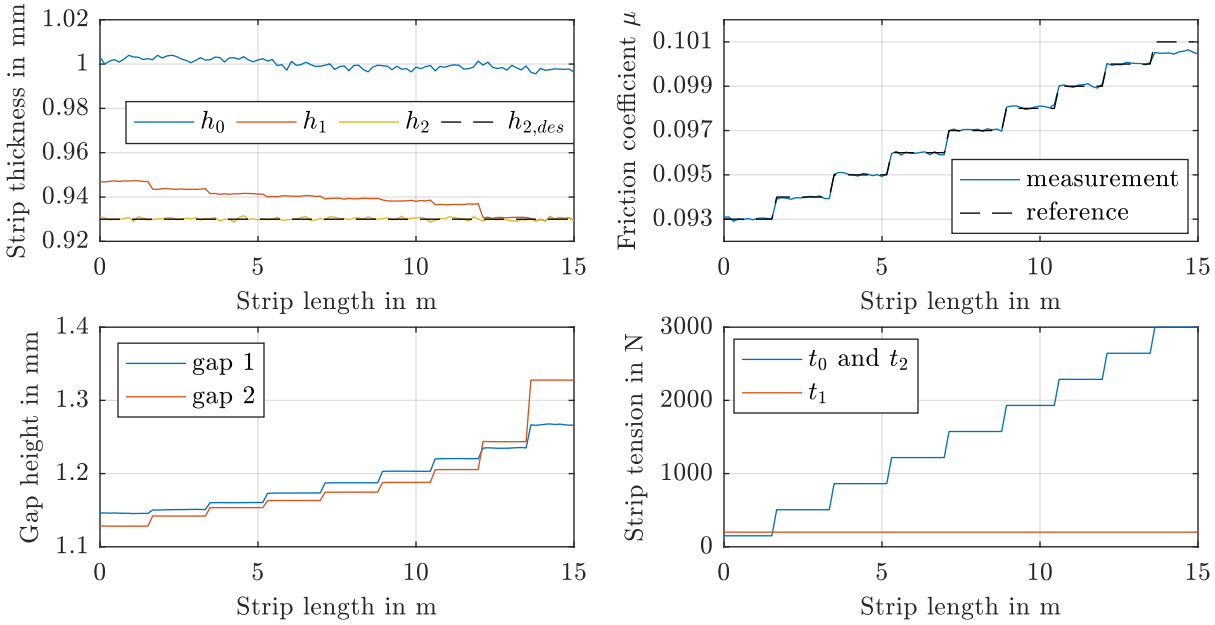

Fig. 7. Simulative results of independent control of strip thickness and friction coefficient μ.

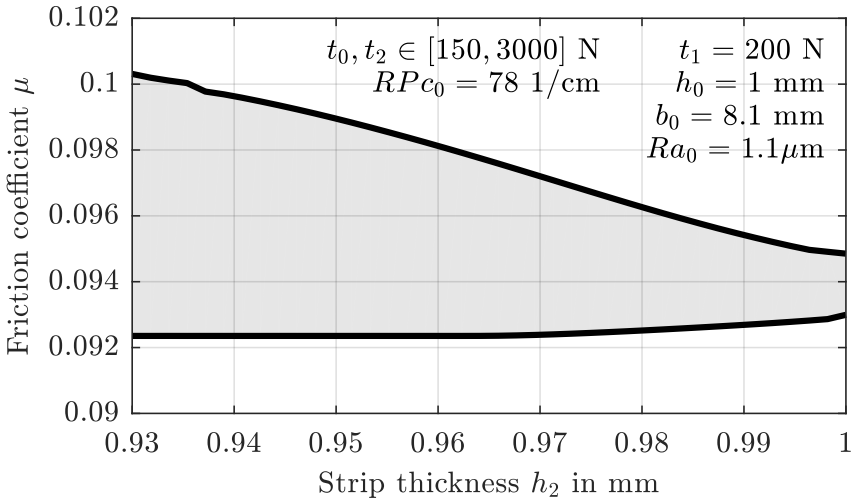

Fig. 8. Simulative evaluation of the realizable process window for DC04.

Summary

In this work, the influence of Ra and RPc on the friction coefficient of the considered deep drawing process is investigated in experiments and simulations. The results show that a higher Ra and lower RPc decrease the friction coefficient under the given conditions. Based on this result a preliminary friction model considering the influence of Ra, RPc, normal pressure, and relative speed is proposed. The model is validated qualitatively using deep drawing tests.

The friction model is embedded into a simulated control system for skin-pass rolling. The simulations suggest that the system is capable to control the surface roughness to optimize the tribological property of friction for the subsequent forming process while decoupling a predefined strip geometry

In future work, a more precise friction model should be determined by obtaining more measured data with higher normal stress and considering the asperity flattening during sheet metal forming. In addition, a validation of the simulation results should be performed to evaluate the transferability of the friction model derived from SBT surfaces to skin-pass rolling surfaces. Furthermore, the required roll surface per roll stand that extends the process window of control could be investigated, particularly with regard to the peak number.

About the Editors

Lukasz Madej is a full professor and the head of the Industrial Digitalization and Multiscale Modelling Division at the Faculty of Metal Engineering and Industrial Computer Science at AGH University. His research focuses on the development of modern numerical solutions for the industry and, in particular full-field multiscale modelling models for materials science. He is a member of various scientific organizations, e.g., Polish Association of Computational Mechanics and Polish Materials Science Society. In 2022 he was elected as a Fellow of the CIRP - The International Academy for Production Engineering. Since 2020 he is also a member of the Board of Directors of the ESAFORM. At the same time, he is editor-in-chief of Computer Methods in Materials Science journal and a member of editorial boards in various academic journals, e.g., Steel Research International, International Journal of Material Forming, Journal of Materials Processing Technology or Production Engineering - Research and Development. He is the author and co-author of more than 250 published works, including 5 books. Besides scientific activities, he is also active in the Polish Forging Association, where he holds the position of vice president and in the EUROFORGE as an Executive Board member. More information can be found at the following website: http://home.agh.edu.pl/~lmadej

Mateusz Sitko is an assistant professor at the Faculty of Metal Engineering and Industrial Computer Science at AGH University. His research focuses on the development of multiscale models for microstructure evolution dedicated to high-performance computing environments and the incorporation of virtual and augmented reality tools into industrial applications. He is a member of various scientific organizations, e.g., Polish Association of Computational Mechanics, Polish Forging Association or ESAFORM. At the same time, he is the assistant editor of Computer Methods in Materials Science journal. He is the author and co-author of one book chapter and 35 journal articles. More information is available at the following website: http://home.agh.edu.pl/~msitko/en/

Konrad Perzynski is an assistant professor at the Faculty of Metal Engineering and Industrial Computer Science at AGH University. His research focuses on the numerical modelling of a wide range of industrial processes, including the development of full-field multiscale models for materials science. He is also involved in the modelling and analysis of thin film nanostructures. He is a member of several scientific organizations, e.g., Polish Association of Computational Mechanics or ESAFORM. He is also a core group member of the ECCOMAS Young Investigators committee. At the same time, he is the assistant editor of Computer Methods in Materials Science journal. He is the author and co-author of more than 70 journal articles. More information can be found at the following website: https://home.agh.edu.pl/~kperzyns/
