ESAFORM 2023

The 26th International ESAFORM Conference on Material Forming – ESAFORM 2023 – held in Kraków, Poland, April 19-21, 2023

Editors
Lukasz Madej
Mateusz Sitko
Konrad Perzynski

Peer review statement

All papers published in this volume of "Materials Research Proceedings" have been peer reviewed. The process of peer review was initiated and overseen by the above proceedings editors. All reviews were conducted by expert referees in accordance to Materials Research Forum LLC high standards.

Table of Contents

Preface
Committees

Additive manufacturing

Design and evaluation of liquid channel cross sections fabricated via metal fused filament fabrication
BACIKOGLU Mehmet Canberk, YAMAN Ulas 3

Modeling the shape of additive manufactured parts
BRUNI Carlo, CICCARELLI Daniele, PIERALISI Massimiliano, MANCIA Tommaso 13

Resources and manufacturing technology evaluation of hybrid additive metal laminated tooling for forming
DARDAEI JOGHAN Hamed, HAHN Marlon, AGBOOLA Ololade, TEKKAYA A. Erman 21

Prediction of surface topography change during chain of selective laser melting and burnishing
TEIMOURI Reza, SKOCZYPIEC Sebastian, GRABOWSKI Marcin..... 31

Development and processability of AISI S2 tool steel by laser powder bed fusion
SAGGIONETTO Enrico, FILIPPI Elena, DEDRY Olivier, TCHUINDJANG Jérôme T., MERTENS Anne..... 41

Experimental analysis of cold sprayed precursors for closed-cells aluminum foams
VISCUSI Antonio, PERNA Alessia Serena, ASTARITA Antonello, BORRELLI Domenico, CARAVIELLO Antonio, SICIGNANO Nicola, CARRINO Luigi 49

A machine learning approach for adhesion forecasting of cold-sprayed coatings on polymer-based substrates
PERNA Alessia Serena, CARRINO Luigi, CITARELLA Alessia Auriemma, De MARCO Fabiola, Di BIASI Luigi, TORTORA Genoveffa, VISCUSI Antonio 57

Process-dependent material characteristics of dmls-manufactured specimens
ZETTEL Dominic, BREITKOPF Piotr, NICOLAY Pascal, WILLMANN Roland..... 65

Development of a new method utilizing semi-solid aluminum wires for extrusion based additive manufacturing
NEZIC Nikola, SPETH Marco, ROUVEN RIEDMÜLLER Kim, LIEWALD Mathias 75

In-situ consolidation of additively manufactured continuous fiber reinforced material: Technical approach and results
OBERLERCHER Hannes, LAUX Marius, HEIM Rosmarie, BERNDT Alexander, AMANCIO-FILHO Sergio T., RIEMELMOSER Franz O. 85

Characterisation of the shape memory effect of PET polymer by FFF 3D printing
ERMOLAI Vasile, SOVER Alexandru, LANG Anette..... 93

In process monitoring of geometrical characteristics in laser metal deposition: A comparative study
LATTE Marco, GUERRA Maria Grazia, MAZZARISI Marco, ANGELASTRO Andrea, CAMPANELLI Sabina Luisa, GALANTUCCI Luigi Maria 101

Optical absorption and conduction of copper carbon nanotube composite for additive manufacturing
AYUB Hasan, KHAN Lehar Asip, MCCARTHY Eanna, AHAD Inam Ul, SREENILAYAM Sithara P., FLEISCHER Karsten, BRABAZON Dermot 111

Influence of process parameters and head orientation on bead geometry for coaxial wire laser additive manufacturing
ROCH Clément, TOURNIER Christophe, LAVERNHE Sylvain 119

Additive manufacturing of cermet produced by laser powder bed fusion using alternative Ni binder
PAPY Kevin, BORBELY Andras, SOVA Alexey, FAVRE Julien, BERTRAND Philippe, STAERCK Jean-Marc 129

Fused filament fabrication: Numerical adhesion modeling suitable for semicrystalline polymers
BENARBIA Adel, SOBOTKA Vincent, BOYARD Nicolas, ROUA Christophe 139

Application of the plane-strain-compression-test to determine the local mechanical properties of LPBF-manufactured 316l components
JENSCH Felix, BUHL Johannes, LAUE Robert, HÄRTEL Sebastian 149

Determination of welding heat source parameters for fem simulation based on temperature history and real bead shape
SZYNDLER Joanna, SCHMIDT Alexander, HÄRTEL Sebastian 159

Generating STL for forming trabecular bone structure in additive manufacturing using cell dynamics modeling
ROCHA Adones A., THIRÉ Rossana M.S.M., ARAUJO Anna-Carla 169

Analysis of additively manufactured anisotropic microstructures through crystal plasticity frameworks
BULUT Orhun, GÜNAY Enes, FENERCIOĞLU Tevfik Ozan, YALÇINKAYA Tuncay 179

2D FE modeling of the thermal history of the heat affected zone in AlSi10Mg LPBF
DELAHAYE Jocelyn, HABRAKEN Anne, MERTENS Anne 189

Semi-finished powder of aluminum matrix composite for a direct energy deposition additive manufacturing
JEDYNAK Angelika, ERTUGRUL Gökhan, NEUMANN Andreas, PIPPIG Robert, HÄRTEL Sebastian 199

Rapid tooling development for low volume injection molding of cosmetic compacts
VELLA Andrea, ROCHMAN Arif, VELLA Pierre 207

Composites forming processes

Modeling of 3D fluid-structure-interaction during in-situ hybridization of double-curved fiber-metal-laminates
POPPE Christian, KRUSE Moritz, KÄRGER Luise 219

Modelling the forming of tailored fibre placement preforms: A tetrahedral part with final orthotropic orientations
SIMON Jessy, HAMILA Nahiene, BINÉTRUY Christophe, COMAS-CARDONA Sébastien 231

Proposing a virtual simulation method to predict the shape-fidelity of 3D-knitted-textiles using knit-meshes and geometric invariants
DIETRICH Franz 239

Feasibility study of compression molding for large reinforcement structures in the commercial vehicle sector
LÜCKENKÖTTER Julian, LEIMBACH Jan-Patrick, STALLMEISTER Tim, MARTEN Thorsten, TRÖSTER Thomas 249

Compaction behaviour of magnesium alloy-based fibre metal laminates at varying forming parameters
LIU Zheng, SIMONETTO Enrico, GHIOTTI Andrea, BRUSCHI Stefania 259

Experimental setup and method for the characterization of ply-ply adhesion for fiber-reinforced thermoplastics in melt
PIERIK Rens, ROUWMAAT Thijs, GROUVE Wouter, WIJSKAMP Sebastiaan, AKKERMAN Remko 267

XCT-based microscale analysis of structure and deformability of abdominal wall meshes
SOETE Jeroen, MAES Arne, ROJAS Camilo, KYOSEV Yordan, SCHMIDT Ann-Malin, LOMOV Stepan V., MISEREZ Marc, KERCKHOFS Greet, WEVERS Martine 277

A unit-cell mesoscale modelling of biaxial non-crimp-fabric based on a hyperelastic approach
ZHENG Ruochen, SCHÄFER Bastian, PLATZER Auriane, COLMARS Julien, NAOUAR Naim, BOISSE Philippe 285

In-plane deformation measurements for validation of composite forming simulations
BRANDS Dennis, VAN KAMMEN Kevin M., WIJSKAMP Sebastiaan, GROUVE Wouter J.B., AKKERMAN Remko 293

Manufacturing of hybrid thermoplastic-thermoset fiber reinforced composite and metallization by cold spray technique
PARMAR Hetal, RUBINO Felice, POZA Pedro, CARLONE Pierpaolo 305

Thermo-chemical modeling and simulation of glass/elium® acrylic thermoplastic resin composites
DENIS Yvan, SIDDIG Nihad, GUITTON Raphael, LE BOT Philippe, DE FONGALLAND Antoine, LECOINTE Damien 313

Gate design algorithm to maximize the fiber orientation effectiveness in thermoplastic injection-molded components
PERIN Mattia, BERTI Guido A., LEE Taeyong, QUAGLIATO Luca 321

Investigation of the compaction behavior of uni- and bidirectional non-crimp fabrics
SCHÄFER Bastian, ZHENG Ruochen, BOISSE Philippe, KÄRGER Luise 331

Forming of textile fabrics with additively assembled protective elements on the human body
KYOSEV Yordan, MÜNKS Dominik 339

Process and structural simulation for the development of a pressure vessel through filament winding technology
BIANCHI Iacopo, FORCELLESE Archimede, GALLIANI Francesco, GRECO Luciano, MIGNANELLI Chiara, TREVISAN Giulio 347

Modeling multiaxial stress states in forming simulation of woven fabrics
KÄRGER Luise, SCHÄFER Florian, WERNER Henrik O. 357

Automated programming for the robotic layup process
GAMBARDELLA Antonio, ESPERTO Vitantonio, TUCCI Fausto, CARLONE Pierpaolo 367

Experimental study of woven fabrics forming defects
SHANWAN Anwar, GHANAMEH Mohamas-Fathi, BIJU Aditya, HIVET Gilles 375

Surrogate model of the thermoforming of fiber reinforced thermoplastics
MIDDELHOFF Jan, UJVARI Csenger, HÜRKAMP André, DRÖDER Klaus 385

Investigation on the pultrusion of thermoplastic preimpregnated polypropylene-glass tapes
TUCCI Fausto, RUBINO Felice, ESPERTO Vitantonio, PASQUINO Germana, CARLONE Pierpaolo 393

Crush core forming: An innovative technology to manufacture structural sandwich parts with variable thickness
SORRENTINO Luca, BELLINI Costanzo, PARODO Gianluca, RUBINO Felice 399

An Inverse method for determining fabric permeability in vacuum assisted resin infusion for composite parts forming
VOSNIAKOS George-Christopher, DIMAKOPOULOS Panagiotis J., VASILEIOU Anastasia 407

Extrusion and drawing

Phenomena of tool adhesion at elevated temperature in V-groove friction test of AA7075
FUNAZUKA Tatsuya, DOHDA Kuniaki, KINOSHITA Mizuki, SUZUKI Shiro 419

Effects of cold-drawing and low-temperature annealing on the sensing properties of NiTi alloys
LI Yongji, LIN Jianping, XIAO Yao, MIN Junying 429

Electron backscatter diffraction (EBSD) as a tool for analysis of metal flow in aluminum extrusion
PIRES Michael V., MADURA Jacek, MISIOLEK Wojciech Z., LEŚNIAK Dariusz, ZASADZIŃSKI Józef, JURCZAK Henryk 437

Chevron cracking during full forward impact extrusion of aluminum alloy EN AW 7075 in dependence of heat treatment condition and tribological system
MÜLLER Martina, SCHWARK Niklas, WEISER Ingo F., HERRIG Tim, BERGS Thomas ... 445

Effects of disc milling and indirect extrusion processing on mechanical properties of aluminum-graphene-composites with commercial GNPs
NEGENDANK Maik, GANCHULUUN Enkhtaivan, JAIN Nishant, MÜLLER Sören 455

Yield stress and work hardening behavior of extruded AA6082 profiles under different homogenization and extrusion conditions
WILLIAMS William M., SANDNES Lise, MA Jun, TRONVOLL Sigmund Arntsønn, WELO Torgeir 467

Experimental analysis and modeling of the recrystallization behaviour of a AA6060 extruded profile
NEGOZIO Marco, DONATI Lorenzo, PELACCIA Riccardo, REGGIANI Barbara, DI DONATO Sara 477

Process simulation of friction extrusion of aluminum alloys
DIYOKE George, RATH Lars, CHAFLE Rupesh, BEN KHALIFA Noomane, KLUSEMANN Benjamin 487

Numerical study on cold extrusion of gears varying the extrusion shoulder geometry
DELIKTAS Tahsin, LIEWALD Mathias 495

Investigations into the processing and texture of Pr-substituted NdFeB magnets produced by extrusion
RÜDIGER Alexander, GALL Sven, MÜLLER Sören 505

Friction extrusion processing of aluminum powders: Microstructure homogeneity and mechanical properties
CHAN Chang Yin-Cheng, RATH Lars, SUHUDDIN Uceu F. H., KLUSEMANN Benjamin . 515

Progression of plastic die deformation during copper extrusion
LECHNER Stefan, MÜLLER Sören 523

Investigation on the topological optimization of cooling channels for extrusion dies
PELACCIA Riccardo, REGGIANI Barbara, NEGOZIO Marco, DI DONATO Sara, DONATI Lorenzo 533

Investigation of the skin contamination predictability by means of QForm UK extrusion code
KNIAZKIN Ivan, PELACCIA Riccardo, NEGOZIO Marco, DI DONATO Sara, DONATI Lorenzo, REGGIANI Barbara, BIBA Nikolay, REZVYKH Ruslan, KULAKOV Ivan 543

Crystal plasticity finite element analysis of linear and non-linear extrusion processes
ŞIMŞEK Ülke, MIYAMOTO Hiroyuki, YALÇINKAYA Tuncay 553

Critical comparison of different techniques for producing profiled wires
KWIECIEŃ Marcin, MUSZKA Krzysztof, MAJTA Janusz 563

Forging and rolling

Design of a forging process to individually examine thermal, mechanical and tribological stress in the tool surface zone
BEHRENS Bernd-Arno, MÜLLER Felix, LORENZ Uwe 573

Hot die forging with nitrided and thermally stabilized DLC coated tools
SIEGMUND Martin, KIPP Christian, PEDDINGHAUS Julius, BRUNOTTE Kai, BRÄUER Günter, BEHRENS Bernd-Arno 583

Investigation of the joining zone formation of impact extruded hybrid components by varied forming sequence and partial cooling
PIWEK Armin, PEDDINGHAUS Julius, UHE Johanna, BRUNOTTE Kai, BEHRENS Bernd-Arno 591

Advanced automatic pass schedule design for hot rolling by coupling reinforcement learning with a fast rolling model
IDZIK Christian, GERLACH Jannik, BAILLY David, HIRT Gerhard 601

Beneficial effect of stress superposition on damage reduction in trimming processes
WEIß Alexander, FELDE Alexander, LIEWALD Mathias, ZERFAß Helmut 611

Determination of recrystallisation phenomenon in type 316 stainless steel VIM-VAR ingots during cogging operations
PAQUETTE Arthur, LANGLOIS Laurent, VIOLATOS Ioannis, RAHIMI Salaheddin, DUMONT Christian, BIGOT Régis 621

Study of forming defects and failure occurrence in the radial-axial rolling of super duplex stainless steel rings
MURILLO-MARRODÁN Alberto, GARCÍA GIL Eduardo, FERNANDEZ-GAMBOA Unai, CONDE Aintzane, LOZARES Jokin 629

Detailed study of tube hot rolling process by means of FEM
GARCÍA GIL Eduardo, DURÁN Gorka Llamazares, CONDE Aintzane, MURILLO-MARRODÁN Alberto, ATUTXA Jon Barco 639

Parametric identification on a dynamic behavior model for a forging machine
DURAND Camille, SONG Heyu, BIGOT Régis 649

An analytical approach for modelling incremental disk rolling process
ACAR Sadik Sefa, DINÇER Mehmet Şamil, OZCATALBAS Mustafa 657

Evolution of microstructure during hot incremental disk rolling of a nickel-based super-alloy
DINÇER Mehmet Şamil, OZCATALBAS Mustafa, ACAR Sadik Sefa, MUSIC Omer, ŞIMŞIR Caner 667

Effect of near beta-transus forging parameters on the mechanical and microstructural properties of Ti-6Al-4V – Application to hammer forging
AGIRRE Julen, ERICE Borja, ARRESE Peio, OTEGI Nagore, GALDOS Lander 675

Benchmarking mean-field models available in commercial FE software in application to two-blow forging of IN718 alloy
RESHETOV Aleksey, BYLYA Olga 683

Formability of metallic materials

Total strain on the outer surface of steel sheets in air bending
POKKA Aki-Petteri, KESTI Vili, KAIJALAINEN Antti 695

Prediction of forming limit diagram of automotive sheet metals using a new necking criterion
PHAM Quoc Tuan, ISLAM Md Shafiqul, SIGVANT Mats, CARO Perez Lluis 705

Anisotropic deformation behavior during cup drawing at room temperature of a ZX10 magnesium alloy sheet
HAMA Takayuki, HIGUCHI Koichi, NAKATA Yuto 711

Modelling failure of joining zones during forming of hybrid parts
WESTER Hendrik, STOCKBURGER Eugen, PEDDINGHAUS Simon, UHE Johanna, BEHRENS Bernd-Arno 717

Influence of process parameters and process set-up on damage evolution during stretch drawing of u-shaped profiles
MÜLLER Martina, WEISER Ingo Felix, HERRIG Tim, BERGS Thomas 727

Improved failure characterisation of high-strength steel using a butterfly test rig with rotation control
STOCKBURGER Eugen, WESTER Hendrik, JEGATHEESWARAN Vithusaan, DYKIERT Matthäus, BEHRENS Bernd-Arno 737

Investigation of the influence of loading direction after pre-forming on the formability and mechanical properties of DP600
NORZ Roman, VALENCIA Fabuer R., VITZTHUM Simon, UNGUREANU Bogdan, GERKE Steffen, BRÜNIG Michael, VOLK Wolfram 747

Heat assisted V-bending characteristics of high strength S700MC steel
GÖRTAN Mehmet Okan, CAGIRANKAYA Fatih, OZSOY Oguz 755

A stress-based proposal for wrinkling criterion of clamped surfaces
BORBÉLY Richárd, KÖLÜS Martin L., BÉRES Gábor J. 761

Evaluation of hot and warm forming of age-hardenable aluminium alloys into manufacturing of automotive safety critical parts
MYROLD Benedikte, JENSRUD Ola, HOLMESTAD Jon 771

Nonlinear stress path experiment using mild steel sheet for validation of material model
TAKADA Yusuke, KUWABARA Toshihiko 779

Damage prediction in roll forming of the high strength aluminum alloy AA7075
SUCKOW Timon, GROCHE Peter 787

Multi-scale modeling of the effect of crystallographic texture
REVIL-BAUDARD Benoit, CAZACU Oana 799

Experimental identification of uncoupled ductile damage models and application in flow forming of IN718
VURAL Hande, ERDOGAN Can, KARAKAŞ Aptullah, FENERCIOGLU Tevfik Ozan, YALÇINKAYA Tuncay 807

Deformation analysis of ZnMgAl coated steel sheet using digital image correlation (DIC) system
LISIECKA - GRACA Paulina, MUSZKA Krzysztof, KWIECIEŃ Marcin, DZIURDZIA Jakub 817

Hybrid SPD process of aluminium 6060 for microforming
PRESZ Wojciech, JASIŃSKI Cezary, MORAWIŃSKI Łukasz, ORŁOWSKA Marta 825

Influence of intercritical annealing temperature on formability and mechanical properties of medium-manganese-steel in press hardening
TILLY Karl Johann, PLUM Tobias, BAILLY David, HIRT Gerhard 833

Specific behavior of high-manganese steels in the context of temperature increase during dynamic deformation
JABŁOŃSKA Magdalena B., GRONOSTAJSKI Zbigniew, TKOCZ Marek, JASIAK Katarzyna, KOWALCZYK Karolina, SKWARSKI Mateusz, KOSTKA Michał 839

Effect of prestrain on mechanical behavior of aluminum alloys
VINCZE Gabriela, BUTUC Marilena C., WEN Wei, YÁNEZ Jesús, LOPES Diogo 847

Determination of the forming limit curve of locally annealed aluminum blanks
PICCININNI Antonio, LATTANZI Attilio, ROSSI Marco, PALUMBO Gianfranco 855

Friction and wear in metal forming

Galling-free fine blanking of titanium plates by carbon-supersaturated tool steel punch
AIZAWA Tatsuhiko, FUCHIWAKI Kenji, DOHDA Kuniaki 869

The influence of Particle Hardness on Wear in Sheet Metal Forming
ARINBJARNAR Úlfar, KNOLL Maximilian, MOGHADAM Marcel, NIELSEN Chris Valentin 879

Surface topography effects on galling of hot dip galvanized sheet metal
VENEMA Jenny, CHEZAN Toni, KORVER Frank 891

Influence of increased die surface roughness on the product quality in rotary swaging
FENERCIOĞLU Tevfik Ozan, SARIYARLIOĞLU Eren Can, ADIGÜZEL Erdem, ŞIMŞEK Ahmet Kürşat, KOLTAN Umut Kağan, YALÇINKAYA Tuncay 899

Design of a new simulative tribotest for warm forming applications having high contact pressure and surface enlargement
GALDOS Lander, AGIRRE Julen, ARANBURU Elixabet 909

Incremental and sheet metal forming

Numerical investigation on the deep drawing of sheet metals with an additively applied coating
MÄRZ Raphaela, HAFENECKER Jan, BARTELS Dominic, SCHMIDT Michael, MERKLEIN Marion 919

Numerical and experimental investigation of a backward extrusion process for forming geared components from coil
LEICHT Miriam, HENNEBERG Johannes, MERKLEIN Marion 929

Hot stamping of ultra-thin stainless steel for microchannels
GUO Nan, ZHANG Xianglu, HOU Zeran, YANG Daijun, MING Pingwen, MIN Junying 937

Approaches for load path design for stretch forming based on part surface geometry
REITMAIER Lisa-Marie, BAILLY David, HIRT Gerhard 943

Modifying mechanical properties of sheet metal materials by work hardening mechanisms induced by selective embossing
HEINZELMANN Pascal, BRIESENICK David, LIEWALD Mathias 951

Influence of surface pressure and tool materials on contact heating of aluminum
TRÂN Ricardo, PSYK Verena, WINTER Sven, KRÄUSEL Verena 959

Low-cost tooling concept for customized tube bending by the use of additive manufacturing
TRONVOLL Sigmund A., TREFFEN Helena, MA Jun, WELO Torgeir 969

Experimental investigation of the fluid-structure interaction during deep drawing of fiber metal laminates in the in-situ hybridization process
KRUSE Moritz, BEN KHALIFA Noomane 977

Modification of the surface integrity of powder metallurgically produced S390 via deep rolling
HERRMANN Peter, HERRIG Tim, BERGS Thomas 987

Electrically-assisted deep drawing of 5754 aluminium alloy sheet
DOBRAS Daniel, ZIMNIAK Zbigniew, ZWIERZCHOWSKI Maciej 997

Effect of shear angle in shearing on stretch flangeability of ultra-high strength steel sheets
YAGITA Ryo, KIMURA Shunsuke, ABE Yohei 1007

Effect of reduction ratio in flow forming process on microstructure and mechanical properties of a 6082 Al alloy
MUTLU Mehmet, ÖZSOY Atasan, FENERCIOĞLU Tevfik Ozan, KARAKAŞ Aptullah, BAYDOĞAN Murat 1015

Flow forming and recrystallization behaviour of CuZn30 alloy
MUTLU Mehmet, KARAKAŞ Aptullah, KUŞDEMIR Hakan, KOLTAN Umut Kağan, YALÇINKAYA Tuncay 1021

Mechanical and microstructural properties of AISI 4140 after flow-forming process
YAZGAN Elif, MUTLU Mehmet, AYDIN Güneş, KARAKAS Aptullah, FENERCIOGLU Tevfik Ozan, BAYDOGAN Murat 1029

Simulation of incremental sheet metal forming for making U-channel in two light-weight alloys
BHUSHAN Bharat, RAMKUMAR Janakarajan, DIXIT Uday Shanker 1037

Flange wrinkling in incremental shape rolling
ESSA Abdelrahman, ABEYRATHNA Buddhika, ROLFE Bernard, WEISS Matthias 1047

Innovative joining by forming technologies

Clinching with divided punch to prevent critical neck thicknesses
FALK Tobias, KROPP Thomas, DROSSEL Welf-Guntram 1059

An ANN based approach for the friction stir welding process intrinsic uncertainty
QUARTO Mariangela, BOCCHI Sara, GIARDINI Claudio, D'URSO Gianluca 1067

Modelling of the weld seam in the forming simulation of friction stir welded tailored blanks
BACHMANN Maximilian, RIEDMÜLLER Kim, LIEWALD Mathias, MERTEN Mathias .. 1075

Comparative investigation of partial cooling methods for induction heating of hybrid bulk components for hot forming
INCE Caner-Veli, KATZ Fabian RAATZ Annika 1083

FSW process mechanics and resulting properties for dissimilar Al-Ti T-joints
RANA Harikrishna, BUFFA Gianluca, FRATINI Livan 1091

Influence of process parameters on mechanical properties of lamination stacks produced by interlocking
MARTIN Daniel Michael, KUBIK Christian, KRÜGER Martin, GROCHE Peter 1101

Versatile self-piercing riveting with a tumbling superimposed punch
WITUSCHEK Simon, ELBEL Leonie, LECHNER Michael 1111

Lionel fourment ms on optimization and inverse analysis in forming

On the comparison of heterogeneous mechanical tests for sheet metal characterization
GONÇALVES Mafalda, OLIVEIRA Miguel Guimarães, THUILLIER Sandrine, ANDRADE-CAMPOS António..... 1121

On the inverse identification of sheet metal mechanical behaviour using a heterogeneous Arcan virtual experiment
HENRIQUES Joao, ANDRADE-CAMPOS António, XAVIER José..... 1131

On the constraints and consistency in implicit constitutive modelling using ANNs and indirect training
LOURENÇO Rúben, CUETO Elías, GEORGIEVA Pétia, ANDRADE-CAMPOS António.. 1143

Forming process optimisation for variable geometries by machine learning – Convergence analysis and assessment
ZIMMERLING Clemens, KÄRGER Luise 1155

Identification of the large strain flow curve of high strength steel via the torsion test and FEMU
VANCRAEYNEST Niels, COOREMAN Steven, COPPIETERS Sam 1167

Investigating the suitability of using a single heat transfer coefficient in metal casting simulation: An inverse approach
VASILEIOU Anastasia, VOSNIAKOS George-Christopher, PANTELIS Dimitrios I. 1175

Sensitivity analysis of the of the square cup stamping process using a polynomial chaos expansion
PEREIRA André F. G., MARQUES Armando E., OLIVEIRA Marta C., PRATES Pedro A. 1183

Coupling machine learning and synthetic image DIC-based techniques for the calibration of elastoplastic constitutive models
PRATES Pedro A., HENRIQUES Joan D. F., PINTO Jose, BASTOS Nelson, ANDRADE-CAMPOS Antonio..... 1193

A hybrid VFM-FEMU approach to calibrate 3D anisotropic plasticity models for sheet metal forming
ROSSI Marco, LATTANZI Attilio, AMODIO Dario 1203

Machining and cutting

Manufacturing of graded grinding wheels for flute grinding
DENKENA Berend, BERGMANN Benjamin, RAFFALT Daniel 1213

Modeling of surface hardening in burnishing process
TEIMOURI Reza, GRABOWSKI Marcin, SKOCZYPIEC Sebastian 1223

Orthogonal cutting with additively manufactured grooving inserts made from HS6-5-3-8 high-speed steel
KELLIGER Tobias, MEURER Markus, BERGS Thomas 1235

Machining of PAM green Y-TZP: Influence of build and in-plane directions on cutting forces and surface topography
SPITAELS Laurent, RIVIÈRE-LORPHÈVRE Edouard, MARTIC Grégory, JUSTE Enrique, DUCOBU François 1245

Analysis of Ti-6Al-4V micro-milling resulting surface roughness for osteointegration enhancement
CAPPELLINI Cristian, MALANDRUCCOLO Alessio, KIEM Sonja, ABENI Andrea 1255

Comparison of cutting tool wear classification performance with artificial intelligence techniques
COLANTONIO Lorenzo, EQUETER Lucas, DEHOMBREUX Pierre, DUCOBU François 1265

Hardware implementation of Monte Carlo and RSM method for the optimization of cutting force during turning of NiTi shape memory alloy
KOWALCZYK Małgorzata 1275

Investigation of surface finish and chip morphology in cryogenic machining biomedical grade polyetheretherketone
SAJJA Nikhil Teja, BERTOLINI Rachele, GHIOTTI Andrea, BRUSCHI Stefania 1285

Cutting force in peripheral milling of cold work tool steel
TAMURA Shoichi, MATSUMURA Takashi 1295

Evaluation of the surface integrity characteristics of internal threads machined on lead-free brass alloy
ZOGHIPOUR Nima, TORAMAN Yaren, KARA Koray, BAS Kaan Can, KAYNAK Yusuf 1303

Analytical method for determining cutting forces during orthogonal turning of C45 steel
ŚLUSARCZYK Łukasz, FRANCZYK Emilia 1313

Novel methodology for burr extension estimation on machined SLM surfaces
GINESTRA Paola, QUARTO Mariangela, ABENI Andrea, ATTANASIO Aldo, CERETTI Elisabetta, D'URSO Gianluca, GIARDINI Claudio 1323

On the impact of tool material and lubrication in ball end milling of ceramic foams
ROTELLA Giovanna, SANGUEDOLCE Michela, SAFFIOTI Maria Rosaria, TESTA Flaviano, UMBRELLO Domenico, FILICE Luigino 1331

Superfinishing processes applied on the biomedical implants surface to improve their performance
SAFFIOTI Maria R., ROTELLA Giovanna, UMBRELLO Domenico 1341

Evolution of contact lengths during the turning of treated Ti64 β
WAGNER Vincent, DESSEIN Gilles 1347

Investigation of machining performance of lead-free brass materials forged in different conditions after cooling with liquid nitrogen
ATAY Gokhan, ZOGHIPOUR Nima, KAYNAK Yusuf 1357

Material behaviour modelling

Process-informed material model selection
CONDE Mariana, COPPIETERS Sam, ANDRADE-CAMPOS António 1369

Simple multiaxial tests to assess dynamic ductility of 17-4PH
MANCINI Edoardo, CORTIS Gabriele, CORTESE Luca, UTZERI Mattia, SASSO Marco.. 1379

Nonlinear elastic stress triaxiality dependent constitutive model for fibre-reinforced polymer composites
OBID Štefan, HALILOVIČ Miroslav, STARMAN Bojan 1387

Calibration of thermo-viscoplastic constitutive model under biaxial loadings: A Feasibility Study
WANG Zhihao, GUINES Dominique, LEOTOING Lionel 1397

Extension of the modified Mohr-Coulomb fracture model by a strain rate and temperature dependence
VASQUEZ RAMIREZ Dominyka, WESTER Hendrik, ROSENBUSCH Daniel, BEHRENS Bernd-Arno 1407

Optimizing crystal plasticity model parameters via machine learning-based optimization algorithms
JUAN Rongfei, BINH Nguyen Xuan, LIU Wenqi, LIAN Junhe 1417

Correlation between porosity level and elastic modulus in a foamed hiped Ti alloy
GUGLIELMI Pasquale, CASTELLANO Anna, CUSANNO Angela, PALUMBO Gianfranco 1427

Micro-mechanical study of damage evolution in isotropic metallic materials
KNAAK Karl, REVIL-BAUDARD Benoit, CAZACU Oana 1435

Micromechanical modeling of failure in dual phase steels
AYDINER Ilbilge Umay, TATLI Berkehan, YALÇINKAYA Tuncay 1443

Local and nonlocal strain gradient approaches for size-dependent plastic deformation
ÜNSAL İzzet Erkin, GÜNAY Enes, YALÇINKAYA Tuncay 1453

Suitability evaluation of pre-formed cruciform sample without thickness reduction for high strain values in the center of the specimen under different strains paths
MITUKIEWICZ Grzegorz, LEOTOING Lionel, WANG Guan, GUINES Dominique, GOSZCZAK Jarosław, BATORY Damian 1463

Examination of intrinsic and extrinsic size effect in thin specimens through crystal plasticity frameworks
GÜNAY Enes, BULUT Orhun, YALÇINKAYA Tuncay 1471

Considering the stiffness of the forming tools in the numerical analysis of the ironing process
OLIVEIRA Marta C., NETO Diogo M., ALVES José L., MENEZES Luís F. 1481

ESAFORM 2021 cup drawing benchmark of an Al alloy: Critical follow up analysis of its potentials
OLIVEIRA Marta C., CAZACU Oana, REVIL BAUDARD Benoit, NETO Diogo M., FROHN SÖRENSEN Peter, MA Jun, LIU Wencheng, CRUZ Daniel J., SANTOS Abel D., VAN BAEL Albert, GHIABAKLOO Hadi, HABRAKEN Anne M. 1491

Combined material model to predict flow curves of cold forging raw materials having high strain hardening exponent
ZEREN Doğuş, KOCATÜRK Fatih, TOPARLI M. Burak 1503

Modelling of yield point phenomenon in bake-hardening grade steel
DESHMANE Nachiket S., PERDAHCIOGLU Semih E., VAN DEN BOOGAARD Ton 1511

Digital twin development for the sensitivity analysis of near solidus forming process

Proceedings of the 26th International ESAFORM Conference on Material Forming (ESAFORM 2023)

The 26th International ESAFORM Conference 2023 was held in the historic city of Kraków, Poland, between 19-21 April 2023 at AGH University of Science and Technology.

ESAFORM is an association with the mission to stimulate applied and fundamental research in the broad field of material forming. Its annual conference, the International ESAFORM Conference on Material Forming, is used to achieve one of the main goals of ESAFORM: to spread scientific and technological information related to material forming within academia and industry. The most important idea of this event is to bring together researchers in the field to encourage discussion, collaboration and interchange of ideas.

ESAFORM 2023 was hosted by AGH University of Science and Technology. AGH is a modern state university that develops partner collaborations with colleges and universities in Poland, Europe, and all over the world. AGH is one of Poland's best technical universities, with approx. 18,000 students at 16 Faculties (various engineering faculties, science, sociology, business and management). AGH University widely collaborates with international scientific and industrial partners.

The ESAFORM 2023 was attended by more than 300 participants from 27 countries. During the event, approx. 240 presentations were delivered across sixteen organized mini-symposia focused on a broad spectrum of forming-related topics.

The proceedings present papers from MS01: Additive Manufacturing, MS02: Composites Forming Processes, MS03: Extrusion and Drawing, MS04: Forging and Rolling, MS05: Formability of Metallic Materials, MS06: Friction and Wear in Metal Forming, MS07: Incremental and Sheet Metal Forming, MS08: Innovative Joining by Forming Technologies, MS09: Lionel Fourment MS on Optimization and Inverse Analysis in Forming, MS10: Machining and Cutting, MS11: Material Behaviour Modelling, MS12: New and Advanced Numerical Strategies for Material Forming, MS13: Non-Conventional Processes, MS14: Polymer Processing and Thermomechanical Properties, MS15: Sustainability on Material Forming, MS16: Property-Controlled Forming.

The ESAFORM 2023 was organized under the patronage of the Dean of the Faculty of Industrial Computer Science and Modelling of the AGH University, the Mayor of the City of Kraków and the Minister of Science and Education in Poland. The conference was also co-financed from the state budget under the programme of the Minister of Education and Science called Excellent Science and by many supporting companies.

Keywords: Metal Fused Filament Fabrication, Interior Liquid Channel, Supportless Manufacturing, Material Characterization, Quality Control

Abstract. Metal Fused Filament Fabrication is an Additive Manufacturing method of manufacturing metal parts by using filaments composed of metal powders encased in plastic binders. It is advantageous for manufacturing parts with complex geometries using a wide range of materials, including stainless steel, copper, tool steel, nickel alloys, and titanium. When support structures are not required, complex parts with interior cavities can be produced using this method. In this study, interior channel cross sections for cold plates, the main elements in cooling high-power electronic units, are designed and fabricated without the use of support structures. Specimens are made of 17-4 PH stainless steel and copper using the method with two different systems. Straight and angled interior channels are fabricated separately to investigate the characteristics of supportless manufacturing and observe the sagging or warping effects on the liquid channel faces. Surface roughness and Coordinate Measuring Machine measurements are performed for parts to check if the quality requirements are fulfilled in terms of shrinkage and assembly. Density is determined for parts using the Archimedes method and compared with the porosity results obtained from Scanning Electron Microscope.

Introduction

Additive manufacturing (AM) [1] is a method that can be used to manufacture complex parts with a novel approach. Since AM has more freedom than conventional manufacturing processes it participates more in the industry day by day. With AM, most of the limitations in traditional machining can be eliminated, pushing the limits of design, creativity, and effectiveness in manufacturing. Furthermore, rapidity and affordability are other critical properties of AM that would create an innovative path for cutting-edge technologies and products.

Polymer-based materials and metal powders constitute two major branches in AM when raw materials are considered. According to the desired material and function of the parts, several AM methods can be used. Fused Filament Fabrication (FFF) is one of the most popular AM methods that extrudes material through a nozzle and constructs a part layer by layer. On the other hand, Selective Laser Melting (SLM) [2] is a process that various type of materials in powder form are distributed over a dynamic table and melted by a high-power laser to bond metal powders to each other layer-by-layer according to the 3D geometric model of the desired part. In SLM, parts can be manufactured with aluminum alloy powders, steel powders such as maraging steel, stainless steel, etc., and titanium alloys. These materials can be selected according to the application area, i.e., structural requirements, corrosion levels, thermal properties, etc. [3].

Manufacturing parts with interior channels is challenging due to the design and production criteria. By using traditional methods such as conventional welding, brazing, and friction stir welding (FSW), structures with interior channels can be produced in a limited manner. With the help of recent advancement in AM, especially in SLM, manufacturing limitations have been

decreased. Complicated, cost-effective, and functional parts can be produced as end use artifacts [4]. Manufacturing of these parts with multi-staged conventional methods reduces freedom in design. SLM can produce structures that have voids inside due to the advantageous properties of the process itself [5]. More functional and effective parts with interior channels can be obtained with parameter optimization of AM machinery [6].

As mentioned, the SLM method is highly preferable for metal part production in AM. But a newly developed process called Metal Fused Filament Fabrication (M-FFF) is an alternative approach for metal part production. Developments and studies about this alternative show that M-FFF has great potential in metal production. For example, in the study of Henry et al. [7], 17-4 PH Stainless Steel (SS) is printed via the Atomic Diffusion Additive Manufacturing (ADAM) method on a Markforged Metal X 3D printer. It is shown that the material response is sensitive to extrusion paths and porosity is measured as 3.3% with scanning electron microscopy. Rodriguez et al. [8] manufactured parts with copper using the same 3D printer. The relative density of pure copper is found to be lower than 95%, which is worse than the other two AM technologies, SLM and Electron Beam Melting (EBM). Lower electrical conductivity, yield, and tensile strength are measured in the parts compared to the parts manufactured with SLM. Galati and Minetola characterized the same process [9]. Dimensions of the green parts and the sintered parts were evaluated. Relative density was around 90% for the sintered parts, which was far lower than the published values. Finishing operations must be performed to obtain desired surface finish and accuracy.

Design and Fabrication of Parts

Test parts are designed and manufactured using the M-FFF method to perform preliminary tests and measurements. Design and fabrication steps are explained in this section.

Design.

Parameters such as material, channel type and size, cooling path, and fin location can be optimized and adjusted to increase the thermal performance of a part used in thermal applications. Cross-section of the channel affects the thermal performance of the cold plate proportionally according to its heat transfer area. Since support structures printed inside the part cannot be removed after fabrication, interior channels must be printed without support structures to obtain the desired flow. To produce desired channel geometry, the design process must be performed according to the overhang angle criterion of the selected material.

Copper is used for manufacturing with the M-FFF method, which has advantageous thermal properties for thermal applications. Since pure copper's overhang angle requirement is 50º, angles larger than 50º are chosen for supportless manufacturing of channels. As stated before, the thermal performance of different types of channel cross-sections is one of the key points. Four different channel cross-sections are designed to control the quality of the test parts. 50º of overhang angle is considered during the design of these cross sections. In the first cross-section, droplet alike cross section (CS1) is designed, which is a typical shape for supportless manufacturing. A bigger flow area is formed in the second cross-section (CS2), which is like a triangle. In the third one, a column is constituted in the middle of the cross-section (CS3) to increase the heat transfer area. In the fourth cross section (CS4), two fin structures are added throughout the channel path. Essential dimensions of cross sections are remarked in Fig. 1. Specified cross sections have different perimeters of 12.9 mm, 15.7 mm, 20.7 mm, and 23.2 mm, respectively, which will directly affect the heat transfer area of the interior channel.

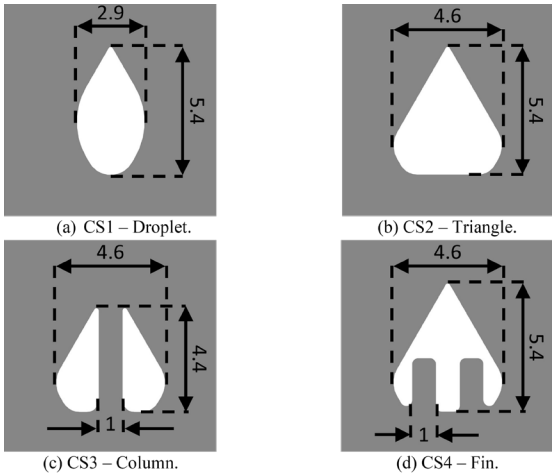

Fig. 1. Dimensions of the cross sections in mm.

Two kinds of testing parts are designed to observe the manufacturability of the cross-sections. In the first testing part (Fig. 2a), the aim is to monitor the quality of the cross-section, supportless manufacturing results, and uniformity of sintered part over a straight channel. In the second part, the same parameters are utilized for the angled channels in Fig. 2b. Also, a cylinder part is designed with 10 mm in diameter and 10 mm in height to determine the density and porosity parameters of copper.

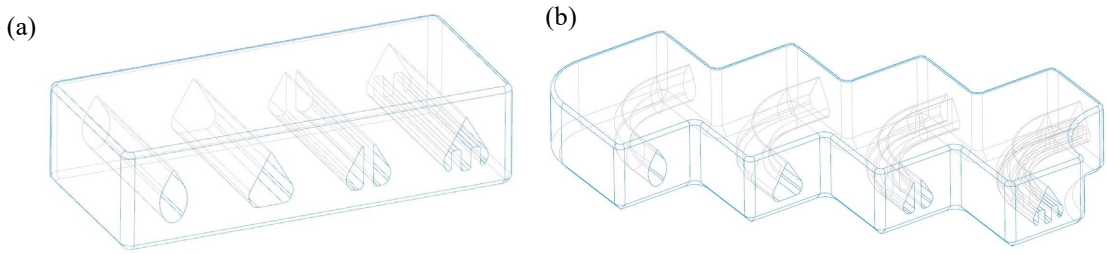

Fig. 2. Wire frames of the straight and angled test parts: (a) straight channels, (b) angled channels.

Outer regions of the parts don't include sharp corners like channel cross sections. Radii are created to eliminate sharp corners and residual stress that shows up during sintering, and to conserve the part's uniformity. In the M-FFF systems, the desired part is manufactured larger than the desired part considering shrinkage due to binder material in filaments. Printing simulation of straight and angled test parts made of copper are demonstrated in Fig. 3. Part details related to printing are noted in Table 1.

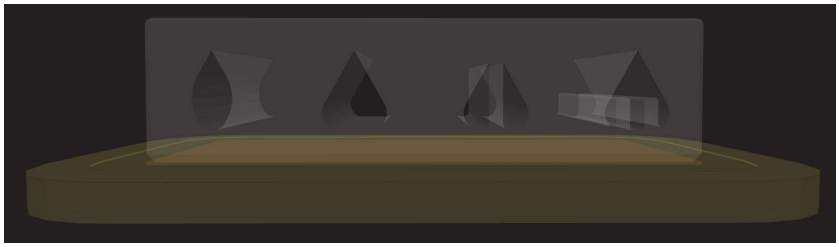

Fig. 3. Support control and layer view in the CAM software. Yellow is raft, orange is ceramic release and white is the part.

Table 1. Properties of the test parts as stated in the CAM software of the M-FFF system.

Test parts	*Straight*	*Angled*	*Cylinder*
Printed dimensions [mm]	46.4x20.9x11.9	66.2x66.2x11.9	Ø11.6x11.9
Final part dimensions [mm]	40x18x10	57x57x10	Ø10x10
Print time [hour]	7.2	13.2	2.5
Wash time [hour]	12.5	31	20
Dry time [hour]	4	4	4
Printed part mass [g]	89.6	178.2	16.3
Final part mass [g]	53.7	111	6.5
Number of wall layers	4	4	4

Fabrication.

Straight and angled interior channels are fabricated separately to investigate the characteristics of supportless manufacturing and observe the pouring or warping effects on the liquid channel faces. The fabrication process is performed using The Metal X 3D printer of Markforged. The Metal X Printer uses the ADAM method, which has a build volume of 300x220x180 mm. The printer has two nozzles, for metal material extrusion and ceramic support release material extrusion. The Metal X printer has two resolution options, 50 and 200 μm. After printing desired parts, green parts, which include both plastic and metal materials inside, are acquired Fig. 4. Green parts are subjected to a washing process to remove binders and clean parts, which results in obtaining brown parts. Then the sintering process is employed on brown parts to remove all plastic and binder materials and bond metal powders together. To obtain uniform shrinkage and prevent warping during sintering, the part is printed on a raft material, the same material as the desired part. A thin layer of ceramic powder between the green part and the raft helps to separate the parts.

Fig. 4. Green state of the manufactured straight and angled test parts.

While printing the test parts, 200 μm resolution is used. Test parts are made of 17-4 PH SS and copper. Since only 17-4 PH SS was initially available in producing company, a straight test part is manufactured with 17-4 PH SS (Fig. 5) to control the convenience of support generation on the CAM software. Then, the straight and angled (Fig. 6) test parts are produced with copper. Also, the cylinder part used in some characterization tests is shown in Fig. 7.

Fig. 5. Straight test part made of 17-4 PH SS.

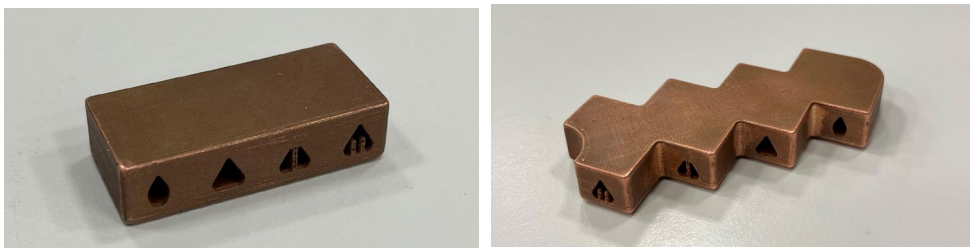

Fig. 6. Straight and angled test parts made of copper.

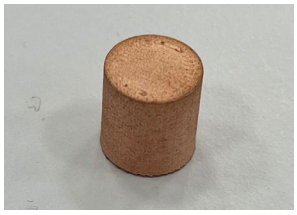

Fig. 7. Cylinder test part made of copper.

Material Characterization and Quality Control

Before material characterization and quality control tests, the test parts are inspected visually. High surface roughness at the bottom face of the test parts is observed due to the ceramic layer between the raft and the metal part. Some defects on the column structure of CS3 and the fin structure of CS4 are observed. Interior faces of the straight and angled test parts are less rougher than the internal faces of the channels manufactured with the SLM method. Measured masses of the test parts and the mass values calculated in the CAD software are stated in Table 2.

Coordinate Measuring Machine (CMM).

Dimensions of the straight and the angled test parts are measured with the Delta Slant gantry type CMM. Mainly, outer dimensions of the test parts are measured with the CMM, such as width, length, and height. For CS1 and CS2, channel height and width are measured with CMM as appropriately as possible. For CS3 and CS4, the CMM probe couldn't touch the faces of the interior channel since the probe diameter is 0.8 mm and the probe is bent while touching the interior faces. In addition, because of the deterioration of the column and the fin structures of CS3 and CS4, the risk of breaking the probe is increased. Thus, a microscope and a digital caliper are used for the measurement of these dimensions.

Table 2. Masses of the test parts.

Test part	Material	Mass in CAD [g]	Actual mass [g]	Difference
Straight	17-4 PH SS	48.9	43.0	-12.1%
Straight	Copper	53.7	54.3	+1.1%
Angled	Copper	111	112.8	+1.6%
Cylinder	Copper	6.5	6.7	+3.1%

Outer dimensions of the test parts are shown in Table 3. When the results are elaborated, it is seen that 17-4 PH SS part has more deviation than the copper counterparts in x- and y-axis, which are length and width, respectively. But in z-axis, 17-4 PH SS has a better result. Similar deviations are observed when the outer dimensions of the copper test parts are compared. For all outer dimensions in all axes of the three test parts, actual dimensions are greater than the CAD models, and much higher tolerances are obtained than the traditional manufacturing methods.

Table 3. Outer dimensions of the test parts.

	Part	*Straight*	*Straight*	*Angled*
	Material	17-4 PH SS	Copper	Copper
Width [mm]	**CAD dimension**	18	18	57
	Actual dimension	18.43	18.14	57.16
	Deviation	0.43	0.14	0.16
Length [mm]	**CAD dimension**	40	40	57
	Actual dimension	40.57	40.27	57.11
	Deviation	0.57	0.27	0.11
Height [mm]	**CAD dimension**	10	10	10
	Actual dimension	10.09	10.29	10.24
	Deviation	0.09	0.29	0.24

The results of the essential dimensions of channel cross-sections are shown in Table 4. Similar results are obtained when the straight and the angled copper test parts are compared. Dimensions for the channel height are less than the nominal dimensions. Fin thicknesses are mostly greater than the nominal dimensions, but there are some deteriorations in the fin thicknesses of both structures. These deteriorations affected average fin thickness negatively. 0.82 mm and 1.32 mm of fin thicknesses are observed when the lower and the upper limits are considered, which can be originated from spoilt extrusion, pouring, and uncontrolled shrinkage, as seen in Fig. 8.

CMM measurements of the cylinder test parts are shown in Table 5. The height of the cylinder is measured to be more than the nominal dimension. The actual diameter of the cylinder is 9.9 mm, with a 0.1 mm deviation from the designed value, which is acceptable when compared with the traditional machining methods.

Surface roughness.

Surface roughness is a surface property that determines the surface quality of a part. Summation of deviations in the normal vector of surface expresses surface roughness. Surface roughness affects the appropriateness of assembly, friction, and wear on the surface. Ra value indicates an arithmetic average of height deviation from the mean profile of the surface, and Rz value indicates the distance between the upper and lower points on the surface that is investigated. Surface roughness of the test parts is measured by the Mitutoyo Surftest SJ-400 device. Ra and Rz values are measured for upper surface, side surface, and bottom surface of the test parts and are indicated in Table 6.

Table 4. Dimensions of the channel cross sections.

	Part	*Straight*	*Angled*
	Material	Copper	Copper
CS1 Height [mm]	**CAD dimension**	5.5	5.5
	Actual dimension	5.34	5.35
	Deviation	-0.16	-0.15
CS2 Height [mm]	**CAD dimension**	5.5	5.5
	Actual dimension	5.36	5.33
	Deviation	-0.14	-0.17
CS3 Height [mm]	**CAD dimension**	4.63	4.63
	Actual dimension	4.18	4.11
	Deviation	-0.45	-0.52
CS3 Fin Thickness [mm]	**CAD dimension**	1.0	1.0
	Actual dimension	1.25	1.07
	Deviation	0.25	0.07
CS4 Height [mm]	**CAD dimension**	5.5	5.5
	Actual dimension	5.36	5.37
	Deviation	-0.14	-0.13

Table 5. Dimensions of the cylinder test part.

	Part	*Cylinder*
	Material	Copper
Diameter [mm]	**CAD dimension**	10.0
	Actual dimension	9.9
	Deviation	-0.1
Height [mm]	**CAD dimension**	10.0
	Actual dimension	10.34
	Deviation	0.34

Table 6. Surface roughness of the test parts.

		Top Surface		Side Surface		Bottom Surface	
Part	**Material**	**Ra [µm]**	**Rz [µm]**	**Ra [µm]**	**Rz [µm]**	**Ra [µm]**	**Rz [µm]**
Straight	Copper	1.95	12.01	6.07	31.65	26.02	105.3
Angled	Copper	1.33	8.3	12.33	51.5	32.79	129.2

As seen from Ra and Rz values of the straight and the angled copper test parts, results are similar to each other. When surfaces are compared, the best surface quality is obtained on the upper surface, which is close to the surface roughness values of machined parts. Regarding the side surface, Ra and Rz values are fairly average and increased compared to the upper surface since the staircase effect is more perceivable. But on the bottom surface, surface roughness is increased significantly due to the ceramic layer residuals. Due to the sintering of the part, ceramic layer becomes more powdery and spoils the quality of the bottom surface of the final part.

Archimedes method.

Undesired porosity throughout the parts decreases the strength of the material and can cause crack propagation after force is applied. Also, density must be specified for the unknown materials to calculate other material properties and obtain the mass. To gain insight into the porosity and density of parts, Archimedes method, a measurement procedure to determine the density of parts, is applied for copper cylinder test parts. This method is based on measuring the test part's weight in air and water where the part is fully submerged. This difference gives the buoyancy force, which equals the weight of the displaced fluid. Since the part is completely submerged and the volume is the same for both cases, the ratio of the density of the test part and the density of the fluid equals to the ratio of the weight of the test part and the weight of the displaced fluid. As built parts are used, which means no machining or grinding operation is applied on the cylinder specimens. Density is evaluated according to the ISO 3369 test standard. Archimedes method is performed by using Precis XB 220A device at 24ºC ambient temperature. Measured densities of copper specimens are calculated via Eq. 1; where m_a is the mass of test piece determined by weighing in air, m_w is the mass of test part in liquid, and ρ_w is the density of distilled water at 24ºC ambient temperature which equals to 0.9973 g/cm^3 as specified in the standard. After the specimens are laid on the attachment in the water side of the device, no significant air bubbles are observed on the outer surfaces of them.

$$\rho = \left(\frac{m_a}{m_a - m_w}\right)\rho_w \quad (1)$$

After measuring the masses of the test parts in air and water, respectively, density values are obtained. The average density value for the test parts is found as 8.6462 g/cm3 where the standard deviation is 0.0383. Relative density is calculated as 96.50%, where Markforged specifies it as 98% in the datasheet for copper used on the 3D printer. That means copper specimens have 3.50% porosity inside on average. Defects in the part, such as open pores or closed pores infilled with air or bubbles, can be the main reason for the difference in relative density, which increases the porosity level of the parts.

Scanning Electron Microscope (SEM) Analysis.

SEM is used to analyze the porosity of the copper parts after sectioning. Manufactured copper cylinder parts are used for sectioning; specimens are machined by a lathe and ground with 800-grit sandpaper to obtain a surface as smooth as possible. Then, the Phenom XL G2 SEM is used to observe sections of the parts in a detailed manner. Randomly distributed voids are detected during screening. Although grinding marks are observed, porous structures are obtained as separable throughout the section. There is no significant distribution of voids on the sectioned

surface according to the occurrence in some specific areas, such as around the peripheral or close to the center. Screening images show that voids are distributed randomly around the sectioned surface. Some images obtained with the SEM are demonstrated in Fig. 9. Images are subjected to image processing on ImageJ software to perform porosity analysis. 3.92% of porosity is obtained, close to the result obtained in the Archimedes method. Average area of the pores is 18.08 μm^2, which corresponds to an average diameter of 4.8 μm.

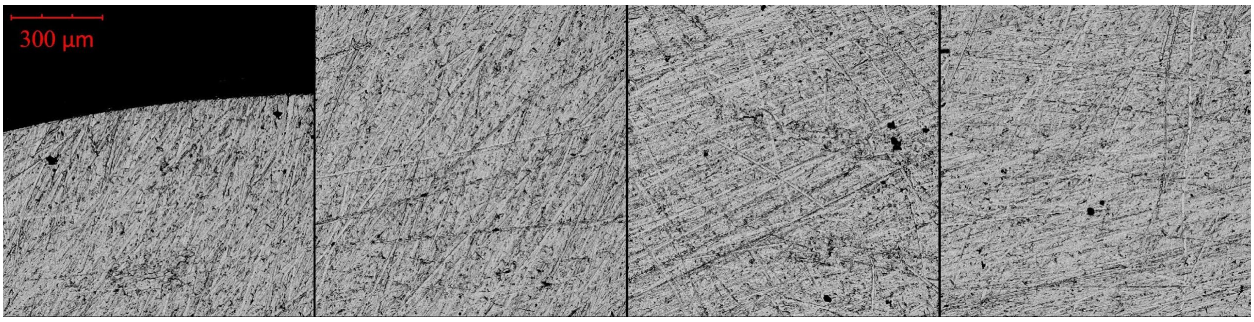

Fig. 9. Some SEM images of the cylinder test parts.

X-Ray Scanning.

X-ray imaging is performed to investigate the interior quality of the channel sections by taking images of the parts. X-ray inspection is done by using the Nordson Dage Quadra 7 instrument with an X-ray power of 160 kV. Details of the channel sections are illustrated in Fig. 10. Since the test parts subjected to X-ray scans are made of copper, details of the channel sections are obtained coarsely in observation because of the high density of copper. As a result of changing the areas of the cross sections, a blurry view around the channel occurs. The column structure of CS3 and the fin structure of CS4 is observed more precisely due to the constant and straight sections.

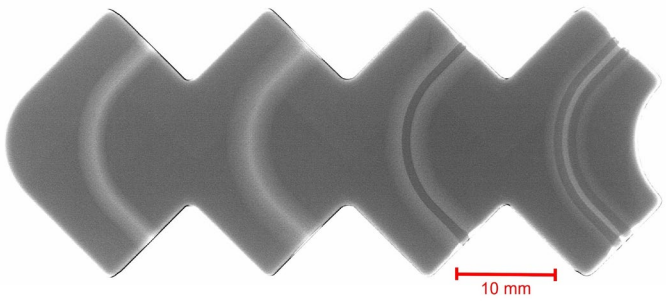

Fig. 10. X-ray inspection of the angled test part.

Summary

In this study, manufactured test parts using the M-FFF method are subjected to preliminary material characterization and quality control tests such as measurement of *surface roughness*, determination of dimensional accuracy with the *CMM*, scanning of parts with the *X-ray* device, calculation of the density with the *Archimedes method* and determination of porosity within the part with the *SEM analysis*. According to the CMM results, dimensions of the test parts are mostly greater than the nominal dimensions. For overall dimensions of the channel sections, mostly smaller dimensions are measured. Surface roughness results are significantly satisfying for upper and side surfaces compared to the SLM method. Thus, the M-FFF method can be used for the parts

that include liquid paths in terms of pressure drop. The result of X-ray scan shows that a device with more powerful X-ray source must be used to obtain images with finer details. Obtained results of density and porosity are lower than the datasheet results, which means that the manufactured parts must be qualified in terms of strength and leakage according to the application area. Despite these, the M-FFF method can be used for fast prototyping due to its speed, price, and modularity. As future works, process parameters and product range may be improved for the M-FFF method.

Keywords: FDM, Modeling, Additive Manufacturing

Abstract. The additive manufactured parts can be made by the use of suitable layer thicknesses of the polymer in order to respect the requirements of a refined geometry and of a surface appearance of the physical object that should be as similar as possible to the original CAD model. An other important variable is the digital datum that can represent a key variable of the realization procedure. The methodology proposed and followed in the present investigation got the objective to get a physical model, through the information obtained by a 3D scanning device, taking into consideration not only the digital treatment but also the building direction to guide the FDM layer deposition in order to realize the required surface appearance. The profiles of the specimen in the digital environment were compared to each other before realizing. The physical object obtained after digital treatment was similar to the one obtained by the original CAD.

Introduction

The prototyping is very useful in the initial phases of the project in order to verify some important features of the object to be definitively realized. In particular those related to the concept, geometrical and ergonomic characteristics. Sometimes such prototypes in particular for polymers got also properties very similar to those obtained by other technologies. For example injection molding widely used in fields when too much resistance values are not required.

The quality of the manufactured component is a function of the technology utilized and, in the sector of the additive manufacturing, on the type of technique among FDM, SLA, polyjet, etc. In particular the layer thickness and the deposition strategy, also represented by the building direction, are the main variables of the manufacturing process.

In addition the digital information for model realization represents an other variable affecting the process. In general the information to the 3D PRINTER is given by the Computer Aided Design and the geometrical information translated into some working formats like those based on the Standard Triangulation Language initially applied on STereoLithography some tens of years ago. Such formats are used by some researchers [1] and by the authors in previous works [2]. But, the input information can be also supplied to the management software of the machine unit using directly control nodes of the realized elements such as curves, surfaces, solids and composition of them [3]. The problem is represented by the amount of information sent into the machine software to generate the control instructions. That means time consumption and queues in processing digital data with related errors in loading and redundant instruction generation.

For this reason the STL represents a simplification in terms of digital information due to the approximation of the surface of the object to be realized with a surface characterized by an elevated number of triangles connected to each other by their vertices or nodes. The solid appearance of the digital object is represented by the versus of surface normal of each triangle. The external versus means a solid object while the internal versus a cavity or hole. Under these conditions the file format and the approximation to the original digital geometry play a key role in the precision of the input file in terms of geometry and then on the physical object respect of requirements [2-4]. Of course smoother and more accurate is the surface of the object better the STL approximation

is. The improvement can be in general obtained managing the approximation tolerance in terms of the distance between the surface of the triangle to the original surface of the object and/or in terms of the number of triangles of the approximating surface.

The problem is represented by the description of the approximating surface when the geometry is detected by some 3D SCANNERS or similar techniques by which is possible to acquire the entire surface of the physical object or part of that. The technique of acquisition naturally determines the quality of the digital information with some musts represented by reduced setup and detection times. Normally but not always the acquired information is represented by a cloud of nodes that can be translated in the different available formats [5]. STL is one of them able to represent with a generally low amount of storing memory the acquired surface of the physical object. Such technique is very useful when some digital archives need to be realized about already existing geometries or when the realized geometry needs to be compared with original one in the computer aided environment [6,7]. Such procedure is very useful when simple geometries are detected while still represents a newness for those geometries characterized by complicated structural elements such as double curvature surfaces [6]. In particular when they are connected with planar ones. When using the described tools some computing phases need to be performed before comparing the detected with the original ones. The level of computing must be of course as high as high is the building performance of the RP machine used [8]. In particular the building strategy represents the key variable to tune other than the layer thickness in order to get a physical model respecting given geometrical requirements.

Considering that a methodology is proposed in order to evaluate the building direction variable in obtaining a FDM physical object, starting from the digital data acquired by a 3D SCANNER on photopolymerized physical model, as similar as possible to that given by the same technique when using original information. A compact FDM machine was used for the purpose with a digital input supplied with the STL format. The digital model was treated in order to increase the quality of the geometry up to the one of the original STL. It was observed that different digital treats are required when different building directions are considered.

Methodology, Digital Treatments and Experiments

Methodology.

The present investigation aims at proposing and applying a methodology to manage the digital data points given by a 3D scanning of an high quality complex surface made in a UV photopolymer shown in Fig.1. In order to use those as input for realizing a physical object with a surface as similar as possible to the one of the original. The acquired geometry was refined in its surface and in the connection between the complex part of that and the planar one. This acting on lines and surface elements and on the number and typology of triangles composing the approximating STL. The main variable of the investigation is represented by the building direction when reproducing by FDM the digital models with and without treatments. The methodology is reported in Fig. 2.

Digital treatments.

The data cloud obtained by the 3D scanner using LED-CMOS systems in order to get the shape of the physical object were computed by CAD in different ways, some of them reported in a previous research of the authors [2] in order to solve the problem of the connection between the complex part of the component represented by the dome and the planar part of that represented by the basis. Fig. 3 shows the particulars of the photopolymer model acquired as digital information. The digital treat was made considering a planar basis of 5.5 mm in order to include the defective scanned zone of the component and then rebuilding completely the basis with a thickness of 5.2 mm. After that the digital model was treated in the STL format improving the number of triangles approximating the CAD surface and applying some smoothing sequences using the Materialise software.

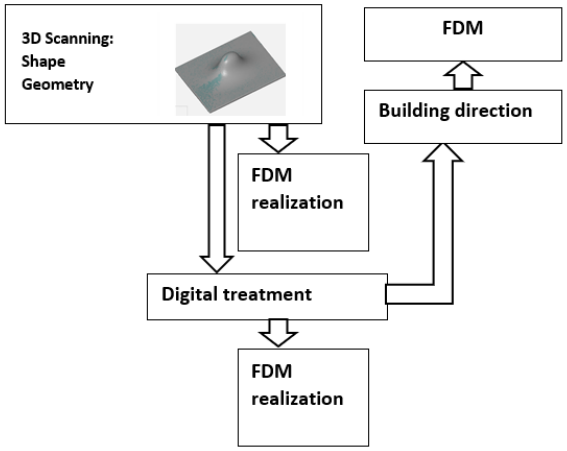

Fig. 2. Methodology.

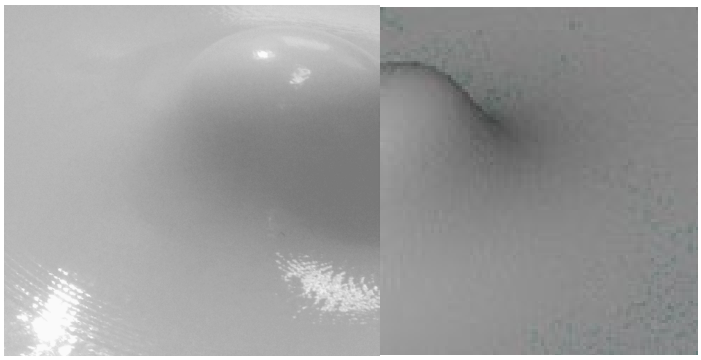

a) b)

Fig. 3. Particulars of the physical photopolymer (a) model and of the STL (b) obtained by the scanning device.

CAD profiles of the shape.

The profiles captured on the original shape in the CAD environment were reported by two equations.

The equation of the profile of the original CAD model in the longest direction:

$$y = -8E\text{-}07x^6 + 6E\text{-}05x^5 - 0.0012x^4 - 0.0091x^3 + 0.4423x^2 - 0.8688x + 0.549 \quad (1)$$

and the equation of the profile in the shortest direction:

$$y = 2E\text{-}08x^6 - 4E\text{-}06x^5 + 0.0002x^4 - 0.003x^3 - 0.0234x^2 + 0.0015x + 24.554 \quad (2)$$

where y represents the axis along the height of the dome and x the one on the basis in the longest and in the shortest directions respectively.

All of the digital models were realized by FDM after the comparison of the original CAD profiles with STL like shown in Table 1.

Table 1. CAD and STL main profiles.

CAD	STL
Original profiles by Eq. (1) and Eq. (2).	Profiles given by CAD. Profiles given before digital treatment. Profiles given after final digital treatment.

Realization of the physical objects.

The manufactured components were realized by a FDM compact machine taking into consideration the building direction. In one specimen the building direction was parallel to dome axis of the model while in the other the building direction was perpendicular. A 0.2 mm thickness layer was used with a filament in PLA material and a temperature of the extruder between 215 and 220°C selected. The scanning velocity of the extruder was 100 mm/s during working and 150 mm/s in idle movements. The comparison among the different physical models realized was made taking into consideration the CAD information, that without and with digital treatment along different building directions.

Results and Discussion

Digital treatments.

They were made in terms of the rebuilding of some reference nodes, lines and surfaces with related control points normally in the critical connections between the complex part of the model and the less complicated part represented by the planar basis. Such problem was already reported by the authors in a previous work of some of them [2]. Those are zones in which the building in the CAD environment requires the due attention and the digital data obtained by the scanning devices need to be always verified in order to be sure that the connections be always ensured. The lack means continuity solutions in the surface of the digital and subsequently of the physical models over those typical of scanning devices [8] and of the 3D printers [9].

Some of these problems may be corrected directly acting on the control points as described preserving the cloud points of the complex part when possible. The STL should be a subsequent way to simplify the problem by considering a surface alone able to approximate the whole mathematical elements of the model prior and after the treatments. The connection problems sometimes evidenced their effects in the physical realized models directly and in those realized by digital information obtained by the scanner. In Fig. 3a) the light waviness at basis of the photopolymerized model is evidenced and captured by the 3D scanning and sometimes amplified depending on the acquisition time, on the device and on some diffusive modes of the LED based light used by the SCANNER (fig. 3b). In Figs. 4a) and 4b) the comparison between 3D scanned STL after basis rebuilding and original STL is reported. After triangle refinement and smoothing the comparison can be observed in figs. 5a) and 5b). The improvement of the surface of the digital model was made using the Materialise software by which a further discretization of the triangulation representing the approximation to the cloud surface detected by the scanning device is made. In that way the dome surface is better described and the connection with the rebuilt plane improved.

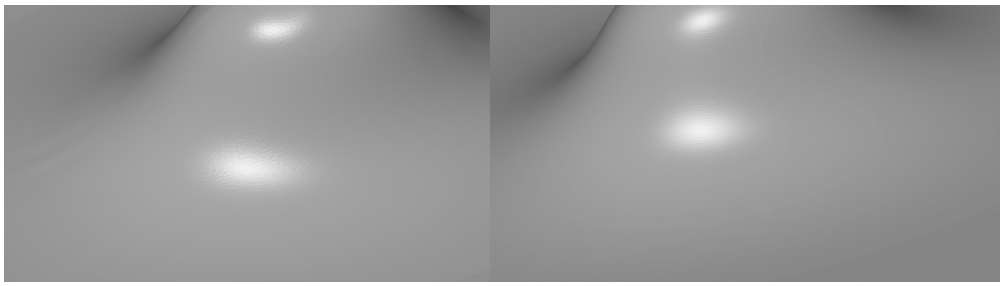
Fig. 4. STL 3D scanned surface (a) and the STL obtained directly by the original CAD (b).



a) b)

Fig. 5. STL 3D scanned surface after digital treatments (a) and STL obtained directly by the original CAD (b).

Profiling.

The different profiles were computed in the CAD environment supported by image analysis techniques and then compared. The equations of the two semi-profiles are reported in the previous paragraph.

The comparison between the STL profile obtained directly by the CAD original model, the profile plot of points of the original CAD model and the STL obtained by the digital rebuilt model is made in the Fig. 6. An excellent approximation to the original profile is obtained in the STL standard.

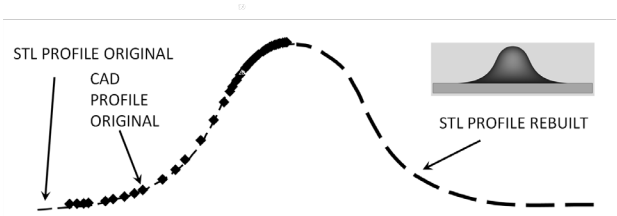


Fig. 6. Comparison between different profiles obtained along one direction of the object: CAD, STL and STL after digital rebuilding.

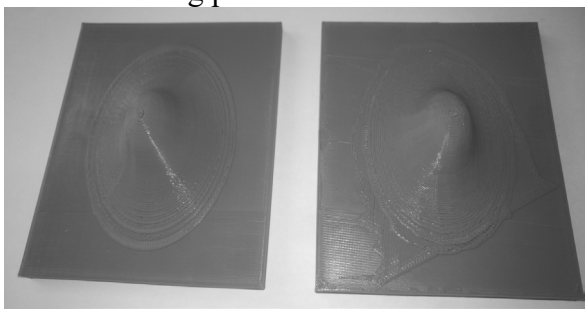
Realization of the FDM physical objects.

In Fig. 7 the comparison between the FDM models realized directly by the original CAD and that generated by the scanning device with the building direction parallel to the dome axis is shown. The problem at the basis is clearly observed. When the building direction is perpendicular to the dome axis the FDM produces its best performance and then the continuity solutions appear evidenced and the difference highlighted as in Fig. 8. In both the cases the waviness detected by the 3D SCANNER is copied on the FDM model reporting not only the original information of the

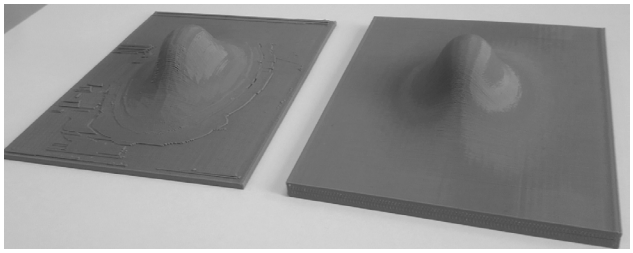
model geometry but also that of the physical photopolymer model from which the digital data were initially acquired. The connection problem to the basis due to the difficulty to catch at the same time the complex part of the model and plan part exists in that phase.

In Fig. 9 the FDM physical objects were realized from digital information detected by the 3D SCANNER after some reported treatments in order to allow the connection between the dome and the planar surface. By such operation the planar level is improved and the connection rebuilt. Such improvement appears able to describe the physical model when the building direction is parallel to the dome axis. But some continuity solutions still persist when the building direction perpendicular to the dome axis is applied as can be seen in Fig. 10. It means that the configuration perpendicular to the building axis requires further digital treatments in order to get a geometry as similar as possible to the one obtained when the original CAD is considered. Further corrections of the geometrical elements, the increase in the triangulation density as well as the smoothing of the STL surface permit the increase in the quality of the surface appearance of the FDM physical object like shown in Fig. 11. In other words the profiles of Fig. 6 are correctly reproduced on the realized models. In this way the FDM physical object appears similar to the surface of the original FDM without the need to plan a machining phases.



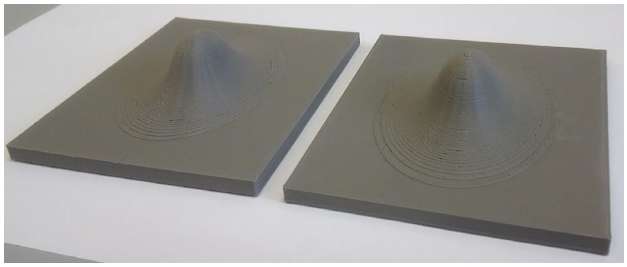
a) b)

Fig. 7. Comparison between FDM physical object realized by the CAD original data (a) and that directly obtained by the 3D scanning device information (b) with building direction parallel to the dome axis.



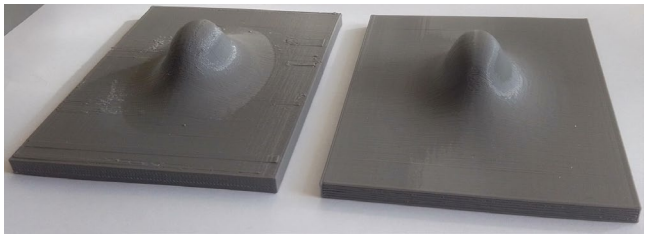
a) b)

Fig. 8. Comparison between the physical object obtained by the digital data directly given by the 3D scanning device (a) and model made by FDM considering the original CAD data (b) with building direction perpendicular to the dome axis.



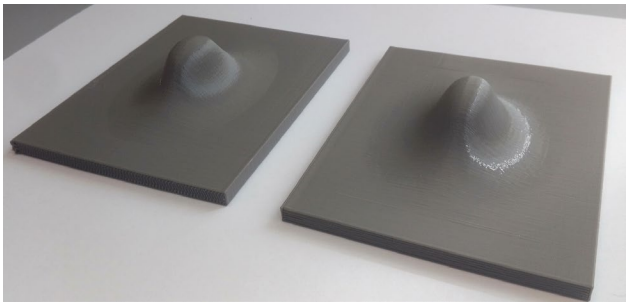
a) b)

Fig. 9. Comparison between the FDM model obtained after digital treatments (a) and that given by the original CAD (b) with the building direction parallel to the dome axis.



a) b)

Fig. 10. Comparison between the FDM model obtained after the digital treatment (a) and that given by the original CAD (b) with the building direction perpendicular to the dome axis.



a) b)

Fig. 11. Comparison between the FDM model obtained after further digital treatment (a) and that given by the original CAD (b) with the building direction perpendicular to the dome axis.

The results can be reported in terms of the dome height. In particular the realized FDM object obtained by the 3D SCANNING device with the building direction perpendicular to that gives an height of 20.52 mm with a thickness basis of 2.63 mm. The rebuilt model without the final digital treatment is about 23.68 mm while the one obtained after is about 23.6 mm. The original data get a FDM model with a dome height of about 23.79 mm.

Such results are very useful in particular when these methodologies, as already reported by other authors [10,11], need to be applied in a manufacturing system.

Summary

The investigation aims at defining the best profile shape of the STL model under given conditions taking the dome reference from a 3D SCANNED one and by applying different digital treatments in the computer aided environment in order to get a physical result as similar as possible to that obtained by the original CAD information. In the realization of the FDM models the building direction variable is considered.

First of all the basis of the STL model was rebuilt and the connection with dome properly managed. But such digital treatment was able only to permit the realization of a FDM physical model with a building direction parallel to the dome axis. With a further treatment consisting mainly in a heavy refinement of the triangles approximating the cloud points a smoother surface of the dome than before was obtained. The final treatment got a profile very close to the STL of the original CAD model as shown by the comparison of them and to the original CAD information described by two equations obtained through the longest and shortest sides of the model.

Finally, the comparison between the two main FDM physical models, in particular the one obtained directly by the original CAD and the other one given after the digital treatment of 3D scanned data allows to state that they are similar to each other. Under the conditions of the present investigation when treating polymers the building direction represents the key variable for the obtaining physical surfaces respecting requirements. To do that many digital treatments are required.

Keywords: Sheet Metal Lamination, Laser Metal Deposition, Deep Drawing Tools

Abstract. The rough surface finish caused by the stair step effect is the major drawback in the application of sheet metal laminates in rapid tooling. The application of laser metal deposition (LMD) and subsequent post-processing (milling, ball burnishing, and laser polishing) to reduce the stair-step effect in hybrid additive metal laminated forming tools was recently presented. In the present study, the energy consumption and manufacturing time of the hybrid process are compared with the conventional (milling plus hardening by heat treatment) as well as with full LMD and milled components. The hybrid process requires significantly less energy and manufacturing time compared to the LMD components. Since the surface hardness is sufficient for tooling in the hybrid process, no additional hardening is required, also resulting in a shorter manufacturing time and lower energy relative to the conventional method (depending on the part mass, a minimum of 29% is faster). The optimal sheet laminate combination based on the economic criteria for the tool with a radius of 6 mm is presented.

Nomenclature

Symbol	Unit	Description	Symbol	Unit	Description
E	MJ	Energy consumption	C_L	mm	Cutting length
a	mm	Length of square part	X	-	Mass ratio of final part to the initial
d	mm	Diameter of cylindrical hole	T	s	Process time
c	-	Ratio of thickness to length	ρ	kg/mm^3	Density
t	mm	Sheet thickness	SEC	MJ/kg	Specific energy
n	-	Number of sheet layers	Q	mm^3/min	Material removal rate
m	kg	Mass of part	f	mm/min	Feed rate
a_e	mm	Radial depth of cut	P_L	W	Laser power
V	mm^3	Volume of stair step	a_p	mm	Axial depth of cut

Introduction

Metal sheet lamination or layer laminate manufacturing (LLM) as a rapid tooling method was patented for show molds in 1942 by Hart F.V [1]. For several years, different industries, especially the automotive industry, showed high-interest beginning in the 1980s [2]. However, the main drawback of the LLM method is the segregated surface, named the stair step effect, due to the stacking of sheets with different thicknesses to build a defined radius or angle. There are various methods for reducing the stair step effect in forming tools made of sheet metal laminates. The state of research in this area (use of a flexible intermediate layer [3], chamfering the corner of the laminae [4], machining of the laminae [5], ball burnishing [6], brazing or soft soldering [7]) is

already summarized [8]. In [8], the stair step effect was reduced using laser metal deposition (LMD). Based on the DIN EN ISO/ASTM 529000 [9], direct energy deposition (DED) is a subcategory of the additive manufacturing (AM) process in which concentrated energy is applied to the filling material. LMD is also a DED process in which a laser is used as an energy source and metal powder as the filling material. The main advantage of the application of LMD is that the manufactured tool does not require an additional hardening process. The local heating of the surface during LMD, compared to heating the entire part for hardening in conventional manufacturing, can result in significant energy savings. In [8], three post-processing processes (milling, ball burnishing, and laser polishing) have been explored to produce an improved surface. By milling, the extra material is machined from the deposited surface. In ball burnishing, the surface roughness is improved by plastic deformation. Laser polishing involves re-melting the surface with a laser (without additional powder) to improve the roughness. It is shown that the post-processing by ball burnishing can improve the tool's hardness; however, the best surface roughness is achieved by milling.

In the following, the economic aspect of the introduced hybrid additive laminated tooling concept is compared with the conventional method (milling followed by hardening) and with the fully deposited part by LMD, which is milled afterward to improve the surface roughness. In addition, an approach to identify the optimum sheet combination is provided.

Procedure and Methodic

Sheet lamination offers the possibility of combining different sheet thicknesses. As shown in Fig. 1, the number of possible sheet combinations with three sheet thicknesses 0.5, 1, and 2 mm increases exponentially with increasing radius. The selection of the proper combination is a multi-objective optimization depending on the required tool strength, energy consumption, cost, and placement of functional elements, e.g., sensors, heating, or cooling channels. This study will lower the number of possibilities based on energy consumption and manufacturing time.

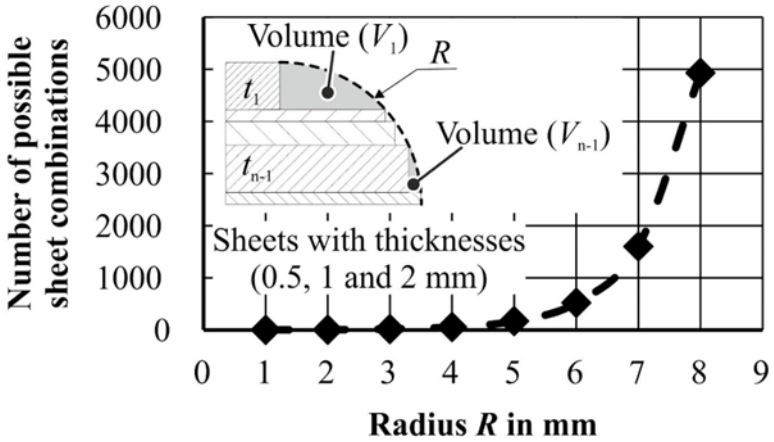

Fig. 1. Number of the possible sheet combinations for different radii with 0.5, 1, and 2 mm sheet thicknesses.

For systematic evaluation, it is necessary to define the process route of each method. As shown in Fig. 2, the hybrid additive laminated tooling starts with manufacturing the sheets. The sheets are laser-cut in different thicknesses and stacked based on the proper order. Next, the stair step areas (volumes) are filled with LMD, followed by post-processing.

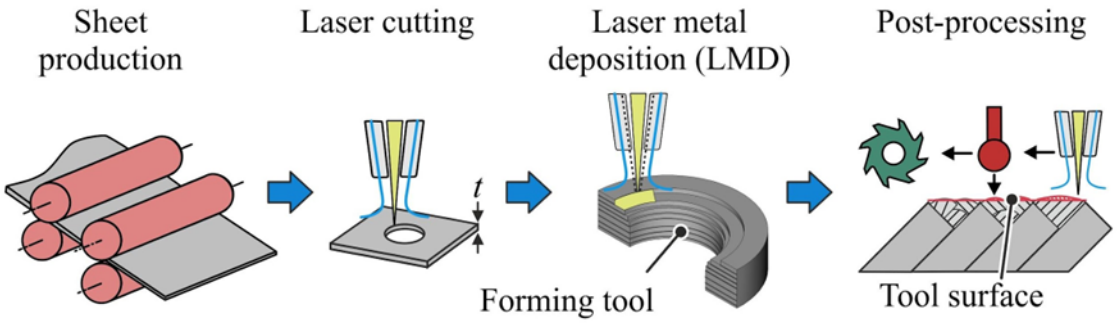

Fig. 2. Process route of hybrid additive laminated tooling.

For the calculation of the total energy consumption of hybrid additive laminated tooling (E_T^H) as shown in Eq. 1**,** the energy of sheet production (E_S), cutting energy by laser (E_C), required energy for the production of powder (E_P), and deposition (E_D) during LMD, and finally, the energy consumption during post-processing (E_{PP}) are considered.

$$E_T^H = E_S + E_C + E_P + E_D + E_{PP} \quad (1)$$

For the energy consumption of the conventional method (E_T^C), only the production energy for bulk material (E_B), milling (E_M), and hardening (E_H) are studied, as seen in Eq. 2:

$$E_T^C = E_B + E_M + E_H \quad (2)$$

To calculate the energy consumption of a fully deposited part by LMD with milling (E_T^{LMD}) as post-processing, the powder production (E_P), deposition (E_D), and milling (E_M) energies are taken into account (see Eq. 3).

$$E_T^{LMD} = E_P + E_D + E_M \quad (3)$$

For the estimation of the production time (T) for each process (hybrid, conventional, and fully LMD), the manufacturing time of the sheet, bulk material, and powder production are not considered.

Hybrid additive laminated tooling.

Since the manufacturing energy and time for a systematic evaluation strongly depend on the part geometry, it is assumed that an academic square part with length a and with a cylindrical hole with diameter d has to be manufactured (Fig. 3a). The ratio c is defined as the thickness of the part as a fraction of the length. In the hybrid process, it is assumed that the part is made from n sheets with a constant thickness t (Fig. 3b). The same geometry is used for the calculations for the conventional and fully LMD parts.

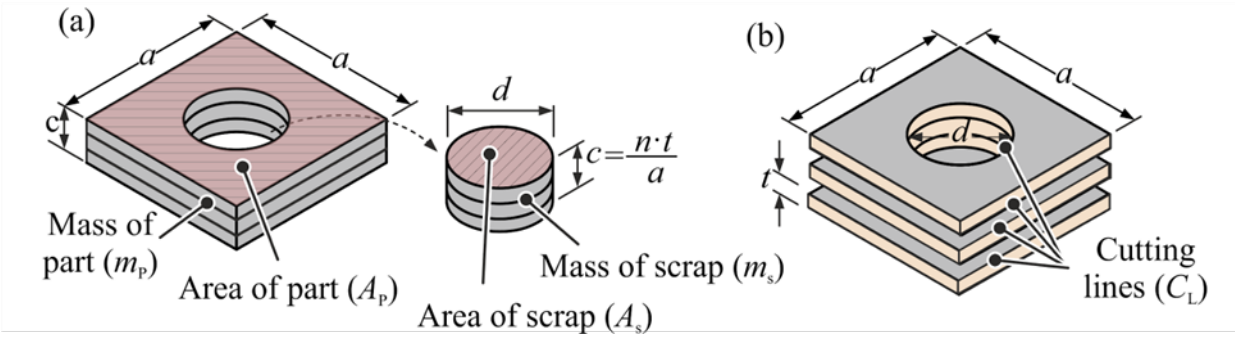

Fig. 3. (a) Assumed geometry for calculations (b) cutting length (C_L).

The mass ratio (X) is defined as the mass of the final part (m_P) to the mass of the initial state ($m_P + m_s$) as shown in Eq. 4. By taking into account that all the used sheets have an equal density (ρ), the mass ratio (X) can be defined as a ratio of final part surface (A_P) to the total initial surface ($A_P + A_s$), as illustrated in Fig. 3a. It yields the relation of the length of the square (a) and hole diameter (d) as provided in Eq. 4.

$$X = \frac{m_P}{m_P+m_S} = \frac{A_P}{A_P+A_S} = 1 - \frac{\pi d^2}{4a^2} \Rightarrow d = a \cdot \sqrt{\frac{4(1-X)}{\pi}} \tag{4}$$

Considering volume constancy, the length of the square (a) can be determined as:

$$c \cdot a^3 = \frac{m_P}{X \cdot \rho} \Rightarrow a = \sqrt[3]{\frac{c \cdot m_P}{X \cdot \rho}} \tag{5}$$

For the determination of the energy required for laser cutting, it is required to compute the cutting length (C_L) of sheets (Fig. 3b). The cutting length (C_L) is the sum of the perimeter of the square and the hole as provided in Eq. 6. Replacing the Eq. 4 and 5 in the Eq. 6 yields the cutting length (C_L) as a function of the material yield ratio (X), density, sheet thickness, and final part mass:

$$C_L = (4a + \pi d)n \; n = \frac{ca}{t} \Rightarrow \; (4a + \pi d)\frac{c.a}{t} = \frac{1}{4t}\left(\frac{c \cdot m_P}{X \cdot \rho}\right)^{\frac{2}{3}} \cdot \left(\sqrt{4\pi(1-X)} + 4\right) \tag{6}$$

The cutting length is calculated for three sheet thicknesses (Fig. 4a). It is concluded that the thinner the sheet thickness, the higher the cutting length for the same final part mass. For calculating the energy required for the laser cutting, the cutting information of the laser machine, model TC1005 from the company Trumpf, is used. Three steel sheets with a thickness of 0.5, 1.0, and 2.0 mm are used for the calculations. The feed rate for cutting the sheets with thicknesses 0.5, 1.0, and 2.0 mm are 9, 8, and 5 m/min, respectively. A laser power of 1700 W is required for cutting 0.5 and 1.0 mm sheets and 1200 W for 2 mm sheets. The total energy consumption of the machine for laser cutting the 0.5 and 1.0 mm sheets equals 42 kWh and 38 kWh for 2 mm sheets [10]. The cutting time can be calculated based on the cutting length (C_L) and feed rate during cutting. Afterward, the total energy consumption for laser cutting (E_C) can be calculated for different steel sheet thicknesses, as shown in Fig. 4b, assuming the density of steel (ρ) is 7900 kg/m^3. It can be seen that for the same final part mass, the thicker sheet thickness requires lower energy for cutting.

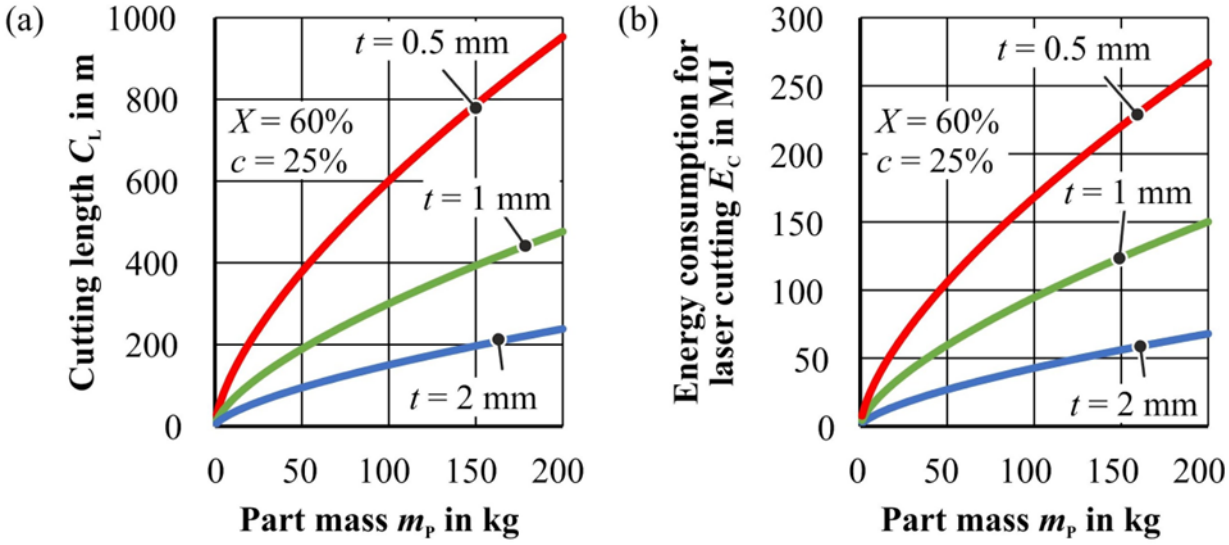

Fig. 4. (a) Cutting length, C_L (b) cutting energy with TC1005 machine.

Based on [11], the production of a 1 kg sheet requires 19.37 MJ of energy. Therefore, the required energy for sheet production (E_S) is equal to 19.37 [MJ/kg] · ($m_P + m_s$). The energy required for the production of the powder differs depending on the production method. According to [12], for producing the powder by gas atomization, 24.48 MJ/kg of energy is needed. In the hybrid method, it is assumed that the mass of the sum of the stair step volumes ($m_{Step} = \rho \cdot \sum_{i=1}^{n-1} V_i$), see Fig. 1, is 1% of scrap mass (m_S), i.e. the required powder by laser metal deposition (LMD) is 1% of m_S. The required powder energy production (E_P) for hybrid additive laminated tooling is $E_P = 0.2448$ [MJ/kg] · m_S. The deposition energy consumption with Lasertec 65 3D machine from the company DMG MORI as reported by [13], is 76.11 MJ/kg. By considering 1% of the scrap mass, the deposition energy for the hybrid method is $E_D = 76.11$ [MJ/kg]· ($0.01 m_S$) or $E_D = 0.7611$ [MJ/kg] · m_S.

Since only the sheet thickness of 1 mm will be considered in the rest of the calculations, it is assumed that the track distance during the post-processing is 1 mm and that for ball burnishing and laser polishing, the tool moves through the whole cutting length (C_L). The essential energy required for ball burnishing is considered based on the Ecoroll hydraulic aggregator HGP6.5, which is $E_{Ep.}^{B} = 3\,kW$. For laser polishing, the laser power during the polishing is considered as essential energy consumption ($E_{Ep.}$), where $E_{Ep.}^{L} = 1000$ W. The energy required for post-processing for the hybrid method (E_P^H) by ball burnishing and laser polishing is $E_P^H = T_P^H \cdot E_{Ep.}$, where T_P^H is the post-processing time. To compute the energy required for milling, the specific energy of finishing (SEC_F) from [14] is used, i.e. $SEC_F = 5.79$ MJ/kg. It is assumed that 20% of the deposited material (1% of m_S) needs to be milled. Therefore, the required energy is:

$$E_{PP}^{Hybrid} = 0.2 \cdot 0.01 \cdot m_S \cdot SEC_{Finishing} = 0.01158\,[MJ/kg] \cdot m_S \quad (7)$$

To determine the milling time, the radial depth of cut (a_e) and axial depth of cut (a_P) need to be defined to calculate the material removal rate $Q = f \cdot a_P \cdot a_e$ where f is the feed rate of the cutting tool. Therefore, the milling time is calculated as $T_M^H = \frac{Q_F^H}{0.01 \cdot m_S}$.

Conventional method.

For the production of bulk materials per kg, according to [15], 17.73 MJ of energy is required. This value is used to calculate the total energy required for producing bulk material in the conventional method:

$$E_{Bulk} = 17.73\ [MJ/kg] \cdot (m_P + m_s) = \frac{17.73}{X} \cdot m_P \quad (8)$$

The milling process is divided into two steps: rough milling and finishing. The specific energy (SEC_R) for rough milling is 0.848 MJ/kg [14]. The 99% of the scrap mass must be rough-milled, and the rest should be machined by finishing. The total energy and production time for the milling of the conventional method are calculated as shown in Eq. 9:

$$E_M^C = \left(0.99 \cdot SEC_R + 0.01 \cdot SEC_F\right) \cdot m_s = 0.8974 \left[\frac{MJ}{kg}\right] \cdot m_s \; and \; T_M^C = \frac{Q_F^H}{0.01 \cdot m_s} + \frac{Q_R^H}{0.99 \cdot m_s} \quad (9)$$

The energy consumption of the hardening process is significantly dependent on the type of hardening and furnace type. In this study, the furnace N120/85 HA from the company Nabertherm with an energy consumption of 13.6 kWh, is used for the calculations. It is assumed that the part will be quenched at 850 °C. According to [16], the required time for heating a part with a thickness of 80 mm is one hour. Considering the thickness of 80 mm and the thickness-to-length ratio (c) of 25% (see Fig. 2a), the length of the square (a) is calculated to be 320 mm. For steel, the corresponding weight will be approximately 64.7 kg. Considering the hour of homogenizing time, the required energy and time are evaluated as shown in Eq.10. Here, it is considered that during the homogenizing, the furnace works with 50% of its maximum power. It is noted that 1 kWh equals 3.6 MJ.

$$E_H^C = \frac{\left(13.6 + \frac{13.6}{2}\right) kWh}{64.7\ kg} \cdot 3.6 \frac{MJ}{kWh} \cdot m_{P.} = 1.14 \cdot m_P \; and \; T_H^C = \frac{2\ h}{64.7\ kg} \cdot m_P = 0.031 \cdot m_P \quad (10)$$

Fully deposited part (LMD plus milling).

For calculating the energy consumption of fully LMD parts followed by milling, the extra powder is required to be considered. This powder is waste material discharged during the positioning of the nozzle. This value is assumed as 20% of the final part mass. With this, the energy consumption for the powder production for the fully LMD part and the required energy during the deposition are:

$$E_P^{LMD} = 24.48 \left[\frac{MJ}{kg}\right] \cdot (0.2 \cdot m_P) = 4.896 \left[\frac{MJ}{kg}\right] \cdot m_P \; and \; E_D^{LMD} = 76.11 \left[\frac{MJ}{kg}\right] \cdot m_P \quad (11)$$

Considering the 1% of the part mass that needs to be milled, the required energy and time for the conventional method are:

$$E_M^{LMD} = 0.01 \cdot SEC_F \cdot m_{P.} = 0.0579 \left[\frac{MJ}{kg}\right] \cdot m_P \; and \; T_M^{LMD} = \frac{Q_F^{LMD}}{0.01 \cdot m_P} = \frac{\rho \cdot f \cdot a_p \cdot a_e}{0.01 \cdot m_P} \quad (12)$$

Results and Discussion

The energy consumption and manufacturing times are calculated based on the equations provided in the previous section and considering the following process parameters for the different processes in Table 1.

Table 1. Process parameters for milling, laser polishing, and ball burnishing.

Process	Laser polishing	Ball burnishing	Milling	
			Rough	Finishing
Feed rate f in [mm/min]	1000	900	600	200
Laser power P_L in [W]	1000	-	-	-
Radial depth of cut a_e in [mm]	-	-	25	25
Axial depth of cut a_p in [mm]	-	-	2	0.25

The total energy consumption for all three processes is shown in Fig. 5. It shows that the fully deposited method (LMD plus milling) has a very high energy consumption compared to the hybrid and conventional methods. It can be seen that there is no significant difference between the hybrid and the conventional method. Also, there is no significant difference between the different post-processing methods since the post-processing portion of the total energy consumption of the hybrid method is insignificant.

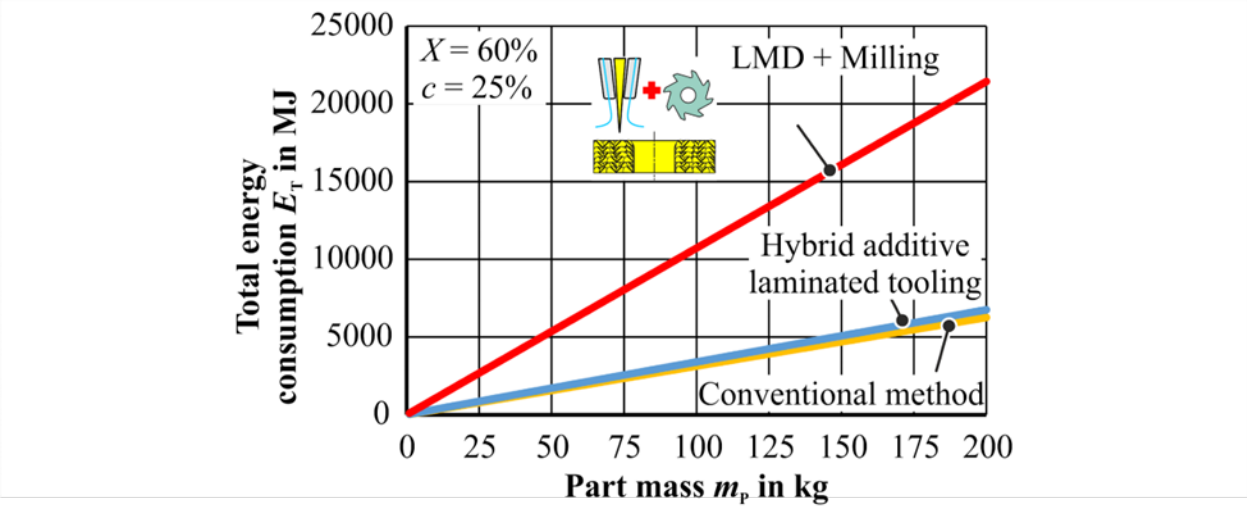

Fig. 5. Comparison of total energy consumption between hybrid, conventional, and fully LMD with the milling method.

The calculated manufacturing time for all three processes in Fig. 6a shows that fully deposited parts require a very high manufacturing time compared to the hybrid and conventional methods. The conventional method has a higher manufacturing time, even without considering the part transportation for hardening, than the hybrid method, as shown in Fig. 6b.
Between the different post-processing methods, the milling shows a shorter time; however, the difference between ball burnishing and laser polishing is insignificant. Since the processing time highly depends on feed rate, track distance, and tool diameter, the order of post-processing would be different. It should also be considered that the advantage of using laser polishing as post-processing is saving the cost of new tools and programming time. Also, laser polishing is a contactless process, so there is no tool wear. Finally, the focal distance of the laser allows the treatment of limited access areas. However, as mentioned, the main drawback is the reduction of the hardness of the treated surface [8].

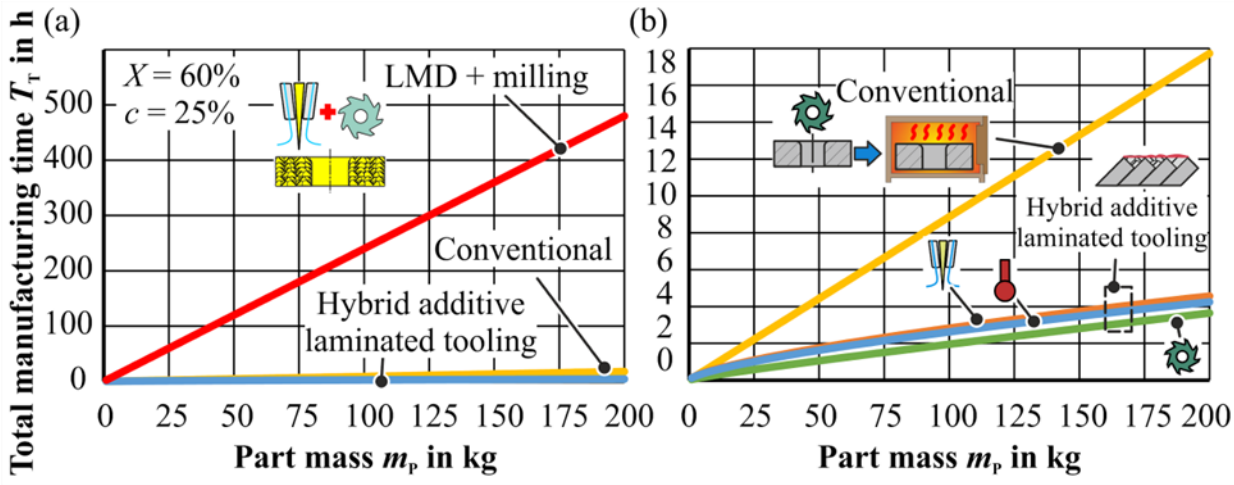

Fig. 6. Total manufacturing time (a) with LMD plus milling (b) without LMD plus milling.

As shown in Fig. 1, a high number of possible sheet combinations exist for each radius. Considering the same mechanical performance for all combinations, i.e. the tool strength is the same for all combinations, the number of sheet combinations can be limited by considering the energy, cost, and manufacturing time issues. For optimizing the sheet combinations, the following criteria are considered:

- The normalized laser cutting time (T_C^N),
- the normalized energy of production of metal powder and deposition energy ($E_P^N + E_{LMD}^N$),
- the normalized energy required for the laser cutting (E_C^N).

These factors (time and energy consumption) are desired to be kept as low as possible. For instance, for a radius of 6 mm, the energy and time are individually calculated and evaluated for all 520 combinations with different sheet thickness arrangements based on the mentioned criteria. The results are plotted in Fig. 7. It can be seen that the break-even point is around 0.33 for all criteria. Considering this value, the number of sheet combinations is reduced from 520 to 24.

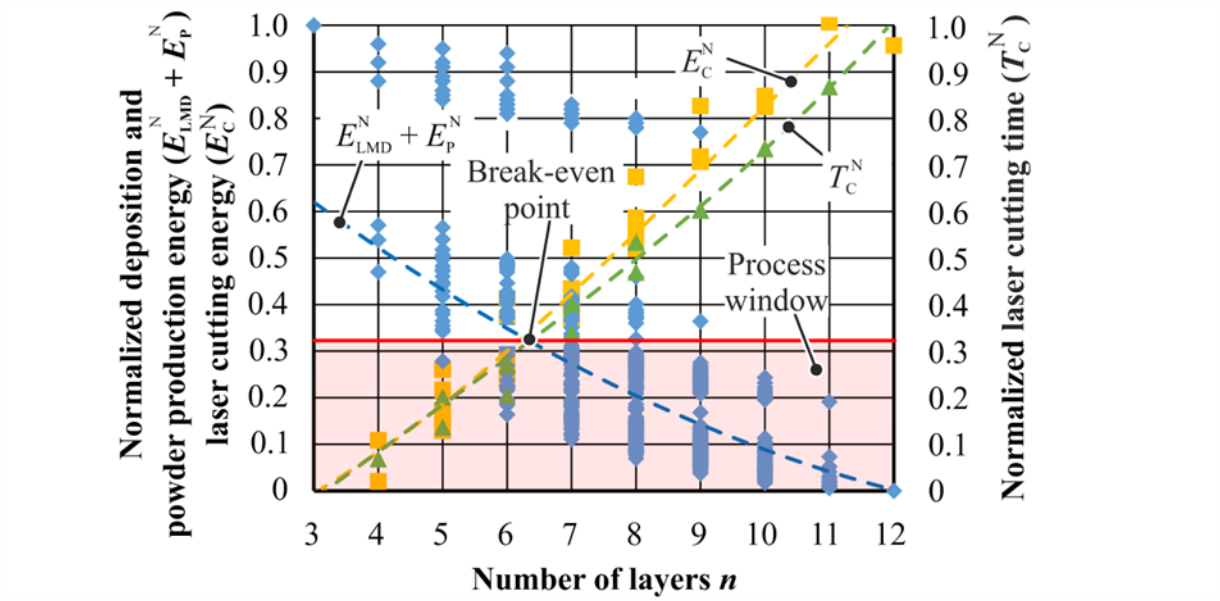

Fig. 7. Determination of break-even point for tool radius of 6 mm.

Summary

A systematic energy and manufacturing time evaluation of the introduced hybrid additive laminated tool manufacturing is provided. The results are compared with the conventional process route (milling followed by hardening) and also with a fully deposited part using laser metal deposition followed by milling as a post-processing method. The results show that the hybrid method is much more economical and faster than the fully deposited method and is comparable with the conventional method. However, the hybrid method is more suitable due to its ability to produce complex shapes in a shorter time. The production time depends considerably on the part geometry, but in this case the hybrid process is at least 29% (depending on the mass) faster than the conventional process. Laser polishing between the three post-processing methods provides an acceptable surface roughness without additional tooling costs and programming challenges compared to milling and ball burnishing but with lesser hardness (around 9% less as deposited). Since sheet lamination theoretically offers a high number of sheet combinations, the economic evaluation reduces the number of suitable sheet combinations for more effective manufacturing.

Keywords: Surface Roughness, Selective Laser Melting, Burnishing, Simulation

Abstract. The present study developed theoretical models for simulation of surface topography and roughness of parts produced by the selective laser melting (SLM) process and their evolution after burnishing as post-treatment. The simulation algorithm has been integrated by combining principles of selective laser melting process, i.e., formation of the melt pool and kinematic of motion, followed by mechanic of burnishing through Z-map approach. To verify the simulation results, 316L stainless steel was 3D printed and then burnished under different burnishing depth. 3D surface profile and surface roughness of as-printed material and those post-processed by surface burnishing (SB) were measured through microscopic examination and surface roughness measurement, respectively. The results obtained through comparison of confirmatory experiments and simulation model affirmed that the proposed approach is accurate enough to predict the surface topography and roughness of as-printed and post-treated samples.

Introduction

Among various approaches for additive manufacturing (AM) of metallic material, selective laser melting (SLM) was significantly attractive to researchers and industries because of its ability to produce parts with complex geometries. However, due to the layer-upon-layer nature of production, the SLM suffers from a poor surface finish.

The post processing of AM samples by surface burnishing (SB) has some advantages over other mechanical surface treatment process. Compared to material-removal process [1-3], the burnishing causes surface sever plastic deformation and results in modification of surface and subsurface layers in terms of hardness, compressive residual stress and microstructure refining. On the other hand, compared to non-material removal process [4-6], burnishing results in superior surface finish. It has been reported that the surface finish of burnished samples can reach optical scale under optimum processing conditions [7]. On the other hand, further advantages of burnishing over the other non-material removal processes is its independency of complicated infrastructures such as ultrasonic apparatus or pneumatic units. The process can be implemented by a simple lathe or milling machine.

Recently, researchers have attracted it for the post-processing of metallic and non-metallic materials produced by AM. Rotella et al. [8] used ball burnishing for the post-processing of stainless steel GP1 produced by SLM. Sunny et al. [9] used interlayer roller burnishing as sequential to SLM to reduce the tensile residual stress of each built layer before addition of next one. Raaj et al. [10] applied SB for post-processing of Inconel 718 manufactured by electron beam additive manufacturing. Brujin et al. [11] stated that the SB is a suitable process for processing polymeric (fused filament fabricated) material produced by 3D printing. They stated that unlike to material removal-based surface finishing, burnishing doesn't change the chemical composition of samples because the temperature rise is limited.

The additive manufacturing chain that includes the SLM and post-processing must be designed and then optimized to a certain level to obtain the desired surface finish. In order to do so, the

developing an integrated simulation model which can predict the final surface finish in short period of the time will be more vital. Thus, in the present work, novel physics-based theoretical simulations are proposed to predict the surface roughness evolution of parts produced by SLM and post-processed by the surface burnishing process. Accordingly, the present work aims to simulate the 3D surface topography and roughness of parts made by SLM and then modified by the burnishing process.

Theoretical Simulation

The topography of the surface in the SLM process is generated through the formation of the solidified melt pool and duplication using kinematic motion. Thus, the shape of melt pool during the printing process must be modelled in the first step. Heat input from the laser power source is calculated using a point moving heat source solution that is successfully used for the SLM process [12]. The point moving heat source solution was derived from a general convection-diffusion equation, which can be expressed as:

$$\begin{cases} T - T_0 = \dfrac{P\eta}{4\pi kR}\exp\left(\dfrac{-V_L(R_T + y)}{2\kappa}\right) \\ \kappa = \dfrac{k}{\rho c} \\ R_T = \sqrt{x^2 + y^2 + z^2} \end{cases} \tag{1}$$

where T is the localized temperature, P is the laser power, η is the coefficient that determines how much of the laser heat source is absorbed by powder; κ is thermal diffusivity, R_T is the distance from the heat source location, V_L is the scan velocity during the printing process that is in y direction; k is the heat conduction coefficient, and ρ is the material density. Fig. 1a represents a schematic illustration of the cross section of melt pool and its geometrical characteristics of the SLM process. It is created by the distribution of temperature induced by moving laser heat sources. The cross-section of the melt pool in xz plane (as shown in Fig. 1a) determines the formation of a surface generation of the SLM process. During the printing process, the maximum melt pool depth can be calculated by substituting the melt temperature in Eq. 5 at the location of $x=0$, $y=0$ as shown in Fig. 1. Accordingly, the molten pool depth (d) is the absolute root of the following equation:

$$\begin{cases} \Delta d + \exp(\Theta d) = 0 \\ \Delta = 2\pi k\left(\dfrac{T_m - T_0}{P\eta}\right) \\ \Theta = \dfrac{V_L}{2\kappa} \end{cases} \tag{2}$$

where T_m is the melting temperature.

According to the reports of several researchers, the profile of the melt pool cross-section is a paraboloid [13]. Accordingly, the equation of cross section profile, the consumed powder bandwidth (W_0) and melt pool width (W) (as shown in Fig. 1b) are calculated by Eq. 3:

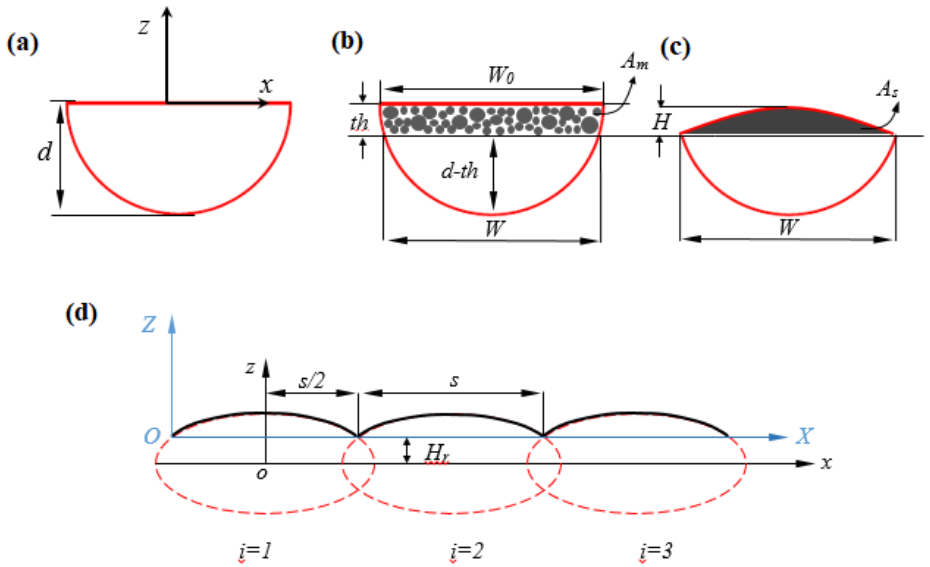

Fig. 1. (a) formation of cross section of melt pool (b) powder band width (c) solidified melt pool and formation of hump (d) generation of surface topography.

$$\begin{cases} z = x^2 - d \\ W_0 = 2\sqrt{d} \\ W = 2\sqrt{d - th} \end{cases} \tag{3}$$

where *th* is the layer thickness.

Once the melt pool is solidified, as a result of surface tension, a hump is formed on the upper side of the melt pool, as shown in Fig. 1c. Liu et al. [13] stated that the profile of the hump is a portion of an ellipse.

In order to calculate the maximum height of the hump area (that is usually called melt pool height), the mass conservation law is utilized. Accordingly, it is assumed that the mass of the region bounded by powder during melting is equal to the mass of the hump region after solidification. Hence, it can be said that the area of the region bounded by powder (i.e., A_m as shown in Fig. 1c) is equal to the hump area (i.e., A_s as demonstrated in Fig. 1e). Therefore, it can be written:

$$H = \frac{4}{W\pi}\left[Wth + 2\int_{\frac{W}{2}}^{\frac{W_0}{2}}\left(x^2 - d\right)dx\right] \tag{4}$$

By printing through a longitudinal direction, the melt pool with a fixed cross-section is lengthened to a predefined length. But, in the lateral direction, the cross sections of melt pools interact based on the hatch spacing value (s). Therefore, only a part of the ellipse contribution in the generation of surface topography, as shown in Fig. 1d. Accordingly, the surface generation equation can be:

$$Z = \left(\frac{2H}{W}\right)\left\{\sqrt{W^2 - \left[X - (i-1)s\right]^2} - \sqrt{W^2 - \left(\frac{s}{2}\right)^2}\right\} \qquad (i-1)s < X < is \qquad i = 1, 2, \ldots N \tag{5}$$

The obtained 3D surface profile of the material after SLM is named H (X, Y, Z).

In order to model the evolution of SLM surface topography after burnishing, Z-map approach is being utilized that transforms the cloud of points from tool coordinate system to workpiece coordinate system through series of transformation matrix. Here the initial surface topography is the H (X, Y, Z) which is obtained for 3D printed material; this matrix will be updated by applying the Z-map transformative model [14]. According to the principle of Z-map model, different

reference frames on the roller, burnishing tool, machine tool, and workpiece were defined and presented in Fig. 3. Here the reference coordinate system O_W-$X_WY_WZ_W$ that is called the workpiece coordinate system. During the burnishing process, the O_W-$X_WY_WZ_W$ is fixed on the workpiece. The O_M-$X_MY_MZ_M$ is called machine coordinate system. Its origin is connected to the machine spindle. It has translational movement with respect to workpiece coordinate system (as shown in fig. 3a-3c). The tool coordinate system, O_M-$X_MY_MZ_M$ has similar origins to the machine coordinate system (Fig. 3b). It is transformed into a machine coordinate system through a rotational movement. The local coordinate system that is located on the roller is shown by O_K-$X_KY_KZ_K$. Depending to the number of rollers distributed on the circumference of the tool (as shown in Fig. 3d), the O_K-$X_KY_KZ_K$ is transformed to the tool coordinate system by a rotation considering the angle between each roller. Accordingly, the main formulation that transforms an individual point on the roller to workpiece coordinate system is:

$$\begin{bmatrix} X_P^W \\ Y_P^W \\ Z_P^W \\ 1 \end{bmatrix} = \begin{bmatrix} \cos\Phi_k & -\sin\Phi_k & 0 & 0 \\ \sin\Phi_k & \cos\Phi_k & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} \cos\omega t & \sin\omega t & 0 & 0 \\ -\sin\omega t & \cos\omega t & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} 0 & 0 & 0 & V_f t \\ 0 & 0 & 0 & 0 \\ 0 & 0 & 1 & R \\ 0 & 0 & 0 & 1 \end{bmatrix} \begin{bmatrix} X_P^K \\ Y_P^K \\ Z_P^K \\ 1 \end{bmatrix} \tag{6}$$

where Φ_k is angle between the k-th roller and tool axes that is function of initial phase and number of roller which can be calculated by Eq. 7. ω is the annular velocity that is $\omega = 2\pi N/60$. Also, V_f is the feed velocity.

$$\Phi_k = \frac{\Phi_0 + 2\pi(k-1)}{N_R} \tag{7}$$

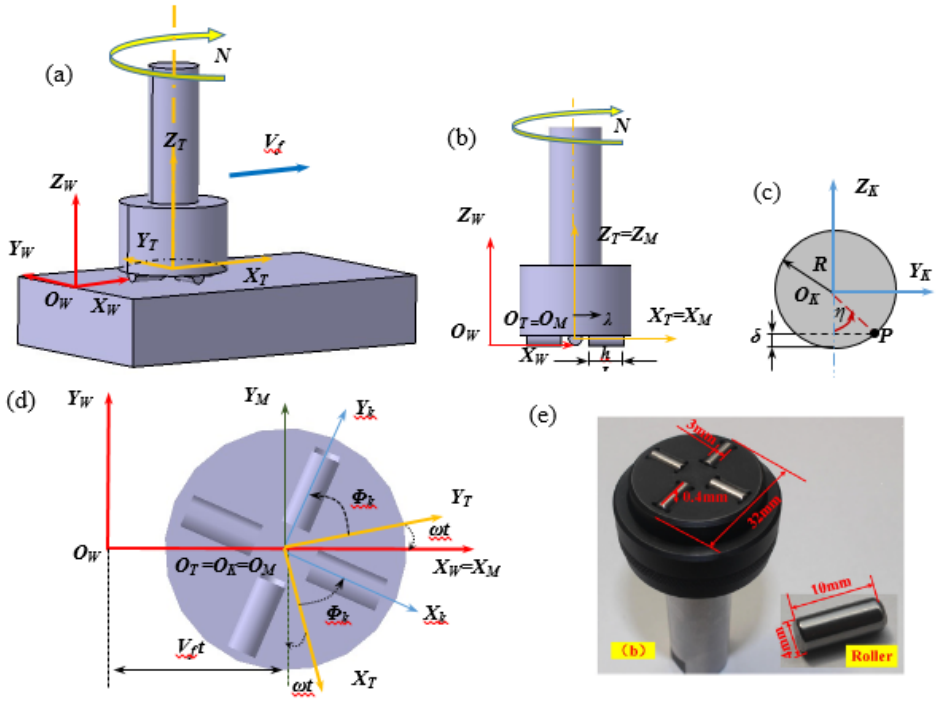

Fig. 2. (a) A schematic illustration of multi-roller rotary burnishing for flat surface including workpiece and tool coordinate systems (b) tool coordinate system (c) coordinate of an arbitrary point P on the roller with radius of r (d) trajectory of an obituary pint of P on different coordinate system i.e. roller, tool, machine and workpiece (e) real rotary burnishing tool with multi-roller.

In order to implement the algorithm, following steps need to be taken into consideration:
a) Initializing the burnishing process: burnishing parameters including the feed velocity (V_f), roller number (N_R), roller radius (R), depth of penetration (δ), and spindle speed (N) are set.
b) Discretization of workpiece surface: here, a slice of the workpiece with length of feed per revolution in X_W direction and width of $2R$ equal to the diameter of the burnishing tool in Y_W direction is considered. Here, the Z-map model of the workpiece with $m*n$ grids is established. The length and width of each grid are selected based on the gridding of the 3D printed surface in such a way that the hatch spacing is divided to 50 elements. Thus, the Δx equals $s/50$. Also, the width of each grid is selected as long as its length, i.e., $\Delta y=\Delta x$. Therefore, the selected region in X_W direction must be divided to:

$$\begin{cases} n_x = \dfrac{f}{\Delta x} \\ n_y = \dfrac{2R}{\Delta y} \end{cases} \tag{8}$$

c) Setting up the time increments: By identifying the processing length equal to f, it can be inferred that the process ends when this length is swept with burnishing tool. Therefore, the processing time can be obtained by dividing the burnishing feed rate i.e., f, by linear velocity i.e., V_f. Accordingly, the time increment (Δt) for processing the mesh length (Δx) with the same linear velocity is obtained by using the following formula:

$$\begin{cases} t = \dfrac{f}{V_f} = \dfrac{V_f \big/ N}{V_f} = \dfrac{1}{N} \\ \Delta t = \dfrac{\Delta x}{V_f} = \dfrac{1}{n_x N} \end{cases} \tag{9}$$

d) Discretization of the roller: Here it must be taken into consideration that the projection length of the roller element must be within the size of the workpiece's grid region. In other words, within each time increment, only one grid point of the workpiece is swept over by the discretized point of roller. In order to discretize the tool, couple considerations must be taken into account: (i) dividing the depth of penetration in different layers: based on the simulation's accuracy, the depth of penetration in axial direction (i.e. direction of Z_K) is divided into other parts and then the depth of each layer is δ_i (i=1, 2, …, n_i) will be $d\delta=\delta/n_i$; (ii) for each δ_i, there is a secant that causes variation of spreading angle. Their values can be calculated using the following equation:

$$\begin{cases} \eta_i = \cos^{-1}\left(\dfrac{R-\delta_i}{R}\right) \\ \delta_i = \dfrac{\delta_{\max}}{n_i} \end{cases} \tag{10}$$

Each layer must also be discretized based on dividing its corresponding spreading angle. Accordingly, the η_i is divided into n_j parts. Thus, each angular increment is calculated by:

$$\eta_{ij} = \frac{2\eta_i}{n_j} \quad j = 1,2,..,n_j \tag{11}$$

The value of n_j can be calculated arbitrary or based on interconnection with workpiece gridding using following equation:

$$\begin{cases} n_j = \dfrac{2\rho_i}{\Delta x} \qquad \rho_i = R\cos\eta_i \\ \eta_{ij} = \dfrac{2\eta_i}{n_j} \end{cases} \tag{12}$$

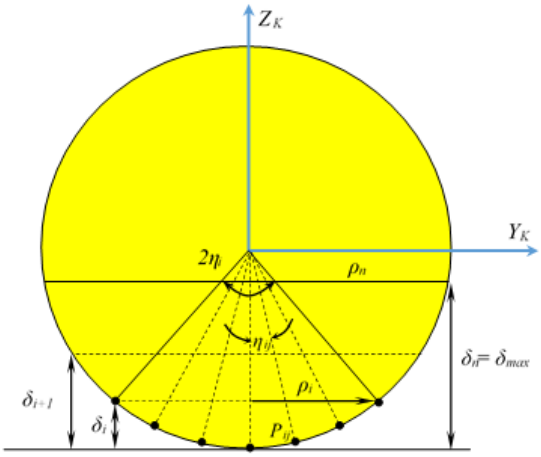

Fig. 3. Discretization of the roller in the contact region to check if the burnishing tool is within workpiece region.

Where Δx is the length of each grid in workpiece. Once the η_{ij} is determined, the position of each point in the roller coordinate system can be identified:

$$\begin{bmatrix} X^K_{P_{ij}} \\ Y^K_{P_{ij}} \\ Z^K_{P_{ij}} \end{bmatrix} = \begin{bmatrix} R \\ r\sin\eta_{ij} \\ -r\cos\eta_{ij} \end{bmatrix} \tag{13}$$

For the time t, the coordinate of the transformed point of the roller from the local coordinate system to the workpiece coordinate system i.e. (X^W_P, Y^W_P) is checked with the X_{max} and Y_{max} in H matrix. This point is accepted if the transformed point is within the workpiece range.

e) Checking the coincidence: For each transformed point (X^W_P, Y^W_P), a coincidence limit compared to workpiece gridding points i.e. H (X, Y) is defined where the distance between the points is less than ε. In other words, if the distance of (X^W_P, Y^W_P) and H (X, Y) is less than ε, the coincidence condition is met. In the present work, the coincidence limit has been set to ε=0.01µm.

f) Checking the engagement: For the coincident points, the values of $Z_P{}^W$ are compared with the Z in H matrix. If the $Z_P{}^W$ is less than Z, in the H matrix, the Z is replaced by $Z_P{}^W$; otherwise, the Z is kept.

g) 3D surface topography: When the process is finished (i.e., t=t_{max}), the updated workpiece matrix determines the final surface topography.

Experiments

In the present investigation, the stainless steel 316 L blocks with dimensions of 70 mm in length, 30 mm in width, and 10 mm in thickness were built by laser powder bed fusion process. An EOS M280 3D printer machine with 1100 nm wavelength discontinuous Yb-fibre laser was used to manufacture samples. The volumetric energy density for fabrication was set on 100 J/mm^3.The samples were printed based on optimized standard EOS parameters with 195W laser power, 1083 mm/s scan speed, 90 µm hatch spacing, and 20 µm layer thickness. As-built samples were detached from a substrate using wire electrical discharge machining.

A multi-roller rotary burnishing process was utilized for post-processing as-printed samples. The commercial burnishing tool model SPF20-S20 manufactured by SUNGINO cooperation comprises four rollers made of hardened steel. The length and diameter of rollers are 10 mm and 4 mm, respectively. During each revolution of the tool, a width of 20 mm can be burnished by this

tool. Thus, its more efficient in the vibration of flat surfaces compared to a single roller (or ball) burnishing tool. Fig. 4 demonstrates the experimental setup.

The main characteristic that needs to be measured in the present study is surface topography and roughness. In order to do so, a 3D surface roughness machine, namely TylorHobson was utilized. Measurements were carried out in a 1 mm^2 squared area.

The experiment was planned for confirmation of the developed model. For the SLM process mentioned in section 3.1, the sample was built based on the standard EOS parameter used for 3D printing of stainless steel 316. Then, the obtained surface topography and roughness of until material were compared with the predicted values.

For the burnishing process, from our preliminary experiments and the developed model, it was found that the main burnishing factor that has the greatest influence on the surface roughness evolution of the SLM sample is the burnishing depth. Thus, in the present study, the burnishing experiments for processing as-built material were carried out by variation of burnishing depth at 0.05 mm and 0.075 mm and 0.1 mm, while the spindle speed and linear velocity were kept constant at 800 RPM and 200 mm/min.

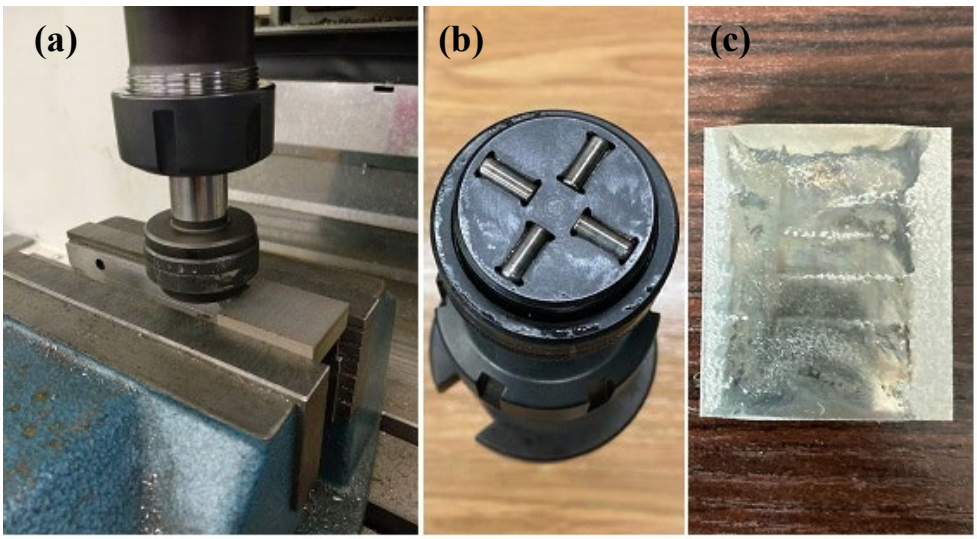

Fig. 4. (a) Burnishing experimental setup (b) multi-roller burnishing tool (c) burnished sample.

Results and Discussion

Fig. 5 illustrates the comparison between the measured and predicted surface roughness (Ra) of different samples. According to the presented results, it is seen that they are in good agreement in general; it indicates that the developed evolutionary simulation is reliable. It is seen that the maximum distance from the peak and valley (Rt) for as-built material measured through surface roughness is 12.303, while the predicted value is 12.276 µm. Moreover, the arithmetic surface roughness (Ra) value for the SLMed sample measured by the experiment was 6.62 µm, while the simulated value is 7.10 µm. For the burnished sample with depth of 0.05mm, the surface peaks are flattened due to plastic deformation. The Rt value was measured at 6.595 µm while the predicted one was at 7.353 µm. Fig. 5 illustrates that the arithmetic surface roughness values which were obtained through experiments and simulation are 2.65 µm and 3.23 µm, respectively. Moreover, for the samples processed by 0.075 mm and 0.1 mm burnishing depth, the measured values of Rt are 4.943 and 2.818, respectively. The Rt values obtained by the simulation model for the same processing conditions are 4.852 and 2.45, respectively. Also, the arithmetic surface roughness value which was measured by experiments are 1.11 µm and 0.288 µm, respectively. On the other

hand, the predicted values of Ra, which the simulation model calculated, are 1.31 µm and 0.355 µm, respectively.

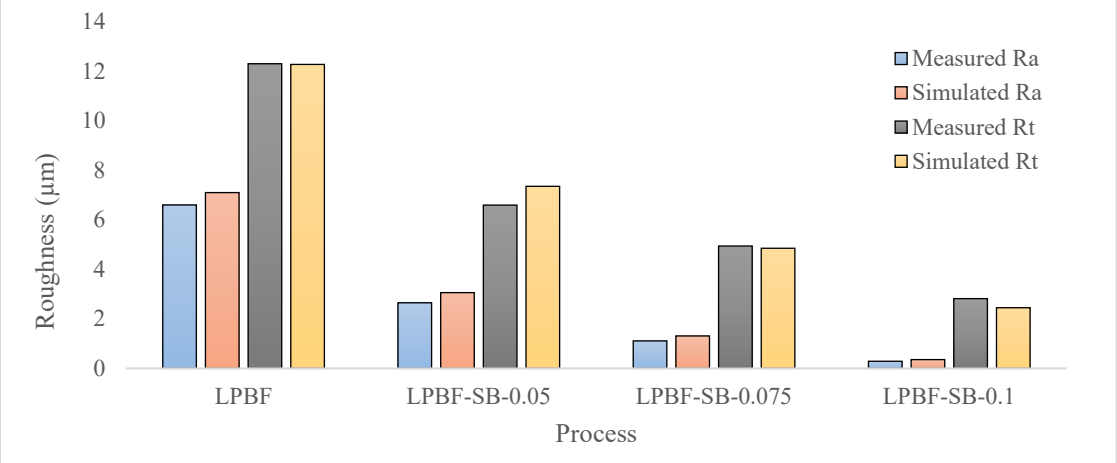

Fig. 5. Comparison between measured and predicted values of Ra and Rt under different conditions.

Fig. 6 shows that there are consistencies between the measured and predicted surface topography of the samples. In all the samples its seen that sinusoidal behaviour exist in one direction and the variation of surface peaks and valleys are following same trends while the burnishing depth increases.

Summary

The obtained results can be summarized as follows:

- The surface roughness of SLMed sample fabricated at EOS standard setting were in close agreement with those derived from the simulation model. The prediction error for calculating the Ra and Rt were about 7.5% and 2%, respectively.
- It was found that the prediction error of the surface roughness increases as burnishing is applied as a sequential process. Also, the error values increase by increasing the burnishing depth. However, the maximum prediction error in the worst case is 18.8% for Ra and 12.8% for Rt. This difference can be attributed to fracture of agglomerated partially fused particles because of high degree of plastic deformation resulting in big scratches on the surface of burnished sample during experiment; which hasn't been included in the model.

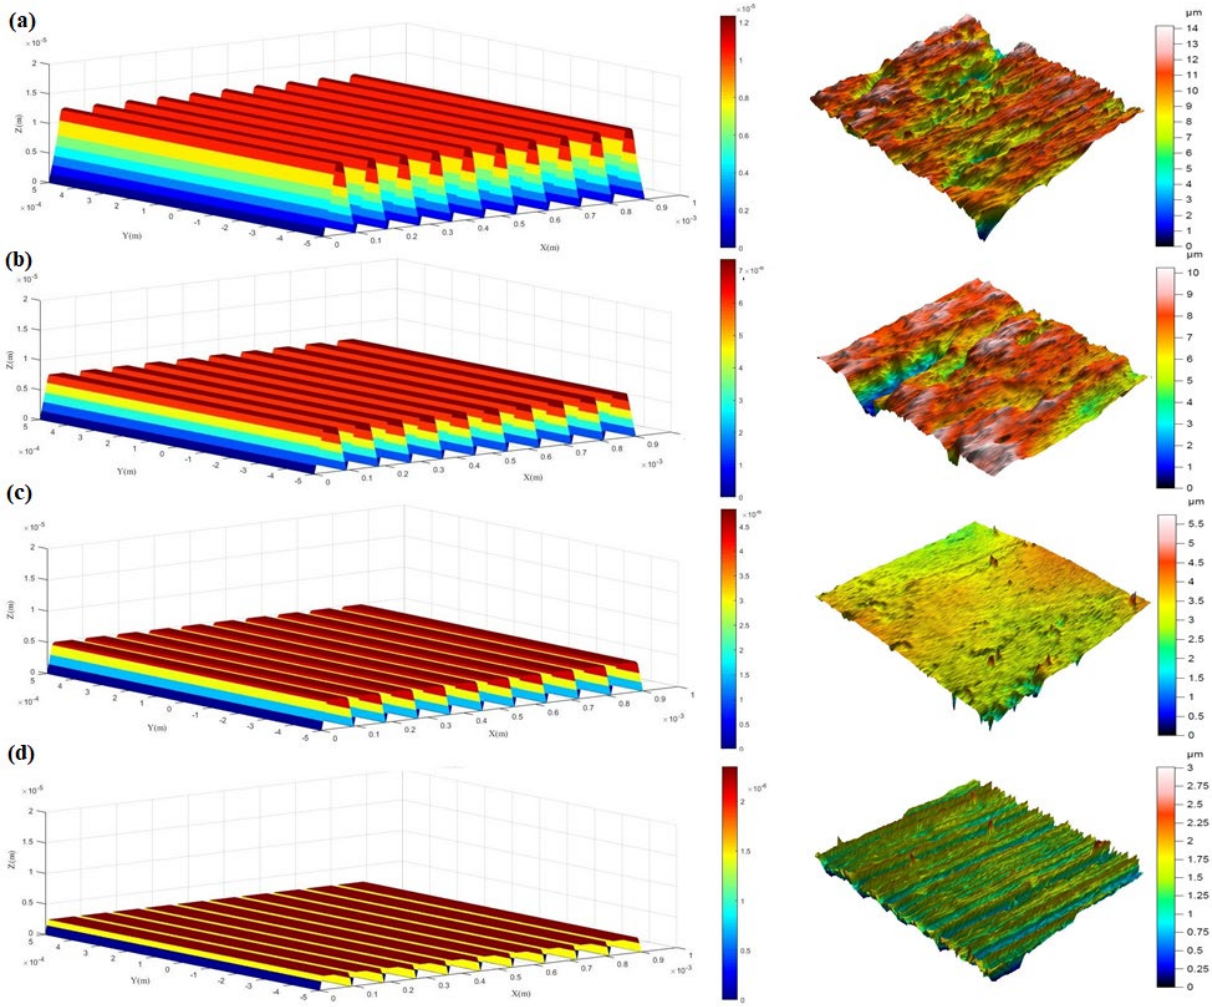

Fig. 6. Comparison of measured and simulated 3D surface topography (a) As-built (b) burnishing depth of 0.05 mm (c) burnishing depth of 0.075 mm (d) burnishing depth of 0.1 mm.

Abstract. Nowadays, the advantages of Laser Powder Bed Fusion (LPBF) technology attract both industry and researchers. Indeed, it is possible to build up complex geometrical parts with higher mechanical properties than those obtained by conventional methods. However, LPBF involves complex phenomena due to the high heating and cooling rates that lead to out-of-equilibrium conditions. For this reason, few metal alloys are easily processable up to now. Nevertheless, research on new steels by LPBF has been growing in recent years, in particular, regarding the development of tool steels. This work thus focuses on the development of the tool steel AISI S2 by LPBF. The process map has been investigated by varying the laser power from 100 to 250 W and the scan speed from 400 to 2000 mm/s. By combining surface analysis by means of profilometer observations, density measurements by pycnometry, defects characterization and quantification and investigations on the melt pool morphology, the best process window is selected to have fully dense, defect-free parts. Furthermore, this study allows to have comprehensive insights on the effect of the parameters on the type of defects generated during the manufacturing.

Introduction

Among Additive Manufacturing (AM) technologies, Laser Powder Bed Fusion (LPBF) is a suitable technique to create near net-shape parts starting from powders. The advantage is to achieve complex parts in terms of geometry, avoiding difficult manufacturing processes. Moreover, the final mechanical properties of parts by LPBF can be higher than those obtained by conventional methods [1].

LPBF process involves complex physical phenomena, such as absorption and transmission of laser energy, rapid melting and solidification of material, microstructure evolution flow in a molten pool and material evaporation [2]. These complex phenomena may result in defects such as gas porosities, lack of fusion areas, cracks, spatters, key-hole porosities and balling [2-5]. Despite the problems and complexity faced during the process, the manufacturing of new alloys by LPBF has been growing over the recent years. Research is focusing on microstructural aspects, to gain comprehensive insights of the effect of the out-of-equilibrium conditions during melting and solidification on the final parts, both in terms of quality and mechanical properties. Significant attention has been given to the evaluation of the melt pool formed during the process [6-10], as it is crucial for understanding the processability and the type of defects generated.

Nowadays, one limitation of the LPBF process lies in the choice of raw material. Indeed, LPBF implies the use of metallic powder usually obtained by Gas Atomization (GA), a process that is difficult to control [11], especially for certain type of alloys. Therefore, few metal powders are easily available in the market (316L, Maraging Steels, Al, Ni and Ti alloys). LPBF manufacturing of other alloys has proved challenging and therefore there is a shortage of supply and demand for the less common raw material on the market.

In particular, tool steels are difficult to process by LPBF, due to their complex chemical composition and poor weldability [12]. Indeed, their high carbon content (up to 1.5 wt. %) promotes the formation of martensite, which leads to crack formation within the printed part under the effect of residual stresses due to rapid cooling. The influence of increased carbon content on LPBF processability has been investigated more deeply in recent studies [12-15]. However, other recent works already showed the possibility to manufacture low alloy steels (~ 0.5 C wt. %) [6,16-21]. The present study thus aims to provide the basis for understanding the processability of low alloy tool steel grade AISI S2. The process map for this steel is developed exploring different sets of parameters. In particular, the volumetric energy density has been used to investigate the effect of different parameters on the types of defects generated and to select the process window for fully dense and defect-free parts.

Materials and Methods

Commercial gas atomized powders AISI S2 Tool Steel (0.49 C, 1.2 Si, 0.6 Mo, 0.6 Mn, Fe bal., wt. %) were used as raw material, provided by Sandvik Osprey LTD. The powder is in a spherical shape with a mean size of 31 µm, as revealed by SEM observations (Fig. 1). The bulk density of powders (ρ_{bulk} = 7.8 g/cm^3) was measured by means of a gas pycnometer AccuPyc II Serie 1345.

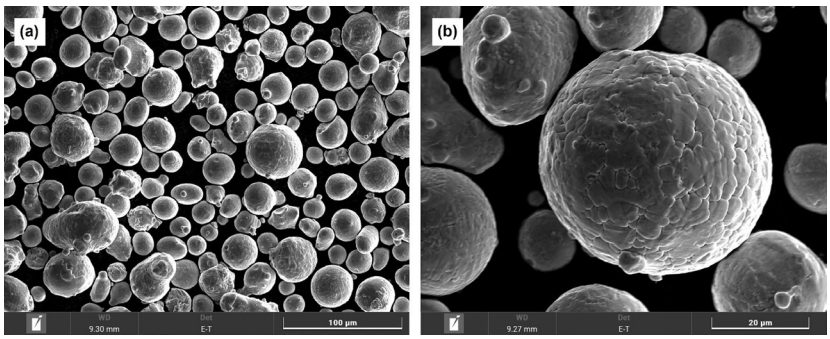

Fig. 1. SEM micrographs of (a) AISI S2 powders and (b) zoom on a particle with spherical morphology.

Starting from the powders, 20 cubes of 10x10x10 mm^3 were produced with an Aconity MIDI LPBF machine under Argon atmosphere. Different power (P) and scan velocity (v_s) were used (Table 1). P is considered as low (100 W), moderate (150 W), medium (200 W) and high (250 W). v_s is considered as low (400 - 800 mm/s), medium (800 - 1250 mm/s) and high (1250 - 2000 mm/s). A laser spot size of 80 µm with a gaussian distribution, a layer thickness (t) of 30 µm and a hatch spacing (h) of 80 µm were used for all samples. The scanning strategy implied a rotation of 90° for each layer, with no contouring. No substrate preheating was applied. Fully printed samples showed good dimensional tolerances (Fig. 2a), according to the desired initial geometrical features. Samples 1-2-3-6-11 were stopped during the manufacturing process due to evident surface defects that affect the quality of the subsequent layers (Fig. 2b-c-d). These samples were not considered for subsequent density measurements and profilometer analysis.

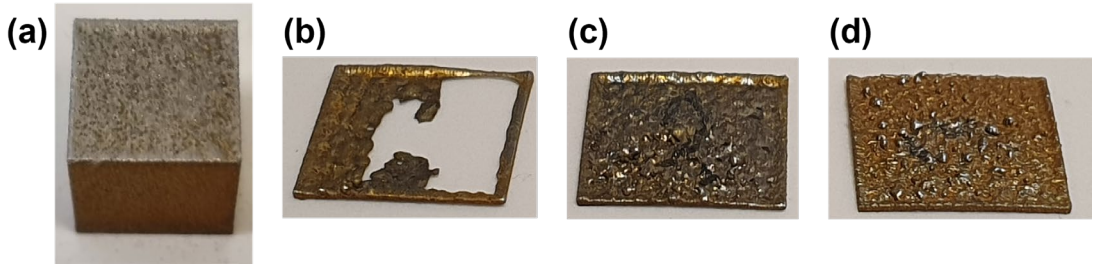

Fig. 2. Examples of (a) a fully printed and (b), (c), (d) interrupted samples.

The volumetric energy density (E_d) was used to correlate the results observed with the processing parameters (Eq. 1).

$$E_d = \frac{P}{t*h*v_s} \quad (1)$$

Table 1. Processing parameters and volumetric energy density for each sample.

Sample	P [W]	v_s [mm/s]	E_d [J/mm^3]
1	100	400	104
2	100	600	69
3	100	800	52
4	100	1000	42
5	100	1200	35
6	150	500	125
7	150	750	83
8	150	1000	63
9	150	1250	50
10	150	1500	42
11	200	500	167
12	200	750	111
13	200	1000	83
14	200	1500	56
15	200	2000	42
16	250	500	208
17	250	750	139
18	250	1000	104
19	250	1500	69
20	250	2000	52

After production, the density of each sample (ρ) was measured through a gas pycnometer and the relative density was calculated using the bulk density of powders, according to Eq. 2.

$$\%\, Density = \frac{\rho}{\rho_{bulk}} * 100 \quad (2)$$

The surface of the as-built samples was checked using an Alicona Infinite Focus G5 optical profilometer for roughness analysis. All the as-built samples were cut by Electro Discharge Machining perpendicularly to the laser scan direction of the last layer to obtain the cross section. After cutting, samples were hot mounted with an electrically conductive bakelite, then ground and polished down to 1 μm. Defects within the cross sections were analyzed through an optical microscope Olympus BX60 and quantify through Olympus Stream Analysis Software. Nital 3% was used to etch the cross sections.

Results

According to Eq. 2, all samples show a density above 96.5 %. A good correlation is observed between the density value and the fraction of internal porosity obtained by image analysis (Fig. 3a). In image analysis, all kinds of defects are considered. Small gas porosities are detected in all samples. Key-hole porosities at the bottom of melt pools are observed in samples produced with high E_d (Fig. 3b). Large spatters containing a porosity are detected in samples with low v_s (Fig.

3c). Cracks perpendicular to the building direction, initiated from the edge are detected in a few samples, without any specific correlation with processing parameters (Fig. 3d). Lack of fusion defects are visible in samples with low E_d (Fig. 3e).

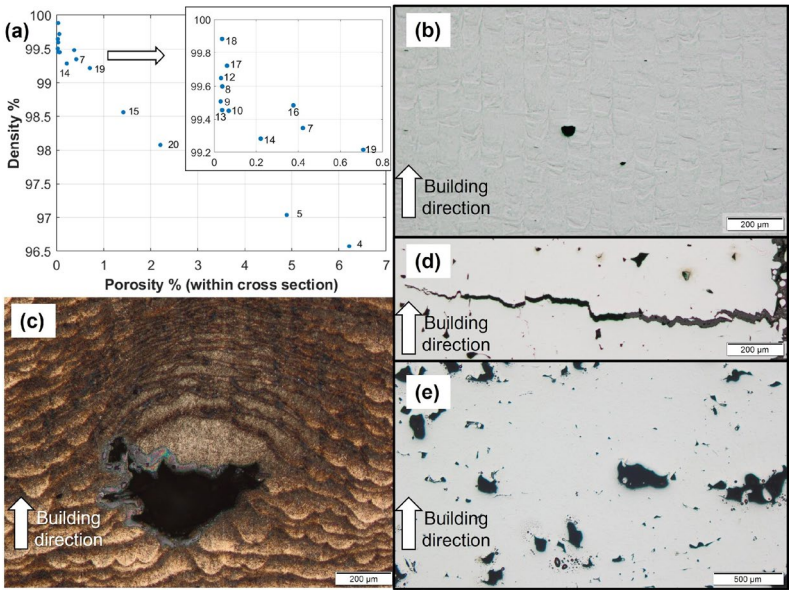

Fig. 3. (a) Correlation between density and porosity, (b) key-hole porosity, (c) entrapped porosity within large spatter, (d) crack perpendicular to the building direction initiated from sample edge and (e) lack of fusion defects.

Fig. 4 shows the most representative overviews of the sample's cross sections together with the corresponding zoom on top area. Nital etching allows to observe the features of the tracks within the sample and to distinguish the brighter top layer. The melt pool morphology is clearly visible. Increasing E_d (from left to right in Fig. 4) leads to a change in the type of defects due to a different melt pool morphology.

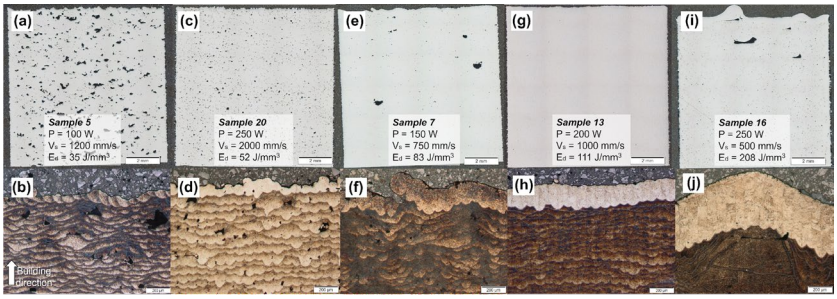

Fig. 4. (a), (c), (e), (g), (i) Cross section overviews and (b), (d), (f), (h), (j) zoom on tracks and top layer after etching with Nital.

Profilometer observations reveal different features of the surface roughness. The surface aspect depends on the quality of the scan tracks generated by the laser passage. The scan tracks generated with low E_d as result of low P (Fig. 5a) are more irregular than those obtained with high P (Fig. 5b). With intermediate value of E_d, P and v_s, the surface appears more regular, with only small spatters (Fig. 5c). On the contrary, high E_d and P and low v_s lead to an irregular surface despite the good overlapping of the scan tracks (Fig. 5e). In general, low v_s results in an irregular surface (Fig. 5d).

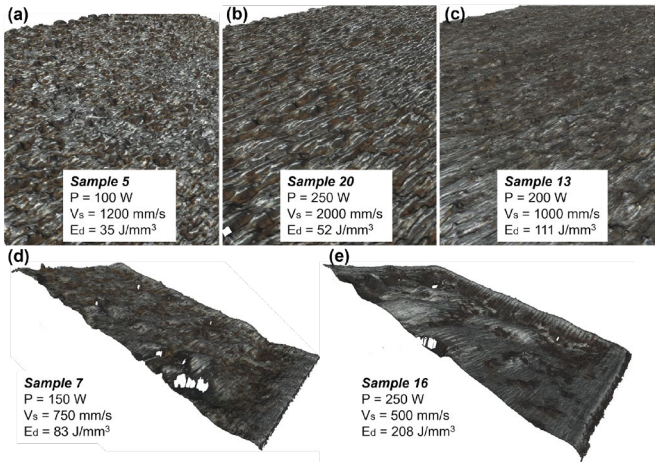

Fig. 5. Profilometer observations of the top surface after printing.

Discussion

The first approach in the LPBF of a new alloy consists in searching the best parameters to achieve fully dense and defect-free samples. Process maps are commonly used for this purpose. Although the primary aim is to obtain the best parts, investigations of defects generated using different parameters can provide good insights of both the alloy studied and the pure functioning of the LPBF process.

In this work, the effects of the two variable parameters (P and v_s) are investigated together with the variation in E_d (Eq. 1). All samples are compared in terms of density, amount and type of defects, tracks overlapping, melt pool morphology and surface quality. Particular attention is given to the quality of the top surface and the morphology of the melt pool within the top layer. Indeed, they can provide useful indications of the defects that may form in a hypothetical subsequent layer and thus understand the phenomena that have occurred in the layers below.

The use of low/moderate P (100 - 150W) and low v_s (400 - 800 mm/s) (samples 1, 2, 3, 6 and 7) does not allow for fully printed samples. The printing was stopped, excepted for sample 7. Despite the wide range of E_d (52 - 125 J/mm^3), the low P could not generate sufficient liquid phase for the powders to bond together, resulting in poor densification [3]. The metallurgical bond between layers is also compromised, leading to the possible material tear out (Fig. 2b), as also occurred in the top layer of sample 7 (Fig. 4f). Moreover, the low v_s causes an unstable melt pool generating big spatters (Fig. 2c-d) [22] that are not re-melted by the subsequent passage of the laser. If spatters are larger than the layer thickness, the spreadability of a new layer of powders is impeded, causing gaps and compromising the metallurgical layers bond [4]. Large pores (~ 400 µm) are found for instance in sample 7, that are located inside a big spatter (Fig. 3c). As the process advances, the presence of poorly printed layers leads to an irregular surface (Fig. 5d), affecting the printing of the subsequent layers.

With similar P (100 - 150 W) but higher v_s (1000 - 1250 mm/s) (sample 4 and 5), low E_d values (~ 40 J/mm^3) generate a shallow melt pool (Fig. 4b) [6]. As consequence, the metallurgical bond between two subsequent layers is compromised, causing the presence of lack of fusion areas (Fig. 4a-b) [5] that leads to low density (Fig. 3a). In this case, the poor metallurgical bond is caused by balling phenomena [3], visible in the top surface (Fig. 5a) where the tracks are clearly discontinuous. The increase in v_s is thus seen to avoid the generation of large spatters. This is easily understood since the higher v_s allows a faster cooling of the melt pool, and decreases the possibility of melted droplets being splashed out of the melt pool [22].

Low E_d values (~ 54 J/mm^3) resulting from higher P (200-250 W) and high v_s (1500-2000 mm/s) (samples 14, 15, 19, 20), leads to similar observations. Indeed, balling phenomena also occur, bringing about a low density (Fig. 3a) due to lack of fusion areas (Fig. 4c-d). However, this effect

is more restrained than observed at lower P. Indeed, the parts density is higher and the internal porosity are lower (Fig. 3a). In the present case, the higher P allows a better melting of the powders, leading to a better overlapping of the tracks as visible in the top layer (Fig. 5b). Furthermore, the melt pool height increases (Fig. 4d), allowing a better metallurgical bond with the previous layer. Therefore, the little increase of E_d (from 40 to 54 J/mm^3) results in a better processability, but the level of defects remains still high (Fig. 3a and 4c).

The combination of a moderate/medium P (150-200 W) and a medium v_s (750-1200 mm/s) (E_d = 50 - 111 J/mm^3) allows to achieve fully dense and defect-free parts (sample 08, 09, 10, 12 and 13). Indeed, this combination of parameters generate an ideal melt pool (Fig. 4h), regular and homogeneous within the cross section. The tracks have a proper overlap, which affects positively the density of the samples (Fig. 3a) and the spreadablilty of the subsequent powder layer. Indeed, no defects are found (Fig. 4g). Only small gas porosities are observed, which does not adversely affect the quality of the final part. Small spatters are visible in the top surface (Fig. 5c), but these can be easily re-melted by the subsequent laser passage. This range of parameters and especially the combination 200 W / 750-1000 mm/s (Ed ~ 97 J/mm^3) is thus considered as optimum for the realization of AISI S2 steel parts manufactured by LPBF.

Finally, high P (250 W) and low v_s (500-1000 mm/s) lead to a high E_d (104-208 J/mm^3) (sample 11, 16, 17 and 18). The deep melt pool (Fig. 4j) allows a good overlap of the tracks (Fig. 5e), resulting in high density above 99,5% (Fig. 3a). Despite this, the high E_d causes an instability of the melt pool, that is clearly irregular within the cross section (Fig. 4j). Indeed, increasing the melt pool depth also increases the possibility of gas entrapment, resulting in higher porosity. The large porosity detected (Fig. 4i) may be formed due to denudation process of powders around the melt pool due to the high E_d [2]. Key-hole defects (Fig. 3b) are also observed, formed due to the high E_d that causes metal evaporation and generate a recoil pressure towards the melt pool bottom [23]. Furthermore, the combination of low v_s and high E_d increases spattering [4], in terms of number and size of spatters. As a result, the spreadability of the subsequent layer of powders is compromised. The final part exhibits many surface irregularities, as shown by profilometer observations (Fig. 5e) and in the top layer of the cross section (Fig. 4i).

Based on the above explanations, it can be assumed that the “not processed” window (Fig. 6) results in an insufficient E_d to generate an adequate melt pool. Extensive balling and lack of fusion areas are expected due to the low P (100 - 150 W) and the high v_s (1500 - 2000 mm/s).

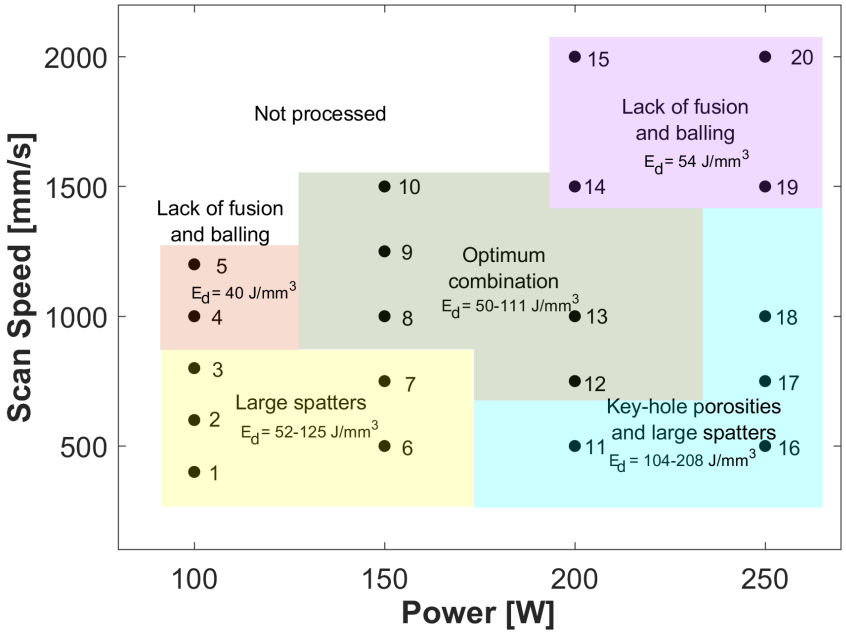

Fig. 6. Process map for AISI S2 tool steel by Laser Powder Bed Fusion.

Summary

The processability of the tool steel AISI S2 has been investigated and a process map has been built considering surface morphology, density measurements, defects characterization and quantification, tracks overlapping and melt pool morphology. The main outcomes can be summarized as follows:

- Medium v_s (750 - 1000 mm/s) and P (200 W) (Ed ~ 97 J/mm^3) allow to achieve fully dense and defect-free parts;
- High v_s (1000 - 2000 mm/s) and low E_d (35 - 69 J/mm^3) cause lack of fusion and balling, regardless of the P applied;
- Low v_s (400 - 1000 mm/s) and mostly high E_d (69 - 208 J/mm^3) cause large spatters and key-hole porosities, regardless of the P applied;

This work establishes a reference for further investigations of LPBF S2 tool steels. Furthermore, it lays the ground for the development by LPBF of new steels based on the modification of the S2 tool steel or similar grades.

Abstract. Metal foams are a relatively new class of materials with many interesting combinations of physical and mechanical properties. Among them, the closed-cells aluminum foams are the most interesting for structural applications in the aerospace industry. There exist different methods to produce metal foams. An innovative manufacturing technique was developed in this study, proving the possibility to produce closed-cells aluminum foams through the cold spray additive manufacturing technology (CS). In particular, two different sets of samples were produced by varying the cold spray process parameters aiming at: i) studying the advantages and the issues of cold spray for manufacturing precursors for metal foams; ii) analyzing the correlation among the CS printing strategy and parameters, the foaming process and the physical and the morphological characteristics of the resulting foams; iii) finally, finding appropriate conditions to form closed-cells aluminum foams via CS.

Introduction

It is a matter of fact that, in the aerospace industry, the main trend at the design stage is currently directed toward the wider employment of lightweight materials, due to obvious environmental and economic reasons [1]. In this scenario, the closed-cells metal foams are rapidly emerging as a new class of advanced materials with very low specific weight and novel physical, mechanical, thermal, electrical and acoustic properties due to their cellular structure consisting of solid metal containing a large volume fraction of gas-filled pores [2].

Metal foams of different metals are available, such as: aluminum, nickel, magnesium, lead, zinc, copper, bronze, titanium, steel and even gold [3]. The more used in structural applications are aluminum foams that are characterized by low density coupled with high energy absorption capacity, high specific stiffness and reduced thermal and electrical conductivity; these materials can be used as core for sandwich structures, internal anti-buckling reinforcement for thin walled structures and so on [4,5].

The closed-cells aluminum foams can be manufactured through several methods [6]. The gas-releasing particle decomposition in semi-solids process, which is known as powder compact melting technique (PCMT), starts from a compacted powders mixture of aluminum alloy and a blowing agent in form of fine particles, obtaining the so-called foamable solid precursor [7]. Heating the precursor to a little above the melting temperature of the alloy leads the compacted metal matrix in a semi-liquid viscous state; the foaming agent decomposes and releases hydrogen,

which blows bubbles in the soft alloy. Under these conditions, the released gas forces the melting precursor material to expand, modelling a highly porous structure.

In order to ensure satisfactory foaming results, appropriately starting powders have to be chosen [8]. The most suitable materials for foaming are pure aluminum or cast alloys (e.g. AlSi10Mg and AlSi12) coupled with titanium hydride (TiH_2), which is the foaming agent. Several other foaming parameters, which have to be suitably controlled, influence the final foam quality. The most important are powder mixing composition, particles dimensions and shape, distribution of blowing agent within the metal matrix, compaction pressure, time and temperature of foaming and heating rates [9].

Based on the mechanisms ruling PCMT, an innovative manufacturing technology was developed by the authors in this study, proving the possibility to produce closed-cells aluminum foams through the cold spray additive manufacturing technology. The problems encountering when using the traditional PCMT-based manufacturing processes for foams can be overcome through cold spray [10].

CS is a significantly greener, low-temperature, non-combustion, and scalable alternative process with an extraordinary potential. The bonding concept in CS is based on kinetic rather than thermal energy. During CS, feedstock powder particles (5-50 μm) accelerated to supersonic velocities (300-1200 m/s) by preheated compressed gas passing through a convergent-divergent nozzle, undergo severe plastic deformation upon impact and bond to the substrate [11]. CS, as a "cold" technique, can be used to process thermally sensitive materials [12,13], like the powder-based solid precursors for metal foams. The key idea is spraying the powder mixture on a metallic substrate and then carry out the foaming process in order to obtain the final foamed component. The shape of the precursor can be ruled by using a complex shaped substrate or by imposing a complex trajectory at the cold spray gun.

In line with this topic and with the scope to explore in details the developed manufacturing process, two different sets of samples were produced by varying the cold spray process parameters aiming at: i) studying the advantages and the issues of cold spray for manufacturing precursors for metal foams; ii) analyzing the correlation among the CS printing strategy and parameters, the foaming process and the physical and the morphological characteristics of the resulting foams; iii) finally, finding appropriate conditions to form closed-cells aluminum foams via CS.

For this scope, AlSi10Mg fine powders were mixed with titanium hydride particles to form the powder mixture precursors. Then, the low-pressure cold spray facility was used for the powder deposition by using different CS printing parameters; hence, the foaming process was carried out. SEM observations of the cross-sections of both the precursors and the resulting foams were carried out, pointing out the effectiveness of the process and the critical issues to be faced when cold spraying precursors for metal foams.

Materials and Methods

Micron sized powders of aluminum alloy AlSi10Mg and titanium hydride TiH_2, provided by LPW South Europe and Dymet, respectively, were used in this experimentation. The particle mean size of AlSi10Mg powder is 25 μm, while the mean diameter of TiH_2 particles is 10 μm.

The powder mixture was obtained through the sound assisted fluidization bed processes; the use of fluidization makes it possible to handle and process large quantities of powders, so obtaining a mixing to the scale of the primary particles [14]. The fluidization and mixing tests of these cohesive fine powders were performed by the experimental apparatus schematically reported in Fig. 1. It consists of a metallic fluidization column equipped with a porous plate gas distributor to maximize the uniformity of the gas flow rate entering the column. The acoustic field is introduced inside the column through a sound wave guide located at the top of the column. Pure dry nitrogen from a compressed tank is used as fluidizing gas. All the tests were carried out at room temperature and ambient pressure conditions. Both the preliminary fluidization/mixing tests and the

preparation of the final AlSi10Mg-TiH_2 mixtures to be used to produce the metal foam precursors were performed in this experimental apparatus.

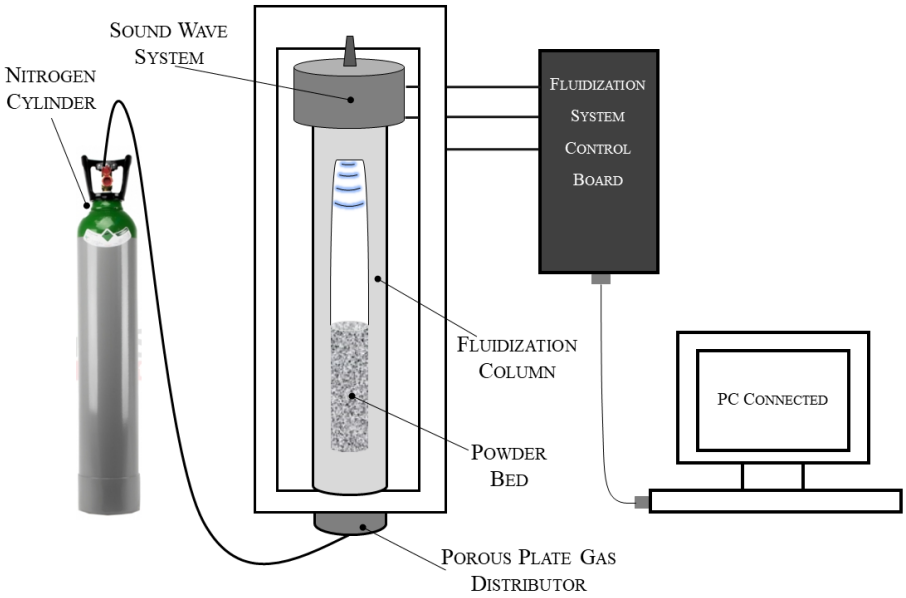

Fig. 1. Sound assisted fluidization bed process apparatus.

A mixture with a 2.5 wt.% of TiH_2 was prepared. The following fluidization process parameters were used based on preliminary fluidization/mixing tests: i) gas flow rate: 70 l/min; ii) acoustic field: 80 dB-150 Hz; fluidization time: 30 min. The SEM picture (Fig. 2) shows the effective mixing achieved with the blowing agent particles homogeneously dispersed within aluminum alloy powder.

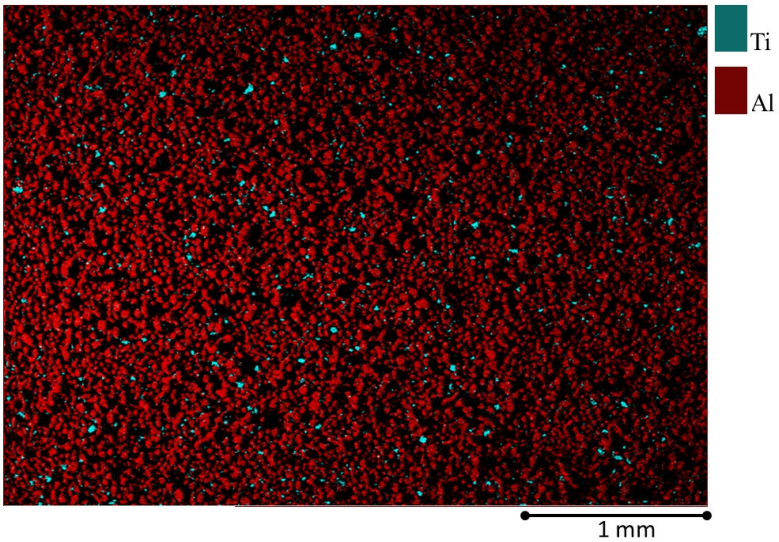

Fig. 2. SEM picture showing AlSi10Mg-TiH_2 mixture achieved through sound assisted fluidization bed process (2.5 wt.% of TiH_2, nominally).

The low-pressure cold spray facility was used for spraying the powder mixture constituting the foamable precursors. The spraying parameters such as fluid temperature and fluid pressure, stand-off distance (the distance between the substrate and the nozzle) and horizontal speed nozzle across the substrate were chosen after a preliminary experimental campaign that is not discussed in this paper for the sake of brevity. Two different sets of samples were produced by varying the cold

spray process parameters, in agreement to what reported in Table 1. The first raw of Table 1 reports the CS process parameters (CS_L) used to obtain less compact precursors characterized by internal microporosities that should promote the bubbles growth and the formation of lightweight materials. The second raw reports the CS process parameters (CS_H) used to manufacture more compacted precursors.

Table 1. Deposition process main parameters.

	Gas used	Gas temperature [°C]	Gas pressure [bar]	Stand-off distance (SoD) [mm]	Speed nozzle [mm/s]
CS_L	Air	400	6	30	1.0
CS_H	Air	600	7	5	1.0

The mixture was sprayed on a C40 thin steel plate producing a 30x40 nominal plane shape. One single pass was imposed to the spray gun, in agreement with the strategy shown in Fig. 3a. Macrographs of the foamable solid precursors manufactured via cold spray under CS_L and CS_H process conditions are shown in Fig. 3b and Fig. 3c, respectively.

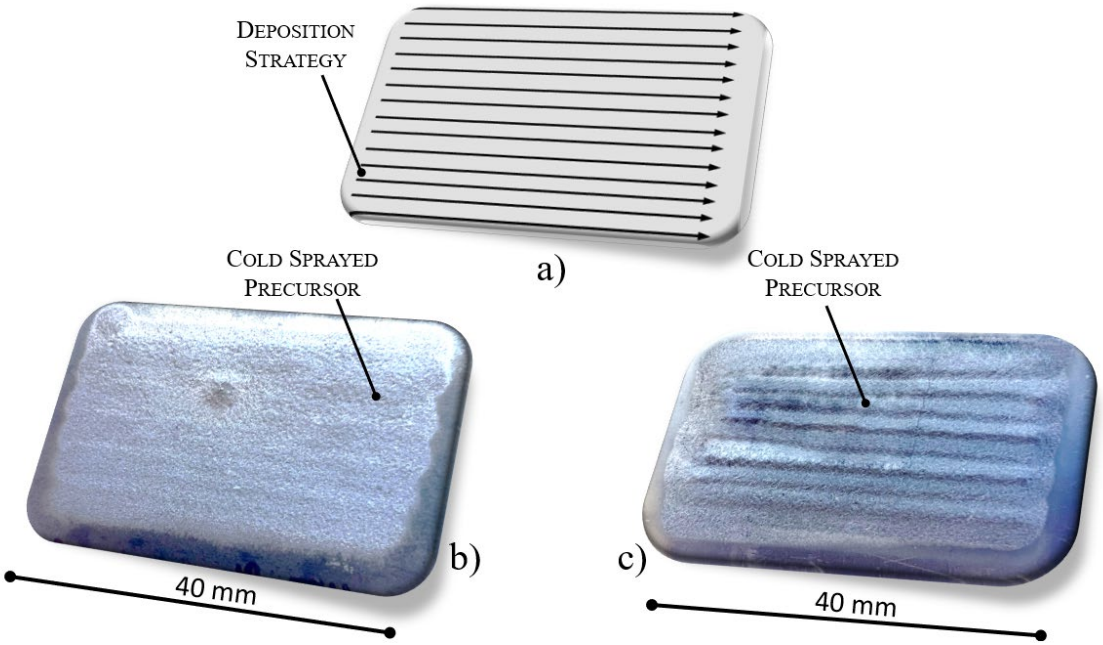

Fig. 3. a) Cold spray deposition strategy; b) macrograph of foamable solid precursor produced with CS_L process parameters; c) macrograph of foamable solid precursor produced with CS_H process parameters.

All the precursors made via cold spray were inserted within a preheated furnace set at a temperature of 660°C for the foaming process. The time needed for expansion was estimated in the range of 4-6 minutes; afterwards each sample has been taken out from the furnace and cooled at room temperature.

The cold sprayed precursors (obtained via CS_L and CS_H process parameters) before foaming as well as those resulting from the foaming process were cut for the cross-section observations. Hence, all the specimens were mounted and prepared according to the international ASTM standards for metallographic analyses through SEM microscopy. The blowing agent distribution after the cold spray deposition was analyzed, the shape of the cell and the expansion of the foam

were examined for the foamed samples. EDS inspections were also carried out with the scope to analyze the phenomena resulting from the foaming process, highlighting the critical issues of the manufacturing technology, for leading optimized process conditions.

Results and Discussion

The results from the SEM observations of the cross-sections of the cold sprayed precursors before foaming obtained by using CS_L and CS_H process parameters are reported in Fig. 4 and Fig. 5, respectively.

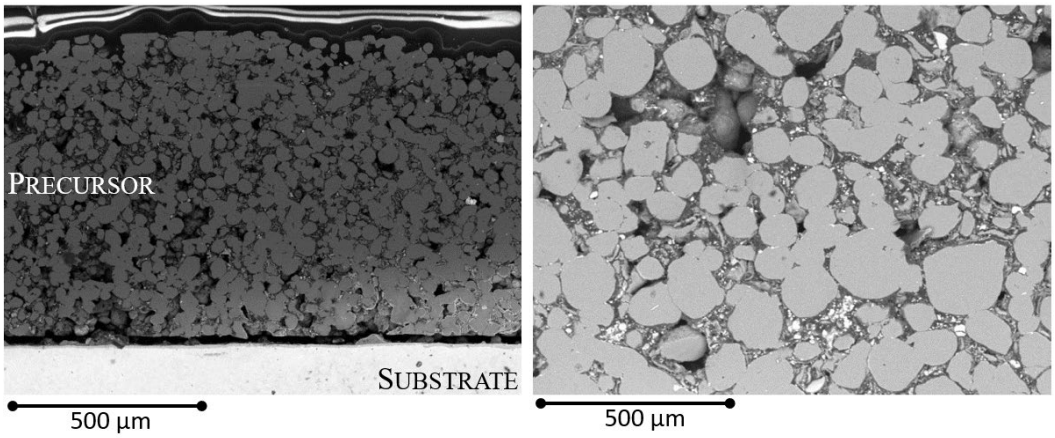

Fig. 4. SEM observations of the cross-sections of the cold sprayed precursors before foaming obtained by using CS_L process parameters at a) 150x, b) 500x.

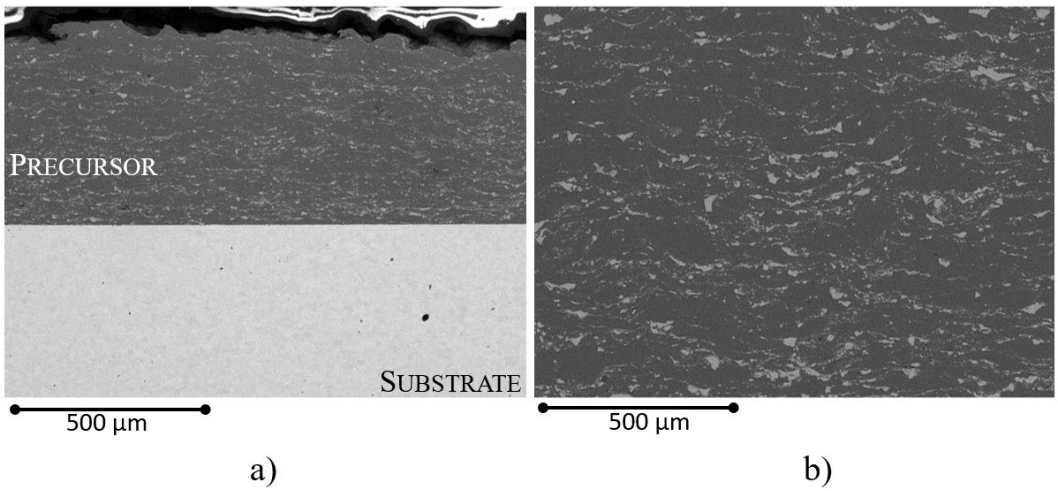

Fig. 5. SEM observations of the cross-sections of the cold sprayed precursors before foaming obtained by using CS_H process parameters at a) 150x, b) 500x.

From Fig. 4a the thickness of the specimen was estimated to be equal to about 800 µm. Moreover, voids and microporosities are well visible with the particles that are not completely deformed during the impact. This is clearer by looking the picture in Fig. 4b at 500x magnification. The white particles are the fragile TiH_2 powders that keep entrapped among aluminum particles, forming cluster and agglomerations homogeneously dispersed within the metal powders.

The cold sprayed precursors obtained by using CS_H process parameters are denser and more compact, as expected from literature [15], the particles deformed and flattened, and the coating thickness reduced at about 500 µm, due to particles compactness (Fig. 5a). The higher magnification picture in Fig. 5b shows a precursor appearing quite dense and free of porosity, with

the foaming agent particles (the lighter zones in the figure) homogeneously dispersed within the aluminum-silicon matrix. In fact, as proved in literature [16,17], the cold spray technology can create metal matrix composite depositions by mixing fragile materials with ductile material particles that deform and promote the coating formation and grow-up. Moreover, a stratification of TiH_2 particles, related to technology employed, can be identified.

Anyway, in both the examined cases, EDS analyses confirmed a weight percentage of TiH_2 within the coatings equal to 2.5±0.5 wt. %., proving the capability of CS to deposit the AlSi10Mg-TiH_2 mixture of precursor.

Fig. 6 shows the micrographs of the cross-sections of the aluminum foams obtained starting from the above-described precursors.

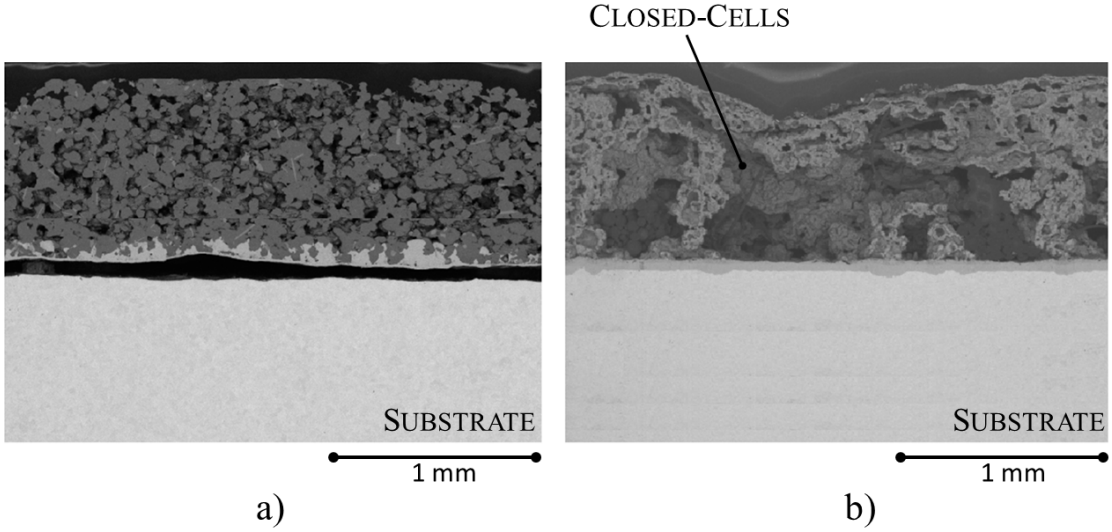

Fig. 6. Micrographs of the cross-sections of aluminum foams produced starting from precursors obtained by using: a) CS_L process parameters; b) CS_H process parameters.

It can be seen from Fig. 6a that no foaming occurs when the precursor is not quite compacted, and the CS process parameters are not properly set. In this case, the foaming agent was not capable of expanding the thick and so-already existing porous structure. The possible reason is that the oxygen entering within the porous material oxides completely the metal matrix that cannot expand and form the bubbles under the force of hydrogen released by TiH_2 dissociation mechanism. On the contrary, it can be seen from Fig. 6b that the material expands when the precursor is denser and well compacted, leading to a foam relative density [3] equal to 0.35, with the foam percentage porosity of 65%. Under these conditions, the aluminum matrix melts, and the foaming agents blows to form the closed-cells aluminum foams.

Summary

Based on the experimental results presented and discussed in the previous sections, the following conclusions could be drawn:

- The cold spray technology seems to be an effective technique to produce precursors for closed-cells aluminum foams.
- The sound assisted fluidization bad processes can be used to mix effectively micron size AlSi10Mg and TiH_2 particles forming the precursor, under the following process parameters: i) gas flow rate: 70 l/min; ii) acoustic field: 80 dB-150 Hz; fluidization time: 30 min.
- An existing porous structure for the precursor does not enhance the foaming process and the bubble formation.

- The CS process parameters need to be properly set (appropriate process parameters were found here: gas temperature: 600°C, gas pressure: 7 bar, SoD: 5 mm) to produce dense, compact and free of porosity metallic precursors, which are the characteristics to be ensured for a successful foaming.

Keywords: Machine Learning, Cold Spray, Composites, Neural Networks, Thermal Spray

Abstract. Cold spray is a novel production technology for creating metallic layers on various materials. Using a pressurized gas travelling at supersonic speeds, the metallic particles are accelerated and impact the target surface obtaining adhesion through mechanical interlocking between the powders and the substrate. This method is especially well suited for coating thermosensitive materials like composites since it only requires a little amount of heat, as the powders remain in a solid state. The quality and comprehension of this manufacturing process can be greatly improved by using machine learning techniques. In order to evaluate the characteristics of the particle's deformation upon collision, the goal of this work is to forecast it using machine learning approaches. The parameters chosen as an input for the model were related to 3 macro-categories: process parameters, powder parameters and substrate parameters. As regards the output parameters, flattening and penetration were chosen as they are the main characteristics of the coating on which homogeneity and adhesion depend. In order to obtain reliable results, a mix of data FEM and experimental data were used to train the neural network. The model was then tested on a dataset of experimental data.

Introduction

The drive to reduce weight and manufacturing costs has raised the demand for polymeric materials dramatically in recent years. Thermosetting polymers, in particular, have become widely employed in a variety of industries, including aerospace, since they may be used as matrix for fibre-reinforced composite materials. However, as environmental concerns become more generally acknowledged, the use of thermosets is severely limited since they cannot be reused or recycled once the curing process is complete. High-performance thermoplastic materials, such as PEEK or ABS, are gaining popularity because of their high toughness, high melting temperature, and 100% recyclable nature.

Nonetheless, several applications remain out of reach because of these materials' poor surface qualities, such as poor wear and scratch resistance and low electrical conductivity. As a result, surface metallization may be the best option for combining the benefits of metals with thermoplastic polymers. However, when using the most common metallisation procedures, the melting temperature of the metallic materials to be sprayed must be reached, modifying its original properties and causing thermal distortions in the substrate.

Cold Gas Dynamic Spray, which uses kinetic energy and involves temperatures well below the melting point of the metallic particles, can be an adequate alternative for improving the surface properties of polymers [1].

This approach is based on the high-speed impact of solid-state metallic particles; no chemical reactions are required, and deposition is made possible in large part by mechanical interlocking between the particles and the substrate [2].

Although this technology has been widely explored and employed on metal substrates, the underlying physics when the substrate is a polymer is yet unclear [3]. Because the final coating characteristics (such as powder deformation or penetration depth, which are closely related to coating adhesion) depend on a variety of factors, including the properties of the metallic powder and the polymeric substrates, as well as the spraying parameters set for the process, it is currently impossible to accurately predict how the metallic particles will behave when they impact on various substrates.

For this reason, several computer models have been developed recently to mimic the Cold Spray process' operational parameters and predict how a particle would behave when it comes in touch with a substrate [4-6]. The coating process utilized on polymers and composites, however, has only been the subject of a small number of publications published so far. A physical model that could precisely depict the processes that occurred when metallic particles were deposited on non-metallic substrates, however, was not practical to develop. In order to validate those models, it would be necessary to gather hundreds of testing scenarios and outcomes utilizing top-of-the-line tools (including sensors and high-speed cameras).

In this scenario, machine learning might potentially reduce the number of required experimental trials. As machine learning (ML) solutions are typically considered "black boxes," in order to have accurate forecasts, it is necessary to feed the model with accurate and numerous data. For this reason, training the model with a mix of experimental data, which are accurate but often scarce and fragmented, and computational data obtained from Finite Element models (FEM), which do not suffer from the issues of experimental data but are less accurate, could be a good solution to obtain accurate predictions of the coating characteristics.

With knowledge of the process parameters, particles and substrate characteristics, a machine-learning approach is used to forecast the deformation and flattening of the metallic particles after deposition.

Using low-pressure equipment, 30% of the data from the training set and the entire test set were collected experimentally, employing SEM analyses to determine the flattening and penetration depth.

The remaining test dataset was produced by performing a FE simulation of copper, aluminium, steel and particles collision upon PEEK and ABS-based polymeric substrates. Three best Machine Learning models have been selected: Linear regression, Gaussian process regression and Neural networks. In order to provide a methodological approach for future studies, a comparison of the results obtained with a dataset entirely composed of data obtained from the FE model and of the results obtained with the dataset composed of a mix of experimental and FEM data is proposed.

Materials and Methodologies

Input and output parameters**.**

The input parameters for the employed strategies fall into three macro-categories: impact velocity, which includes all the other process parameters such as temperature and pressure; *powder parameters* (Yp), which represent the yield strength of the powder material and *parameters of the substrate* (Ys), i.e. the yield strength of the substrate material, which also takes into account the presence of the fibres since these, if positioned appropriately under a layer of matrix at least comparable to the size of the powders, only stiffen the substrate, thereby causing a variation of the yield strength. The considered output parameters are the *penetration depth* of the particle and the *flattening*. The definition and evaluation of both parameters is furtherly illustrated in the following sections.

Dataset.

As highlighted in the introduction, the datasets employed were constructed employing both FEM and experimental data. In particular, the first training dataset is composed of 30% experimental data and 70% FEM data (mixed data), while the second dataset contains only FEM data. The test dataset for both suggested models is fully made up of experimental data.

CS experimental input data generation.

The substrate selected for the deposition was Polyether-ether-ketone (PEEK) and Acrylonitrile butadiene styrene (ABS), both unreinforced and reinforced with long carbon fibres.

The copper, aluminium and steel spherical powders were provided by LPW South Europe. Low-pressure cold spray equipment (DYCOMET) was used to conduct the aforementioned depositions.

Air was used as the carrier gas since earlier research found no discernible changes when other carrier gases were used [7–9]. The samples were positioned on a platform, and the spraying gun was installed on a robot (HIGH-Z S-400/T-CNC-Technik) and operated remotely while operating perpendicular to the substrates. The process parameters employed and the characteristics of the powders employed for the experiments are highlighted in Table 1.

Table 1. Characteristics of the powders and process parameters employed for the CS experiments.

Particle parameters	***Copper***	***Aluminium***	***Steel***
Mean radius [μm]	20	18	23
Yield strength (Yp) [GPa]	0.033	0.18	0.29
Process parameters			
Inlet Gas temperature [°C]	100 - 400	100 - 400	100 - 400
Standoff distance [mm]	10 - 4	10 - 4	10 - 4
Inlet gas pressure [MPa]	0.5 - 0.6	0.5 - 0.6	0.5 - 0.6
Gun traverse speed [mm s^{-1}]	7.5	7.5	7.5

For the purpose of measuring the flattening of the powders, the top surface of the coating was examined. The mean radius of the particles after the collision with the substrate (r) was measured using Image J software to calculate the percentage of particle flattening, defined as $r/r_0\ [\%] = \frac{(r-r0)}{r0}100$, where r_0 is the mean radius of the particle before the impact. The flattening values taken into account are the average flattening values calculated on three separate 500x500 micron micrographs that were examined. In order to evaluate the radius before and after the impact, SEM micrographs were analyzed through the Image J software, as portrayed in Fig.1.

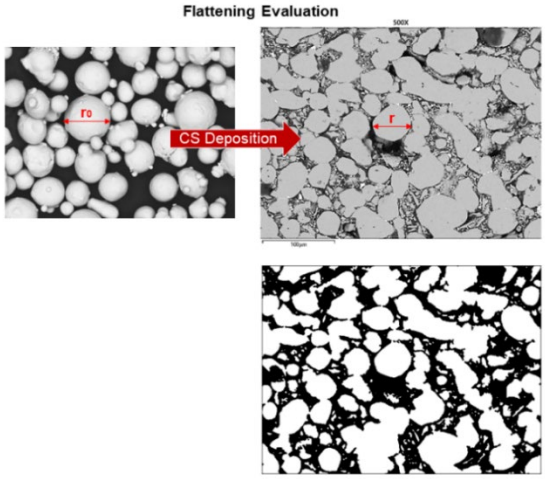

Fig. 1. Evaluation of the particles' mean radius before (r_0) and after the deposition (r).

To measure the penetration depth, the specimens were cut perpendicular`r to the top surface to inspect the cross-section and evaluate the height of the particle upon the impact [Hs0]. The penetration depth was defined as $Hs\,[\%] = \frac{(Hs_0 - Hs)}{Hs}\,100$. The specimen cross section was analysed in order to evaluate the height of the particle after the impact, SEM microscopy was employed as shown in Fig 2.

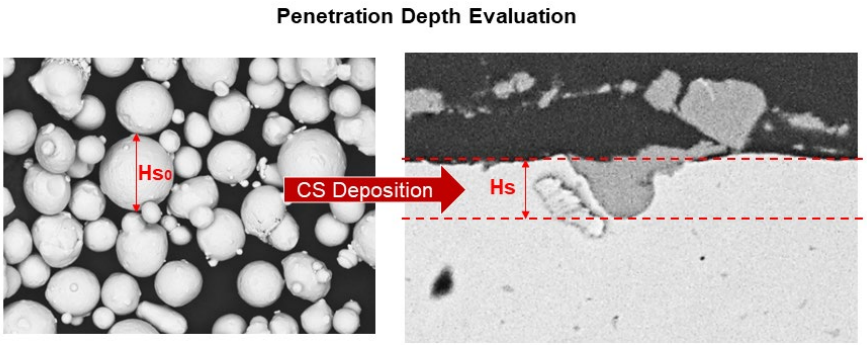

Fig. 2. Evaluation of the particles' mean height before (Hs_0) and after the deposition (Hs).

FEM input data generation.

A Lagrangian reference frame, which is frequently utilized in literature to represent high-velocity impact with minimal computing expense, was employed to model both the particle and the substrate. Using a 2D-axisymmetric model and an explicit dynamic analysis that took into account adiabatic heating effects, it was possible to simulate a spherical particle hitting perpendicular to a substrate that is at least five times bigger than the particle. This particle-to-substrate size ratio was determined by assuming that the elastic waves reflected from the boundaries did not reach the interface upon impact.

In keeping with the average particle size of the powder utilized for the experimental tests, a particle diameter of 20 microns was used for the simulation. The features of the substrate and the particles have been identified via earlier experiments using the supplies on hand at the testing site.

The Johnson-Cook model for plastic materials was used to model the behaviour of both the particle and the substrate's materials, and one of the ABAQUS software's algorithms—the surface-to-surface penalty contact algorithm—was used to model the interaction between the substrate and the impacting particle. The impact simulations were performed for each material combination (copper, aluminium, 316L steel, on PEEK and ABS) by varying the particle's speed between 50 m/s and 350 m/s with an increasing step of 30 m/s. The model generated 50 different values for the particle's penetration and flattening ratio depending on the input parameters.

ML Approaches and Performance Evaluation

We used three machine learning approaches: Linear regression (LR) Gaussian process regression (GPR) and Neural networks (NNs). LR is a simple method for determining a linear relationship between variables. This relationship illustrates the functional connection between the independent and dependent variables for a specific dataset. Consequently, LR models the unknown or dependent variable and the known or independent variable as a linear equation [10].

GPR is a nonparametric Bayesian method used for regression [11]. It performs well on small datasets and it infers a probability distribution model over all acceptable data-fitting functions. The neural network employed is a function-fitting neural network with three layers which is trained on the whole dataset. It can generalize an input-output relationship after training the data.

In order to evaluate the performance of the ML approaches, we calculated the Root-mean-square error (RMSE) [11], the R-Squared [12], the Mean Squared Error (MSE) [13] and Mean Average Error (MAE) [14].

RMSE is the square root of the squared mean error and is an outlier-sensitive metric.

R-squared is a linear regression model goodness-of-fit metric which represents the proportion of the variance in the dependent variable explained by the independent variables. R-squared measures the strength of the association between the model and the dependent variable.

The MSE indicates the mean squared discrepancy between the observed data values and the estimated data values.

MAE represents the distance between the predicted value and the measured value. When the values of these metrics are low, the model is more accurate.

Results and Discussion

In this section, the experimental results on the FEM dataset and the mixed dataset (FEM and experimental data) will be shown and discussed. Below are the best findings from each experiment.

Experiments with FEM-based dataset.

Observing the output by training the model with FEM data, it was possible to assess that the best models on the test set for penetration and flattening prediction were the forecast obtained with the GPR method (see Fig.3 and Fig.4). More specifically, the GPR model shows improved the penetration values and a decline in flattening performance. To comprehend this decline in flattening model evaluation metrics, further studies need to be conducted.

Penetration depth prediction (GPR)	
RMSE	1.45
R-Squared	0.73
MSE	2.1026
MAE	0.7654
Prediction Speed	~2200obs\sec

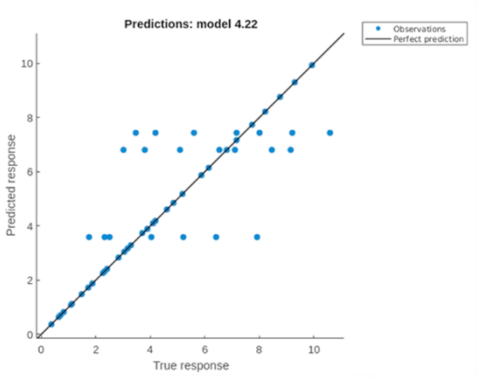

Fig. 3. Performance for the penetration depth prediction for FEM data.

Flattening prediction (GPR)	
RMSE	4.7387
R-Squared	0.34
MSE	22.451
MAE	2.0051
Prediction Speed	~1900obs\sec

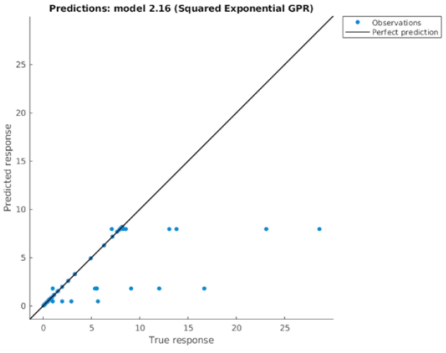

Fig. 4. Performance for the flattening prediction for FEM data.

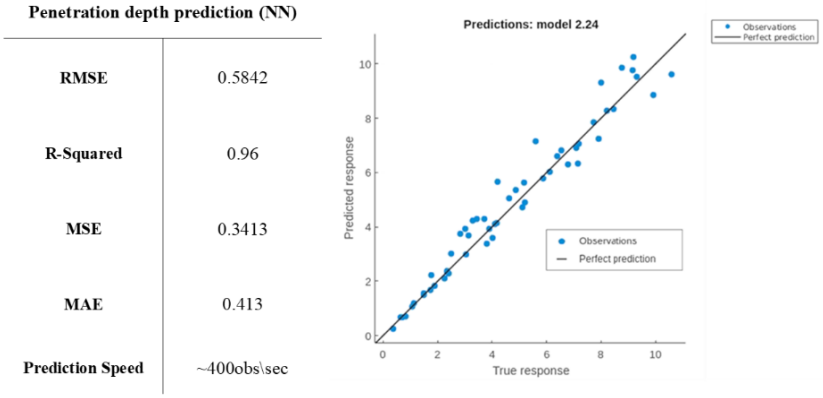
Since the error values are quite small, we may conclude that the FEM models are capable of approximating the experimental data fairly correctly. In this context, machine learning can be an excellent tool for accelerating finite element analyses, which require a high computing cost. For this reason, machine learning may be used to simplify the models without losing information or to perform predictions on additional combinations of materials without the need to run additional simulations.

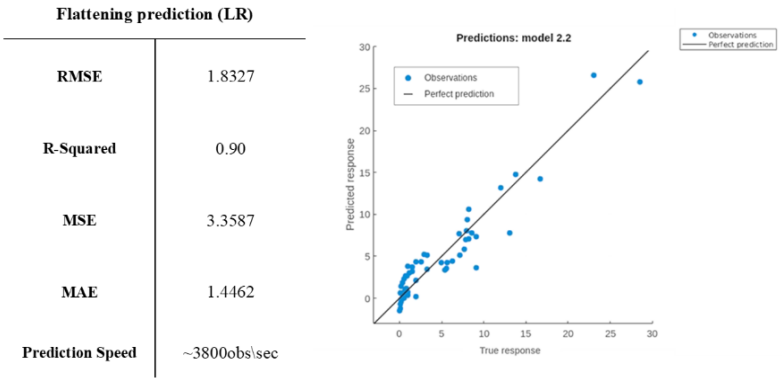
Experiments with dataset MIX.

The top models for the penetration on the test set are NN and LR for the flattening prediction, according to training the model with mixed data, as we can see in Fig. 5 and Fig. 6.



Penetration depth prediction (NN)	
RMSE	0.5842
R-Squared	0.96
MSE	0.3413
MAE	0.413
Prediction Speed	~400obs\sec

Fig. 5. Performance for the penetration depth prediction for mixed data.



Flattening prediction (LR)	
RMSE	1.8327
R-Squared	0.90
MSE	3.3587
MAE	1.4462
Prediction Speed	~3800obs\sec

Fig. 6. Performance for the flattening prediction for mixed data.

It is possible to observe that by integrating the training set with experimental data, the prediction error may be furtherly lowered. In fact, by including 30% of experimental data in the training dataset, it is possible to obtain more accurate models.

Future investigations are required in order to assess the optimal value of the ratio between the experimental data and the FEM data in the training set, in terms of the accuracy of the prediction and the resources employed to create the dataset. In Fig. 7, we depicted the comparison of performance for penetration and flattening. For penetration, the best results, except for R-Squared, are achieved when the models is trained with mixed data. A similar behaviour is also evident when we consider the flattening output parameter.

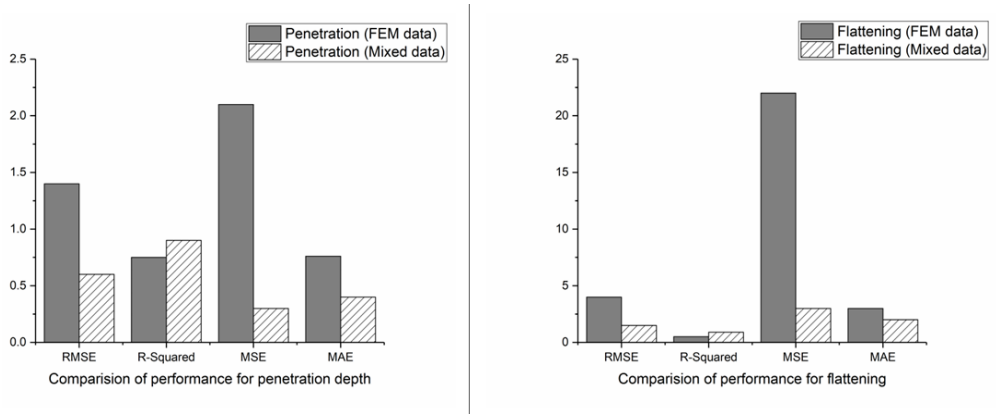


Fig. 7. Performance for penetration and flattening prediction for FEM and mixed data.

Summary

This study provides an overview of how machine learning techniques can be used to more accurately predict particular coating features, such penetration and flattening, in order to increase process efficiency. To be more precise, two sets of data, FEM data and mixed data (experimental and FEM data), were used to test various models, and the best ones—the GPR, LR, and NN—were selected.

The performed experiments show that the models get more accurate as the amount of data available increases. In particular, models fit the data better when trained on the mixed dataset. By providing a preliminary examination of the contribution of the parameters influencing the coating deposition, the use of machine learning appears to contribute to the optimization of the Cold Spray process. Future research can assist expand the dataset required to train the models and forecast the ideal combinations of parameters which will enhance the coating process.

Abstract. Direct metal laser sintering is a 3D-printing technology involving a multitude of physical phenomena requiring the fine-tuning of multiple parameters (e.g., laser power, layer thickness) to achieve satisfying fabrication results [1]. Modifying each of these parameters can significantly influence the resulting material characteristics of the fabricated parts [2]. This work investigates the impact of the modification of the process parameters on the material characteristics of hardened aluminum specimens. A design of experiments was used to fabricate 85 aluminum specimens using 17 printing parameter sets. The specimens' dimensional accuracy, surface roughness, hardness, density, porosity, and thermal conductivity were investigated. Standardized, as well as self-designed test setups were used for this purpose. Furthermore, porosity measurements and microstructural investigations were performed using scanning electron microscopy and reflected light microscopy.

Introduction

Direct metal laser sintering (DMLS) is a well-known manufacturing technique that fabricates metallic structures following the layer-by-layer deposition principle. The metallic powder is selectively melted by a high-energy laser beam, following instructions from a 3D-CAD model (STL format). The solidification of tiny melt pools generated along the laser tracks create strong bonds between the different layers [3].

Due to the high process complexity of DMLS, every alloy requires tailor-made printing parameters ("standard parameter sets") to achieve maximum part density. Each parameter (e.g., hatch distance) can indeed influence one or several of the involved physical phenomena during printing (e.g., powder bed formation, fluid dynamics of the molten pool, solidification, residual stresses, heat absorption), resulting in strongly differing micro- and mesostructures [4]. It is also possible to modify these parameters to adjust the material characteristics of the fabricated structures (e.g., porosity). Furthermore, this can achieve parts with specific material characteristics (e.g., mechanical strength, thermal conductivity, damping capacity). However, to adjust the properties as desired, it is necessary to study all the involved phenomena, their mutual influence and their impact on the solidified micro- and mesostructure.

In this paper, we present the results of our work aimed at determining the influence of the main DMLS process parameters on the material properties of manufactured parts. We followed a design of experiments (DoE) methodology, and fabricated 85 specimens with 17 different sets of printing parameters (5 specimens per parameter set). The material characteristics (dimensional accuracy,

surface roughness, hardness, density, porosity, and thermal conductivity) were then investigated using professional and self-designed tools.

Method and Material

The process regarding the development, fabrication, and characterization of aluminum specimens with different material characteristics is schematically shown in Fig. 1.

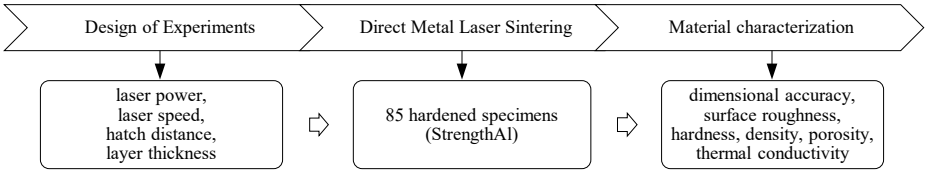

Fig. 1. Process for investigating the material characteristics of aluminium specimens fabricated with different printing parameter sets.

Design of Experiments. A DoE was performed, using the following variable parameters: laser power (P) [W], laser speed (v) [mm/s], hatch distance (h) [mm], and layer thickness (t) [mm]. The full factorial design (4 factors, 2 levels) results in 16 experiments with different energy densities (E) [J/mm³] given by:

$$E = \frac{P}{v \cdot h \cdot t} \quad (1)$$

To detect non-linear dependencies between factors, we added the "center point" experiment corresponding to the average values of parameters.

The specimens had the shape of rectangular solids (12*12*75 mm³), directly attached to the build platform without a support structure. Each printing parameter set from the DoE (17) was used five times. We, therefore, fabricated 85 specimens in total. The powder material is "StrengthAl" from the company m4p GmbH, a hardenable high-strength aluminum alloy consisting of Aluminum (main alloying element), Magnesium, Silicon, Scandium, Titanium, Zirconium, Manganese, and Chrome [5].

Direct Metal Laser Sintering. The fabrication of the specimens was executed with an EOS M290 printing system with a build volume of 250*250*325 mm³ and a 400 W Yb-fiber laser (spot size 100µm). A ceramic blade (hard recoating) was used for the powder recoating, and Argon as an inert gas. The platform temperature was set to 180°C. The exposure sequence of the specimens was directed against the gas flow to keep the concentration of impurities as low as possible. The "stripes" exposure pattern was used (stripe width 7 mm), and the rotation angle was set to 67°.

The specimens were hardened afterward (precipitation hardening – 6 hours, 350°C, slow cooling in the air). Machining (milling, turning) was then performed on the specimens to achieve proper test geometries.

Material characterization. One set of specimens (17 different printing parameter sets) was used for microstructural investigations and porosity measurements via scanning electron microscopy (SEM) (JSM-IT500 – JEOL) and reflected light microscopy (RLM) (Axio Imager.M2m – Zeiss). The specimens were embedded in cold embedding resin (CEM 1000 Blue Pulver) with subsequent grinding and polishing operations (Silicon Carbide paper – grain size P1200, diamond suspension – grain size 3 µm, Silicone Dioxide suspension – grain size 0.05µm). The metallographic specimens were then further treated with a Keller-Wilcox etchant.

The four remaining sets of specimens (4x17 specimens) were used to investigate the specimens' dimensional accuracy, surface roughness, hardness, density, porosity, and thermal conductivity. All tests were performed at room temperature (20°C).

Material Characteristics

Dimensional accuracy.

The dimensional inspection of the specimens (as-build) was executed using an outside micrometer (Micromar 40 ER – Mahr) with a resolution of 0.001mm. Both side lengths of the quadratic specimens were measured ten times (20 measurements per specimen). The dimensions as a function of the applied energy density are shown in Fig. 2.

There is quite a large dispersion in the measurement results (the standard deviation is high, for a given energy density, but there is also significant variability depending on the energy density: 11.906 – 12.433 mm). This phenomenon is at least partly due to the increase in the size of the melt pools when the energy density increases. Bigger melt pools also tend to aggregate more particles on the edges of the test specimens. It can be seen, however, that specimens fabricated with the same energy density but with different printing parameter sets (e.g., 112.23 J/mm³) show differences regarding their dimensions (red circles vs. black crosses).

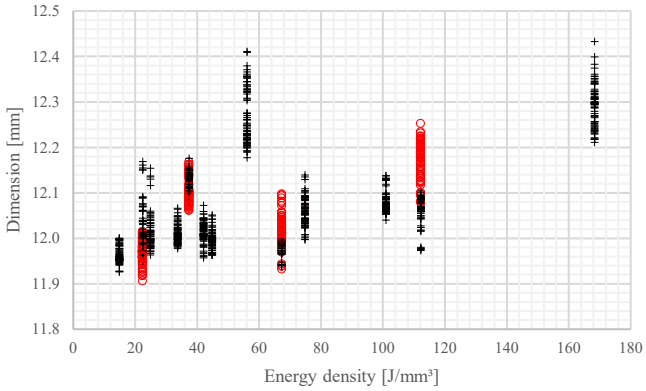

Fig. 2. Dimensional accuracy of printed specimens as a function of the applied energy density.

Surface roughness.

The surface roughness of the specimens (as-build) was measured using a perthometer (MarSurf GD25 – Mahr). Each side of every specimen was measured twice (8 measurements per specimen). The arithmetic average roughness (R_a), the average peak-to-valley profile roughness (R_z), and the maximum peak-to-valley profile height (R_{max}) as a function of the applied energy density are shown in Fig. 3.

The graph shows a correlation between the applied energy density and the surface roughness. The surface roughness slowly increases with the applied energy density, partly due to the increase of the size in the melt pools. Indeed, more particles adhere on the edges of bigger melt pools, which results in rougher surfaces. However, the energy density partly explains the observations. Specimens fabricated with the same energy density but with different printing parameter sets (e.g., 112.23 J/mm³) may not have the same surface roughness (red vs. black).

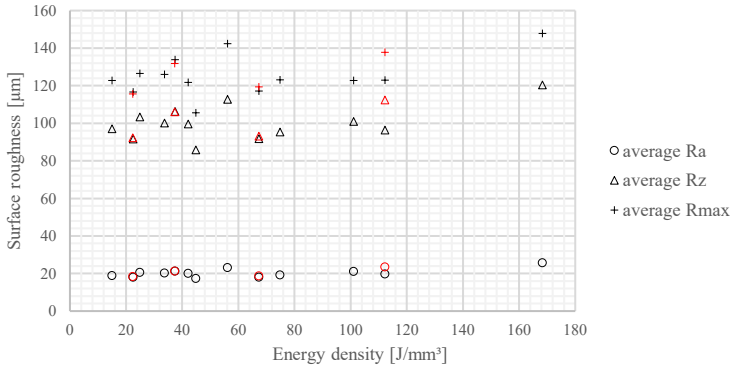

Fig. 3. Surface roughness of printed specimen as a function of the applied energy density.

Hardness.

The hardness testing of the specimens (milled) was performed using a universal hardness testing machine (ZHU 187.5 – ZwickRoell). Here, the Vickers hardness (HV) was measured using a diamond pyramid with an angle of 136° and a test force of 98.07 N. Each side of every specimen was measured twice (8 measurements per specimen). The HV as a function of the applied energy density is shown in Fig. 4.

The range of variation of the measurement results is extensive (46.2 – 163.1HV). The results show that the hardness increases to a certain energy (~70J/mm³). It then decreases again. This phenomenon is a consequence of the different printing parameter sets (different energy inputs) in combination with the subsequent hardening process. In the case of DMLS parts, hardening ("solution heat treatment") already occurs during the fabrication process when the melt pools quickly cool down. The second annealing step, called "aging treatment" still has to be performed afterward. Therefore, the solution heat treatment varies due to the different energy inputs of the printing parameter sets. Besides, specimens fabricated at lower energy densities show a more significant standard deviation in the measurement results than those fabricated at higher energy densities due to differences in the resulting porosity. The probability of hitting a (hidden) pore with the indenter is much higher in a porous material than in a more homogeneous one (the porosity increases when the energy density decreases, as shown later in this paper). It can also be seen that specimens fabricated with the same energy density but with different printing parameter sets (e.g., 112.23 J/mm³) show differences regarding their hardness (red circles vs. black crosses).

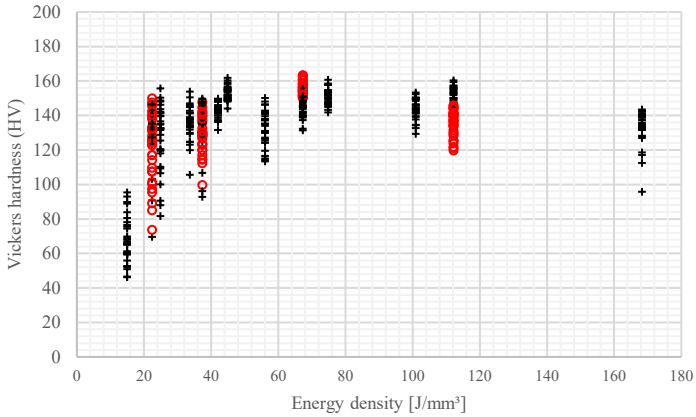

Fig. 4. Vickers hardness of printed specimens as a function of the applied energy density.

Density. The density (ρ) [g/cm³] of the specimens (milled) was determined according to:

$$\rho = \frac{m}{V} \quad (2)$$

where m [g] is the mass, and V [cm³] is the volume of the specimens. The specimens' weight was measured using a high-precision scale (AG204 DeltaRange - Mettler Toledo) with a resolution of 0.0001g. The specimens' volume was calculated using the dimensional inspection's measured volume. The density as a function of the applied energy density is shown in Fig. 5.

The range of variation of the measurement results is wide (2.21 - 2.65 g/cm³). The density significantly increases up to an energy density of about 30 J/mm³ and stays more or less constant above this point. There are no significant differences between specimens fabricated with the same energy density but different printing parameter sets (e.g., 22.45 J/mm³, red circles vs. black crosses).

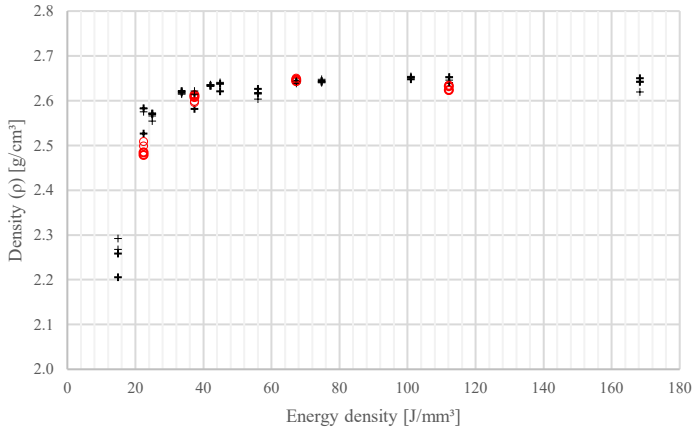

Fig. 5. Density of printed specimens as a function of the applied energy density.

Porosity and microstructure.

The porosity (pore size and pore size distribution) of the 17 metallographic specimens was measured using RLM and image processing software (ZEN core – Zeiss). The average total pore area in percent as a function of the applied energy density is shown in Fig. 6.

The range of variation of the measurement results is large (0.04 – 21.16%). The porosity significantly decreases for an energy density below 30 J/mm³. It stabilizes around 30 J/mm³ before slightly increasing for higher energy densities (>110 J/mm³). Specimens fabricated with the same energy density but with different printing parameter sets (e.g., 22.45 J/mm³) show differences regarding the average total pore area (red circles vs. black crosses).

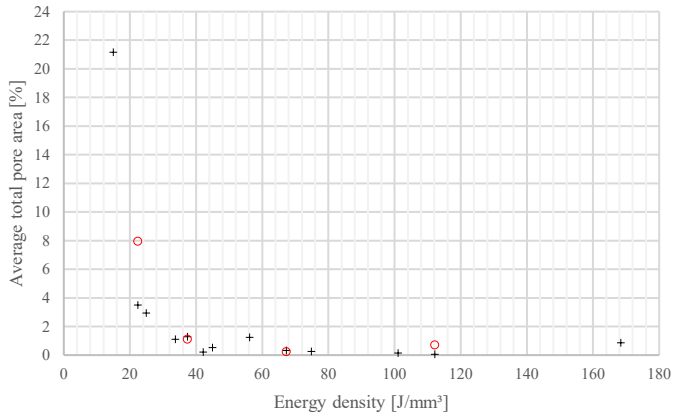

Fig. 6. Average total pore area of specimens as a function of the applied energy density.

The structure of the 17 metallographic specimens was further investigated using RLM and SEM. In this paper, we compare two specimens, the one with the lowest porosity (0.04%), and the one with the highest porosity (21.16%).

At first, the metallographic specimens (polished, not etched) were investigated using RLM, as shown in Fig. 7. Here, the different porosities are noticeable (Fig. 7, A vs. Fig. 7, B). A closer look at the porous structure (Fig. 7, B) shows that the pores are homogeneously distributed throughout the entire geometry. Due to irregular cooling rates (which depend on the build height and geometry of the printed part), DMLS parts can have an inhomogeneous microstructure with anisotropic material characteristics [6]. In our case however, the build height did not appear to influence the pore size and pore size distribution.

The metallographic specimens (polished, not etched) were further investigated using SEM, as shown in Fig. 8. Here, a magnification of 50 was used. The pictures clearly show the differences between the specimens regarding porosity. In the image of the porous structure (Fig. 8, B), fine powder particles that were not melted during the print job are still visible. There are significant differences in the size and shape of the pores. Also, note that the build direction cannot be detected from the pictures.

The metallographic specimens were etched to investigate them via RLM further, as shown in Fig. 9. Now, the typical laser beam tracks due to the layer-wise manufacturing principle of DMLS are visible. Fine powder particles are again apparent in Fig. 9, B. Splashes or inclusions could not be detected.

In addition, Energy Dispersive X-ray Spectroscopy (EDX) was used to investigate the distribution of alloy elements in three different specimens (porosities: 0.23%, 1.11%, and 21.16%). The results show that Aluminum (the main alloy element) and Magnesium are homogeneously distributed, also around pores. The remaining alloy elements (Silicon, Scandium, Titanium, Zirconium, Manganese, and Chrome) could not be detected due to the detection limit of the EDX apparatus (0.2% by mass) (JSM-IT500 – JEOL).

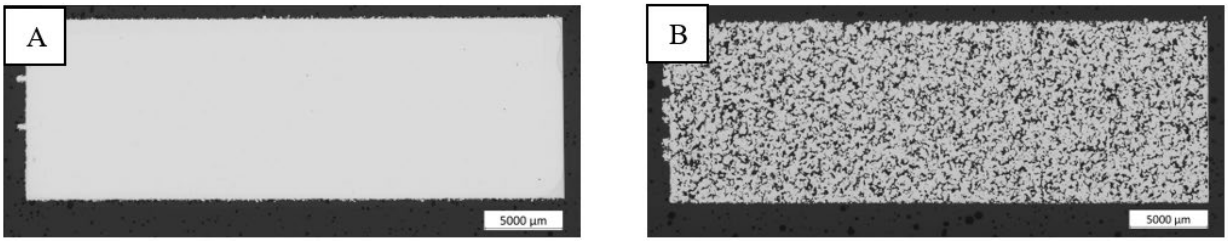

Fig. 7. RLM images of metallographic specimens showing different porosities (polished, not etched). A: dense structure fabricated with 112.23 J/mm³. B: porous structure fabricated with 14.96 J/mm³.

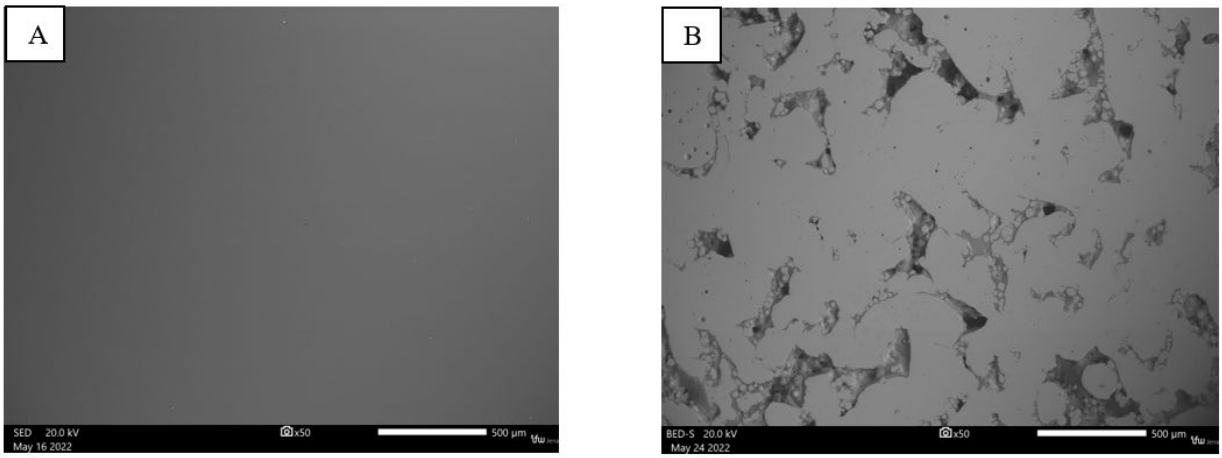

Fig. 8. SEM images of metallographic specimens showing different porosities (polished, not etched, magnification 50x). A: dense structure fabricated with 112.23 J/mm³. B: porous structure fabricated with 14.96 J/mm³.

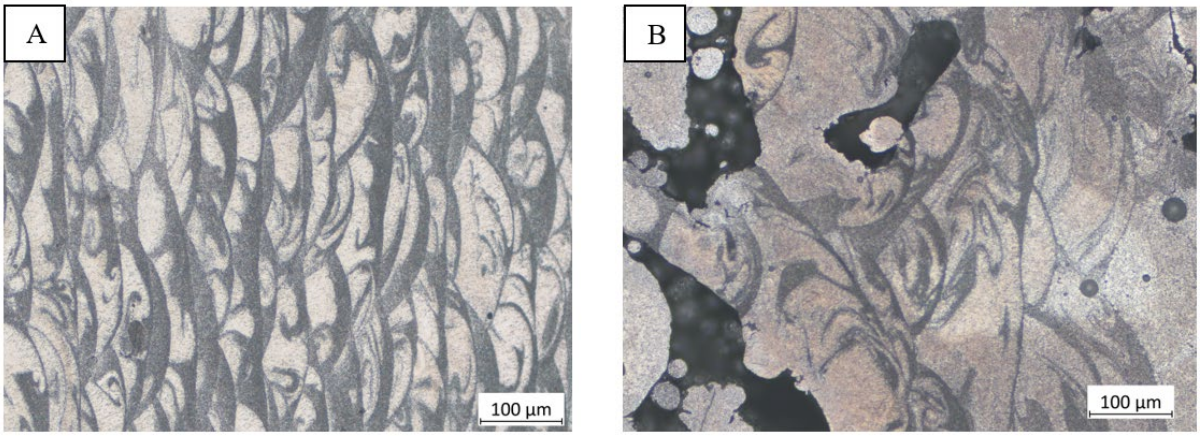

Fig. 9. RLM images of metallographic specimens showing different porosities (polished and etched). A: dense structure fabricated with 112.23 J/mm³. B: porous structure fabricated with 14.96 J/mm³.

Thermal conductivity. The specimens' thermal conductivity was measured using a self-designed test setup consisting of a hot plate (50°C) and a cold plate (0°C). On both plates, flux sensors are installed to measure the heat flux. PT1000 sensors are attached to each side of the specimens to measure the temperature gradient, as illustrated in Fig. 10.

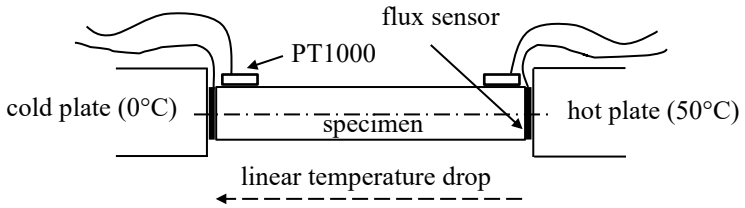

Fig. 10. Schematics of the self-designed test set-up used to measure the thermal conductivity of the fabricated samples.

The sensors are connected to an Arduino board, and digital tabletop multimeters are connected to a computer. The measured values are then used to calculate the thermal conductivity (λ) [W/mK] in Matlab (MathWorks) using:

$$\lambda = \frac{\phi \cdot x}{\Delta T \cdot A} \tag{3}$$

The heat flow (Φ) is obtained by:

$$\phi = \frac{Q}{t} \tag{4}$$

where (Q) [J] is the heat flux, t [s] is the time, x [m] is the length of the specimen, ΔT [K] is the temperature gradient between the two PT1000 sensors, and A [m^2] is the surface area of the specimen extremities in direct contact with the flux sensors.

We verified the validity of the measurements using a series of reference measurements using a known material with a thermal conductivity of 180 W/mK. All measurement results were located between 189.5 W/mK (5,3%) and 95.6 W/mK (4.4%). The average value for all 20 measurements was 179.02 W/mK.

Every printed specimen was measured five times. The measurement time was 180s. Fig. 11 and 12 show the thermal conductivity as a function of the applied energy density and the porosity.

Fig. 11 shows a wide range of variations in the measurement results (48.78-112.39 W/mK), probably due to substantial porosity variations between the different specimens, as shown in Fig. 12.

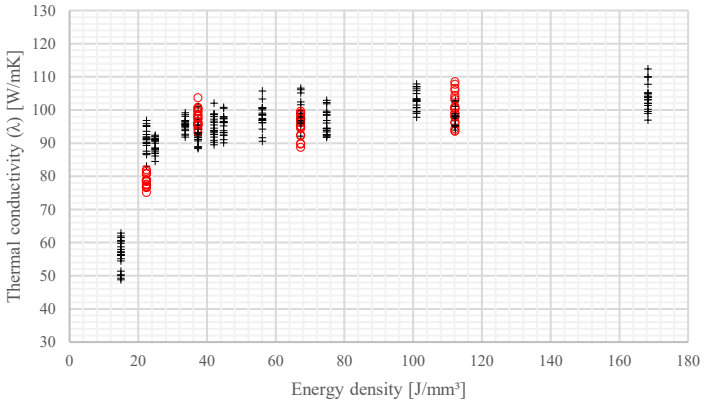

Fig. 11. Thermal conductivity of printed specimens as a function of the applied energy density.

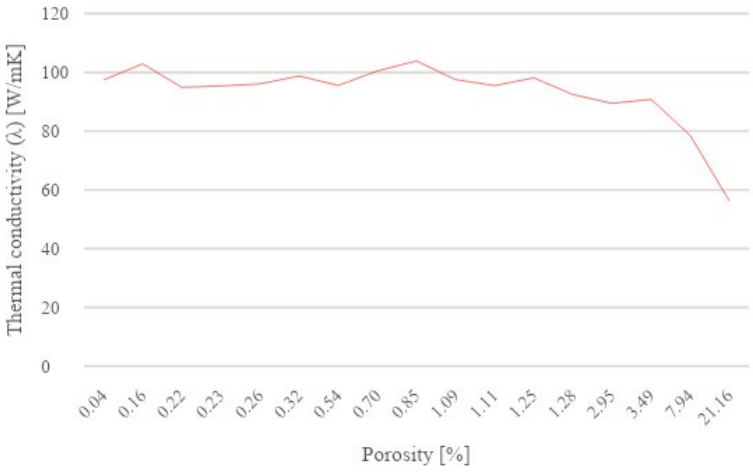

Fig. 12. Thermal conductivity of printed specimens as a function of the porosity.

Summary

An EOS M290 printing system was used to fabricate 85 aluminum specimens (StrengthAl) with 17 printing parameter sets, following a DoE approach (5x17 specimens). The modified printing parameters are the laser power (P) [W], laser speed (v) [mm/s], hatch distance (h) [mm], and layer thickness (t) [mm]. The specimens were then hardened (precipitation hardening) for 6 hours at 350°C with slow cooling in air. The specimens' dimensional accuracy, surface roughness, hardness, density, porosity, and thermal conductivity were then measured using professional tools and a self-designed test setup. Microstructural investigations were also performed using RLM and SEM.

The results show that changes in the process parameters (P, v, h, t) strongly affect the material characteristics, and while some variations follow visible trends, the energy density alone does not fully explain them. The hardening process also has an influence. Further work is required to better understand the physical mechanisms active during the formation and solidification of the melt pool.

Keywords: Wire-Feed Additive Manufacturing, AlSi7Mg, Semi-Solid Processing

Abstract. In the field of additive manufacturing (AM) technologies, the development of metal-based extrusion processes constitutes a significant industrial trend in the recent years. Respective processes are differentiated into powder bed, powder-fed and wire-fed depending on the used feedstock. Among those, powder-fed AM represents the most widely used approach, despite its physical limitations leading to intense thermal gradients and an uncontrollable defective microstructure of produced parts. In this context, extrusion-based AM using a wire semi-finished product in the semi-solid state offers a novel alternative for the direct processing of metallic alloys, avoiding the limitations mentioned. For this reason, a new method for consecutive extrusion of semi-solid AlSiMg aluminum wires has been developed at the Institute for Metal Forming (IFU, Stuttgart, Germany), particularly investigating the influence of the material´s microstructure on the process result. By modifying microstructure via heat treatment, a specific modification of the rheological material behavior can be achieved in terms of a pronounced shear-thinning characteristic, thus systematically affecting extrusion and deposition. First, an experimental setup for continuously extruding semi-sold aluminum wires was realized. Subsequently, experimental investigations were carried out on the extrusion of aluminum wires prepared via the strain induced melt activated (SIMA) process as well as untreated aluminum wires, using a conductively heated printhead concept. The objective was to determine process parameters necessary for successful extrusion and deposition of the modified aluminum material as well as the final proof of concept regarding a specific transformation of the material´s microstructure during the extrusion process.

Introduction

Additive manufacturing (AM) represents one of the most rapidly advancing manufacturing technologies in recent decades and has a particular importance for various industrial sectors, for example in the field of product design, automotive engineering as well as aerospace and bio-medical technology [1,2]. In this context, especially AM of metals has become substantial for producing industries. The AM processes applied here are categorized according to the raw material and the energy source used. In terms of the raw material, a distinction is made between powder bed, powder-fed and wire-fed processes. The energy sources used to melt the raw material as rapidly as possible include electron beam, laser or electric arc [3]. However, such AM processes still suffer from a wide variety of technological disadvantages. Due to the high energy input during the production of metallic AM parts, for example, complex thermal gradients can occur in the workpiece's volumes, leading to defects such as porosity, lack of fusion, part distortion, cracks and delamination [4]. In addition, especially powder bed-based melting or sintering methods entail high production costs and a long process duration [5].

Against this background, recent studies in the field of Additive Manufacturing (AM) focus on the development of a wire fed semi-solid AM process route. Wire as feedstock offers some significant

advantages based on the simpler process set up and higher deposition rate in contrast to powder resulting in a shorter process duration on the one hand and overall reduced equipment and production costs on the other hand [6]. The general process methodology based on wire as a feedstock involves heating the material into semi-solid state inside of the print head as well as a subsequent deposition in layers onto a print bed, similar to conventional fused deposition modeling (FDM) with plastics. Thereby, the direct processing of metallic alloys in the semi-solid state can be achieved through the specific control of the microstructure present in the material and therefore the resulting rheological behavior. The pronounced shear-thinning characteristic of semi-solid metals with a globular microstructure enabling the production of three-dimensional structures due to a low viscosity during extrusion and a dimensional stability of the deposited material [7].

Initial investigations in the field of semi-solid AM have been done in respect to the processing of low melting lead alloys, showing the general feasibility of this approach [8,9,10]. In the following, the semi-solid extrusion of magnesium alloy wires on a modified FDM-printer was discussed by Lima et al. [11]. Here, focus was put on the transformation of the feedstock material into the required globular microstructure within the print head. For aluminum alloys, first investigations using a conductively heated print head and an Al4018 welding wire were carried out by Herhold [12]. However, due to high friction as well as an inappropriate temperature distribution inside the print head, no satisfying results were obtained. Sharma et al [13] applied a modified print head design utilizing induction heating to temper an iron core and through conductive heat transport thereby the actual aluminum wire that is passed internally. This approach resulted in a steady state extrusion of a four-layer rectangular test piece made of Al5356 wire. Englert et al. [14] adapted the aforementioned inductive heating approach by equipping an extrusion nozzle with a modified induction coil. In the process, though, no cross-section reduction of the wire in the printhead has been implemented, and only continuous heating was realized. In this way, an Al4018 wire could be heated directly within the nozzle to subsequently produce cubic shaped parts. In both cases, however, interactions between the induced magnetic field and the print bed, the deposited part and other components of the machine assembly occurred.

In order to improve the semi-solid wire-fed AM process of aluminum alloys, a deeper understanding of the material behavior during the process is needed. Current state of the art focused on inductive heating of the wire, thereby successful extrusion could be investigated. However, due to the induced electro-magnetic field, interactions with the layered specimen as well as the machine parts could be observed. Additionally, in semi-solid forming normally a solidification pressure is needed, to produce a defect-free microstructure, which is difficult to apply with an inductive heating coil. In this paper the evaluation of viable process parameters for semi-solid additive manufacturing utilizing aluminum wire and a conductive heated print head design is presented, to eliminate the mentioned negative effects of the inductive heating approach. Thereby, an implementation of the specific transformation of the material´s microstructure into the extrusion process itself and the conductive heating design can reduce the overall process complexity, allowing a low-cost production approach.

Material and Methods

Raw material. When additive manufacturing is performed with semi-solid metal wires, particular attention must be paid to the liquid phase content of the material structure, as this crucially influences the continuous extrusion process. Here, low liquid phase contents result into increased extrusion forces and possible clogging of the nozzle, whereas high liquid phase contents enhance the formation of droplets at the nozzle opening. The formation or presence of droplets during extrusion has been referred to as an undesirable factor by several authors [8,12,13] resulting in a reduced accuracy of the manufactured parts. Due to the strong correlation between the processing temperature or rather the liquid phase content associated therewith and the resulting material´s

flow behavior, selection of a suitable aluminum alloy is a key issue. In this regard, suitable metal alloys for semi-solid metal forming processes usually offer following properties:

1. Solidification range (ΔT), defined as the temperature range between solidus and liquidus temperature, should found as extended as possible. Here, a range between 20 and 130 °C is recommended. [15]
2. Temperature sensitivity of solid phase content (−dφs/dT), which indicates the change in solid phase content per temperature unit for a specific alloy composition, should not exceed 0.015 [16]. Thus, in general a 1.5 % change in solid phase content of the melt is permissible for every 1 °C change in temperature. [15]
3. Processing temperature specifies the temperature interval in which the required solid phase content of 0,4-0,7 for the respective semi-solid processing procedure is present. [17]
4. Globular microstructure leads to shear-thinning material behavior and is therefore a mandatory requirement for semi-solid forming processes. [18]

Based on the alloy-specific requirements described above, an Al4018 welding wire from Drahtwerk Elisental W. Erdmann GmbH & Co. [19] has been chosen as raw material for the investigations presented in this paper. Table 1 shows the chemical composition of the material used, according to Drahtwerk Elisental W. Erdmann GmbH & Co. [19] and its thermophysical properties in accordance to the above-mentioned selection criteria.

Table 1. Chemical composition of Al4018 welding wire in wt.% [19] and its thermophysical properties [20].

Si	Fe	Cu	Mn	Mg	Zn	Ti	Al
7,19	0,14	0,00	0,00	0,6	0,00	0,02	Base
ΔT = 65 °C			−dφs/dT = 0.004			processing temperature = 565-595°C	

Fig. 1a) shows the microstructure of the wire material used, which is characterized by an enclosed silicon phase (dark) in an α-Al phase (bright). This cold worked microstructure is transformed to the necessary globular microstructure in the aluminum welding wire through heating into the semi-solid state as a sub step of the strain induced melt activated (SIMA) process [21]. In the present case of processing given Al4018 wire, a cross-section reduction of 44 % was performed in the last drawing stage, which means that the threshold value of 30% specified by Loué and Suéry [22] has been exceeded and a sufficiently high cold forming ratio with regard to optimal SIMA process requirements is reached. For heat treatment a convection oven was used to heat up the sample to a temperature of 575°C for a period of 15 minutes. In general, thixoforming operations require a solid phase content of 0,4-0,7 [17]. Therefore, within the corresponding temperature range for the present alloy (approximately 565-595°C), isothermal holding at 575°C has been chosen [20]. After heat treatment the aluminum filament was quenched in water. Fig.1b) illustrates the resulting microstructure, consisting of globular α-Al grains embedded in eutectic phase (intergranular) and eutectic phase enclosed within solid grains (intragranular).

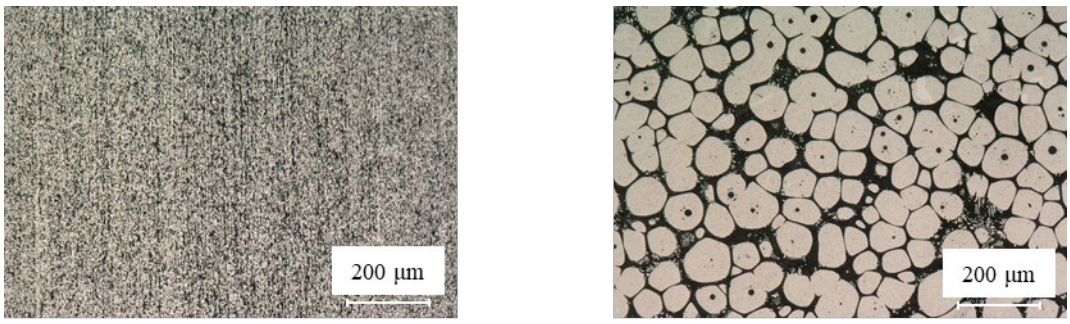

Fig. 1. Microstructure of the utilized Al4018 welding wire as is a) and after heat treatment b).

As an evaluation criterion to determine suitability of the generated microstructure for semi-solid additive manufacturing, grain size and grain shape were calculated using the image analysis software Fiji. Perfect globular grains feature a shape factor of unity. In general, a globular microstructure that is suitable for semi-solid forming is considered to feature a shape factor between 0.6 and 1 and a grain size smaller than 100 µm [23]. Compared directly, the microstructure produced in the filament material by heat treatment with the chosen parameter combination has an average grain size of 71 µm and a shape factor of 0.75 and is therefore within the stated limits. The heat-treated welding wire with a globular microstructure is utilized for extrusion and deposition studies in the course of semi-solid additive manufacturing.

Additive manufacturing setup. A prototype 3D-printer equipped with wire-feed and conduction heating devices was developed and built up for the present study. This AM setup consists of custom as well as commercially available components. Fig. 2 shows the setup used on the left and a schematic illustration of the printhead cross section on the right.

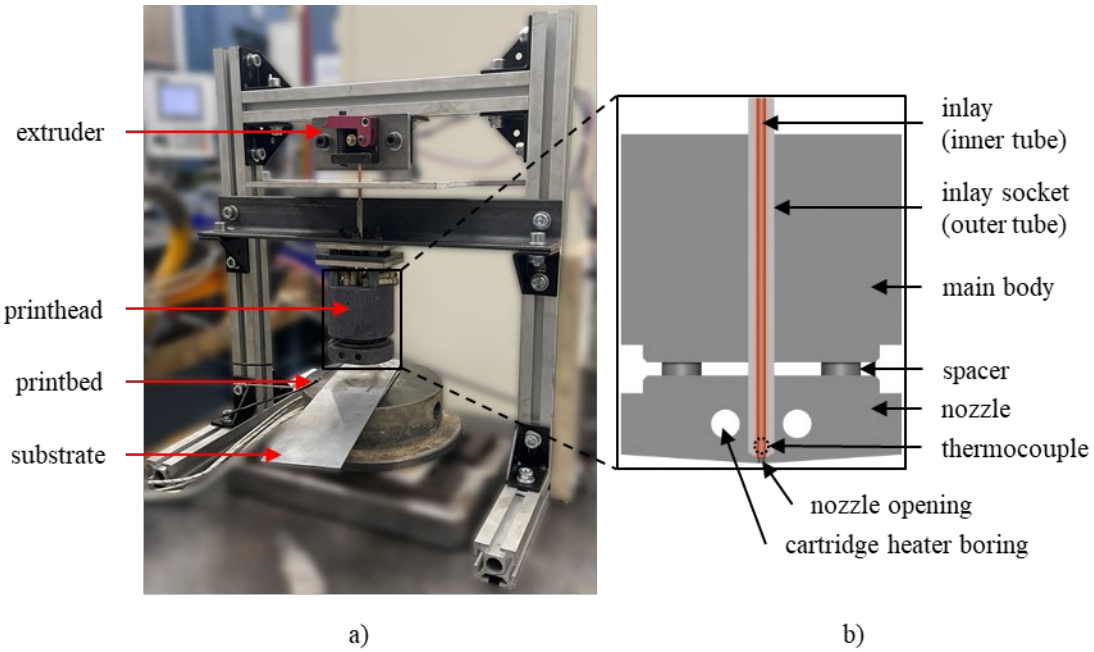

Fig. 2. Photograph of the additive manufacturing setup used a) and CAD rendering of the printhead cross section b).

The general design of the printhead includes a modular setup consisting of a main body and a nozzle separated by spacers. These spacers, between nozzle and main body, allow for thermal

decoupling of these components from each other through the resulting air gap whereby a large temperature gradient as well as separate heating of the two components can be realized. The guidance inside the printhead has been designed with an exchangeable inlay, allowing guide sleeves from different materials and with different diameters to be investigated. A conventional pinch roller extruder, which is usually applied for FDM with plastics, is used for wire feeding. The extruder is driven by a stepper motor, whose speed and thus the wire feed rate is controlled through the open source software *Estlcam*. For tempering the nozzle, conventional cylindrical cartridge heaters with an electrical power of 200 watts are inserted in appropriately prepared mounting holes. Control of the heating cartridges and thus of the temperature distribution within the nozzle is performed via a control unit. Thereby, current nozzle temperature can be measured by means of a thermocouple (Type J) integrated into the printhead and connected to the control unit.
For extrusion objectives, the aluminum wire having a diameter of 2 mm and a section length of 1 m is first supplied to the pinch roller extruder. After leaving the extruder, the Inlay guides the wire until its heating into semi-solid state inside the nozzle and its subsequent extrusion through the nozzle opening. For the final deposition of the semi-solid aluminum, a heated print bed is used on which an additional 2 mm thick aluminum sheet is placed serving as a substrate. The relative movement of the substrate to the print head is performed manually. Entire extrusion and deposition of the semi-solid aluminum wire takes place without inert gas atmosphere.

Experimental procedure. The aim of the investigations presented in this paper was to produce primitive samples with a simple geometry using the principle of semi-solid AM to demonstrate the fundamental feasibility of the project at hand. These samples should feature a homogeneous microstructure without defects and metallurgical joint between the layers. For this purpose, the extrudability of the heat-treated welding wires having a globular material structure was first investigated using the AM setup described above. During these investigations, numerous process parameters were changed according to Table 2 in order to initially demonstrate feasibility of the semi-solid AM process and afterwards to determine its ideal parameter combinations.

Table 2. Parameter variation extrusion trials.

Experimental parameter			
Wire material	heat-treated (575°C, 15 min)		
Material of Inlay	stainless steel	copper	brass
Inner diameter of Inlay [mm]	Ø 2,1		Ø 2,4
Nozzle temperature [°C]	565-630 (gradual increase in 5°C steps starting with 565°C)		
Main body temperature [°C]	540		560

Due to the modular concept of the printhead, especially the influence of different materials and variations of the inner diameter of the inlay on the extrusion process could be investigated during the experiments. Here, copper, brass and stainless steel with internal diameters of 2.1 mm and 2.4 mm were analyzed. The inlay socket was made from stainless steel in all tests conducted and provided secure seating for the inlay inside the printhead as well as its reinforcement due to low wall thickness. Regarding the temperature distribution in the printhead, a constant main body temperature was maintained in all tests, while the nozzle was heated in 5°C increments, starting at 565°C. The starting temperature of 565°C at the nozzle corresponds to the required processing temperature range for the considered aluminum alloy in the semi-solid state, which is between

565°C – 595°C. The feed rate was set to 1 mm/s, corresponding to an approximate deposition rate of 3,1 mm^3/s, in all experiments carried out. The quality of the final extrusion samples was evaluated on the basis of the external appearance and microstructural analysis. For this purpose, a digital light microscope with a maximum magnification of 5000x was used. The preparation of the samples involved mechanical sanding and polishing followed by etching of the sections with 5 % NaOH solution for 60 s. Finally, a transfer of the ideal process parameters found, was performed to the processing of untreated welding wire. The objective behind this approach was the implementation of the necessary microstructural transformation into the extrusion itself and therefore eliminate the additional step of heat treatment.

Results and Discussion

Based on the experimental results obtained, the influence of, on the one hand, the design of the guidance (inlay) and, on the other hand, the printhead temperature control on the extrusion quality were evaluated. With regard to the guidance, the tests performed showed extrusion of the aluminum wire with an inner diameter of 2.1 mm rather than 2,4 mm. This is due to the fact that the bigger inner diameter results in a larger air gap between the tube wall and the wire having a diameter of 2 mm, leading to a significantly lower heat transfer. Actually, no melting and thus no extrusion of the aluminum welding wire was observed with the inlay variant having a diameter of 2.4 mm. Because of this, further investigations on the guidance material were only carried out using the inner diameter of 2.1 mm.

In the examinations on suitable materials for the guidance, stainless steel, copper and brass were investigated in combination with the temperature settings for nozzle and main body listed in Table 2. When combining brass as material for the inlay and a nozzle temperature of 590°C, as well as both main body temperatures listed in Table 2, continuous extrusion could be achieved. However, a more detailed analysis of the nozzle cross-section after the performed tests revealed the positioning of the melting zone located near the contact area between aluminum wire and extrusion shoulder, the entire brass inlay had been disintegrated (see Fig. 3). This disintegration of the brass guidance can be attributed to diffusion of alloying elements into the semi-solid aluminum in combination with subsequent mechanical abrasion. Therefore, a brass inlay is not suitable for the semi-solid AM process in terms of a reliable process control.

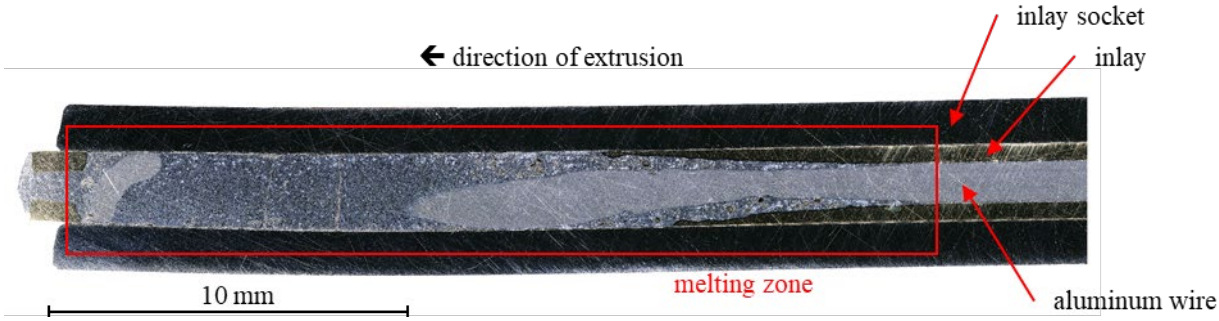

Fig. 3. Cross section of the inlay (brass) and inlay socket (stainless steel) with melted aluminum.

For stainless steel and copper as inlay materials, melting of the aluminum wire could be observed for a nozzle temperature of 590°C due to the formation of droplets at the nozzle opening, but no further extrusion. This can be attributed to the friction between the guidance and the semi-solid aluminum alloy itself, which prevented extrusion. However, by increasing the nozzle temperature up to 615°C in the case of stainless steel and 625°C for copper and simultaneously turning off active heating of the printhead main body, extrusion of the semi-solid aluminum gets feasible. The applied heating strategy relocated the melting zone closer to the extrusion shoulder and also decreased its dimensions. As a result, this led to reduced friction between guidance and wire, thus enabling extrusion.

The above described methodology for the extrusion of heat-treated wire also led to successful extrusion of untreated aluminum wires. Regarding this, Fig. 4 shows respective cross-sections of nozzles with a) stainless steel and b) copper as guiding material. The stainless-steel inlay reveals a gradual melting and simultaneous transformation of the untreated aluminum wire over a length of ~4,9 mm. The copper inlay, on the other hand, shows a significantly shorter melting and transformation zone, which is exclusively present at the immediate extrusion shoulder and nozzle opening. During the extrusion tests, the significantly larger melting zone within the stainless-steel inlay implied higher friction between the semi-solid aluminum and the guidance causing an increased force demand for the extrusion process in comparison to the copper inlay. Furthermore, when using the stainless-steel inlay, a nozzle temperature reduced by 10°C compared to the copper inlay had to be used in order to restrict the formation of the melting zone. Without reducing the nozzle temperature applied in the case of the steel inlay, no extrusion has been achieved using the extruder applied in the present study, since the required feeding force clearly exceeded the available capacities of the stepper motor. Even with an adapted temperature profile, steady-state extrusion was only present to a certain degree while using the stainless-steel inlay, as the force provided by the extruder was partially insufficient due to stick and slip effects and stagnation of the wire feed occurred. For the copper inlay, the forces required during the process to extrude the semi-solid aluminum did never exceed the extruder's capacity due to the already explained comparatively small melting zone (see Fig. 4).

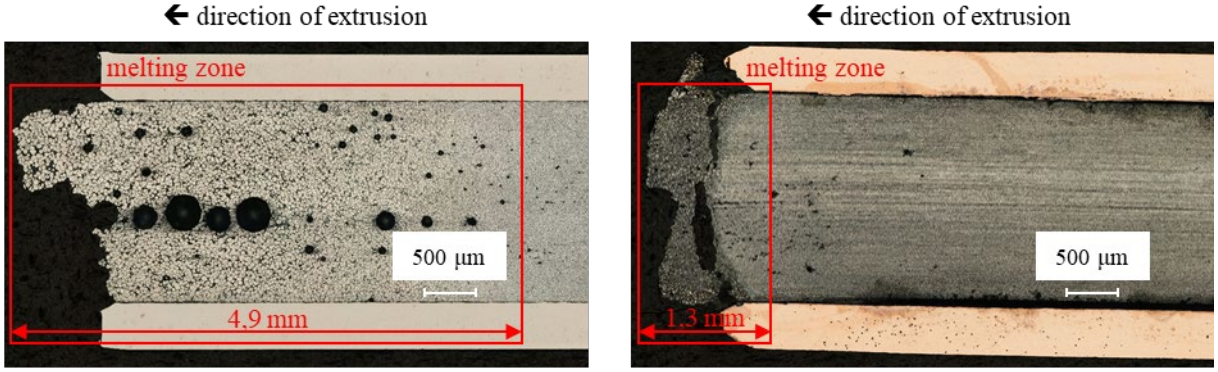

Fig. 4. Nozzle cross section with stainless steel a) and copper inlay b).

Table 3 shows the parameter combinations determined in the course of the extrusion studies providing a suitable operating window for steady state extrusion of aluminum welding wires.

Table 3. Best parameter combinations for extrusion and deposition.

Material Inlay 1	Inner diameter Inlay 1 [mm]	Temperatur nozzle [°C]	Temperature main body [°C]	Wire material
stainless steel	2,1	615	not heated	heat-treated, untreated
copper	2,1	625	not heated	heat-treated, untreated

Fig. 5 presents the resulting microstructure of fully extruded samples from untreated welding wires. In both cases, it can be seen that a complete transformed microstructure consisting of globular α-Al-grains embedded in an eutectic matrix is present. The smaller average grain size in the sample extruded with the copper inlay is attributed to the shorter holding time of the material in the semi-solid state caused by the reduced melting zone. This fact also contributes to the

considerably finer porosity, since the coalescence occurring in the semi-solid state with advancing holding time leads to coarsening of pores. Both of the presented grain sizes are sufficiently small for semi-solid extrusion however the smaller grain size produced through extrusion with the copper inlay is generally considered a beneficial factor and has a positive effect on the extrudability of the semi-solid aluminum.

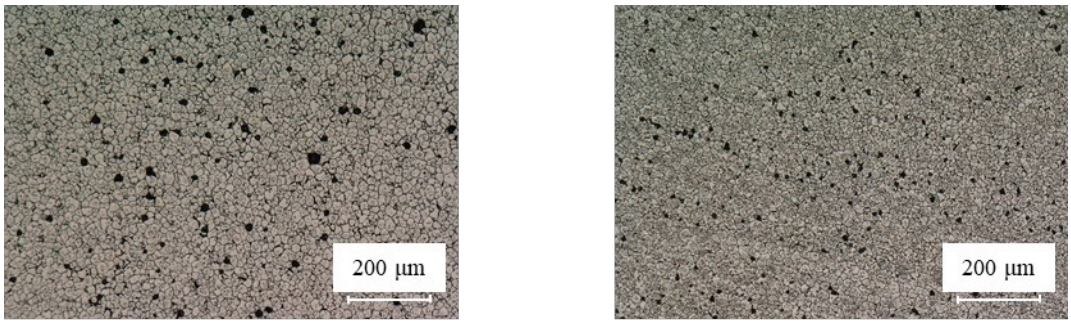

Fig. 5. Microstructure of extruded untreated aluminum wires with a) stainless-steel and b) copper inlay.

The manufacturing of a basic specimen took place using an untreated aluminum welding wire with the copper inlay as well as the corresponding process parameters listed in Table 3. Fig. 6a) shows the sample after extrusion and deposition of the semi-solid aluminum using the ideal process parameter combination. During the trials, a heated print bed with temperatures between 550-600°C was needed in order to achieve a good bonding of the layers. This can be attributed to the semi-solid state of both the already deposited and the just extruded aluminum, that enables an interface-free bonding of the two layers shown in Fig. 6b). The porosity described above is also found in the extruded specimen and can be classified as a defect in the material indicated by intergranular pores.

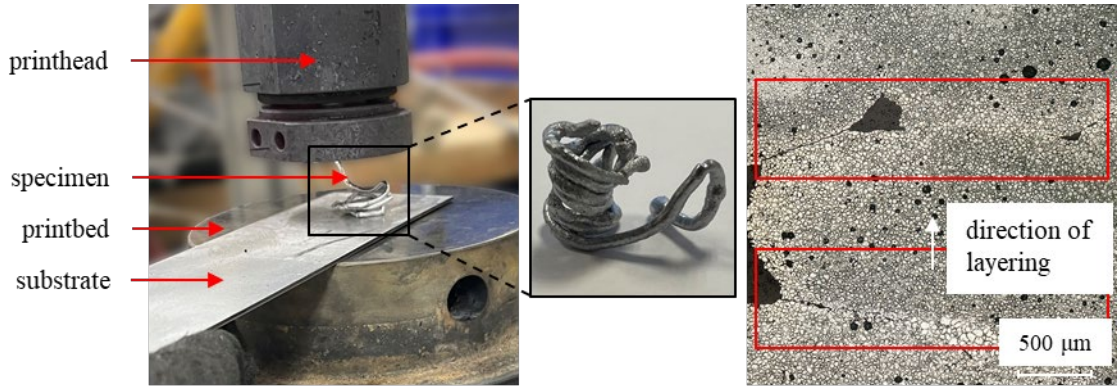

Fig. 6. Experimental procedure and specimen manufactured a), microstructural analysis of the specimen b).

Summary

In the present study, a novel manufacturing method has been presented enabling semi-solid additive manufacturing of aluminum wire utilizing a conductively heated printhead design. This also involved the fabrication of basic specimens by using a heated print bed as well as a manually moved aluminum substrate (6000 series) with a deposition rate of up to 3.1 mm^3/s. Thereby the required microstructural transformation of the untreated aluminum wire took place during heating inside the printhead, eliminating the need for an additional heat treatment. In the course of the experimental evaluation, three different inlay materials as well as variations of the inner diameter were tested. For 2.4 mm as an inner diameter no melting or extrusion could be observed due to an

excessive air gap and therefore poor heat transfer between guidance and aluminum wire. With brass as guidance, disintegration of the inlay material occurred in the melting zone, while stainless steel led to stagnant extrusion caused by a large melting zone resulting in high friction along with stick-and-slip effects. Copper with an inner diameter of 2.1 mm was found to be the most suitable choice and consequently has been applied for the fabrication of simple specimens featuring a partial interface-free bonding of consecutive layers. However, the extruded material also exhibited defects in form of porosity.

In future studies, a dedicated machine setup will be developed, which enables a controlled movement of the print bed in x-, y- and z-direction at a pre-defined speed. In addition, a reworked printhead concept including a heat sink will be implemented in the system in order to be able to influence the dimensions of the melting zone.

Keywords: Additive Manufacturing, Continuous Reinforced Fiber, Deconsolidation, Consolidation Processes, Composite Material, Mechanical Properties

Abstract. Additive manufacturing (AM) of continuous fiber reinforced composites (CFC) is becoming increasingly important in the field of lightweight construction. The major advantage lies particular in the automated manufacturing process and in the production of complex geometries. Most work was done with traditional fusion filament fabrication (FFF) and the lack of separate consolidation units. AM CFCs produced in this manner have shown increased consolidation-related volumetric flaws -i.e. deconsolidation defects decreasing mechanical performance. The presence of deconsolidation defects, normally indicates either poor process parameters selection or inadequate in situ consolidation. Recently, there were several efforts in modifying the FFF of CFCs to minimize deconsolidation defects through in situ thermo-mechanical pressing. However, there are only limited fundamental knowledge on the in situ thermo-mechanical consolidation of FFF-CFCs. The present paper analyses the stated problem and proposes ways to decrease deconsolidation in FFF CF-PA6 laminates. For this purpose, we used a self-developed FFF 3D Printer coupled with a thermo-mechanical pressing unit. The influence of extrusion-, consolidation temperature, printing speed and in situ consolidation pressure on laminate microstructure and flexural strength was investigated. A comparison with FFF laminates printed in a common 3D printer was performed. The controlled 3D printing consolidation process leads to a homogeneous distribution of fibers in the matrix material and to an improvement of the material parameters of the reinforcing composite.

Introduction

Due to the efforts to increase efficiency, minimize costs and reduce emissions, many branches of industry are undergoing radical changes. Lightweight engineering through 3D printing provides measures towards these goals, as it allows several effects to be achieved at the same time: a) Lightweight engineering saves emissions in transport industry. b) In combination with 3D printing, it makes it possible to produce complex lightweight components economically in a resource-saving manner. c) Due to its flexibility and automation possibilities, 3D printing can be used particularly well in the field of structural element design. When high-performance materials such as composites are used, it becomes interesting for the automotive and aerospace industries. 3D printing is increasingly recognized as a technical solution in these areas and will significantly change the way complex, ultra-lightweight components are manufactured.

The company Markforged (MF) was a pioneer in industrial use of AM CFC and produces components with considerable complexity. The mechanical properties of materials produced with this technology are lower than those of conventionally produced fiber composite components, such as those produced with automated tape laying or cast polymer molding technology. One of the reasons for the weakening properties is the high void content in the laminate caused by a poor choice of printing process parameters and resulting an inhomogeneous distribution of fibers in the matrix material [1,2]. An insufficient utilization of the reinforcing fibers is the result and can lead to premature failure of the component. In a preliminary investigation, the influence of consolidation in 3D printing of CFC was shown. It has been found that increasing the contact pressure on the molten filament can lead to a reduction in voids in the laminate and an improvement in mechanical properties [3-6].

Increased consolidation is not feasible with standard 3D printing technology of fiber composites. What would be required is a time-delayed additional consolidation in the range of the crystallinity temperature of the matrix material. This is the aim of the present work, which describes a technology for in-situ consolidation.

For this purpose, a self-developed consolidation printer (CP) and the MF technology were used. The following approach is considered: Specimens of the used material are printed with the CP technology under controlled conditions at the crystallinity temperature and compared with the test specimens of the MF technology. Material tests and microstructure analyses are carried out and compared with each other. By preparing microsections of the specimens, a closer look inside the structure of the material is obtained which defines the basis for further understanding in terms of its homogeneity.

Materials and methods

Parameters on the behavior of the matrix material as a function of time and temperature are not part of the manufacturer's specifications. For this purpose, preliminary tests had to be carried out, which are necessary for a controlled thermal consolidation of the material. The preliminary examination of the filament, the technical approach of the MF printer and CP, the test specimens and the defined process parameters are documented below.

Filament material.

The thermoplastic prepreg used in this study was a 1K roving of continuous carbon fiber, which was pre-impregnated with a nylon matrix (CF-PA6) [7]. The CF-PA6 filament has a diameter of about 0.389 [mm] and a fiber volume fraction f of 35.0 ± 0.1%. This value is in accordance with results reported by other authors, such as He et al. [8]. After a differential scanning calorimetry (DSC) analysis the glass transition temperature, crystallinity temperature and the melting temperature of the CF-PA6 prepreg material as well the PA6 matrix material of MF without reinforced fibers was determined (see Table 1).

Table 1. Results of DSC measurement.

Material	Glass transition temperature [C°]	Crystallinity temperature [C°]	Melting temperature [C°]
CF-PA6	66	169	225
PA6	54	163	242

CFC 3D printer.

To analyze the conventional consolidation strategy of 3D-printed CFC, the mechanical technology as well as the software of a Mark-two printer of MF was used. The mechanical construction of the MF printer has been reported by the manufacturer and in many papers [9-11]. For a consistent printing quality, some adjustments are made according to the manufacturer: The distance between the nozzle tip and the printer has to be set with a shim leveling to 0.127 [mm] by a constant nozzle temperature to 250 [°C]. A new continuous fiber filament role with a low moisture content was used for printing the test samples. To ensure a good hold of the printed pattern on the print bed, an adhesive glue, recommended by the manufacturer, was applied on the print bed. The default parameters of MF at the slicer software Eiger are used as printing condition for the CFC CF-PA6 material print.

Consolidation printer.

For a detailed consolidation study a consolidation test bench was developed and constructed. All technical functions for continuous fiber 3D printing are similar to MF. The printing bed is moving in x-, and y-axis direction and the printer head is moving in z-axis direction with a trapezoidal Tr8 x 1.5 [mm] thread. The filament feeder, cutter, hotend and nozzle are MF components. With this technical setup, the process and the printing quality of MF can be reproduced. In order to implement the influence of the consolidation, an in situ thermomechanical consolidation roller is installed after the nozzle tip. There is no mechanical coupling installed between the nozzle and the consolidation unit. Therefore, the fiber can only be deposited in x-direction and no curved paths are possible with this setup. Each path must be deposited individually to obtain the part width of the three-point bending specimen (see Fig. 2 CP Specimen).

With a load cell (HBM PW4M), the current consolidation pressure in the printing process was measured. The diameter of the consolidation roll is 26 [mm] and is tempered with a 12 [V] 30 [W] cartridge heater. The rotation of the consolidation roller is transmitted to the CFC filament by the contact pressure. The distance between printing nozzle and the consolidation role is adjustable and is in this study about [mm]. The consolidation roll is on the same level as the nozzle tip and applies a contact force about 5 [N] to the filament.

The printer was prepared with an open controller board from GT2560 Ref A+ and can be operated with an open-source slicer software. Various process parameters such as speed, temperature and the layer height can be changed additionally. These parameters were controlled with the Repetier-Host software (Hot-World GmbH & Co. KG). The G-code for the specimen geometry is developed independently in-house and imported into the control system of Repetier-Host. The schematic process of the consolidation test bench is shown in Fig. 1.

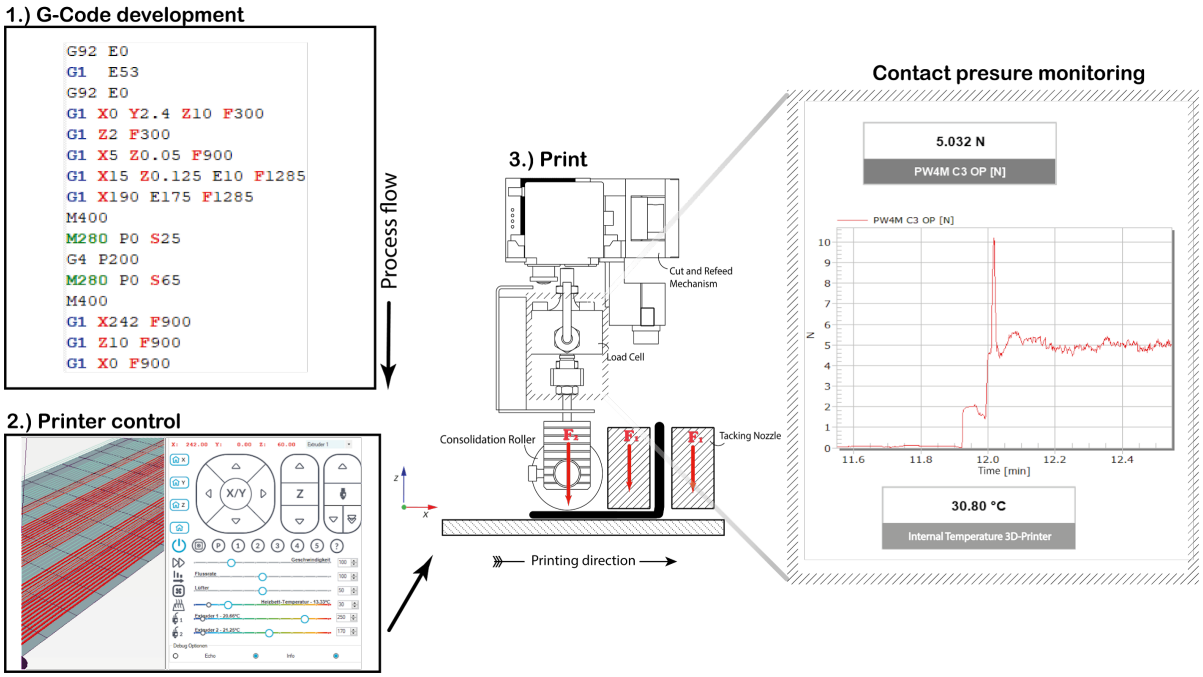

Fig. 1. Schematic process of the consolidation test bench.

Specimen geometry and mechanical testing.

The material tests were carried out using three-point bending tests. The dimensions are 60 x 15 x 2 [mm] (length x width x thickness) following the testing standards ISO 14125 with a line offset of approx. 0.9 [mm]. The pure PA6 coating and CFC loops at the reversal points produced by the MF printing process are removed. The printing strategy as well as the printing composition of the MF and the CP specimen is shown in Fig. 2. Each specimen consists of 14 layers, with 15 lines per layer. The layer height, printing speed and nozzle temperature for both printers were chosen of the default settings of MF and is listed in Table 2. The consolidation force on the CP samples is about 5 [N] for each line, while simultaneously maintaining the matrix material at its crystallinity temperature of 170 [°C] (see Table 1). In order to obtain reliable results of the mechanical tests, eight test samples are produced per series.

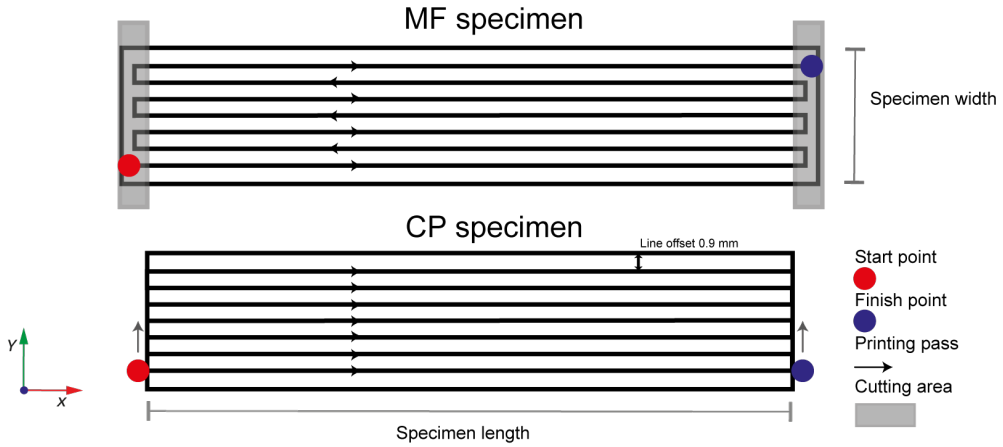

Fig. 2. Print path in a layer of MF and CP.

The three-point bending tests were conducted on a universal testing machine Z020 (Zwick/Roell). The manufacturer's software testXpert II was used on the testing machine to initialize the test parameters and record the test data.

Process parameters and data analysis.

The process parameters of the CP printer were controlled and measured with the Repetier-Host software and are listed in Table 2. The control of the process parameters of the MF system was realized with the Eiger software and contains the standard parameters of MF (see Table 2).

Table 2. Printing conditions.

Variation	Fiber-orientation	Nozzle height [mm]	Consolidation force roller [N]	Printing-speed [mm/s]	Nozzle tip temp. [C°]	Consolidation roller temp. [C°]	Printing bed [C°]	Internal temperature 3D-printer [C°]
CP	0°	0.127	5	15	250	170	30	30
MF		0.127	-	15	250	-	-	30

An HBM QuantumX MX1615 interface was used for data acquisition of consolidation pressure and chamber temperature of the CP printer. The visualization and data storage were implemented with the software catmanEasy. To ensure the correctness of the measured data, a reference measurement was made using a high-resolution balance.

Microstructural analysis.

The binocular microscope Axio Lab.A1 with a 5X and 20X magnification (Zeiss, Oberkochen) was used to observe the fiber distribution as well as the void content of the test specimens. The images were taken with a 2.0 MP Pixel-Fox digital camera (Dietermann & Heuser Solution, Greifenstein-Beilstein) and processed with the manufacturers image measuring software.

Results

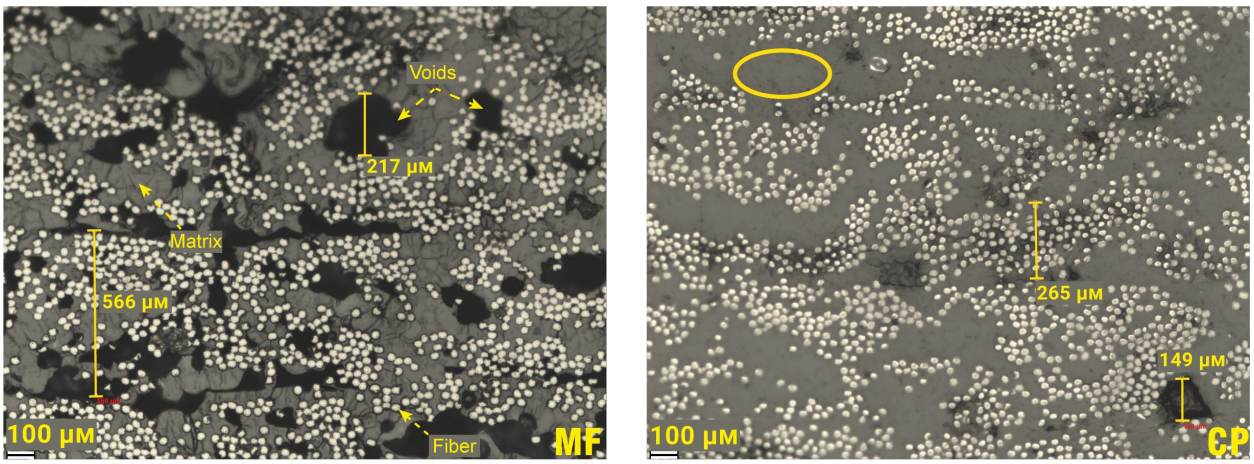
In order to be able to assess the quality of the laminate, detailed information is required on the micro- and macrostructure as well as the respective mechanical properties of the laminate. For this purpose, the following investigations were carried out.

Cross-sectional observation.

Typical examples of cross-sectional microscopy images of the MF and CP specimens in the direction perpendicular to the fiber are shown in Fig. 3.

The 3D printed laminates of MF (see Fig. 3a), show a lot of micro and macro voids in the laminate. Larger voids have a size of approximately 200 [µm]. Individual layers with insufficient intimate contact are to be recognized in the observation. Layers in the laminate have a height of approximately 600 [µm] and indicate a deconsolidation mechanism in the printing process. Further, horizontal cracks indicate a delamination. The fibers show a good distribution in the matrix material.

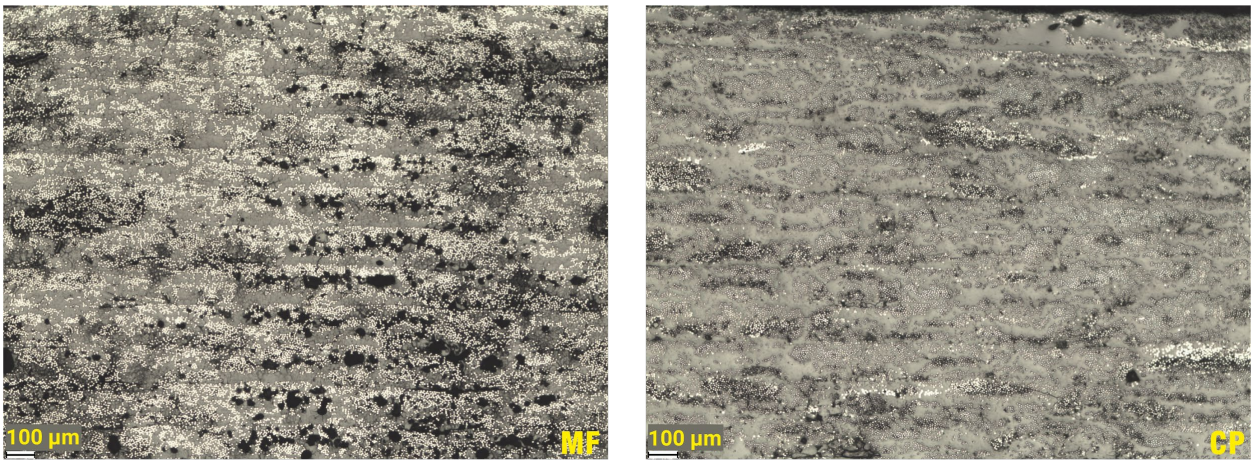
On the right side on Fig. 3 the laminate of the CP test bench specimen is shown. This laminate has hardly any micro and macro voids. Individual layers are partially marked with larger matrix areas (see Fig. 3b yellow circle). A reduction in deconsolidation is shown in the region of the joining zone of each layer. The layer heights are significantly lower compared to the MF samples and are about 270 [µm] (see Fig. 3b).



a) b)

Fig. 3. Microscopy images of a cross-section perpendicular to the fiber direction with a 20X magnification of a) MF and b) CP laminate with 14 layers.

Fig. 4 shows the laminates of MF and CP in 5X magnification. An expected high number of voids and delamination in the MF composite can be seen (see Fig. 4a). CP has a uniform mesostructure with a low proportion of voids (see Fig. 4b).



a) b)

Bending test results.

Fig. 5 shows the bending strength a) and the bending modulus b) of unidirectional CFC specimens printed using MF and CP, respectively. The average values of bending strength and bending modulus are 38.9 ± 3.2 [GPa] and 518.1 ± 42 [MPa] for MF specimens, and 39.2 ± 3.9 [GPa] and 610.9 ± 32 [MPa] for CP specimens, respectively. The CP specimens show an 15% improvement in bending strength and about 1% improvement in bending modulus.

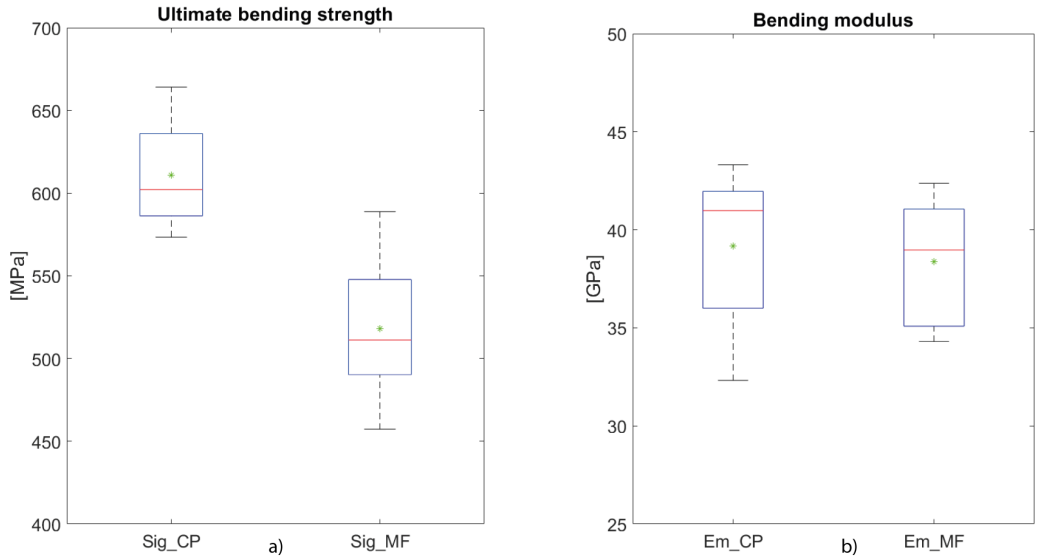

Fig. 5. Comparison of ultimate bending strength a) and bending modulus b) of the MF and CP technology.

Summary

In this study, a technical approach of a time-delayed thermal-mechanical consolidation of 3D printed CFC was investigated firstly. After a DSC analysis of the CF-PA6 material the glass transition temperature, crystallinity temperature and the melting temperature was determined. The CP test bench had the same technical approach as the MF printer, except for an additional in-situ thermo-mechanical consolidation unit. In the printing process, a force of 5 [N] was applied on the filament at a temperature close to the crystallinity temperature of the matrix material. In order to analyze the effects of in-situ consolidation in terms of microstructure and mechanical properties, a comparison was made with the printed test samples of MF technology.

The adopted process of in-situ consolidation has shown an improvement of the mechanical properties and the microstructure (15% for the bending strength and 1% for the bending modulus). In addition, the reduction of the void content was found in the CP composites in comparison to the MF composites. In summary, the MF laminates show clear signs of deconsolidation, while the CP composites are much more homogeneous.

In a next study, the influence of in-situ consolidation on the voids in the laminate and on the distribution of the fiber matrix will be analyzed. For this purpose, a traditional 2k full factorial design of experiment (DoE) will be used to investigate the different influences of the process parameters and microstructure of the 3D printed CFC laminate.

Keywords: Shape Memory Effect, Shape Recovery, PET, Fused Filament Fabrication

Abstract. In recent years the interest in finding new shape memory polymers has increased. Withal, fewer studies approached the use of regular materials such as polyethene terephthalate (PET), a widely available material. The research investigated the shape memory characteristics of regular PET 3D printed samples in two testing cycles. The recovery temperature was determined through dynamical mechanical, followed by tensile testing and heat treatment of the specimens. The results show PET has good shape memory properties, recording a slight increase in shape recovery during the second testing cycle without affecting the sample integrity. The thermal analysis of the recovered material shows that heat treatment time or/and temperature need to be improved to stabilise the PET material structure.

Introduction

Fused Filament Fabrication (FFF) is an extrusion-based additive manufacturing technology that uses filament shape thermoplastic materials as a feedstock. The material is heated until it reaches a viscous state and deposits layer-wise to build parts [1].

FFF disposes of a large variety of materials, including regular (polylactic acid), engineering grade (e.g., polycarbonate), or even high-performance polymers (e.g., polyether ether ketone) [2,3]. The technology is used for many applications, such as conceptual models, functional prototypes, tools and fixtures, replacement parts, biomedical applications, and others [4].

The design and production of a Shape Memory System (SMS) is another application of FFF. They are referred to as 4D printing because of their shape-changing behaviour over a period of time. These SMSs are compliant mechanisms that achieve motion based on a stimulus, in this case, shape change. This can be thermal, electromagnetic, light or pH-based and others [5-6].

The SMS is characterised by one or more shape-changing sequences and depends on the number of constituents. This way, the SMS can be divided into single, double, triple and multiple material mechanisms [5-7]. Regardless of the number of constituents, the working principle of polymeric SMS was classified into three mechanisms. The first is the dual-state mechanism. Here the permanent shape is memorised by the strong links of the polymeric chains (i.e., covalent bonds) and the temporary shape is maintained by the weak links (e.g., chain entanglements). The second is the dual-component mechanism. This one uses a more rigid component to "remember" the permanent shape and a softer one for the temporary shape. The third is the partial transition mechanism which uses a mixture of materials to provide the transition phases [8-10].

The shape memory properties are evaluated through the Fixity ratio (R_f) and Recovery ratio (R_r). Those are used to determine the Shape Memory Index (SMI) of the SMS [5-7] as follows:

$$R_f = \frac{\varepsilon_u}{\varepsilon_m} \quad (1)$$

$$R_r = \frac{\varepsilon_m - \varepsilon_p}{\varepsilon_m} \quad (2)$$

Content from this work may be used under the terms of the Creative Commons Attribution 3.0 license. Any further distribution of this work must maintain attribution to the author(s) and the title of the work, journal citation and DOI. Published under license by Materials Research Forum LLC.

$$SMI = R_f \times R_r \quad (3)$$

where ε_m is the specimen's elongation at 100%, ε_u is the elongation after release, and ε_p is the elongation after recovery.

For heat-sensitive SMSs, the permanent shape results after the part's manufacturing (i.e., after printing). Then the part is heated (at a temperature T_1 above the glass transition temperature) and deformed to a temporary shape. Then the permanent shape is recovered by heating the part at the same temperature, T_1 [5-7].

Polyethene terephthalate (PET) is a semicrystalline thermoplastic material and is characterised by both amorphous (i.e., transparent) and crystalline (i.e., opaque) phases [11,12]. It is widely used in the food industry for food and liquid containers [13,14] and as feedstock for additive manufacturing technologies such as FFF as a new or recycled material [15,16].

This work focused on evaluating the shape memory effect of specimens made of regular, neat PET. The sample deformation was made at room temperature in two testing cycles compared to the standard testing procedure. Shape memory specimens' cold deformation is documented in the literature [10,16,17]. The results show PET shape recovery is possible even after two cold deformation cycles.

Materials and Methods

The chosen material was a natural PET filament from BasicFil. This was printed as samples (i.e., type 5 of ASTM 638-14) using an Ultimaker 3 printer. Before printing, the material was dried in an oven at 65°C for four hours. The manufacturing instructions were generated using Cura 5.2.1 slicing tool using the main parameters described in Table 1.

Table 1. Printing process parameters.

1	Nozzle diameter (mm)	0.4	13	Print speed (mm/s)	30
2	Layer thickness (mm)	0.15	14	Travel speed (mm/s)	250
3	Extrusion width (mm)	0.4	15	Retraction distance (mm)	7
4	Number of walls	4	16	Retraction speed (mm/s)	35
5	Wall ordering	Outside to inside	17	Combing mode	Not in skin
6	Z seam position	Back left	18	Avoid printed at travel	Yes
7	Top/bottom layers	11	19	Z hop height (mm)	1.6
8	Top/bottom pattern	Lines	20	Regular fan speed (%)	15
9	Lines direction (°)	45/135	21	Maximum fan speed (%)	30
10	Extrusion temp. (°C)	245	22	Brim distance (mm)	0.1
11	Bed temp. (°C)	70	23	Brim width (mm)	3
12	Initial layer speed (mm/s)	15	24	Enclosure	Yes

The printing speed was controlled independently by each constructive element of the sample (e.g., walls, solid fill). The first layer and the brim were printed at a lover speed (i.e., 15 mm/s) to increase the adhesion with the build plate. To avoid the samples' deformation outside the gauge length, the walls closing was positioned in the samples' back left side (Fig. 1). This prevents closing contours from being placed by the slicing tool in the specimens' gauge or transition zones. Compared to the ASTM 638-14 standard specifications, the sample's thickness was increased to obtain an equal number of bottom and top layers. This way, the resulting thickness is 3.3 mm.

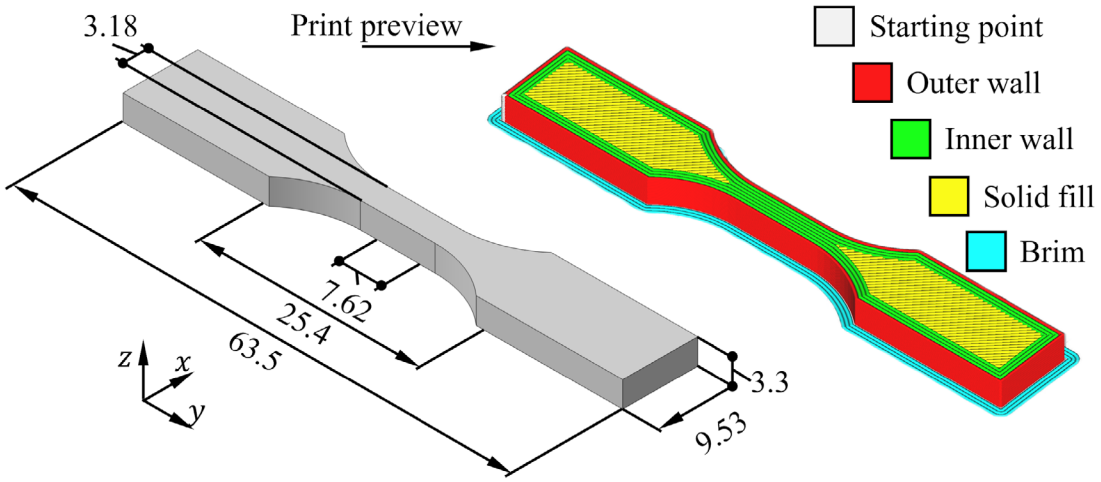

Fig. 1. CAD and printed specimen configuration.

The shape memory properties were determined by using the following steps:

1. Measurement of specimens' gauge length after marking;
2. Deformation at cold with 1 mm/min up to ε_m, the100% elongation;
3. Sample holding between clamping system for 5 minutes at ε_m;
4. Measurement of ε_u, the elongation after the release;
5. Heat treatment of the specimens in an oven at temperature T_1 for 5 minutes;
6. Measurement of ε_p, the recovery length.

The above-described steps were repeated for a second testing cycle, in which the new gouge length was the ε_p from the previous cycle. The testing cycles were performed with five replicates using an Instron 4411 universal testing machine with a load cell ok 5 kN. At the moment of testing, the laboratory had a temperature of 21°C and 52% moisture.

The heat treatment temperature T1 was established through dynamic mechanical analysis using TA instruments DMA 2980 equipment. Furthermore, to better understand PET's shape memory behaviour, musters of specimens' gauge zone at ε_u and ε_p were thermally analysed using Differential Scanning Calorimetry (DSC). An additional set of samples was prepared for the DSC measurements. The used equipment was a DSC 3+ from Mettler Toledo.

Results and Discussion

A dynamic mechanical analysis of the PET material was done to determine the recovery temperature for the shape memory characterisation. The test was performed in the multi-frequency method using a single cantilever bending at a frequency of 1 Hz. The temperature scans were performed at 2°C/min starting from 0 to 151.4°C when the material lost its properties. The glass transition temperature, T_g, occurs in a range, not on a single point or value. Based on the storage modulus onset, the T_g is at 76.22°C. It is the temperature at which this blend of PET starts to lose its mechanical properties. According to the loss modulus, the upper limit of the T_g range is 81.90°C. Usually, for shape memory polymers, the upper limit of the T_g is given by the tan δ modulus [10], because it is higher than the others. For the chosen blend of PET, the resulting tan δ modulus T_g value lies between the previously mentioned temperatures. All three diagrams are presented in Fig. 2. Based on these findings, a heat treatment temperature of 80°C was considered optimum for sample shape recovery.

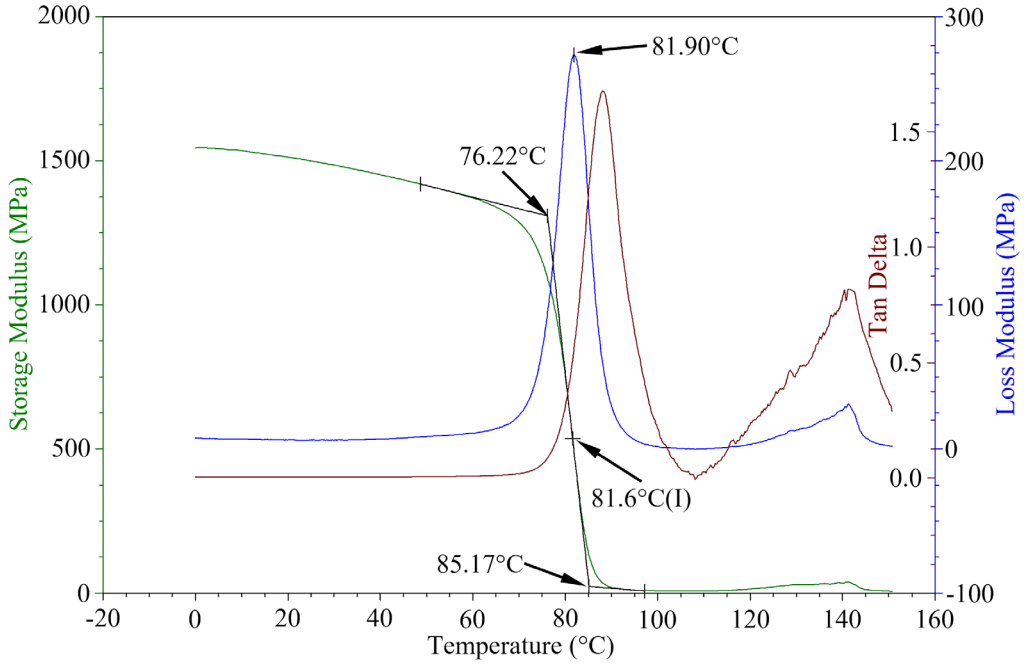

Fig. 2. Dynamical mechanical analysis of the chosen PET material.

All tested samples recorded similar deformation and shape recovery. In the first deformation-shape recovery cycle, the specimens presented a necking at the level of the gauge (see Fig. 3b). After the heat treatment at 80°C for 5 minutes, they partially recovered their shape (see Fig. 3c). Withal, in the second deformation-shape recovery cycle, the PET samples showed better shape memory effect compared to the previous one (see Fig. 3c and 3e).

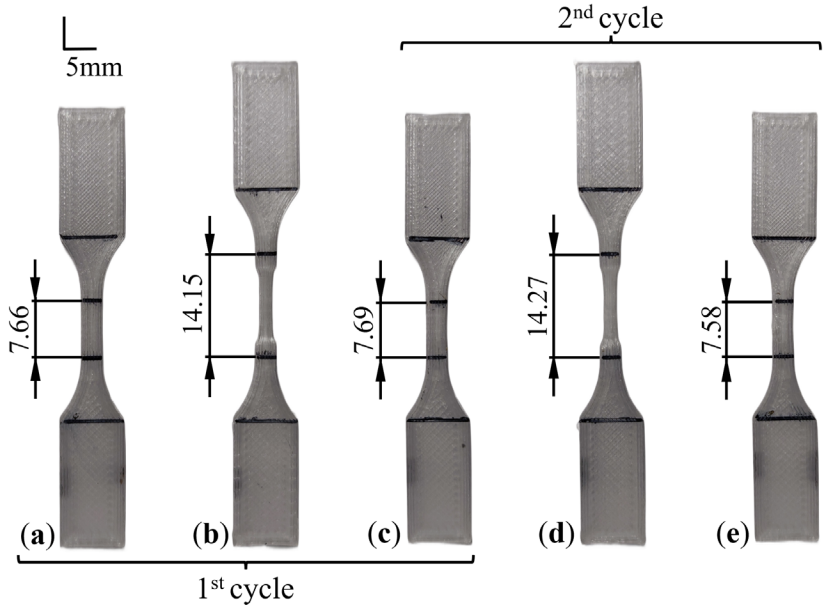

Fig. 3. Example of the PET samples at each step of the testing plan, with (a) initial, (b) first deformation, (c) first shape recovery, (d) second deformation, and (e) second shape recovery.

The fixity ratio, Rf, calculates the capacity of a material to memorise a shape by dividing ε_u at ε_m (Eq. 1). As presented in Fig. 4, the printed PET showed a good Rf in both of the testing cycles.

The samples recorded a slight increase in the second cycle compared to the first; the average fixity ratio is approximately 95%.

The recovery ratio, Rr, provides information regarding the materials' capability to recover their original shape when heated at temperature T_1. In the Fig. 4 plot, it is shown that in the first cycle, the PET samples showed an average recovery of 99.27%, and in the second cycle, it slightly increased to 100.19%. An example of the recovered parts is shown in Fig. 3.

The shape memory index gives information regarding materials' shape memory properties based on the previously presented ratios. Fig. 4 shows that PET samples averaged an SMI of 94.45% in the first testing cycle. The same samples gave an SMI average of 96.62% by performing a second set of trials. The resulting plot for each sample is presented in Fig. 4.

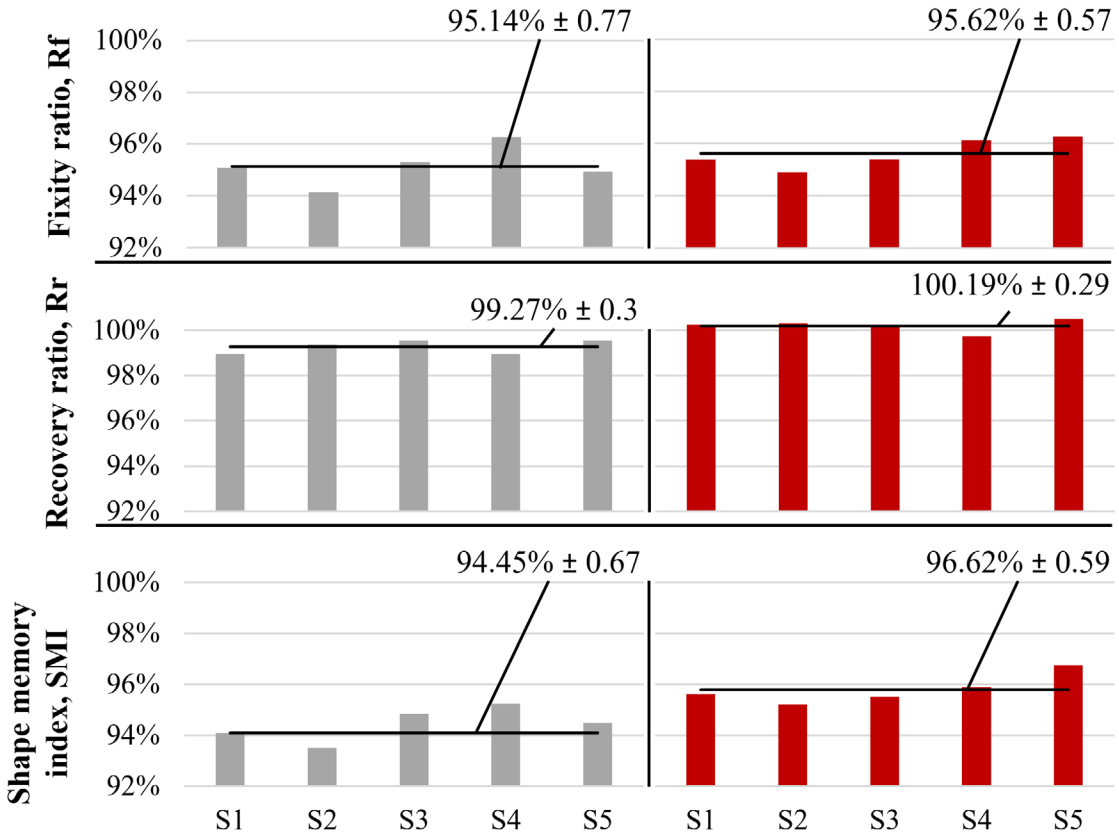

Fig. 4. Fixity ratio, recovery ratio and shape memory index of the tested samples.

To obtain more information regarding the shape memory properties increase in the second cycle, the stress-displacement plots of samples were analysed. Choosing the displacement instead of strain gives a more objective view as the specimens were elongated unevenly (see Fig. 5). At the first elongation, the samples showed similar peaks of the maximums stress with an average of 44.96±0.68 MPa and average stress at yield (at ε_m) of 28.33±0.28 MPa, in the second deformation cycle gave average maximum stress of 38.84±0.54 MPa and a 27.43±0.5 MPa yield average. By analysing the plots (see Fig. 5), it can be observed that the highest difference between the two cycles is at the maximum peak. For the rest of the tests, the results were comparable. As the samples are stretched, they follow the same pattern. First, a decrease of the load between 1 and 1.5 mm of displacement as the sample is necking. Then a slight but constant increase of the strength at yield.

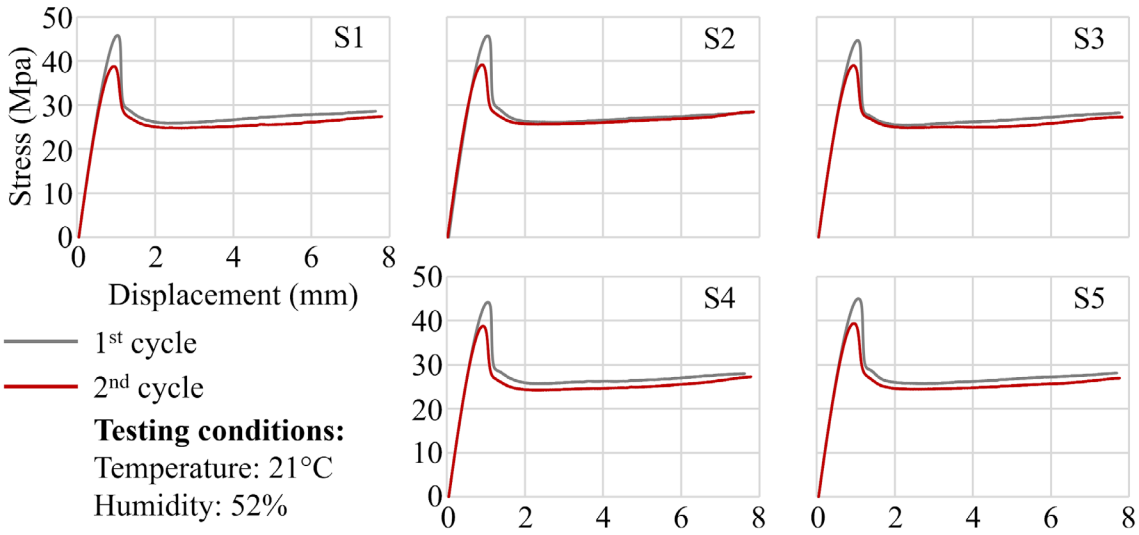

Fig. 5. Stress-displacement diagrams of the tested samples.

As the samples were elongated during the tensile test, the material situated in the gauge zone started to change its appearance from clear-transparent to an opaque white colour. This means that by stretching the sample, a change in crystallinity occurs in the material structure, from an initial amorphous to a semicrystalline state (Fig. 3). To find more information about the material behaviour, several DSC analyses were done on musters taken from the gauge zone. All studies were done by heating the material with 5 K/min from 20 to 100°C.

The first analysis was performed on a sample elongated at 100% (Fig. 3b). The result is presented in Fig. 6. It can be observed that between 40 and 60°C, the stretched material is taking energy, receiving a heat amount of 1.49 J/g. Because the material is deformed, it tends to regain its normal shape and consumes energy.

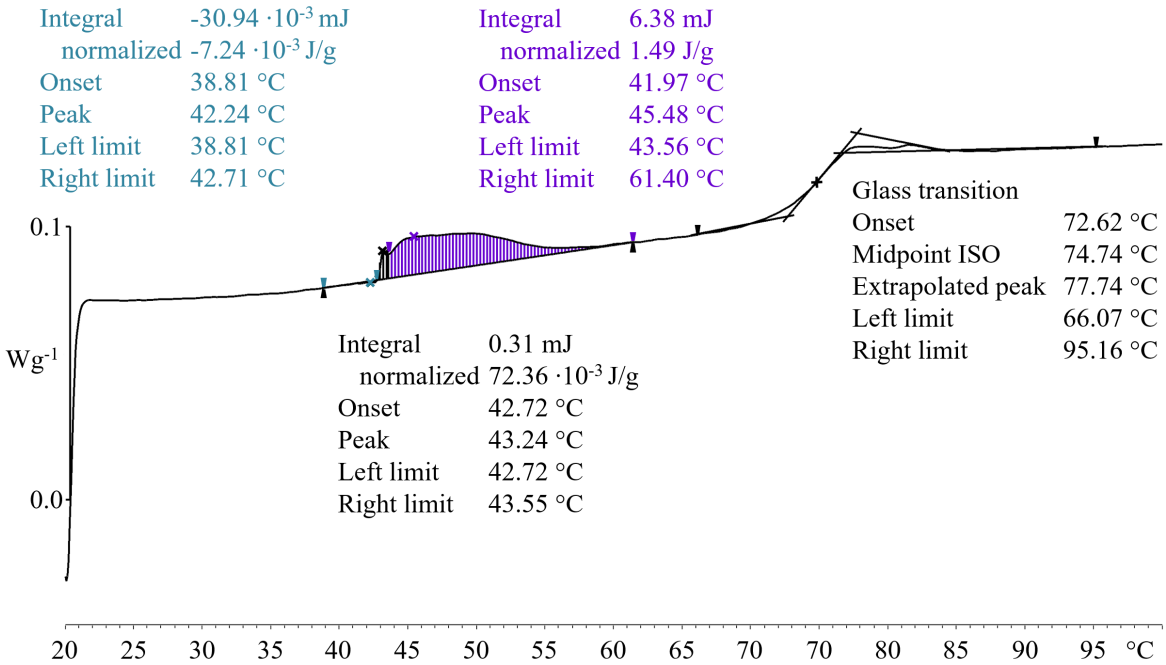

Fig. 6. DSC diagram of a first cycle elongated sample.

For the samples, after the first shape recovery, the DSC curves show that the heat-treated material is also absorbing energy between the 34 and 63°C range (see Fig. 7). However, the amount of energy required is less compared to the elongated materials. The material absorbed 0.72 J/g for the first sample, respectively 0.53 J/g for the second.

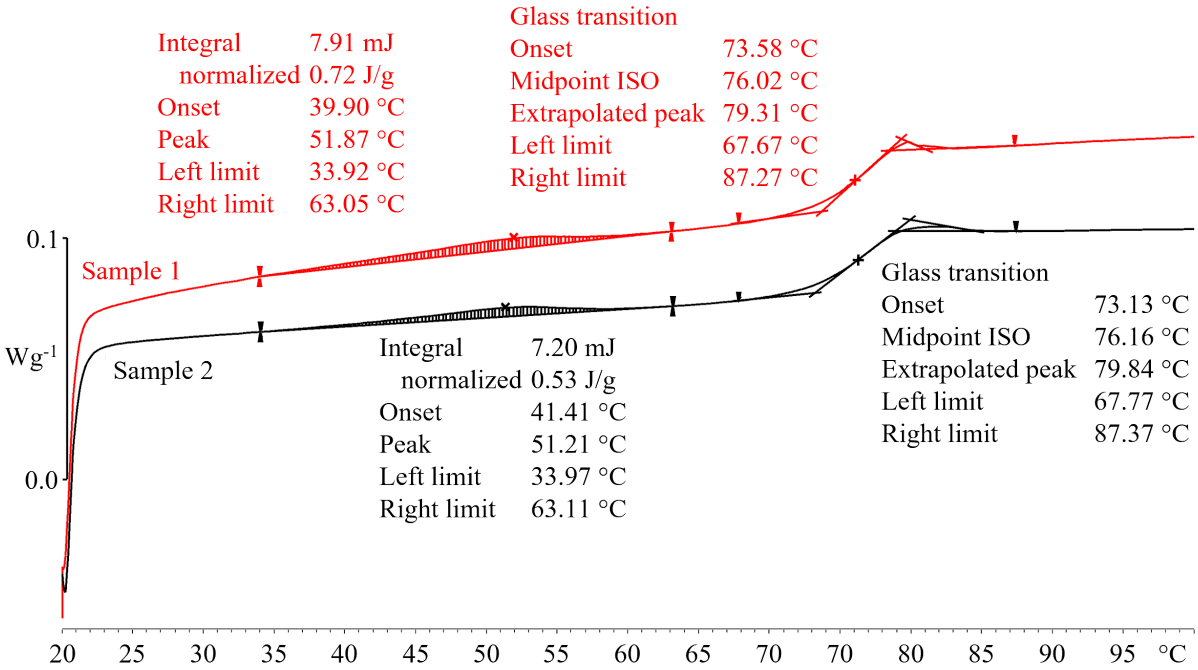

Fig. 7. DSC diagram of shape recovered samples.

Thermoplastics are characterised by covalent bonds of the polymeric chains and weaker bonds resulting from the chains' entanglements [11]. When stretched, the capacity of the chains to align with the load direction before breaking gives the maximum elongation. During the heat treatment, the polymeric chains tend to recover their natural state and reform the chains' entanglement. The DSC analysis of the heat-treated PET (Fig. 7) shows that the material required additional energy from the system. This suggests that an insufficient temperature or/and recovery time during the heat treatment possibly affected the polymeric chains' entanglement reformation. This aspect correlates with the decrease of the average maximum stress of ≈6 MPa during the tensile testing (Fig. 5). Further investigations are required for the structure of the elongated and heat-treated material to understand the PET shape memory properties better.

Summary

PET is a common thermoplastic material widely used in the food industry due to its good mechanical properties and processability. However, its shape memory properties were not thoroughly evaluated.

This study focused on evaluating the shape memory properties of PET 3D printed samples in two deformation-shape recovery cycles. Even if the samples' deformation was performed at cold, they obtained an average shape fixity of ≈95 in both testing cycles. On the other hand, the PET recovered its initial shape on an average of ≈99% testing cycle, respectively ≈100% in the second.

DSC analyses of the material heat-treated after elongation suggests that recovery temperature or/and time were not chosen accordingly to allow polymeric chains to entangle enough.

Further investigations are needed to better understand and control the PET material shape recovery during heat treatment.

Abstract. Although it is experiencing a wide diffusion, there are still several limits to the use of additive manufacturing (AM) for the fabrication of metal components. This includes low productivity, poor dimensional accuracy and uncertainty about the mechanical properties of the final parts. The main cause of these undesirable effects lies in the intrinsic complexity of the metal AM processes, such as Laser Metal Deposition (LMD). Accurate monitoring of the process and optimization of the process parameters are therefore of fundamental importance to ensure the overall quality of the product. Nowadays, several optical methods are under development for the monitoring of geometric characteristics and their correlation with specific process parameters, such as the standoff distance. This paper presents a comparative study between two optical in-process monitoring methods performed on AISI 316L multilayer samples produced by the LMD process. The first is a laser line section method based on a laser diode mounted on the deposition head, while the second method uses a high-resolution CMOS camera placed on the horizontal plane with a front view of the sample. In both cases, ad-hoc image processing algorithms were used to process the data, reconstruct the morphology of the component, and extract geometrical information. Results were then validated using an offline scanning system and micrographic analyses. Both proposed systems allowed the monitoring of the deposition quality using appropriate Key Performance Indicators (KPIs). The study showed a good capability of the prototype systems to detect deposition defects due to undesired variations of the process conditions and to monitor the standoff distance.

Introduction

Despite the widespread adoption of additive manufacturing (AM), there are still several limitations to the use of some technologies for the fabrication of metal components. Laser Metal Deposition (LMD) is an AM technique implemented in several industrial sectors thanks to its several advantages. Although it is still characterized by poor dimensional accuracy, mainly due to variable thermal cycling, localized heat accumulation, irregular powder flow, etc. [1]. In-situ monitoring and process control can be used for avoiding unpredictable build failures and minimizing the time and cost of post-process characterization procedures [2].

The monitoring of the LMD process is carried out in different fields: monitoring of the thermal field for the high temperatures developed by the laser during the process [3], monitoring of the powder flow [4] and monitoring of geometrical parameters of the produced component [5]. Among the several outputs that need to be monitored and controlled to ensure the quality of the process/component, standoff distance and layer height are very important. In fact, a wrong standoff distance can lead to height deviations from the ideal building path [6].

Nowadays, several optical methods are under development for the monitoring of geometric characteristics and their correlation with specific process parameters. These methods are based mainly on the use of CCD/CMOS camera, laser scanners and structured light scanners.

The CCD/CMOS cameras are widely used, as they are flexible and easy to implement. These systems can be used to monitor the melt pool geometry, its temperature, and the layer height during the process. Although, these method are not particularly suited for the evaluation of complex freeform geometries and they have been mostly applied to simple geometries such as thin walls [7]. In some monitoring system setups, the CCD/CMOS cameras are mounted on the deposition head. Toyserkani and Khajepour [8] studied a closed-loop control system for LMD process, based on a CCD or CMOS camera. A pattern recognition algorithm returned the tracks height and the angle of solid/liquid interface in real-time and the PID controller used these feedbacks to modify the laser pulse energy in order to improve the output. Hsu et al. [9] proposed a vision-based inspection system made up of three digital cameras for measuring the cladding height in the Direct Energy Deposition (DED) process. After the calibration of the system, an image-processing technique is employed to isolate the laser nozzle and the melt pool in the captured images. The height of the coating is then calculated using the distance between the nozzle tip and the center of the melt pool.

On the other hand, laser scan systems are also implemented in various works in the literature. This technique is based on the triangulation principle and, mounting the equipment on the deposition head, a three-dimensional representation of the built component can be obtained [10]. With respect to the CCD/CMOS cameras, this monitoring technique is usually more expensive and require additional movements of the deposition head during scanning. Nevertheless, the monitoring of complex geometries is less difficult to perform. In [11], Rodriguez-Araujo et al. used a scanning system based on a CMOS camera coupled to a laser line mounted to the laser head to acquire the 2D profiles of the deposited layers. Cao et al. [12] used a commercial laser displacement sensor to study the surface topography detection of 24CrNiMo alloy steel produced by direct laser deposition. Arejita et al. [13] presented a closed-loop control algorithm that dynamically controlled the melt pool size, deposition speed and standoff distance combining data from a laser line profiler and a NIT Tachyon 1024 micro-core MWIR camera.

Structured light 3D imaging systems project coded patterns into the object rather than a single line and utilize a coding approach to calculate the depth of each observed point. The precision of the measurements strongly depends on the calibration of the equipment according to the measured volume, but an acceptable accuracy can also be obtained by basic equipment [7]. Some authors have used a 3D scanner to monitor the part geometry [14]. Garmendia et al. [15] have integrated a structured light-based scanner into a DED system in order to obtain a complete reconstruction of the manufactured geometry, making possible to monitor the product quality while it is being built, avoiding any suspension of the production process or offline measurement.

Due to the high cost of the components, the complexity of the additional movements required for 3D scanning and the harsh environment in which the systems are operating, laser line scanners and structured light 3D imaging have become popular only in recent years [7].

Regarding the investigated geometries, in the literature, most studies deal with the monitoring of monolayers or thin walls component [16,17], while few studies focus on the geometric monitoring of massive and multilayer components made by LMD [18,19].

This work presents a comparative study between two optical in-process monitoring methods performed on AISI 316L massive multilayer samples produced by the LMD process. The first is a laser line section method (LL) based on a laser diode mounted on the deposition head, while the second method uses a high-resolution CMOS camera (FC from now on) placed on the horizontal plane with a front view of the sample. In both cases, ad-hoc image processing algorithms were used to process the data, reconstruct the morphology of the component, and extract geometrical

information. Results were then validated through an offline scanning system and micrographic analyses.

Material and Methods

The monitoring systems compared in this work were a laser line scanner and a high-resolution camera (Fig. 1(a)). The first system comprised a laser line diode with λ=532 nm and 5 mW of power as light source and an industrial CMOS camera (IDS UI148xSE-C) as receiver equipped with a 12.5 mm lens. These two components were assembled on an aluminum support structure properly designed to make the system configuration flexible according to the sample geometry. This system was configured as a layer wise system and it requires an additional movement of the deposition head after the completion of each layer. Data were acquired in a video format with a framerate of 8 frame/sec, while the scan speed was set to 200 mm/min (equal to the deposition speed). In this way the resolution, meant as the distance between two adjacent points on each single profile, was on the order of 0.06 mm, while the resolution along the scan axis was on the order of 0.4 mm depending on the camera frame rate and scan speed.

The second monitoring system consisted of a high-resolution camera, DSLR CANON EOS 760D equipped with a 50 mm lens focused on its minimum distance. The camera was placed on the horizontal plane with the lens oriented to get the sample length (Fig. 1(a)).

With the aim to compare the above-described systems, two samples (sample A and B in Fig. 1(b)) were fabricated by means of a LMD system, with the same material, geometry, and process parameters.

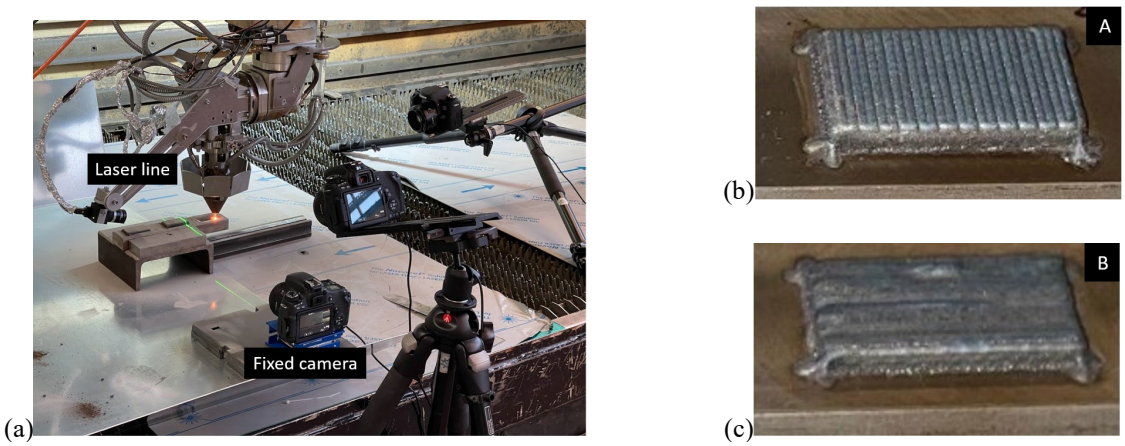

Fig. 1. (a) LMD with the monitoring systems (laser line on the left and fixed camera on the bottom), (b) sample A and (c) sample B.

The LMD system was a prototypal machine composed of a 3 kW CO_2 laser source and a pneumatic powder supply system. The AISI 316L stainless steel powders were carried by the gas to the 3-way multijet nozzle that conveyed them into the melt pool. Helium with a flow rate of 5 lpm was used as carrier gas, while with a flow rate of 11 lpm was used as shielding gas. The spot diameter was equal to 2 mm. The substrates (with a thickness of 25 mm) were also made of AISI 316L stainless steel. The samples were multilayer massive blocks (10 layers) with dimensions of 25 x 50 mm^2. These components were realized by adopting a bidirectional hatch strategy with a 90° rotation of the deposition direction at each layer and consequent modification of the deposition starting point. A 30% overlap between adjacent tracks was used. The sample A was realized in standard operating conditions, while during the fabrication of the sample B, defects were induced: laser shutdown at layer 3, powder flow suspension at layer 5, and deposition speed variations (50% and 150%) at layer 7.

Materials Research Proceedings 28 (2023) 101-110 https://doi.org/10.21741/9781644902479-12

Both methods followed a similar workflow, as shown in Fig. 2. The laser line scanner (LL), after the frame extraction and image processing (conducted by using an ad-hoc MATLAB algorithm), provided a detailed 3D point cloud of each sample layer. The latter was analyzed by GOM Inspect software for the computation of specific process indexes in order to check their suitability for process anomalies and defect detection. On the other hand, after the frame extraction and image processing, the high-resolution fixed camera (FC) provided a 2D single profile of the sample which was a local description of the geometry of the sample (the track facing the camera).

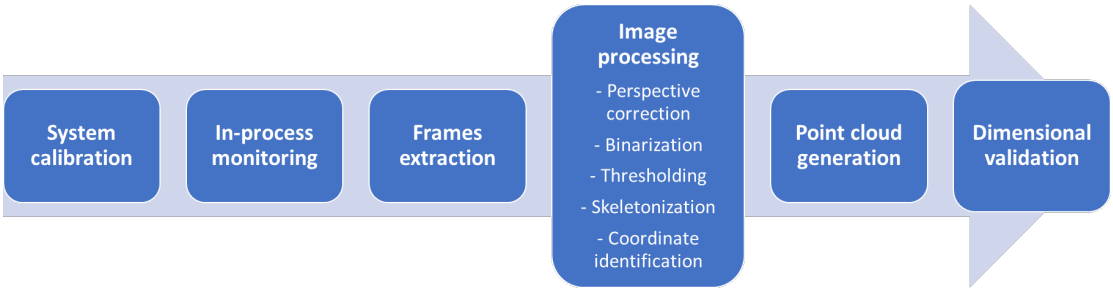

Fig. 2. Process monitoring workflow.

The collected data from both monitoring systems were then analyzed considering geometrical parameters. The average layer height was evaluated as the average distance of each layer point with respect to the base plate. The min-max layer height range and standard deviation were also considered.

The actual standoff distance was calculated as the difference between the design height of the tool center point (i.e., the tip of the nozzle) with respect to the base plate and the average height of the deposited layers, measured with the monitoring methods described above. In this way, it was evaluated the actual distance of the nozzle from the deposition plane and it was compared with the design (theoretical) standoff distance (*SOD_T*), which was set at 12 mm for this kind of nozzle. As can be seen from Fig. 3(a), the FC analysis of the different parameters can be done in-process. On the contrary, the LL analysis is performed at the end of the deposition of each layer. Fig. 3(b) shows one of the frames processed with this last method.

(a)  (b) 
Fig. 3. (a) Frame analyzed by the FC system and (b) by LL system.

The validation procedure of the considered monitoring methods was carried out with an offline 3D scanning system (HandySCAN 3D by Creaform) with known accuracy used for the reconstruction and measurement of the external surface of the entire samples. Additionally, the samples were trimmed, polished and chemically etched, in order to perform a micrographic analysis (Hirox MXB-10C) for estimating the height value of each deposited layer.

Results and Discussion

The point clouds collected for each layer by the LL system were analyzed by means of the GOM Inspect software and, as first check, a colored map was extracted showing the height of each point with respect to the base plate (see Fig. 4). As it is possible to observe, the colored maps well described the layer surface, highlighting the differences between sample A and B with the detection of the areas affected by the induced defects. More in details, at layer 3 the laser shutdown produced a lack in the deposited material, which can be seen from the missing traces on the layer surface. At layer 5, the interruption of the powder flow had a similar effect on the part morphology. It is worth highlighting also how at layer 5 there is still a propagation of the defect induced at layer 3. Finally, at layer 7 the variation of the deposition speed induced a huge protrusion. It was not possible to perform the same analysis by the high-resolution camera due to the different nature of the two monitoring systems.

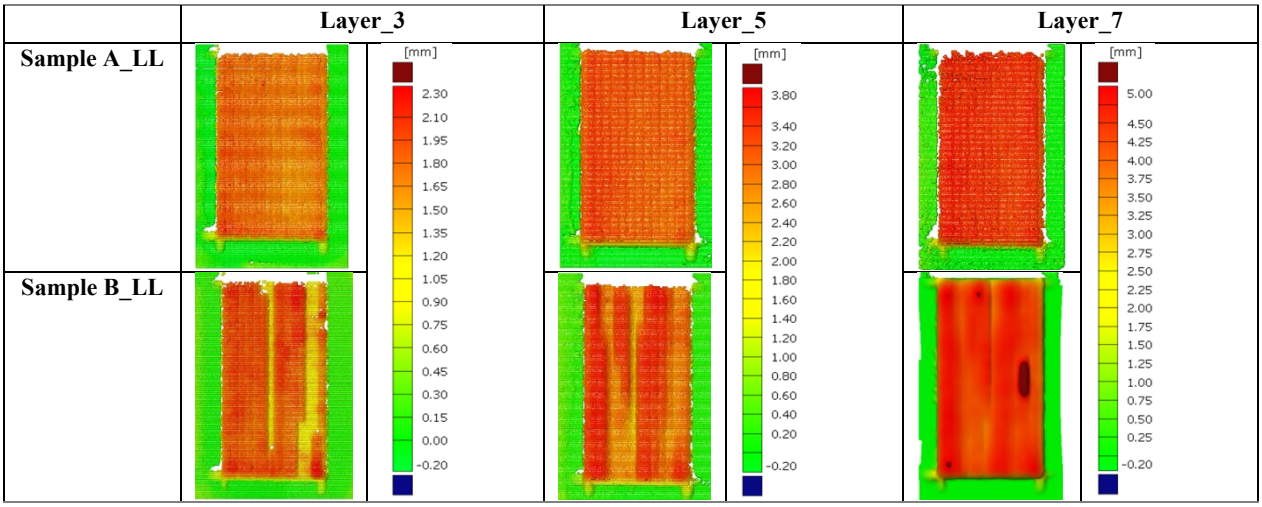

Fig. 4. Colored map showing the layer surface at layer 3, 5 and 7.

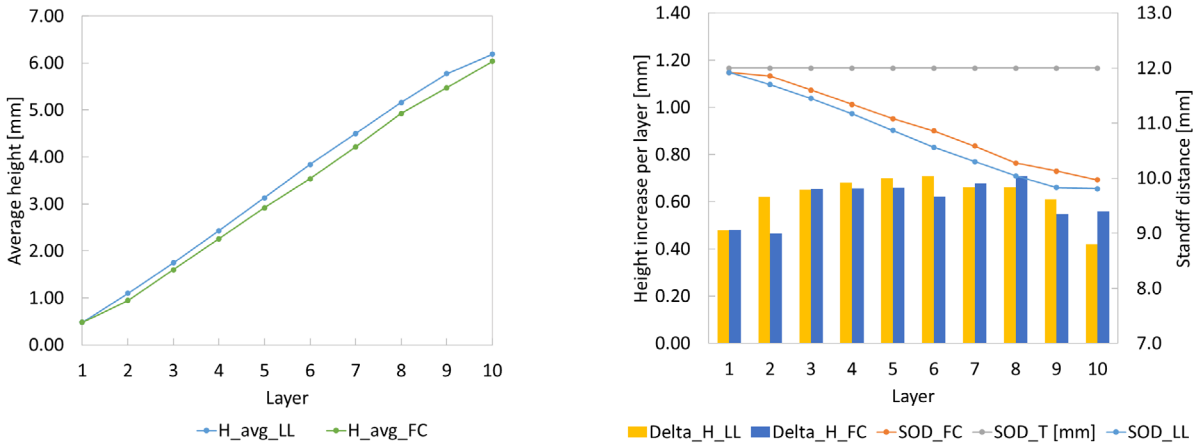
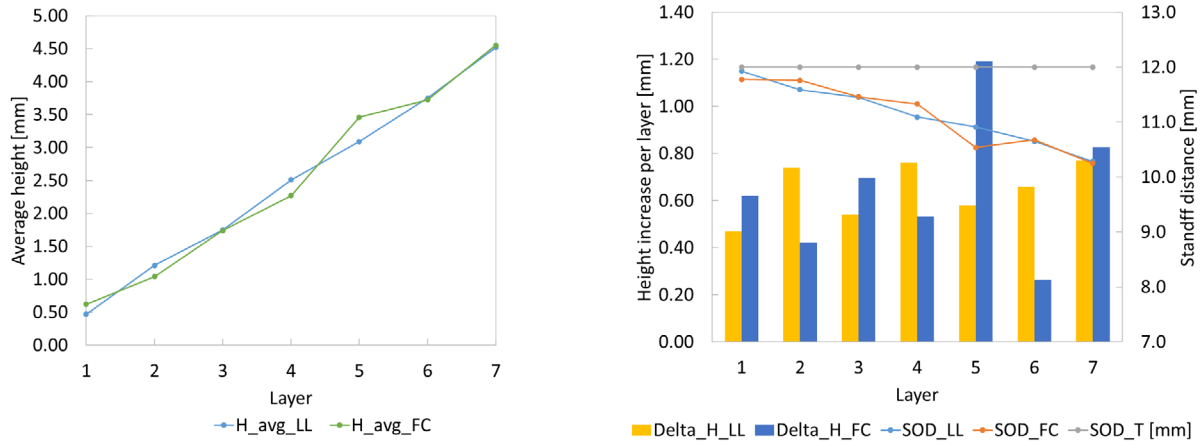
After the analysis of the entire layer surface made on the LL point clouds, the cumulative average height and the average layer height for each layer were evaluated for both LL and FC systems. The min-max height range and standard deviation were also computed in order to examine the variability within the entire layer surface for the LL and along the single profile for the FC. As shown in the Fig. 5(a), referring to the sample A, both systems enabled the effective monitoring of the cumulative average height (*H_avg*), showing a quite good convergence. This is because the layer surface was fairly homogeneous, without significant irregularities and defects, in accordance with the micrographic data and scan performed by the HandySCAN 3D. As reported in Fig. 5(b), the layer height values evaluated for each deposited layer (*Delta_H*) were quite similar with maximum differences on the order of 0.15 mm. It was also noted that the standoff distance (*SOD*) tends to decrease with the increase of the layer number. Slight reductions in standoff distance usually leads to a variation in the laser power density and powder flow distribution, deviating from the optimal conditions [4]. As a result, the amount of caught powder and the layer height decreases [20].



(a) (b)

Fig. 5. (a) Cumulative average height and (b) average layer height evaluated for each layer of the sample A.

The same evaluations were carried out on sample B. In this case, as can be observed from the graph (see Fig. 6), the deposition of ten layers was not possible as for sample A, due to the critical reduction of the standoff distance at layer 7 (layer growth higher than expected). The abrupt standoff distance reduction is to be avoided because it can cause equipment problems due to close interaction between nozzle and component. Considering the cumulative average height (see Fig. 6(a)) and the layer height (see Fig. 6(b)), there was still a convergence of results, with a significant difference registered at layer 5 where, from the colored map reported in Fig. 4, defects due to the powder flow interruption and the propagation of defect induced at layer 3 can be observed.



(a) (b)

Fig. 6. (a) Cumulative average height and (b) average layer height evaluated for each layer of sample B.

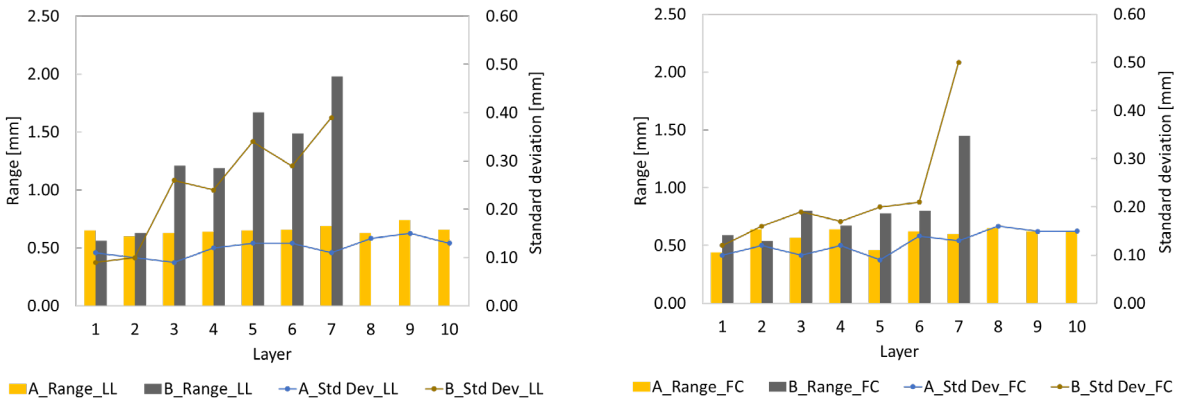
More generally, due to the 2D nature of the data coming from the FC, only the upper profile of the part facing the camera can be evaluated. This means that every process anomaly causing lack of materials within the layer, not affecting the first trace, is undetectable by this monitoring system (layer 5). On the other hand, when defects cause protrusions (anomalous material accumulation) within the deposited layer, even if these are not located along the side facing the camera, the FC technique is capable of detecting the irregularity (layer 7). Considering the layer 3, quite a good

convergence was found between LL and FC even in the presence of lack of material due to the laser interruption. Although, the area affected by the defect has a small extension with respect to the entire layer surface (see the colored map in Fig. 4), and it had a little influence on the average height value.

The standoff distance was also almost convergent with a more significant deviation registered at layer 5, for the above-mentioned reasons. Thus, both systems enabled the effective monitoring of the individual layer height and cumulative average height of the component, as well as the evaluation of the standoff distance for sample A and, to some extent, also in the presence of induced defects (sample B).

Although, from a monitoring point of view, the average layer height did not clearly indicate the onset of defects observed on sample B. For this reason, besides the average value, the min-max layer height range (*Range*) and standard deviation (*Std_Dev*) were also considered for the defect detection. In this case, considering first the LL system, there was an increase of these two indicators at layer 3, propagating at layer 4, a subsequent increase at layer 5 and another increase at layer 7 in correspondence of the last induced defect (see Fig. 7(a)).

Considering the FC system (Fig. 7(b)), in this case the range and the standard deviation were less sensitive to the induced defects except for the layer 7. The FC system indeed is capable of identifying, apart from the track facing the camera, only protrusions and accumulation of material exceeding the height of the visible track, see Fig. 3(a). Defects in the form of lack of material are not identified by this method.



(a) (b)

Fig. 7. (a) Monitoring of the min-max layer height range and standard deviation performed by the LL method and (b) performed by the FC method.

Finally, the validation of the monitoring results was carried out considering the 3D reconstruction and the micrographic analysis of sample A. In the first method, the validation was conducted on the sample A. With this aim, a 3D comparison between the point cloud of the layer 10 obtained with the LL and the mesh obtained with the HandySCAN arm was carried out (see Fig. 8(a)). The estimated absolute average deviation was on the order of 0.055 mm, with maximum values approaching 0.2 mm. These deviations could be caused by unmolten residual powder that remains on the sample after the last layer deposition and which the process gas is unable to move away from the sample. This thin film of powder could slightly alter the in process scanning with LL.

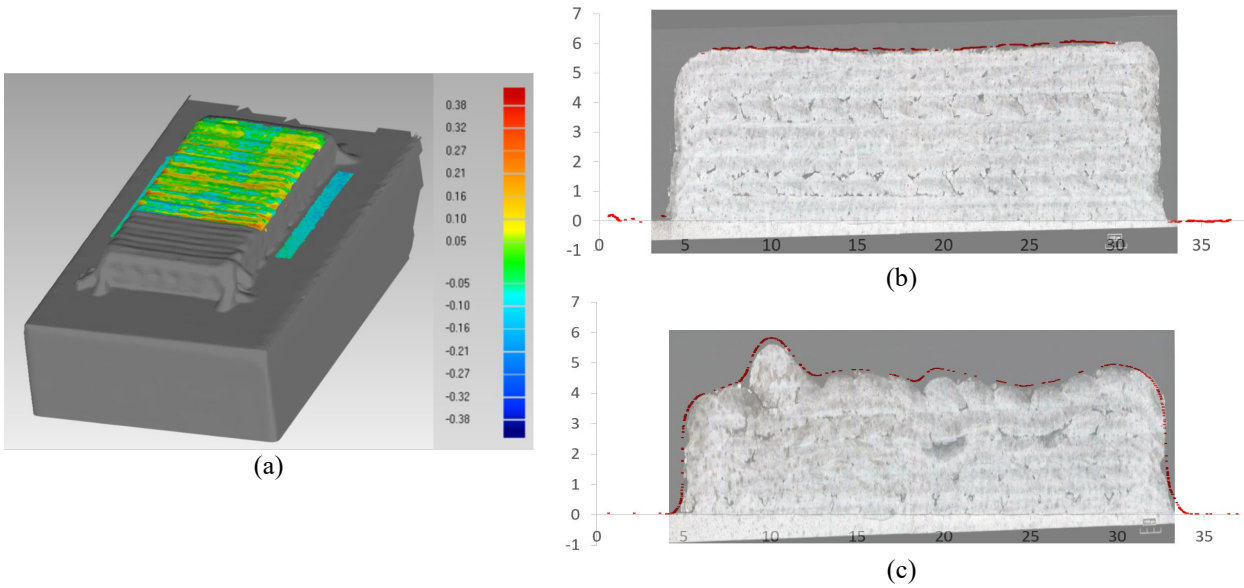


Fig. 8. (a) Comparison between the point cloud of the layer 10 obtained by the LL technique and the mesh obtained by the HandySCAN arm for sample A; (b) comparison between macrography and profile obtained by the LL method for sample A and (c) sample B.

The second method for the validation was a micrographic analysis. From Fig. 8(b) it is possible to observe a good correspondence between the transversal profile extracted from the LL system and the cross-section achieved by the micrographic analysis. Using this method, it was possible to evaluate the cumulative average height as well as each average layer height on the sample section. Micrographic analysis of sample B was also performed and compared with the profile extracted from a corresponding section (Fig. 8(c)).

Results for sample A are then reported in Fig. 9. The maximum deviation found with respect to metallography, for both techniques, was 0.13 mm.

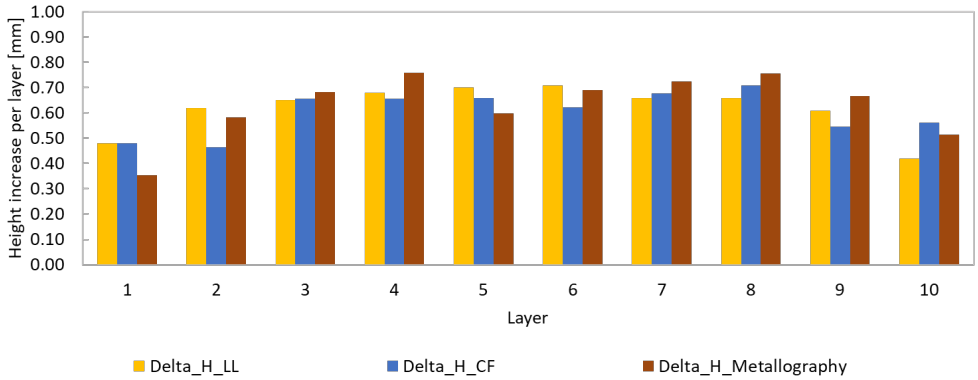

Fig. 9. Comparison of layers average heights as determined using each of the methods.

Summary

A comparative study between two optical in-process monitoring methods performed on AISI 316L multilayer samples produced by the LMD process has been presented. The first was a laser line section (LL) method based on a laser diode mounted on the deposition head, while the second method used a high-resolution CMOS camera placed on the horizontal plane (FC) with a front view of the sample. The systems enabled the effective monitoring of the average height of deposited layers and of the standoff distance. These also allowed the monitoring of the deposition

quality by means of appropriate KPIs as the min-max layer height range and standard deviation. The conducted analysis has shown remarkable results:

- The LL system was capable of evaluating the entire layer surface. At first, the 3D comparison tool allowed the detection of all the induced process defects in both forms, lack of material (layer 3 and 5) and material accumulation (layer 7). It was also possible to assess the average layer height, the min-max range and the standard deviation of the height values recorded at each layer, allowing a rapid detection of process defects.
- The FC system was capable to retrieve a single profile of the side facing the camera, which was almost sufficient to describe the layer geometry for the sample A (without induced defects), but it became ineffective when tested on sample B for the detection of defects in the form of lack of material.
- Regarding the standoff distance evaluation, the FC method offer the possibility to measure it directly via image analysis (nozzle – part distance), while the LL method allows only an indirect computation through the calculation of the height of the part.
- Both methods are threshold dependent in the image analysis, especially the FC when it is used in-process due to continuous variation of environmental light conditions. The use of illuminators is than recommended, in both closed and open chamber applications.
- Another important criterion for comparing the LL and FC methods is the capability to work in-process. In this case the FC method has advantages because it can work in-process and it does not require an additional movement of the deposition head to measure the layer surface. In this way, it can evaluate both the layer height and the standoff distance and it can generate an alert when the measured values exceed selected safety thresholds. On the other hand, the FC method appears to be more suitable for single track monitoring and generally simple geometries, while LL is more suitable for complex geometries requiring multi track and multilayer strategies.

Abstract. The applications of nanotechnology are growing widely as nanoscale structures provide unique properties such as high surface area unique plasmonic response and excellent conductivity that can be utilized for a wide range of applications. Optical absorption expansion of copper using carbon nanotube composite is one of the applications of nanotechnology for additive manufacturing of metals, particularly copper. Cu-CNTs mixtures at different percentage concentrations will be prepared via Resodyn, an acoustic mixer machine. Pure copper powder will be used with a spherical powder shape. The evaluation of the samples will be performed via spectroscopy to determine the reflection and thermal absorption of the light by the Cu-CNTs composition. The enhancement in the thermal absorption of Cu powder via additions of CNTs leads to the improvement in the bonding of particles by absorbing laser power. Due to the lower thermal expansion coefficient, sintering is possible at lower laser powers < 40%.

Introduction

Copper is one the unique metals having ductility and exceptional electrical and thermal conductivities of $58x10^6$ S/m and 400 W/m.K [1-3] Therefore, many engineering applications are possible due to these properties such as heat exchangers and heat sinks, thermal energy storage systems, etc., [4,5]. Moreover, heat transfer is further enhanced by making some geometrical changes by making fins, extended structures, and porous structures[6]. Metal Additive manufacturing (AM) has made it possible to manufacture complex structures with high accuracy and less material loss. Therefore, several complex components are being manufactured using different metals [7,8]. Despite having favorable properties, copper has the disadvantage of having high reflectivity which makes it difficult to manufacture using AM techniques such as L-BPF. The reflectivity of the copper can be reduced by increasing the absorption of the copper powder.

Considerable work is noted in the literature on additive manufacturing of copper powder. Lykov et.al [9] performed the additive manufacturing of pure copper powder using selective laser melting with a laser power of 200W. They manufactured cuboidal shape geometries and measured the maximum achieved relative densities. A maximum of 88% relative density was reported at 200W of the laser power. Jadhav et.al [10] also used pure copper to produce parts with a laser power of 300W. In their work lower relative densities were achieved due to insufficient diffusion of heat within the copper particles. Due to very high thermal conductivity, the heat was dissipated instantly from the melt pool. The issue of the lower laser power was addressed in numerous studies using high laser power up to 1kW which resulted in 96% relative densities of manufactured parts. However high laser power resulted in significant reflectivity due to that damage to the optical mirror [11–13]. In solution to this problem, the green and blue lasers were also by various authors

[14]. The remedy to address this problem is either by playing with laser parameters such as laser power and scan speed etc. or by modifying the absorption rate of the copper powder.

In the present work, Cu-CNTs powder mixture with CNTs having percentage concentrations in the range of 0.1%-0.3% CNTs was prepared using a Resodyn, an acoustic mixer machine. The cold isostatic hydraulic pressing method was used to fabricate the copper pellets. The copper powder was used with a spherical shape[15]. The evaluation of the samples was performed via spectroscopy to determine the reflection and absorption of the light by the Cu-CNTs composition. The enhancement in the thermal absorption of Cu powder via additions of CNTs leads to the improvement in the bonding of particles by absorbing laser power. Due to the lower thermal expansion coefficient, sintering is possible at lower laser powers < 40%.

Material and Methods

The experimental setup for the laser sintering of carbon nanotubes composite mixed copper powder consisted of Resodyn, an acoustic mixer machine to mix Cu-CNTs in different concentrations. Cu-CNTs pellets were produced via compaction by using Autotouch 40Ton Hydraulic Press. Sintering was performed via fiber laser (I.P.G) having a wavelength of 1064nm and 200W power in a custom made sintering rig capable of maintaining an inert environment to avoid any oxidization and contamination.

The copper powder and CNTs were mixed using Resodyn, an acoustic mixer machine, and compacted using the hydraulic press. The effects of mixing ratios on the quality of samples are investigated experimentally. From Sigma Aldrich, a copper powder with spherical-shaped powder particles was used. Different weight percentage ratios of CNTs were added to achieve higher laser absorption and less reflection. In mixing and compaction, CNTs weight percentage was the operating parameter. To get the same size pellets compaction parameters were the same for all sets of experiments. During the compaction process, a die with a diameter of 20mm is used, which results for each sample, the diameter remains constant.

The Cu-CNTs composite spectroscopy was performed with Perkin Elmer Spectrum Two FTIR a well-known and easy-to-use equipment for spectroscopy.

Table 1. Physical properties of Copper and CNTs.

Product Form	Particle Size	Purity (%)	Melting/Boiling (C)	Density (kg/m^3)
Powder (spheroidal)	10-25 μm	98%	1083.4/2567	8960
Carbon nanotube (Multiwalled)	10-20 nm	95%	3652-3697	2200

Compaction of Cu-CNTs.

The present work demonstrates cold isostatic pressing using hydraulic press technology of Cu-CNTs mixtures. Spherical-shaped copper powder is received from Sigma-Aldrich with a purity of 98% having a particle size of 10-25 μm and multiwalled carbon nanotubes are received from Cheap Tubes with a purity of 95% and length of 10-30 μm. Further technical and physical properties of copper powders and carbon nanotubes are listed in Table 1. Cold isostatic hydraulic pressing is a well known method for powder compaction. The compaction process is illustrated in Fig. 1, where the compressive force is applied by moving the piston from the bottom of the compaction die. 20mm diameter Cu-CNTs pellets were produced using this die. The compaction pressure for each pellet was 793 MPa and the compaction holding time was 10 mins.

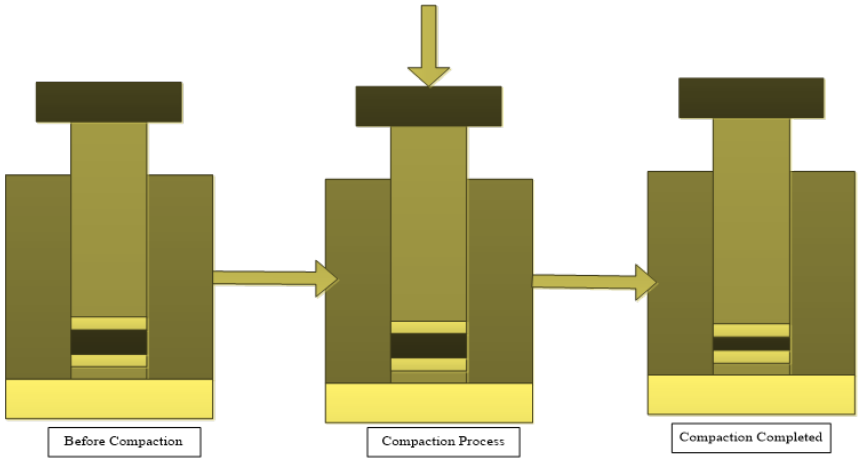

Fig. 1. The Schematic Diagram of Autotouch Hydraulic press compaction process.

Laser sintering.

The laser sintering of the Cu-CNTs composite pellets was carried in controlled temperature and air pressure, using a specially designed laser sintering rig shown in Fig. 2. The laser sintering rig contains two Calex PMU21 USB infrared temperature sensors to record the sintering temperature, UVFS Broadband Precision Window, -B Coated from Thorlabs to allow the laser beam to the sample and Argon gas connection to avoid oxidation and contamination during laser sintering. Fiber laser from IPG of 200W is used for laser sintering having wavelength of 1064nm. The laser sintering parameters are shown in Table 2. The laser spot size is fixed at 5µm.

Results and Discussion

Spectroscopy of Cu-CNTs Composition.

Before performing the spectroscopy on Cu-CNTs samples, the reflectance of the pure copper pellet was measured and compared with the broadband mirror.

Fig. 3 presented the reflectance of pure copper where the reflectance of the copper pellet was measured laser wavelength of up to 1070 nm. The reflection and absorption of the Cu-CNTs and the pure copper are shown in Fig. 4. From the spectroscopy of the pure copper powder, it is observed that reflection is 100% at 1064 nm of wavelength. This high reflection of copper powder causes difficulties in laser sintering at low laser power and the reflection of the laser beam can damage the laser source. The addition of multiwalled CNTs reduces the reflection of the copper and increases the laser absorption. From Fig. 4 it can be analysed that the reflection of the Cu-CNTs gradually decreases with the increase of CNTs. The addition of 2% (mass) of CNTs reduced copper powder reflection at 1064 nm of wavelength by 8% compared to the pure powder.

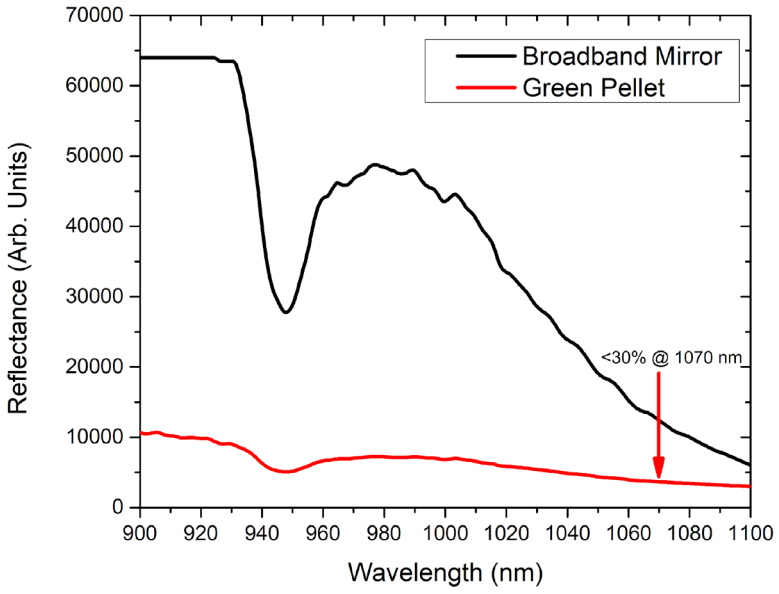

Fig. 3. Comparison of the spectroscopy results of green pellet and broadband mirror.

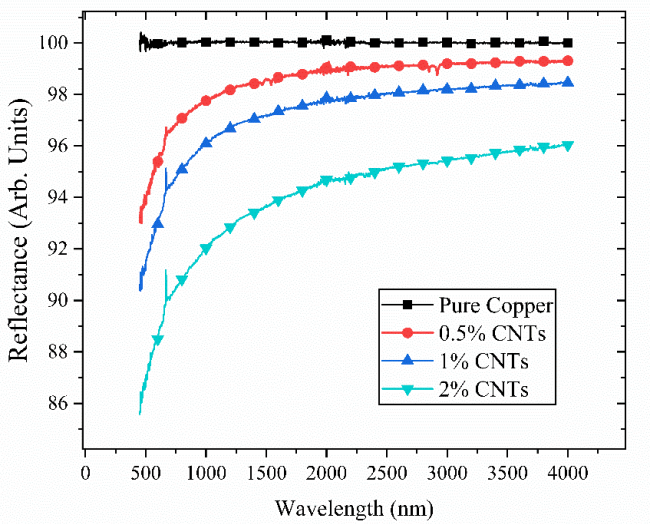

Fig. 4. The results for the reflectance of pure copper powder and Cu-CNTs powder with 0.5%-2% CNTs by mass percentage.

Laser sintering of Cu-CNTs Composition.

The pure copper compacted pellet was first laser sintered in the specially designed laser sintering rig shown in Fig. 2. The pure copper powder compacted pellet was first sintered to adjust the laser parameters. Fig. 5(a) shows the laser sintered pure copper pellet in the laser sintering rig with an Argon gas environment to prevent contamination and oxidation. Fig. 5 (b) shows the laser sintered pure copper pellet in an open atmosphere environment which clearly shows the contamination and oxidation. The laser parameter for pure copper sintering is shown in the Table 2. Fig. 6 (a), (b), (c), and (d) present the maximum pellet temperature for different scan speeds and laser power percentages. Fig. 6 (a) indicates that increasing the power percentage up to 40% and lowering the scan speed of the laser from 5 mm/s to 1 mm/s resulted in the pellet temperature being up to 570°C. Similarly, Fig. 6 (b),(c), and (d) present the temperature rise as a function of laser power and scanning speed for the Cu-CNTs powder containing 0.5%-1.5% of the CNTs. The same sintering parameters were used for the copper pellet having CNTs. Cu-CNTs pellet having 0.5% (mass%) of CNTs achieved the maximum temperature of 594 °C while with 1% and 1.5%, CNTs raised the pellet temperature up to 618°C and 657°C. Comparing to pure copper, with 1.5% CNTs 13% higher temperature was achieved which shows better absorption of the laser beam power into copper pellets.

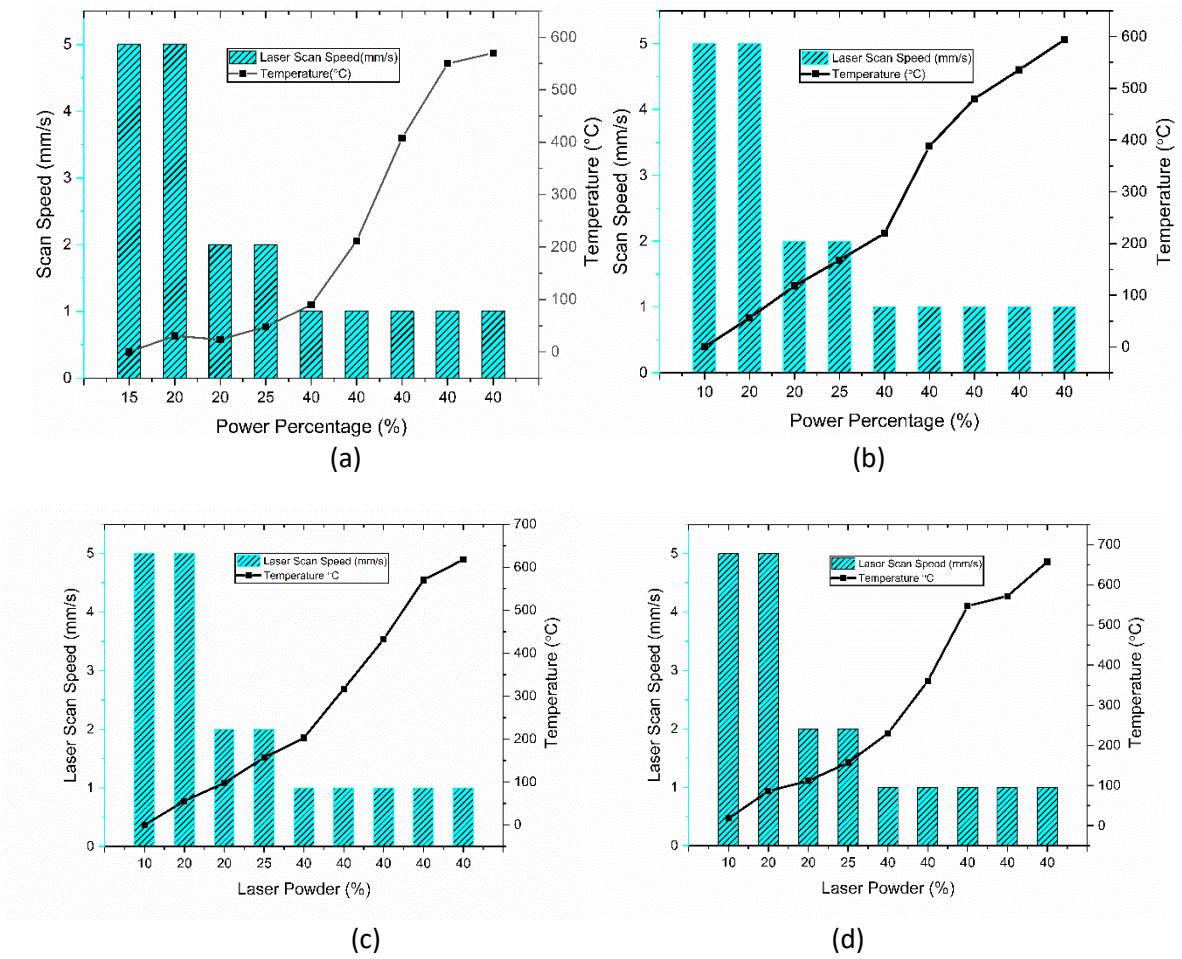

Fig. 6. The sintering temperature of pellet as a function of laser power percentage and laser scan speed (a) Pure copper powder (b) 0.5% CNTs mixed copper composite (c) 1% CNTs mixed copper composite (d) 1.5% CNTs mixed copper composite.

Microstructure of laser sintered pellets.

Cu-CNTs compacted laser sintered samples have mechanical properties that are determined by the microstructure distribution. The microstructure of the laser sintered pellets were analysed using Zeiss EVO LS-15 SEM. Fig. 7 shows the SEM images of laser sintered pellets without using polishing. Fig. 7 (a) shows the microstructure of the laser sintered pure copper pellet. The higher reflection of pure copper causes the loss of mechanical bonding of the powder particles leaving small pores on the surface. The addition of 0.5% of CNTs in the copper powder increased the bonding of the powder particles. Fig. 7 (b) shows the overlapping of the powder particles. In Fig. 7 (c), the addition of CNTs 1% of copper resulted in good consolidation of the particles and increases small pores on the surface comparing 0.5% of CNTs. The increase of CNTs percentage of 1.5% in copper resulted in high density in the pellet. Fig. 7 (d) shows the melted particles due to heat expansion in the pellet. The higher persistence of CNTs in the copper caused coarse particles on the surface of the pellet.

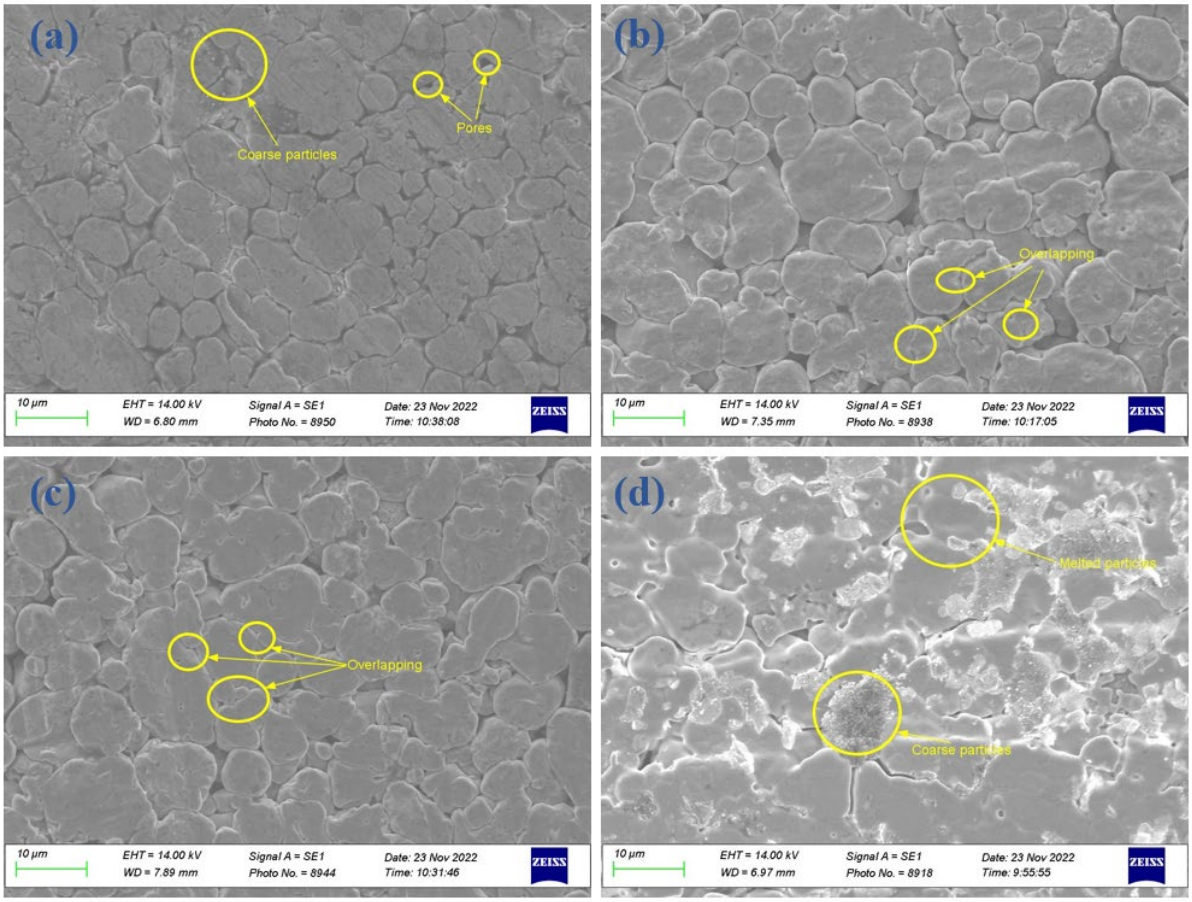

Fig. 7. SEM image of laser sintered samples (a) Pure copper pellet (b) 0.5% Cu-CNTs (c) 1% Cu-CNTs (d) 1.5% Cu-CNTs.

Summary

In this paper, the copper powder absorption was modified by adding different percentages of carbon nanotubes (CNTs). CNTs were added up to 1.5% to increase the laser power absorption ability of the copper powder. Spectroscopy was performed and results revealed that the reflectance of the copper powder by the addition of CNTs was decreased by 8%. Lesser contamination and oxidization were observed by using a specially designed laser sintering rig. The temperature of the pellet during sintering was controlled by adjusting the laser operating parameters. Improved consolidation of powder particles was observed by using a sintering rig as compared to the laser sintering in the open atmosphere environment.

Keywords: Additive Manufacturing, Laser Wire, Bead Geometry

Abstract. Among Directed Energy Deposition (DED) processes for metallic materials, Wire Laser Additive Manufacturing (WLAM), distinguishes itself by the use of a laser beam to melt a metallic wire and produce beads. Successive depositions of overlapping beads generate volumes to obtain parts. Thus, controlling bead geometries is essential for the additive manufacturing process. Several research works have studied these geometries and the influence of the main manufacturing parameters on their dimensions, but few investigated the effect of feeding direction or wire angle. Moreover, all studies on wire angle were carried out with lateral feeding and a constant laser orientation. This paper focuses on the influence of the deposition head orientation for a coaxial wire feed with 3 laser beams on bead geometries. An experimental campaign is conducted with different orientations relatively to a horizontal substrate and the external profiles are measured using optical instruments in order to extract the average profiles and characteristic dimensions. Results indicate an influence of the head rotation around its axis and lateral tilt on the height, width, and asymmetry of the beads.

Introduction

Metal additive manufacturing represents a major challenge for the development of new production strategies. Several processes are already in use, with either powder or wire as feedstock material. The use of wire results in simpler installations by reducing the constraints linked to powder handling, while producing solid parts with large volumes, as observed in Wire Arc Additive Manufacturing (WAAM). Wire Laser Additive Manufacturing (WLAM) is also based on a metallic wire, but with a laser beam as energy supply. Several configurations can be found in this category, depending on different technological choices or additional elements. For example, hot-wire limits the laser power required for manufacturing [1]. Differences are also possible in terms of material and power input, as the wire can be supplied along a different axis as the laser beam or along the same one, resulting in a coaxial configuration. This technology can be achieved by the use of multiple laser beams [2] or a ring beam [3].

Because of the wide variety of experimental devices and possible use cases, each installation requires the set-up of manufacturing recipes, often in an empirical manner by conducting several experiments. The usual approach consists in manufacturing single beads to define the initial process parameters, then in the study of overlapping beads to obtain surfaces, and finally in the study of layers, for single-bead walls or massive parts. Two profiles can be identified to describe single bead geometry: the external profile, also called reinforcement, and the internal profile, called penetration (Fig. 1). Rather than describing the complete geometries, specific dimensions are often used to characterize beads, as seen in figure 1 with width W, height H, contact angle θ_c and penetration P. Other typical dimensions not shown in the figure are the cross-section area A, which is considered as the additional area relatively to the initial part, and the dilution ratio, defined by the ratio between the area of the bead penetrating the substrate and the total area.

The existing literature proposes several models to describe the reinforcement profiles, including elliptical [4,5], sinusoidal [6] or polynomial models of degree 2 [7,8] or 4 [9]. A comparative study by Ding et al [10] highlights that most of these models present a satisfactory representation of the beads, while Xiong et al [11] establish that the optimal model is linked to the ratio between wire feed speed and travel speed. Most studies focus on relations between bead dimensions and the main process parameters: laser power, wire feed speed and travel speed, showing that width and height can vary independently. Abioye et al [12] and Medrano-Tellez [13] establish that the link between power and wire feed speed is essential to guarantee stability, with two main process defects: dripping when power is too high compared to wire speed and stubbing when it is too low.

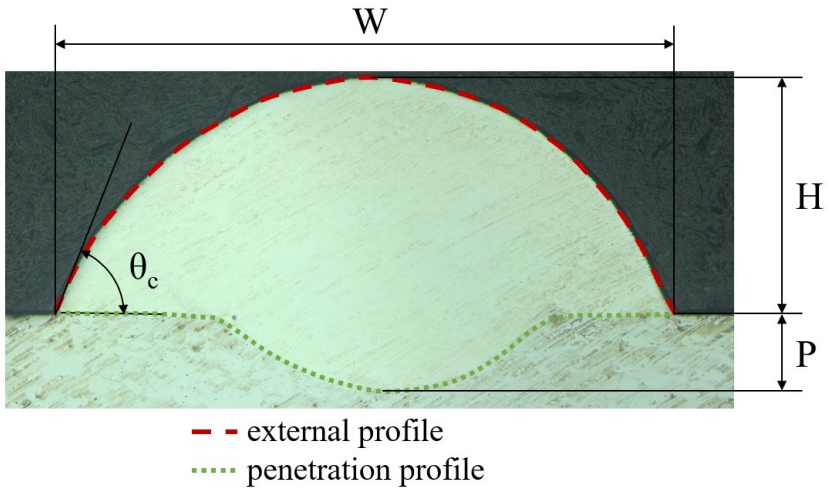

Fig. 1. Cross section of a bead with its dimensions.

One study focuses on feeding direction and found that it influences the appearance of the beads, with front feeding resulting in smoother beads [14]. For lateral configurations, where both laser beam and wire have different axes, the angle between wire and substrate also influences the produced geometries. However, the deposition head considered in this study uses three laser beams distributed around the wire to obtain a coaxial configuration. No articles investigating the influence of orientation and inclination on bead geometry for coaxial heads were found in the available literature. Most papers for coaxial technologies focus exclusively on wire feed speed, travel speed and laser power, with an occasional mention of the distance between the beams intersection point and the workpiece [15]. However, head orientation relatively to the travel direction can vary during manufacturing. In addition, variations in head tilt relatively to the substrate can be used to gain collision-free access to specific areas of the workpiece, or to manage gravity.

Therefore this study focuses on whether the tilt and orientation angles of a 3-beam coaxial head to the substrate have an effect on produced external bead geometries. This paper presents the experimental setup and process conditions before describing the method used to identify the effect of both head tilt and rotation. The obtained results are then presented and discussed before concluding.

Experimental Setup

The additive manufacturing cell (Fig. 2) is based on laser-wire technology, implemented by a Coaxworks head carried on a ABB IRB4600 robot and using an Ytterbium fibre laser power source with a maximum power of 4 kW. The feedstock is a 1.2 mm diameter IN718 wire and the parts are produced on S235 JR steel substrates which are 80mm long, 40mm wide and 10mm thick. A Xiris weld monitoring camera is attached to the head, enabling process monitoring. In addition,

the head's optics are protected by a flow of compressed air to expel smoke and spatters, and the weld pool is protected from oxidation by a flow of Argon at a pressure of 2 bars.

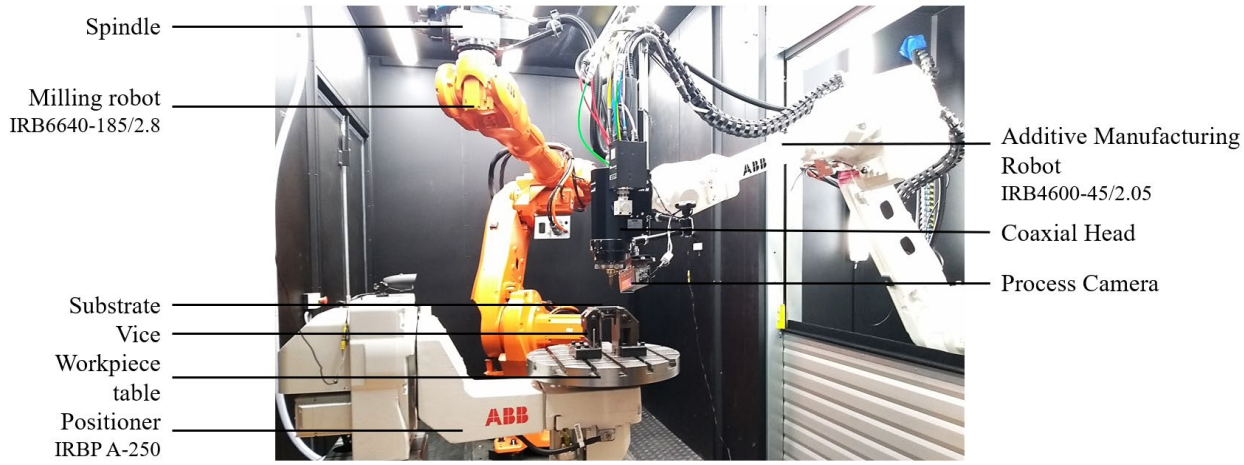

Fig. 2. Overview of the WLAM setup.

The head divides the initial beam into three laser beams, equally placed around the vertical axis of the head (z-axis) at 90, 150 and 30° angles to the x-axis respectively for beams 1, 2 and 3, and with an angle of 17.5° to z. In standard production configuration, the head is oriented so that its z-axis follows gravity.

Initial tests established a process window depending on three usual parameters (power, wire feed speed and travel speed) regarding both stubbing and dripping defects. In addition, two additional phenomena were observed. At low laser power and low wire speed, lack of fusion appears (Fig. 3a), where the energy is sufficient to melt the wire, but not the substrate, resulting in a bead without adherence. This phenomenon was already observed by Medrano Tellez [13], who characterizes it by a head speed too high for the power. In contrast, with low travel speed and high wire feed speed while keeping sufficient laser power to melt it, a wider and higher melt pool than other beads is obtained. Its behaviour is close to that of a liquid (Fig. 3b), similar to what can be observed in WAAM.

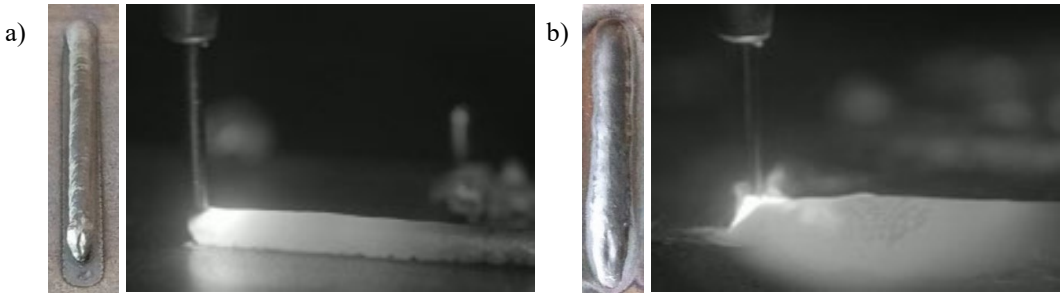

Fig. 3. Beads and process views for two defects: lack of fusion on the left and liquid behaviour on the right.

Method

According to the process window, an operating point with a travel speed of 1 m/min, a wire speed of 2 m/min and a power of 2.2 kW is used for all experiments. These parameters were determined with a working distance of 2 mm, which means that the intersection point of the three laser beams is 2 mm below the substrate surface. The dotted red segments on figure 4 stand for the axes of the

three laser beams, the continuous red segment for the head axis, and the black outline for the laser spot boundaries.

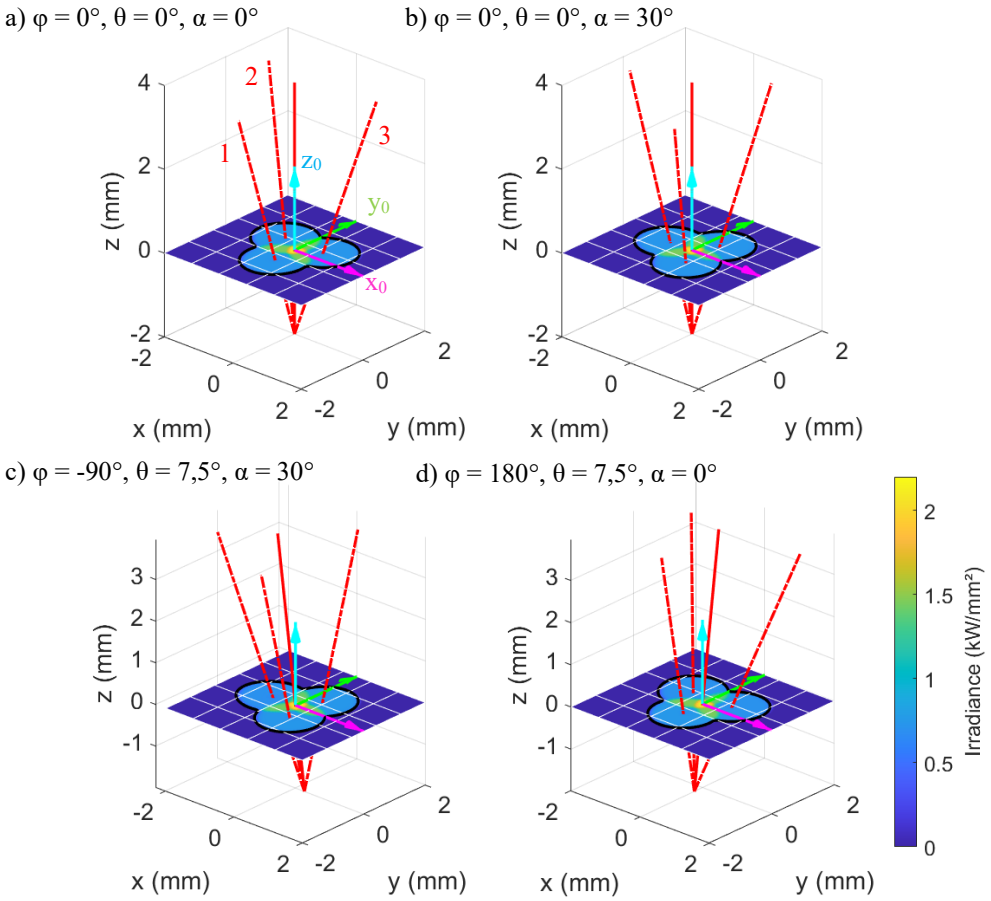

Fig. 4. Power density and laser spot limit for different head orientations.

During manufacturing the substrates remain fixed and the head travels along the x_0 axis of the substrate in the positive direction, with different orientations. To describe the head orientation, an intrinsic Euler formalism is used, corresponding to a rotation of angle φ (precession) about z_0, corresponding to the tilting direction, followed by a rotation of angle θ, called tilt, about x' and finally a rotation of angle ψ about z''. The angle $\alpha = \psi + \varphi$ will be used and referred to as head rotation, as it approximates the total rotation of the head around its axis when θ is small (0.2° deviation for θ = 7.5°). The limits of these angles are fixed by technological constraints (cable management and laser safety), with α constrained in the interval [-70°;70°] and θ inferior to 8°. For the experiments θ varies on two levels between 0 and 7.5°, φ on 8 levels between 180 and 135°, and α on 5 levels between -60 and 60°. Only the value φ = 0° is considered for θ = 0°. Therefore 45 tests were carried out, with four 60 mm beads deposited on each substrate, spaced 8 mm apart with a waiting time of around 1 minute to reduce the possible effects of thermal accumulation. Preliminary tests established that geometries of beads produced under these conditions are independent of manufacturing order. The produced parts were measured using an optical 3D measurement system over an area of 3.6 mm by 3.6 mm in the bead centre. The deposition direction x_0 was identified before subdividing the y_0 axis into 1000 intervals between -2 and 2 mm, resulting in a local height distribution for each value of y, corresponding to the variations in height inside the measurement window. The mean value and the standard deviation σ of the z values according to y were determined, leading to a statistical bead profile over the entire

measured area. Under the assumption of a Gaussian distribution of the values, a 95% confidence interval can be considered as ±1.96 σ. Using this mean profile, the parameters H, W and A were determined with their confidence intervals. A new value A_r is added, which represents the ratio between the area on the right of the bead (corresponding to positive values of y) to the total area, with the middle of the base serving as centre. This value is only determined for the mean profile and expresses if the bead is tilted to one side, serving as an indicator for asymmetry.

Results and Discussion

Among the 5 beads produced with θ = 0° and varying α, the angles α = -60° and α = -30° present stubbing, contrarily to the other beads which have a smooth appearance (Fig. 5). For α = -60°, the measurement area is not located in the centre but close to the start when stubbing is not as apparent. The dimensions as functions of the angle α are displayed on Fig. 6. The confidence interval for α = -30° is much larger than for the other values, while it does not appear for α = -60° after the measurement zone shift.

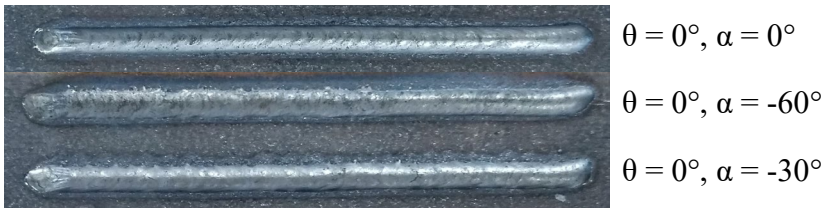

Fig. 5. Beads with or without stubbing (welding direction from right to left).

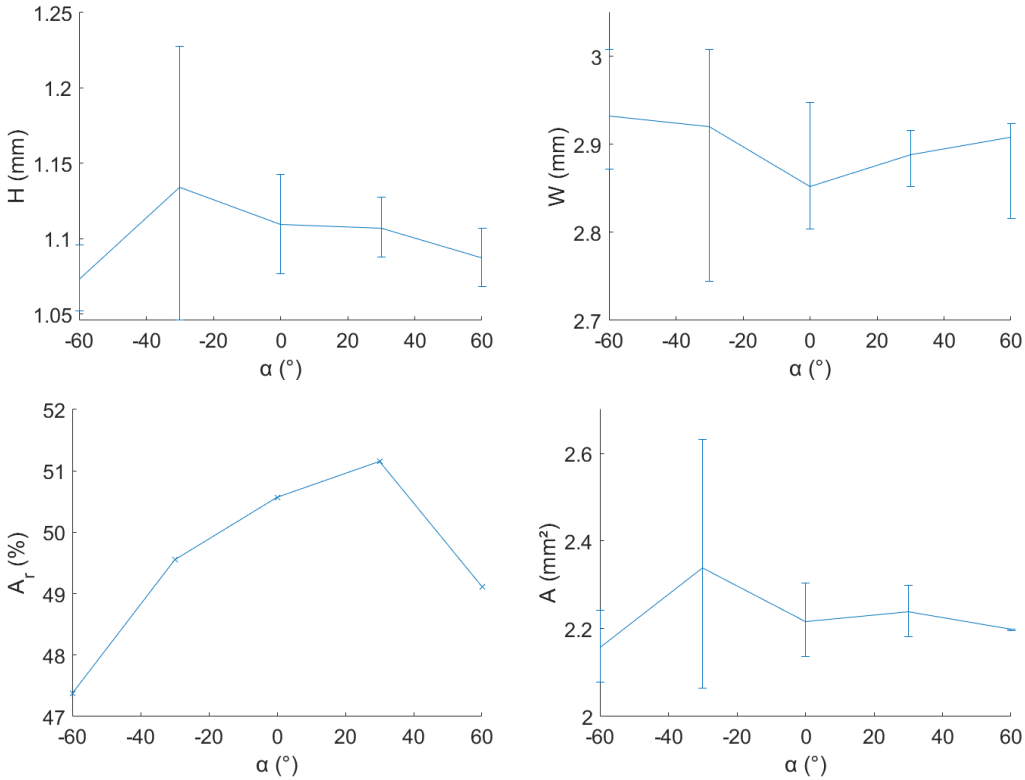

Fig. 6. Variations in bead dimensions for different head rotations.

These results do not show a significant evolution of the dimensions depending of the head rotation, except for A_r. This variation limited to around 4% of bead area indicates that the rotation without head tilt may introduce a slight asymmetry in bead profiles. It is notable that the configuration corresponding to an almost even ratio between left and right is achieved with α = -

Materials Research Proceedings 28 (2023) 119-127 https://doi.org/10.21741/9781644902479-14

30°, which places the beam number 3 on the front and the other two on the back, resulting in a symmetrical distribution on both sides of the melt pool (Fig. 4). Moreover, more matter is displaced to the right when beam 3 is placed on the side where y is positive, and more on the left when on the y negative side.

Some configurations with θ = 7.5° lead to dripping at the start of the bead, where a drop of material remains on the wire before being deposited, leading to a shifted start of the bead (Fig. 7). The rest of these beads is stable, which would rather indicate a defect in the starting parameters, particularly the duration between wire positioning and laser start. The variations in dimensions as a function of φ for different values of α are plotted in figure 8, and the dripping conditions do not lead to a wider interval, except for φ = -135°, α = -30°.

Fig. 7. Beads with dripping at the start.

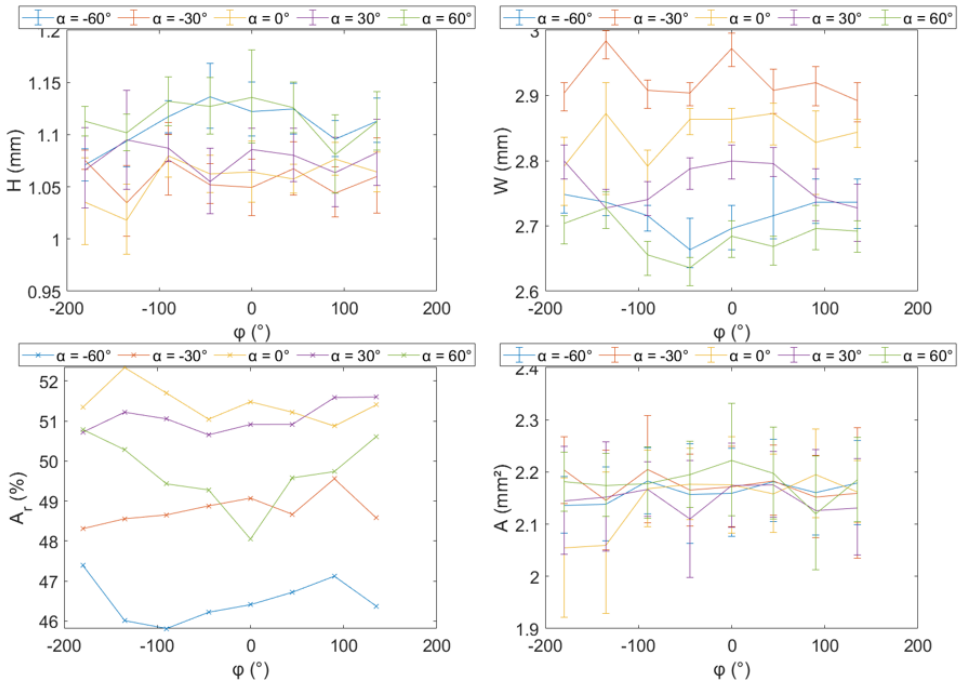

Fig. 8. Variations in bead dimensions for θ = 7.5°.

No significant variations in bead area can be observed, as the differences between mean values are inferior to the confidence intervals. This was expected as the ratio of wire feed speed to travel speed remains constant. Changes can be observed for the width and height, but they remain small (around 10%) and seem to be more related to head rotation than to the tilting direction. To help in the geometry comparison, 5 profiles are selected and displayed on Fig. 9.

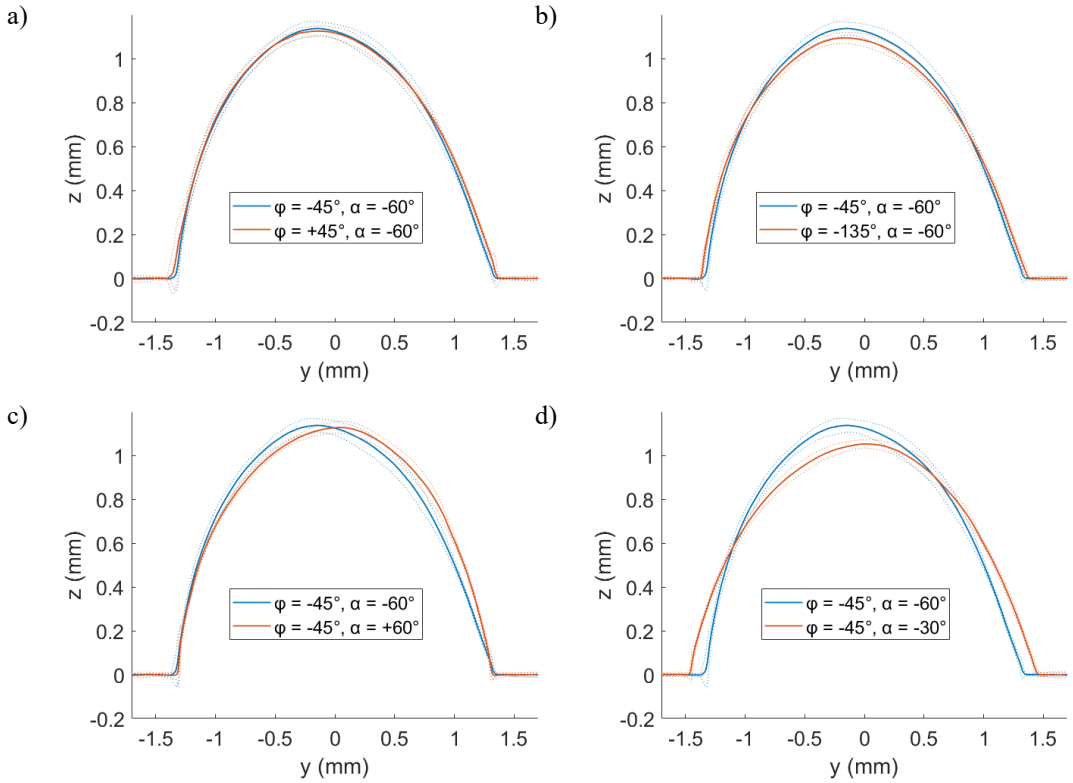

Fig. 9. Comparison of selected bead profiles for θ = 7.5°.

The width seems to depend little on the tilting direction, but more on the head rotation when the head is tilted (Fig. 8), whereas it does not seem to vary without tilt. Indeed, the widths for α = 60° are always smaller than those obtained for α = 0°, in turn smaller than for α = -30°. Fig. 9d compares beads and illustrates the width variation. The maximum width is then obtained for α = -30°, which corresponds to the only configuration tested where one laser beam is at the front of the wire and two beams are at the back (Fig. 10). The effects of head rotation on the ratio between area on the right and total area are observed again, and Fig. 9c shows the asymmetry in the full profile between two orientations.

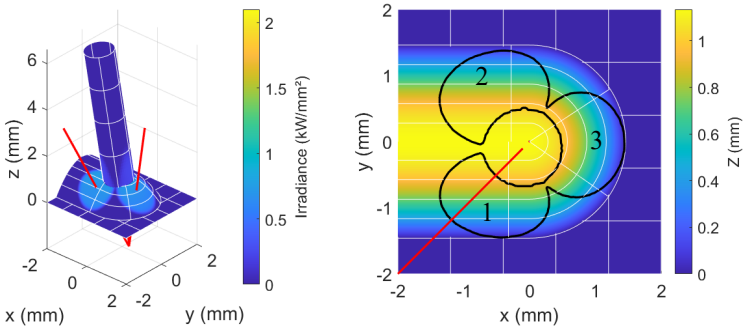

Fig. 10. Laser spot on a nominal bead model with θ = 7.5°, φ = -45° and α = -30°, 3D view on the left and top view on the right.

In contrast to the two previous quantities, bead height depends on the tilting direction. Indeed, variations due to the angle φ are greater than those observed by varying the angle α, but only for α = 60 or -60°. The height of the beads therefore depends on both tilting direction and head rotation. To ease the analysis, the head axis and laser spots are plotted in Fig. 11 for all the configurations of Fig. 9.

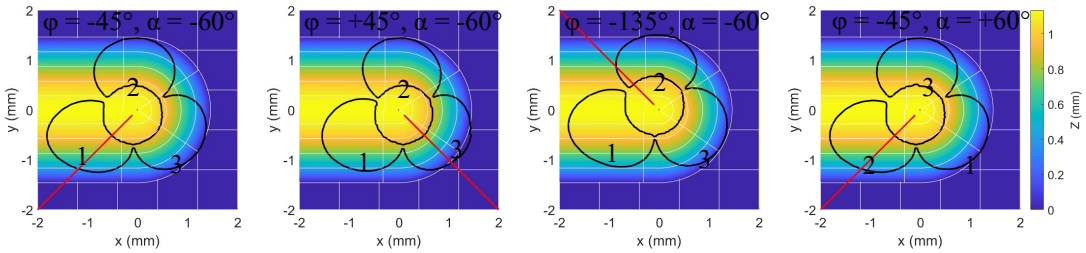

Fig. 11. Comparison of the different configuration of Fig. 9.

For the following discussion two terms are introduced: the front/back tilt to describe the angle around the y axis, and the lateral tilt to describe the angle around x. Thus, between φ = 45 and +45° lateral tilt does not vary, while the head is tilted either towards the front (φ = +45°) or the back (φ = 45°) of the melt pool. Fig. 9a shows that this variation from front to back tilting does not affect bead profile significantly. Fig. 9b highlights that change in lateral tilt leads to change in height without affecting width. Maximum height is obtained by tilting the head to the left side, where two beams are located. Indeed, as seen in figure 11, both α = 60 and -60° correspond to configurations where one laser is aligned with the y axis and on the right side (y positive). However, the configuration α = 0° also corresponds to a beam aligned with the y axis, but no link between α and H is observed for this value. When α = 0°, beam number 1 is aligned with y and located to the left of the profile, while for α = 60° it is beam 3 on the right side and beam 2 on the right side for α = -60°. The observed variations may also be influenced by defects in the power distribution between the beams, or defects in wire positioning. Further studies would allow to quantify their effects on the presented results.

Summary

In this paper the influence of orientation parameters on single beads external geometries was investigated. The beads were measured to extract mean profiles with their associated confidence intervals, allowing to obtain dimensions for the different tested angles. Results showed that head rotation mainly influences the width and asymmetry of the beads, with symmetrical and wide beads obtained when one beam is placed at the front and two beams at the back. For configurations with one beam on one side of the melt pool and the other two on the opposite side, the height of the bead depends on the lateral tilt of the head. No influence of front or back tilting was observed in this study.

The measured variations for a tilt angle up to 7.5° are around 10% of nominal values. A higher tilt angle could amplify these effects but achieving it on this setup would require using the 2-axis positioner, changing gravity direction relatively to the part. This study focused on external geometries without studying the penetration. However, a change in power density can lead to variations in bead-substrate interactions. Further analysis of dilution and penetration are part of the perspectives of this work.

Keywords: Cermet, Tungsten Carbide, Laser Powder Bed Fusion, Hot Isostatic Pressing, Microstructure, Hardness

Abstract. Cermets are composite materials made of a ceramic reinforcement and a metal matrix, generally cobalt as binder, with mass content from 6 to 20 wt.%. Cermets are produced by conventional sintering process and are known for their high hardness, low friction coefficient, high wear resistance, and high melting temperature. Laser Powder Bed Fusion (L-PBF) is an additive manufacturing technology widely applied for direct fabrication of functional metallic parts with complex geometry such as internal channels or lattices structures. Considering several studies, production of cermets by L-PBF process is challenging. Recent publications have demonstrated the feasibility to produce WC-Co parts by L-PBF combined with Hot Isostatic Pressure (HIP) heat-treatment. HIP process is sometimes additionally performed as post-treatment to remove defects. HIP is performed at high temperatures and isostatic pressures in a furnace [1]. In this study, following an experimental design a parametric optimization was conducted in order to maximize the mass density of WC-17Ni. Process parameters were compared to those used for WC-17Co parts from recent study [2]. To improve the printed specimen integrity, the as-built samples were heat-treated. As-built and HIP samples were analyzed and compared in terms of mass density, microstructure, crystallographic phases, and macro hardness.

Introduction

Laser power bed fusion (L-PBF) is an Additive Manufacturing (AM) process employed for the production of complex functional parts using metal powder as feedstock material. The powder material is spread on the build platform by the scraper and compacted by the roller. Laser beam is controlled by the scanner on the XY plane, and the platform is moved in the Z direction. Then a new powder layer is deposited, and the process is repeated until the complete part is built. The final properties of the built parts, such as roughness, porosity, cracking propensity, and mechanical properties, depend on process parameters, such as laser power P (W), scanning speed Vs (mm/s), hatching distance Hd (µm) and layer thickness l (µm) [3-8]. These factors are important because re-melting depends on the amount of the volume energy density VED (J/mm^3) absorbed during the process [9], which is defined by the following equation:

$$VED = \frac{P}{Vs \times Hd \times l} \quad (1)$$

Results in this study will only be reported in *VED* and expressed in J/mm^3. Cermets are composites material made of a hard refractory carbide embedded in a ductile metal binder matrix, usually cobalt matrix. The choice of transition metal such as Co, Fe or Ni, has been done based on their good wettability and solubility of W and C and based on their good mechanical properties. Cermets, also known as Hardmetals are extensively utilized for manufacturing of cutting tools and are classically manufactured by powder sintering [10–14]. Considering several studies, it can be concluded that L-PBF manufacturing of WC-Co parts remains challenging [15–17]. Studies show that preheating of the building plate to a high temperature is a key factor to allow the manufacturing of solid samples with reduced porosity [18]. Recently, the manufacturing of complex-shaped WC-Co parts were also demonstrated in without preheating plate [2]. Even with internal porosity and short cracks could be eliminated by post HIP treatment [19–23]. However, for developments in the field of hard metals, many studies have been conducted to find alternative materials to replace cobalt due to environmental issues related to its production. Therefore, new alternative binders are considered, especially Ni and Fe-alloys. In this study, nickel was chosen instead of cobalt. Nowadays, only a few studies based on the use of nickel as alternative binder could be found in the literature. Gu D. et al. [24–26] present different results using a mix of pure nickel and pure tungsten powder, with a particle size of 45 µm and 2.5 µm respectively. Tungsten carbide is formed by adding free carbon with a particle size of 30 µm, to obtain a tungsten carbide nickel powder with a ratio of 85wt.% W, 10wt.% Ni and 5wt.% C. First test was conducted on L- PBF process using a CO_2 laser. The following suitable parameters were chosen, a laser power of 1200W, a layer thickness of 100µm, a hatching distance of 150µm and a scan speed in the range from 800 mm/s to 1200 mm/s. Volume energy density of 83 J/mm^3 allowed to manufacture W-Ni-C by L-PBF. The samples showed a good densification level of 96,3% and the microhardness of the block-shaped WC formed at a laser scan speed of 800mm/s was 1619.7 $HV_{0.1}$, which increased to a maximum value of 1870.9 $HV_{0.1}$ by increasing the scan speed at 1000 mm/s. Different phases were observed such as the hexagonal WC and the cubic Ni_2W_4C (M_6C) phase [24,25].

Present article focuses on the AM of parts using Ni as alternative binder. First, the possibility to produce L-PBF parts was evaluated by determining the optimal process parameters. In a second step the benefits of HIP post heat treatment process will be evaluated to eliminate residual porosity and cracks. Finally, the microstructure, crystallographic phases and macro hardness will be analyzed. To compare the mechanical properties, manufacturing WC-Ni by L-PBF, was compared with sintered-HIP conventionally prepared WC-Co.

Material and Methods

Characterization of the powder.

Commercially available powder of agglomerated-sintered WC-17Ni, manufactured by spray drying by Oerlikon Metco® was used in this study. The powder was initially developed for thermal spray applications such as HVOF and HVAF. The granulometry distribution was measured using an Occhio 500XY nano particle analyzer (Occhio SA, Liège, Belgium). The particle size distribution is between 15 and 53 µm. SEM images of the particles are shown in Fig. 1. The particles have a spherical morphology. The average size of the WC grains (dark grey) is in the 1-2µm range. The carbide grains are uniformly distributed in the nickel matrix (light grey). Inductively coupled plasma mass spectrometry (ICP-MS) analysis indicates that the chemical composition of binder content was close the range stated by the supplier (C: 4.7 – 5.5, Ni: 14.5 – 19.5). In particular the measured nickel and carbon content was 20.1 wt.% and 5.1 wt.% correspondingly. X-ray diffraction was carried out on initial powder to determine the different phases. The XRD pattern shows only the WC and Ni phases in the initial powder (Fig. 1 d).

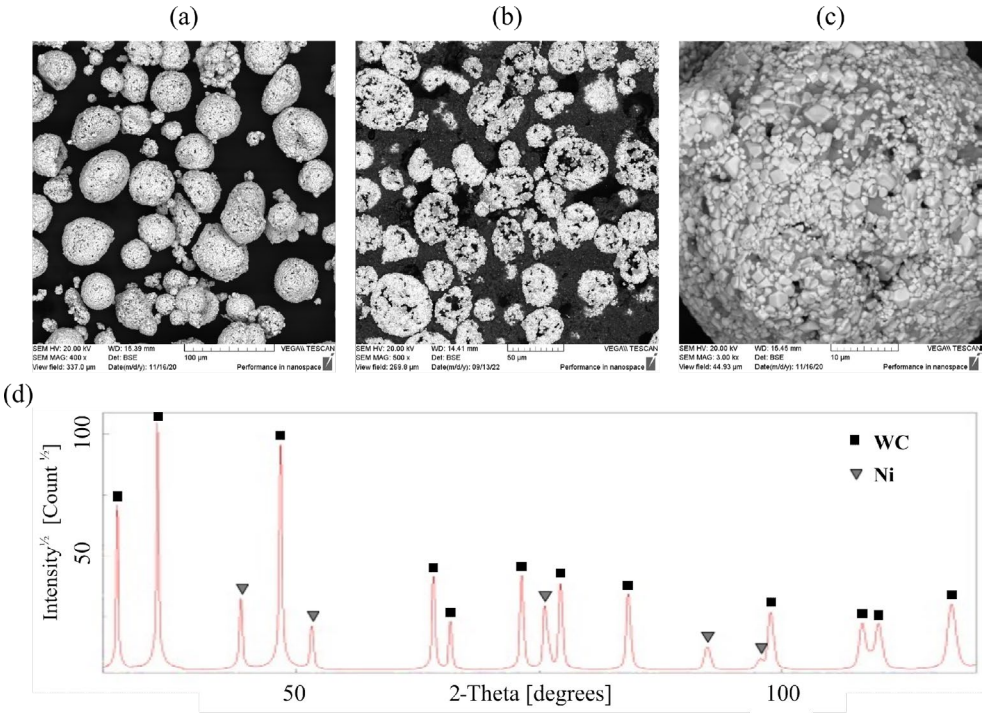

Fig. 1. SEM images of the WC-17Ni particles at different magnification (a) overview at x400, (b) cross section of particles, (c) overview at x3000 and (d) XRD pattern of WC-17Ni powder.

L-PBF and characterization equipment.

Pro X 200 DMP equipment supplied by 3D Systems® was used. The volume of the working chamber where the parts were manufactured was 140 × 140 × 125 mm^3. The L- BF machine was equipped with a 400 W fiber laser having a wavelength of 1070 nm. To prevent oxidation the working chamber was filled with nitrogen during manufacturing. Cube-shaped samples with dimensions of 10 × 10 × 10 mm^3 manufactured using L-PBF were used for post-treatment in order to reduce porosity. Samples was subjected to capsule-free HIP, which is a cycle applied during industrial processes. HIP was performed at 1450 °C with a furnace maintained at a pressure of 40 MPa for 5h. The relative density of the manufactured parts was determined by image analysis of microscope images using ImageJ [27]. The microstructure and elemental distribution were analyzed using a Zeiss Supra 55VP v2 SEM and EBSD maps were also recorded. X-ray diffraction (XRD) was employed for phase analysis using an X'PertPro MPD diffractometer with CuKα radiation. Phase quantities were obtained from Rietveld analysis performed with the MAUD software [28]. Vickers hardness (HV) was determined by applying a load of 30 kg for 10 s to all samples. Palmqvist toughness was determined by crack propagation measurement after indentation test [29].

Results and Discussion

Optimization of process parameters.

In this study, the possibility to produce cermet by L-PBF without preheated plate and the optimal process parameters will be determined. L-PBF process parameters were determined following a designed experimental optimization (DEO). Two different step was realized, first, single tracks were deposited with a powder layer thickness of 30 µm with different laser power and scan speed. Single tracks width was measured in order to determine the hatching distance.

Table 1. Ranges of L-PBF manufacturing parameters applied in the experiments.

Layer thickness [µm]	30
Laser power [W]	160 - 200 - 250
Scan speed [mm/s]	50 - 100 -150 -200 -250 -400
Hatching distance [µm]	80 - 280
Volume Energy Density [J/mm3]	160 - 650
Scan strategy	Rt - Hexagone

Then, 3D objects with simple geometries (cubes and parallelepipeds) were manufactured. The principal purpose of these experiments was to determine the parameters enabling the production of materials with the lowest amount of porosity and cracks. Table 1 summarizes the parameter ranges tested in the DEO. For manufacturing the cubes, two different scanning strategies were used, a hexagon (H) strategy, which reduces the residual stresses in the workpiece and allow creating large surfaces and a classical round trip (Rt) strategy with 90° rotation between each layer. The evolution of the porosity for WC-Ni sample is shown in Fig. 2. For a power of 160W, the porosity was the highest. Many of the cubes were not printed in full height and manufacturing was cancelled during the process. Following these observations, several parameters were set as non-optimal for this powder and parameter ranges were modified. In particular the width of VED window was decreased to 180 J/mm^3 - 300 J/mm^3 for 200W and 250W respectively. At the first stage for a VED of 200 J/mm^3 and for 300 J/mm^3, cubes with a hexagonal scanning strategy were manufactured but, the porosity was high due to inappropriate hatching distance.

For the Rt scanning strategy, samples had the lowest porosity rate of 1.06% and 0.84% for 200W and 250W respectively. Hexagonal scanning strategy shows a minimum porosity of 1.20% at 208 J/mm^3. For the lowest VED of 180 J/mm^3 porosity was the highest but it could be decreased by increasing the VED value.

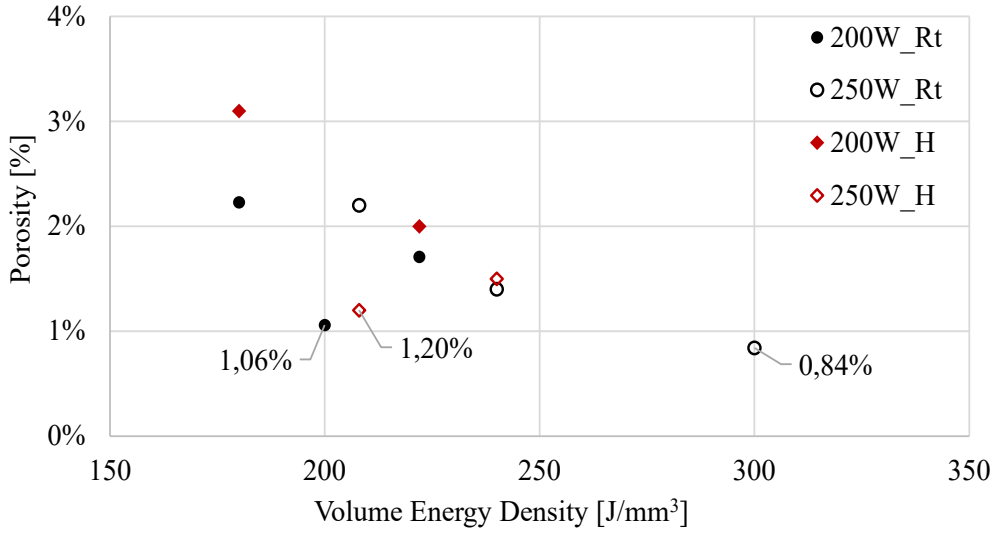

Fig. 2. Sample porosity vs. VED for round trip and hexagonal scanning strategies.

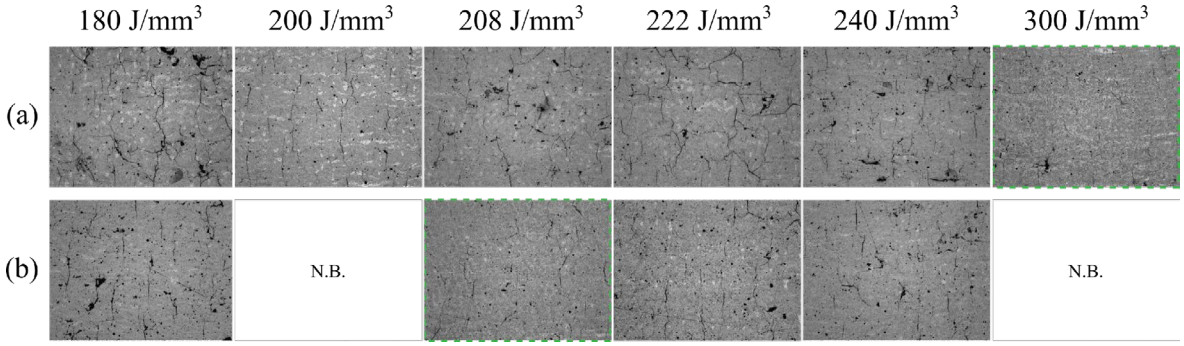
The microstructures of fabricated samples are shown in Fig. 3. Cracks are present in all samples. The smallest number of cracks is observed in the samples manufactured at VED 208 J/mm^3 and 300 J/mm^3 with a hexagonal and round-trip scan strategy respectively. During the fabrication of the samples with larger scanning surface the round-trip strategy presents some difficulties with

several defects. This problem was solved using optimized parameters at 208 J/mm^3 with hexagonal scanning strategy.



N.B. = No built

Fig. 3. SEM images of samples manufactured via (a) the round trip and (b) the hexagonal scanning strategy.

The material optimization stage determined parameters to achieve minimum porosity levels of 1.2% for WC-17Ni. In order to solve the remaining porosity problems, HIP post treatment is applied on the as-built samples (Fig. 4). HIP significantly modified integrity, microstructure and crystallographic phases. In particular, porosities and cracks were no longer visible in the images because high temperature and the external pressure promote material diffusion, allowing for pore and crack closure. According to image analysis, the relative density of the as-built samples was 98.80%, whereas of the samples after HIP post-treatment was 99.99% (Fig. 4 b).

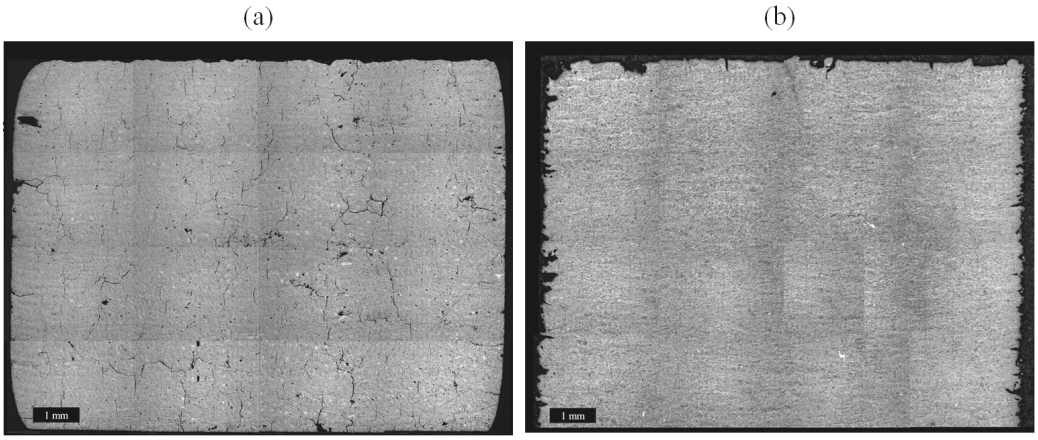


Fig. 4. Cross-section images of (a) as-built and (b) HIP-treated samples.

Microstructure and mechanical characterization.

The results of the XRD analysis performed on the as-built and HIP samples are shown in Fig. 5. The diffractograms show several phases. The most intense peaks correspond to WC.

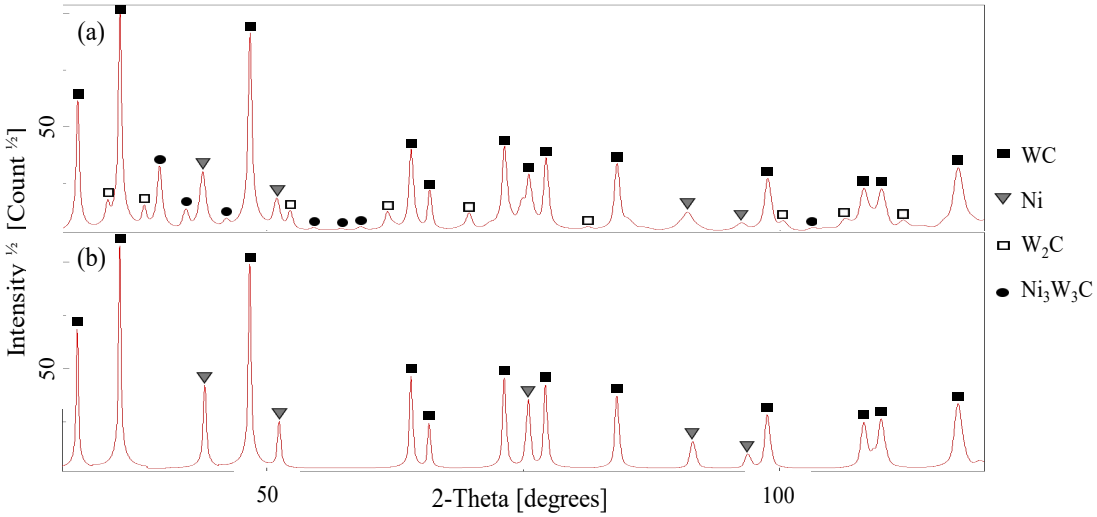

Fig. 5. XRD patterns of (a) the as-built and (b) HIP-treated samples.

At the same time the initial WC carbide has partially diffused in matrix and formed the complex phases such as W_2C carbide and the Ni_3W_3C ternary phase (M_6C). Also, the Ni matrix phase is present in the XRD pattern of the as-built sample. The XRD patterns of the HIP samples are presented on Fig. 5 b. A significant phase transformation is observed for the sample after HIP treatment. In particular, the W_2C carbide and M_6C phase have disappeared. The W-C phase diagram established by Okamoto in 2008 [30], allows to explain the disappearance of the W_2C phase. A temperature of 1450°C during HIP treatment allows the binder dissolution, then slowly cooled to room temperature, which leads to the disappearance of the W_2C phase.

EBSD analysis was performed on different samples to see the distribution of the different phases and to determine the carbide grain size. A 0.2µm step size was used and grains orientation was colored according to the inverse pole figures. No preferential orientation was observed for the samples. An indexing rate of 40% and 85% is obtained for as-built and HIP sample respectively (in Fig. 6 noise reduction was applied). The indexing rate is very low for the as-built sample (Fig. 6a), due to the presence of nano-sized grains making phase detection more difficult. A very large part of the map is non-indexed (black area), the other phases are detected but are present in very small fractions. In the as-built sample the most abundant phases are the WC phase (blue: 32.60 vol.%) and the W_2C phase (green: 9.26 vol.%). The other phases are present in area fractions lower than 1%. The phase distribution map shows a homogeneous distribution of the WC and Ni phases with a respective volume fraction of 72% and 13% for the HIPed sample. Dissolution of the smallest carbide grains is observed. The smallest equivalent WC grain size is 0.23 µm and 0.71µm for as-built and HIP sample respectively. The average grain size increases for the WC grains, from 0.60 µm to 1.58 µm for the HIP sample. The EBSD shows no preferred orientation of the WC grains in the as-built or HIP-treated material. However, a heterogeneous size distribution of WC grains is observed in both cases with zones of small and large grains (Fig. 6c and 6d). Further analysis is required to determine the preferential arrangement of the grains in the single track.

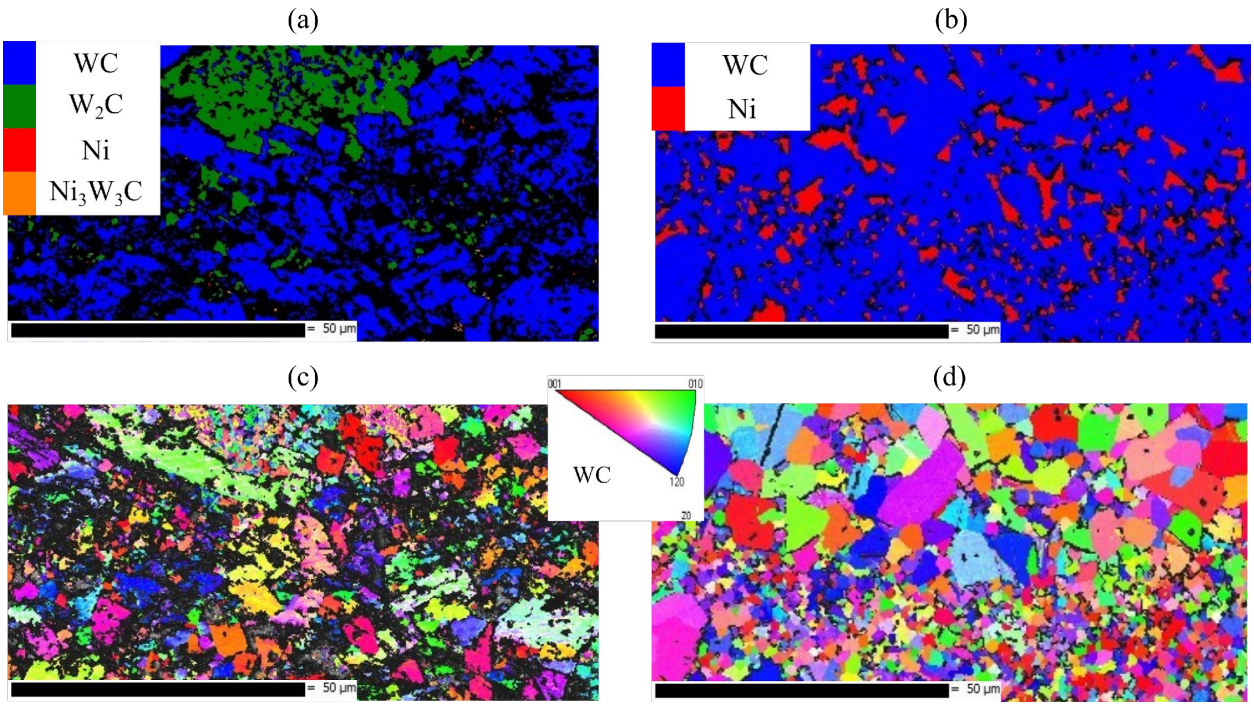

Fig. 6. EBSD grain mapping of WC-Ni (a) As-built and (b) HIP-treated sample and corresponding EBSD orientation map of WC-Ni (c) As-built and (d) HIP-treated.

Macrohardness tests were performed on the as-built and HIP-treated samples. Three measurements were performed per sample according to the standard methods at 30 kg. To reinforce the density obtained by images analysis results, the density variation of the samples is also measured by pycnometer. Results of mechanical tests are shown in Table 2.

Table 2. Characteristic values of the different WC-Ni samples.

Echantillon	Densité [g/cm^3]	HV_{30}	Tenacité Palmqvist [N.mm^{-1}]
As-built	13,94 ± 0,04	992 ± 54	1255 ± 589
HIP	14,15 ± 0,03	966 ± 21	0

Material cracking was observed near the corners of the indent for the as-built sample, which indicated high material brittleness (Fig. 7 a-b). The mean value obtained for the as-built samples was 992 HV_{30}, with a mean Palmqvist value of 1255 N.mm^{-1}. The hardness of the HIP-treated (966 HV_{30}) samples was slightly lower than that of the as-built samples. No material cracking is observed, likely due to elimination of the fragile W_2C phase (Fig. 7 c-d). Some dark points are observed on the optical image of the HIP sample, but these points do not correspond to porosities but to marks due to polishing process.

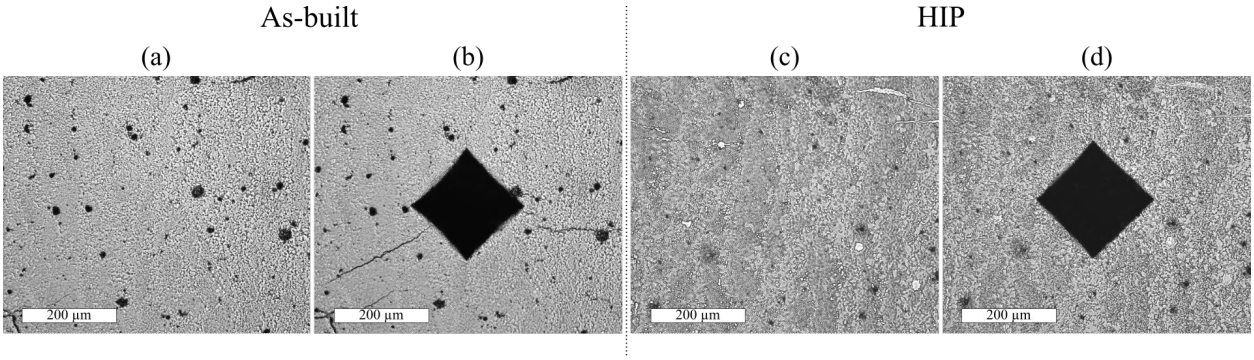

Fig. 7. Optical microscopy images of the WC-Ni samples before and after indentation tests; (a-b) as-built and (c-d) HIP-treated samples.

Summary

The manufacture of WC-17Ni parts using L-PBF was found to be feasible despite the presence of porosities and cracks. Samples with the lowest porosity fraction (1.2%) and highest integrity were obtained using a volume energy density of 208 J/mm^3. The as-built samples contained the brittle W_2C phase and some small-scale pores and cracks. The sample microstructure, relative density, and hardness were significantly improved through HIP post-treatment, resulting in close-to-zero porosity and no cracks. HIP allowed the complete dissolution of the undesirable brittle W_2C and M_6C phases. Initial phase present in the powder is observed in the sample after the HIP process. The macrohardness of the L-PBF-manufactured WC- 17Ni parts are comparable to the values obtained for the sintered WC-Co samples, with a hardness value around 1000 HV_{30}. The feasibility of L-PBF additive manufacturing to generate dense cermet samples using alternative binder as nickel was successfully assessed (Fig. 8).

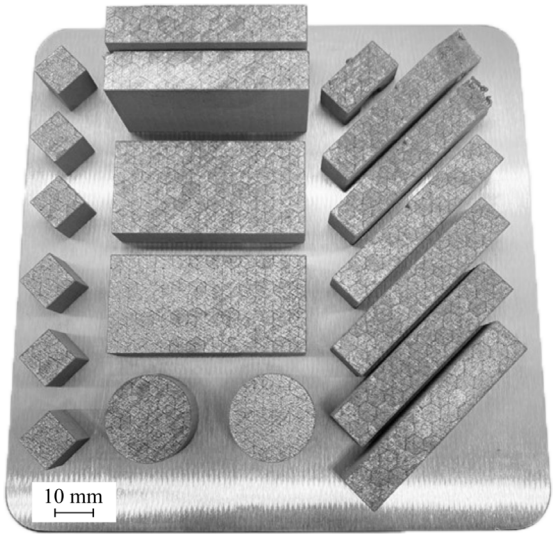

Fig. 8. L-PBF built plateform with samples manufactured from WC-17wt.% Ni powder.

Abstract. Numerous studies have been conducted to improve the adhesion quality at the interface between the filaments which remains one of the weak points in the FFF process. The interfacial adhesion of printed parts has already been investigated by several authors for amorphous polymers. However, for semicrystalline polymers, the influence of crystallization on adhesion kinetics as well as the description of partial melting at interfaces between filaments are not well taken into account in the models describing FFF process. The purpose of this work consists of proposing a predictive multiphysics model that enables the prediction of the adhesion degree for semi-crystalline polymers during FFF process. The coupling of a crystallization and melting model allows the estimation of the crystalline degree evolution at the interface. The use of a recent model predicting the molecular mobility as a function of temperature and crystallization makes it possible to estimate the degree of healing in anisothermal conditions. Finally, a parametric study is performed in order to propose process window improving the adhesion quality.

Introduction

In recent years, additive manufacturing has been the subject of many studies, regardless of the type of technology. The Fused Filament Fabrication (FFF) process being the most widespread, a great deal of attention has been paid to it. It is one of the affordable additive manufacturing technologies with a simple technology and a fast manufacturing speed. Nevertheless, one of the notable limitations of the FFF process is the decrease of the mechanical properties, compared to conventional processes like injection molding. These mechanical properties are low in the direction normal to the interfaces, resulting in high anisotropic properties [1]. The decrease in mechanical properties is related to the presence of porosities and the low interfacial strength between filaments. A lot of researches have been performed to improve the quality of the parts manufactured with this process [1,2].

Adhesion in the FFF process takes place in several steps. First, the material melted by the nozzle is deposited on the previous filament, intimate contact occurs and interfaces develop with the other filaments. This phenomenon called coalescence is strongly controlled by the rheological behavior of the material and the surface tension but also external pressures such as nozzle crushing. When coalescence begins, the healing process starts with the diffusion of polymer chains through the interfaces in order to create a real molecular bond with the others filaments [3].

Coalescence and healing are only possible if the chains present at the interfaces have sufficient molecular mobility [4]. Molecular mobility is governed by the thermodynamic state of the polymers, for the amorphous phase, mobility is restricted below the glass transition [5]. Finally, in

the case of semicrystalline polymers, crystallization may limit the adhesion phenomenon. These mechanisms are therefore strongly dependent on the rheological behavior evolving with the temperature and the crystalline degree of the polymer [6].

Studies were conducted to predict the thermal history of the FFF process and its influence on interfacial adhesion. A large majority of the studies consider the heat transfer at the interface assuming a homogeneous temperature within the thickness of the filament [3,7]. But some studies have proposed thermal modeling at the filament scale in order to estimate more precisely the interface temperature [2]. From these works, numerical Finite Element Method (FEM) models were developed and showed good agreement with experimental tests in the case of amorphous polymers.

However, for semicrystalline polymers, even if some works take into account the influence of crystallization and melting enthalpies o heat transfer, none of them realize a real link with the adhesion physics [8]. The only studies that propose to predict the healing degree as a function of crystalline degree assume that adhesion stops abruptly at the beginning of crystallization [9]. In spite of this approximation the authors obtained consistent results with the experimental. Nevertheless, several studies showed that despite the presence of crystals, for low crystallinity degree, the adhesion mechanism can continue because the amorphous phase still has a certain level of mobility [10,11]. In recent years, a promising time-temperature-crystallization-superposition (TTCS) model has been studied in order to predict the evolution of molecular mobility as a function of temperature and crystallinity and could allow a better understanding of adhesion with semicrystalline polymer [10,12].

Multiphysics Modeling of FFF Process

In this work, heat transfers, phase transformations and adhesion physics are implemented in a coupled multiphysics model. The model does not represent the rheology of the deposited filament. Assuming an instantaneous flow, a non-deformable oblong section will be taken to build the model. The simulation is performed in a single computational step where the use of boolean conditions allows the model to evolve in order to represent the successive filaments deposition. This allows a strong coupling between heat transfers and phase transformations.

The numerical resolution was performed on a 2D model simulated by FEM on COMSOL® software. In agreement with the work of [2], we develop a dimensionless modelling with the simplifying hypothesis that the thermal exchanges occur mainly in the plane orthogonal to the deposition direction. A comparison between 2D and 3D models validated this assumption. The deposition is simulated by the domain activation method and the boundary conditions change according to the deposition steps.

Heat transfer and phase transformation are computed on the whole domain. At each calculation step, the healing degree is evaluated on filaments interfaces in order to predict their evolution over time as a function of temperature and crystalline degree.

The driving mechanisms of coalescence are more difficult to quantify and can make the simulation complex. Indeed, some authors agree that the phenomenon is driven only by viscous effects and surface tension [2,13]. While others describe a strong influence of the printing nozzle pressure on the filament geometry [3].

Based on these studies, our model will consider an oblong geometry with a constant and homogeneous section without defects. The oblong geometry allows to take into account the porosities present between the filaments. The fillet size will be based on micrographic observations of a printed part. An 8 filament high wall was simulated in one step. The model being adaptive, it is possible to simulate a wall of several filaments wide as shown Fig. 1.

Heat transfer.

The thermal model is represented in Fig. 1. In the domain, we solve the energy equation coupled with crystallization and melting. The source term present in the energy equation term depends on ΔH the crystallization and melting enthalpies and α the crystalline degree. In order to represent the effects of the heating nozzle, the initial temperature of each new filament is considered uniform and set to T_{NOZZLE} to represent the extrusion set point. The bottom surface of the first filament is fixed at the temperature T_{BED} throughout the simulation process in order to represent the printing plate setting. Heat transfer between the environment and the deposited filaments are considered only convective. It is considered a constant chamber temperature $T_{Chamber}$ throughout the deposit. The boundary conditions are re-evaluated at each deposit thanks to boolean variables in order to make the model evolve with the deposit. Thermal contact resistances (TCR) were applied between the filaments to represent contact imperfection [2].

The characterizations of thermal conductivity k, heat capacity Cp and density ρ were performed on PAEK (Polyaryletherketone). The thermal property measurements were performed above the glass transition in the semi-crystalline solid state taking into account the influence of temperature. We will consider a linear variation of the thermal properties with temperature and will realize the simplifying assumption that the values are identical whatever the crystalline degree.

Model parameters such as layer thickness, printing speed, nozzle temperature are chosen as representative of real process [14].

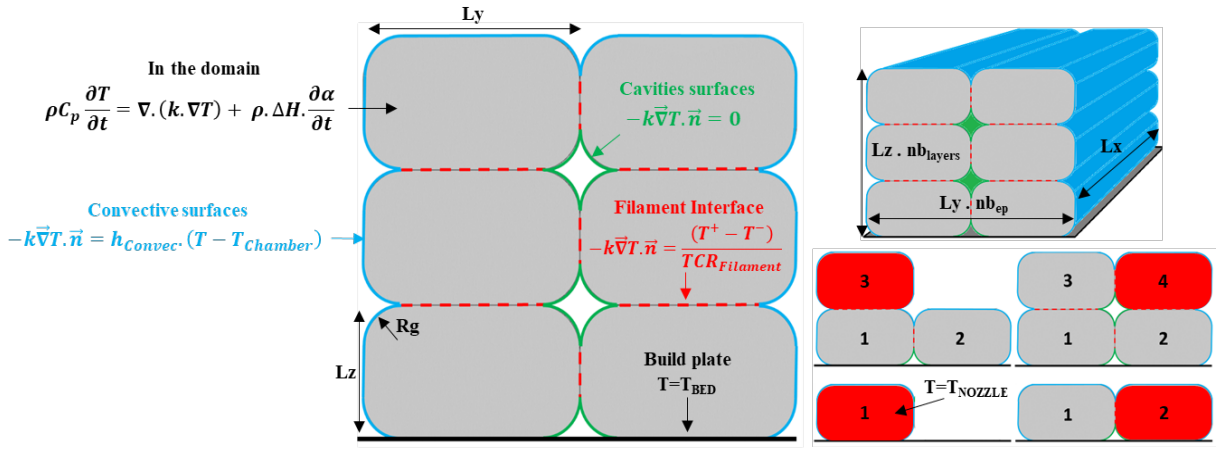

Fig. 1. Schematic representation of the case study.

Phase transformation: Crystallization/melting.

In order to predict the evolution of the crystalline degree as a function of the thermal history, a phase change model including crystallization and melting was added to the model.

Given the high heating rates of the interface during deposition, we will consider that the material undergoes a simple melting without simultaneous melting and recrystallization [15]. It is therefore possible to model the two mechanisms separately by considering a transition temperature $T_{Transition}$ at 300°C.

- Crystallization kinetics

In the case of the FFF process, crystallization generally takes place in non-isothermal conditions. In order to model the formation and growth of crystals we chose the Nakamura model Eq. (1) which is the most widely used in the literature [16].

Materials Research Proceedings 28 (2023) 139-148 https://doi.org/10.21741/9781644902479-16

$$\frac{d\alpha}{dt} = K_{NAK}(T).G(\alpha) \quad , \qquad with\ G(\alpha) = n\,(1-\alpha)[-\ln(1-\alpha)]^{1-\frac{1}{n}} \tag{1}$$

where α is the relative crystalline degree, $K_{NAK}(T)$ the Nakamura kinetics coefficient calculated by $K_{NAK}(T) = K_{AVRAMI}(T)^{1/n}$ obtained in isothermal conditions and n the Avrami index [17].

Furthermore, in the FFF process, when the previously crystallized filament is heated due to the new deposit, it is possible that at low interfacial temperatures the polymer is partially melted. The kinetics of crystallization from a partially melted state is not well explored and no model is available in the literature. We will therefore assume that during a recrystallization from a partial melt, the kinetics is not impacted and therefore the polymer behaves as if it had simply stopped the crystallization. As our PAEK has too high crystallization kinetics to be characterized by differential scanning calorimetry (DSC), a test campaign was performed on fast scanning calorimeter (FSC) to estimate the thermal dependency of the isothermal Avrami coefficients $K_{AVRAMI}(T)$ over the large temperature range [160°C – 300°C].

- Melting kinetics

The melting kinetics has been further explored in the case of thermoplastic polymers. It has been shown that the thermo-kinetic models available in the literature taking into account the heating rate only allow to represent a restricted range of rates [8]. Moreover, these models cannot predict the interruption of melting during isotherm or cooling.

In several works, authors made the assumption that the melting behavior depends only on the temperature by considering an instantaneous mechanism independent of the heating rate over a certain range [18]. In this study, we also have chosen this approach by taking a statistical distribution model of the crystalline lamellae thickness which is temperature dependent Eq. (2).

$$\alpha = \alpha_{max}.Melting(T) \tag{2}$$

Melting function was estimate by temperature integration of the melting peak measured on DSC and weighting α_{max} in order to represent the melting under conditions of incomplete crystallization, case where $\alpha_{max} < 1$.

Implementation of the melting and crystallization models in the same simulation model allows to predict the melting zone and time available for the interfacial healing. For example, it can be seen in Fig. 2 that the interface melted during the deposition because of the heat provided by the hot filament.

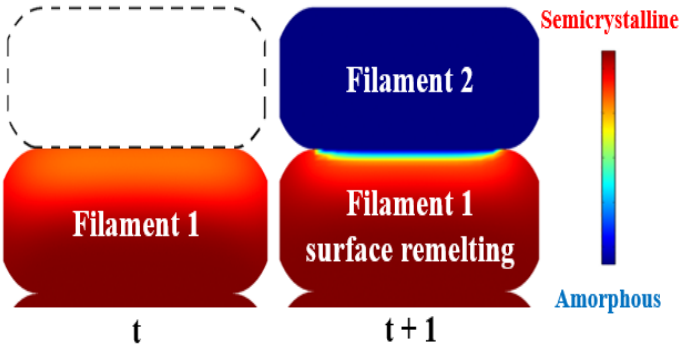

Fig. 2. Remelting of the filament surface after a second hot filament deposition.

Healing coupled with crystallization degree.

Prediction of healing at interfaces was also added in the modelling taking into account the coupling of an anisothermal healing model and a time-temperature-crystallization-superposition model

- Healing model.

In order to represent the adhesion kinetics in the anisothermal case, we proposed to use the empirical model largely defined in Eq. (3).

$$D_{Healing}(t) = \sqrt[4]{\int_0^t \frac{dt}{t_{welding}}} \tag{3}$$

where $D_{Healing}$ is the healing degree and $t_{welding}$ the experimental measured welding times to achieve complete welding of an interface under isothermal conditions.

Several authors showed that in the case of several thermoplastics, the welding times can be considered as equal to the molecule reptation times $t_{reptation}$ [19] with a good agreement with the experiment. In order to simplify the numerical solution, an integrative form was proposed by [2]. Taking into account the assumption that the relaxation times are equal to welding time, we obtain Eq. (4) with Δt the calculation step, and t the simulation time step.

$$[D_{Healing}]_{t+1} = \left(\frac{\Delta t}{t_{reptation}} + [D_{Healing}]_t^4\right)^{\frac{1}{4}} \tag{4}$$

- Time / Temperature / Crystallization Superposition (TTCS).

In order to represent the evolution of the molecular mobility during the process, it is necessary to know the relaxation time of the polymer according to its local environment. To our knowledge, no study takes into account the crystalline degree in its adhesion model. Indeed, while the evolution of molecular mobility as a function of temperature is well known with the time-temperature-superposition TTS, few studies focus on the influence of the presence of crystals on polymer diffusion.

But recently, some studies have converged to present a time-temperature-crystallization-superposition TTCS principle Eq. (5) based on experimental approaches [12].

Materials Research Proceedings 28 (2023) 139-148 https://doi.org/10.21741/9781644902479-16

$$\tau(T,\alpha) = \underbrace{a_t(T_{REF},\alpha_0,T)}_{\textbf{Thermal shift factor}} . \underbrace{a_\xi(T_{REF},\alpha_0,\alpha)}_{\textbf{Cristalline shift factor}} . \underbrace{\tau(T_{REF},\alpha_0)}_{\textbf{Reference time}} \quad (5)$$

where T_{REF} and α_0 are respectively the temperature and crystalline degree reference and τ the reptation time.

The model proposes a shift of rheological properties similar to thermal shift but with the crystalline degree. The postulated TTCS is very promising and has shown its consistency on several polymers. Moreover, several previous studies have shown that the evolution of rheological properties is proportional to the volume of crystallites and not to the shape or size of crystals [20]. These observations suggest that they can be applied to all types of crystallization. Moreover, the principle of TTCS allows to correctly represent the state of molecular mobility in cases of isothermal and anisothermal crystallization. Its general validity must be evaluated in order to apply it widely to all polymer families. Nevertheless, being the only model available in the literature, we will use it to predict the evolution of the mobility depending on the temperature and the crystalline degree. The thermal shift factors were fitted using the Williams-Landel-Ferry equation (WLF) [21] and the crystalline shift factors using a power law as proposed by defined [10] in Eq. (6).

$$\ln[a_t(T_{REF},\alpha_0,T)] = \frac{-C1(T-T_{REF})}{C2+(T-T_{REF})} \qquad and \qquad a_\xi(T_{REF},\alpha_0,\alpha) = 10^{B1.\alpha^{B2}} \quad (6)$$

where C1, C2, B1 and B2 are fitting coefficients.

Rheological measurements were carried out in our laboratory between 360°C and 400°C under nitrogen in the amorphous state in order to estimate the thermal shift factor. The model coefficients of the crystallinity shift factor are taken from the literature [10].

As previously explained, by integrating all these models in the same study, the multiphysics model is able to predict the evolution of reptation time as a function of temperature and crystalline degree in anisothermal condition. In order to explain the model, we have calculated the evolution of the relaxation time for several constant cooling rates. The results are shown in Fig. 3.

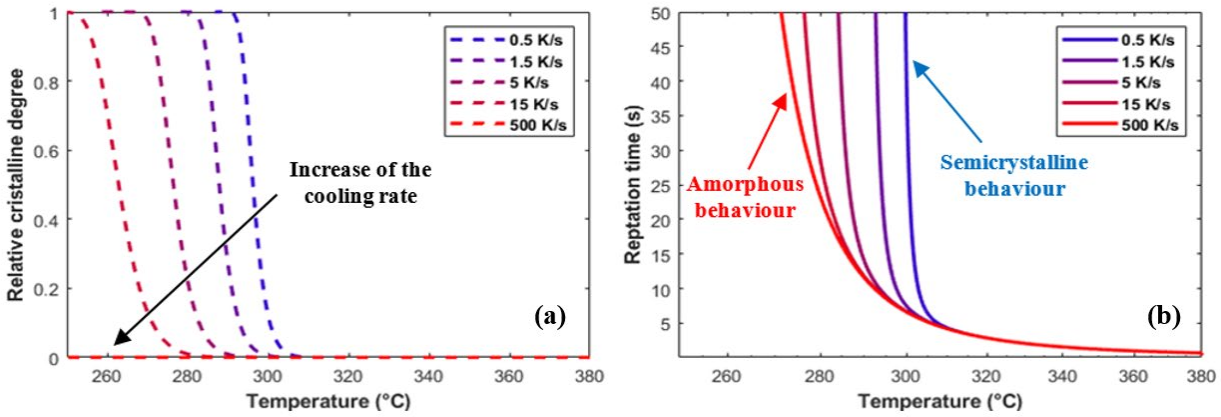

Fig. 3. (a) Relative crystalline degree and (b) the reptation time evolution under different cooling rate.

Fig. 3B represents the evolution of the creep time as a function of temperature and crystalline degree Fig. 3A. We notice that at high speed, the polymer remains amorphous during the cooling and the material follows the TTS law. But when the speed decreases and the material crystallizes, the reptation time increases quickly from the first moment of crystallization.

Results and Discussion

As said previously, a wall of 8 filaments high and 1 filament wide is simulated. All results are evaluated in the middle of the interface between the 5th and 6th layer so the results will begin at 32s. The simulations carried out from the multiphysics model allow to estimate the evolution of the crystallinity rate and the degree of healing according to the thermal history at the interface.

Simulations were performed with the TTCS model and with the TTC model in order to show the importance of taking into account the crystallization on the adhesion. Both cases were simulated with the same parameters except that the crystalline shift factor was numerically fixed at 1 to model the TTS.

With the conditions used in the simulation, it can be seen in Fig. 4, that the 5th filament crystallizes rapidly during cooling. During the next deposition, the heat generated by the upper filament partially melts the interface. The difference in the evolution of the degree of healing between the TTCS and TTS models describes the low molecular mobility of the chains due to the presence of crystals at the interface. Indeed, the final degree of healing is divided by 10.

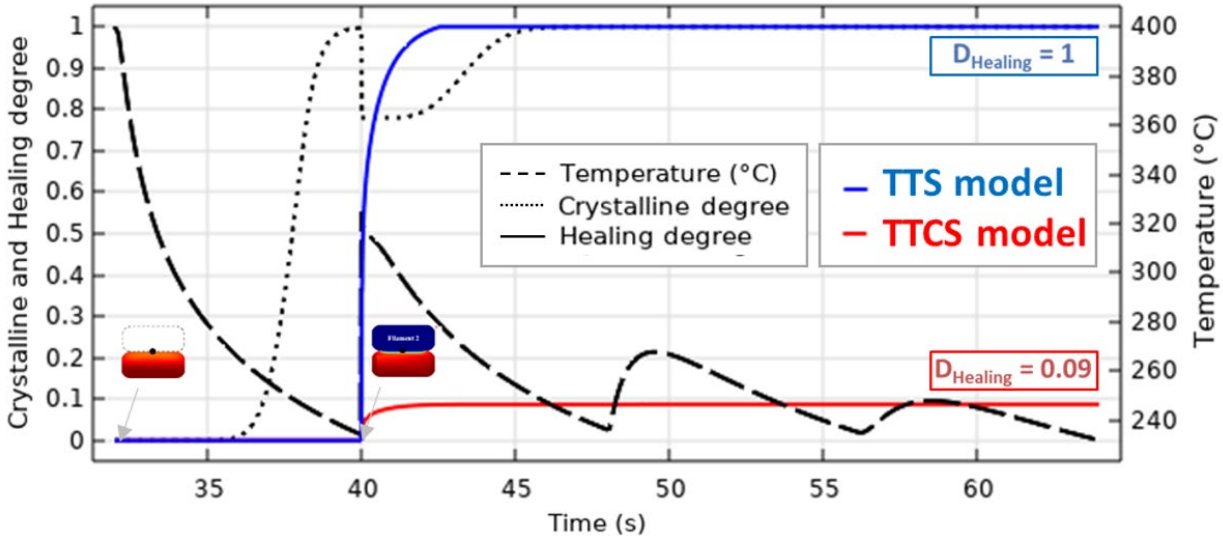

Fig. 4. Evolution of computed temperature, crystalline and healing degree with TTS and TTCS model.

To show the influence of the thermal environment on the adhesion degree, we varied the chamber and bed temperatures between 150°C and 270°C as shown Fig. 5. It is first noticed for temperatures lower than 200°C, *i.e.* where the cooling is fast, that the filament crystallizes completely before the next deposition. In these cases, only melting can allow a noticeable decrease of crystalline degree and thus a better adhesion. Because during deposition the interface temperature is not high enough to allow a total fusion, the healing degree are very low (<0.09). At high temperatures, the crystals are not yet formed at the time of deposition (T≥250°C) therefore a better healing degree is obtained.

This numerical study allows to estimate the process range in order to obtain a correct interface with a complete crystallization at the end of printing. Other parameters such as nozzle temperature, printing speed, number of beads per layer, deposit order can be tested to evaluate their influence on crystallization and adhesion.

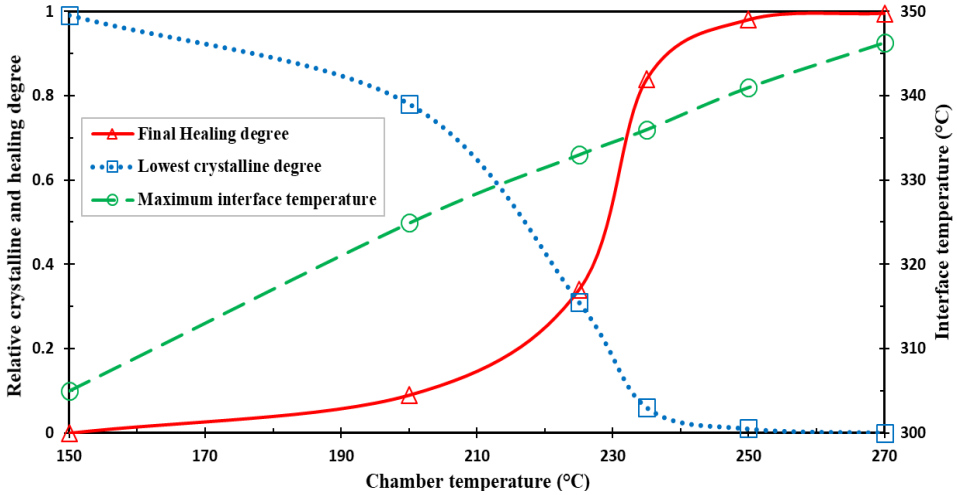

Fig. 5. Evolution of computed maximum interfacial temperature, lowest crystalline degree and final healing degree reaches after deposition as function of chamber temperature.

Summary

A multiphysics model was developed to represent the thermal history, crystalline and adhesion degree evolution at the filament scale in the FFF process. Modeling development allowed to calculate the evolution of the crystalline degree on the whole domain and in particular at the interfaces. Indeed, the model describes crystalline degree remaining after the melting generated by the deposit and the time before recrystallization. A brief parametric analysis demonstrates the non-negligible influence on the crystalline evolution on interfacial adhesion. In fact, it is shown that complete healing is only possible if the crystalline degree is close to zero. This model allows us to understand the influence of many printing parameters on adhesion and therefore to propose groups of parameters in order to improve the printing quality.

In order to confirm that the model correctly predicts the evolution of the crystalline degree as well as the effective adhesion degree of the printed part, an experimental study will have to be carried out and the adhesion values confronted with mechanical tests. Moreover, a next study will aim to model more finely the melting kinetics as well as the recrystallization kinetics through an experimental campaign.

Keywords: LPBF-Process, Local Properties, Plane-Strain-Compression-Test

Abstract. In the Laser Powder Bed Fusion (LPBF) process for metal components, a CAD file is sliced into layers with a thickness of 20-80 micrometers and the component is built up layer by layer. For this purpose, a metal powder layer is applied in each case and melted locally. This process is repeated until the geometry is completely established. The mechanical properties of the manufactured part are controlled by the cooling rate. It is currently not considered in the design of LPBF components, that the printed part has a varying heat flow into the surrounding powder and into the support plate depending on its slenderness. As a result of the different temperature histories, different microstructures with correspondingly different mechanical properties are formed in the untreated state (as-built). These differences must be considered in the component design. In this work, walls of various thicknesses were produced from 316L stainless-steel alloy using the LPBF process. The walls could be used to create plane-strain-compression-test specimens of various heights and orientations. The tests were performed according to Graf et al. [1] and the flow curve was calculated from the force-displacement curve while taking friction into account. Following that, tensile strength, Young's modulus, yield strength, and yield stress were determined inversely. A clear dependence of the mechanical parameters on the degree of slimness was discovered, which was confirmed by microscopic examinations. To summarize, the plane-strain-compression-test is a quick and reliable method for determining the local variation of mechanical properties.

Introduction

Since its development in the 1980s, additive manufacturing has gained in importance from year to year [2]. This results from the large variety of shapes that layer-by-layer construction makes possible. Thus, it is possible to manufacture topology-optimized components where material is only provided along the load paths [3]. Consequently, fewer resources are consumed for such components and the degree of lightweight design is maximized [4]. However, the optimized structure is often very complex and can only be manufactured with a great deal of effort or not at all using conventional manufacturing processes, such as milling or turning [5]. Additive manufacturing processes such as selective laser melting (SLM) are increasingly being used to produce complex shape-optimized geometries [6].

In most cases, the topology-optimized geometry consists of thin structures that converge at the connection points and thus lead to material accumulations. Since thicker component areas cool more slowly than narrow ones, different cooling rates develop in the different component areas [7]. In addition to the grain size, the cooling rate of the material determines the composition of the

Content from this work may be used under the terms of the Creative Commons Attribution 3.0 license. Any further distribution of this work must maintain attribution to the author(s) and the title of the work, journal citation and DOI. Published under license by Materials Research Forum LLC.

microstructure. For example, in steels, martensitic, bainitic, ferritic, pearlitic and austenitic structures can develop [8]. In narrow areas, the cooling rate is higher, which is why a predominantly fine-grained martensitic or bainitic microstructure with an increased tensile strength develops [9]. In thicker areas, the cooling rate is lower, especially in the center of the cross-section, resulting in a coarser-grained softer ferritic or pearlitic microstructure with a lower tensile strength [10]. Furthermore, with an increased cooling rate, the average grain size decreases, which leads to strengthening by grain refinement [11]. Thus, depending on the cross-sectional area, a locally varying property profile develops over the component [12].

For complex components, empirical determination of the phase fractions and the resulting properties is only possible with a great deal of effort. Therefore, these are calculated by means of simulations. Zhang et al. determined the phase composition for Ti-6Al-4V by implementing a phenomenological phase transformation model into conventional simulation methods for additive manufacturing [13]. Another phenomenological microstructure model to determine the phase composition for Ti-6Al-4V was proposed by Nitzler et al. [14]. However, simulations of the L-PBF process to determine the phase composition take a lot of time and have no direct impact on the optimization of the part geometry.

In order to consider the properties resulting from the LPBF process during topology optimization, it is necessary to consider them in advance. This results in new challenges in the modeling of the anisotropic material behavior, the development of robust optimization algorithms and the integration of the process simulation into the structural optimization [15]. Considering the self-weight of the intermediate structure, the process-dependent loads, and the material properties dependent on the process time, Wang et al. provide an approach for a corresponding topology optimization [16]. Another possibility to consider process-dependent material properties is the description of geometry-dependent local material properties. A first step for this is the determination of the phase composition and its coupling with the mechanical properties depending on the slenderness of the manufactured structure.

The plane-strain-compression-test is an efficient test method for calculating the flow curve up to large plastic strains. It is based on the theoretical principles of the work of Nádai [17] and Orowan [18] and converted into a practical test for determining mechanical properties by Watts et al. [19] and Sellars et al. [20]. In this experiment, two opposing punches locally compress a strip-shaped sheet specimen. To avoid stress concentrations and consequently an early specimen failure due to fracture, the use of punches with rounded edges is recommended [21]. However, this increases the friction component, which must be eliminated by calculation to improve the quality of the results. In addition to friction, shearing, i.e. the deformation of material volume to the side of the punch, also has an influence on the measured force [22]. The ratio of punch width to specimen height influences both the friction component and the shear component. The larger this ratio is, the larger the friction component becomes and the smaller the shear component becomes [23]. The aim of the work is to efficiently obtain local flow stress differences in additively manufactured components using the plane-strain-compression-test, which is first investigated on small LPBF manufactured cuboids.

Materials and Methods

Specimen manufacturing.

The plane-strain-compression-specimens of 316L powder from m4p material solutions GmbH were produced with an EOS M290 from EOS GmbH. A laser power of approx. 200 W, a scanning speed of approx. 900 mm/s, a vector distance of 0.1 mm and a layer thickness of 0.04 mm were used. The laser was focused to a diameter of about 0.08 mm and the LPBF-process took place under argon atmosphere. Three narrow walls with a cross-section of 30 mm x 13 mm and a thickness of 1 mm, 1.5 mm, 2 mm and 3 mm were produced in each case in upright (0°) and horizontal (90°) orientation. These already have the final dimensions of the plane-strain-

compression-specimens and are used under as-printed conditions. Furthermore, three blocks each with the dimensions 30 mm x 13 mm x 25 mm were printed in upright and horizontal position. A plane-strain-compression-specimen with a thickness of 1 mm, 1.5 mm, 2 mm and 3 mm was eroded from each of these blocks by the wire EDM machine MAKINO U6 from Makino GmbH. (Fig. 1).

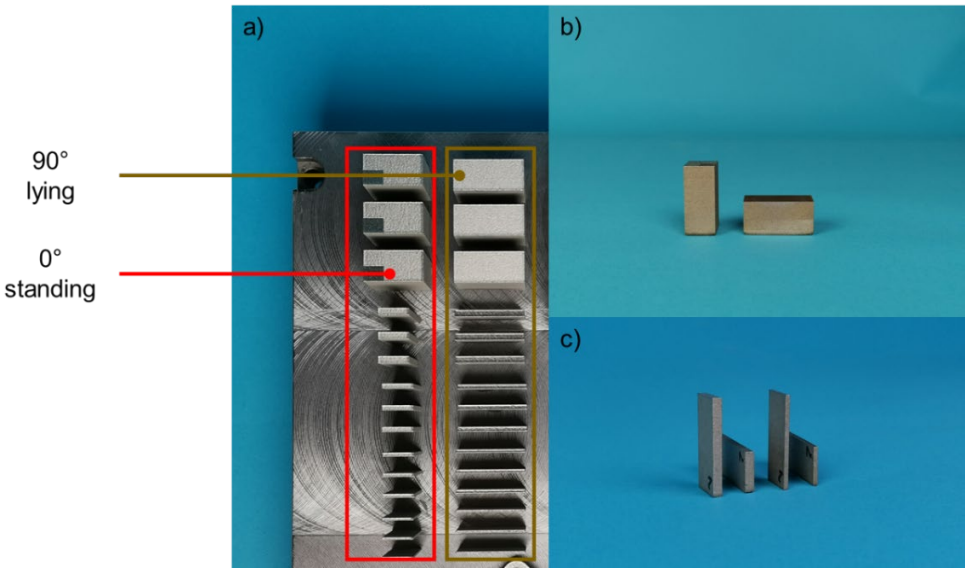

Fig. 1. Printed parts for the plane-strain-compression-test a) on the build plate, b) as blocks for wire EDM and c) as walls.

Plane-strain-compression-test.

The produced specimens were tested in a compression test on a Galdabini Quasar 50 universal testing machine with a maximum test load of 50 kN using 2.7 mm wide punches (Fig. 2). The tests took place under room temperature and with a quasi-static strain rate of $\dot{\varphi} = 0.01\ s^{-1}$ to avoid influences due to microstructural changes of the material.

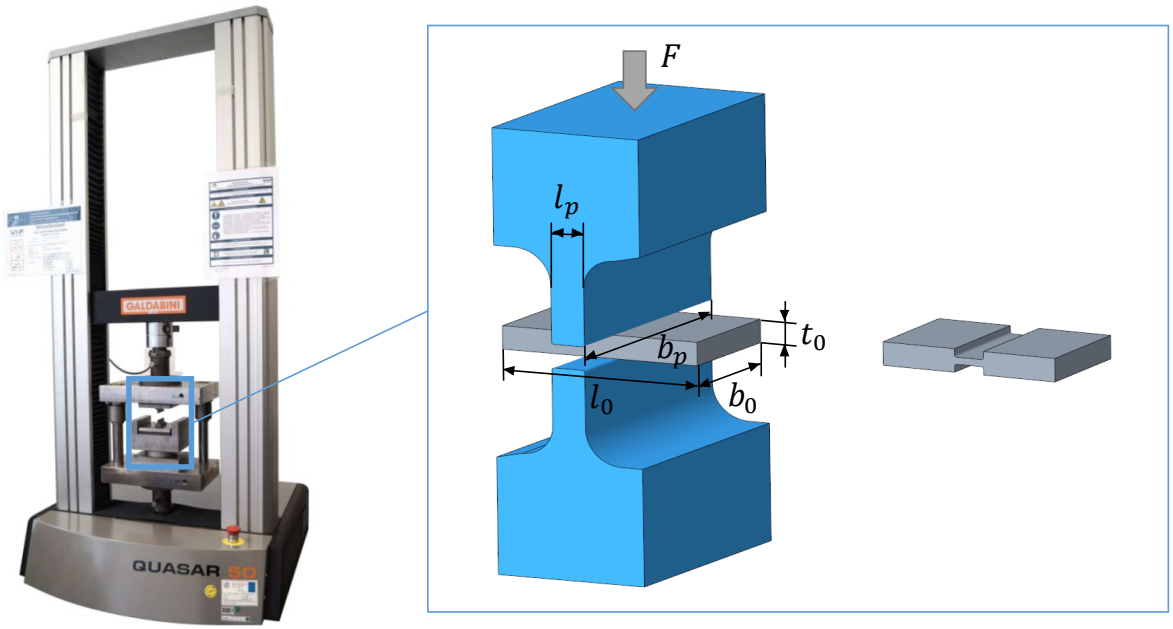

Fig. 2: Universal testing machine GALDABINI QUASAR 50 kN and the schematic structure of the plane-strain-compression-test.

During the test, raw data for applied force F and the distance Δt traveled by the punch. To determine the flow curve, the stress σ_{k_f} was calculated according to equation 1 and the corrected equivalent plastic strain φ according to equation 2 [24, 25].

$$\sigma_{k_f} = \frac{\sqrt{3}}{2} \cdot \frac{F}{A_v} \tag{1}$$

$$\varphi = \left| \frac{2}{\sqrt{3}} \cdot \ln\left(\frac{t_0}{(t_0 - \Delta t)}\right) \right| - \varepsilon_{el} \tag{2}$$

A_v is the product of the punch width l_p and the actual width of the specimen, t_0 the original thickness of the specimen and Δt the distance traveled by the punch. The plastic strain results from the difference between the total strain and the strain ε_{el} until the yield stress is reached. Since this is a comparative study, plastic flow was assumed for all specimens from an elongation of 0.02%.

Microstructure analysis.

Dynamic image analysis according to ISO 13322-2 using the CAMSIZER X2 particle analyzer from Microtrach Retsch GmbH resulted in percentiles D10 = 20 µm, D50 = 32 µm and D90 = 46 µm. The chemical composition of the powder was determined using the BRUKER TIGER S8 fluorescence spectrometer from Bruker Corporation.

To evaluate the microstructure, the specimens were cut perpendicular to the axis of motion of the punches and embedded in an electrically conductive resin. The specimens were then surface ground with 240-1200 µm grit sandpaper, polished with a diamond suspension, and final polished with a < 0.05 µm silica solution. Samples were etched for 12 s and at a temperature of 60°C in V2A acid solution (100 ml water, 100 ml hydrochloric acid and 10 ml nitric acid) and subsequently analyzed using Thermo Fisher Scientific Inc.'s Phenom XL Generation 2 desktop SEM. Both BSD detector analysis and EDX analysis were performed. For EDX analysis, three areas were examined in each sample, from which the mean value was determined.

Results and Discussion

Chemical composition.

Since the very high temperature of over 2800°C [26] for a short time can lead to the evaporation of individual elements and thus influence the mechanical properties, an EDX analysis was performed on all samples over an area of approximately 0.2 mm² (Table 1). From the measurements it can be seen that some of the main elements are lost during the LPBF process and therefore the proportion of minor elements increases from 0.1% to up to 2.7 %. In correlation with Fuerschbach et al., this burnup occurs particularly for the elements iron and nickel, with the manganese content also decreasing slightly [27]. In contrast, the molybdenum content increases by approx. 1 wt.% and the silicon content by 0.1 wt.%. The measured values are in a similar range for all samples regardless of the orientation and the manufactured geometry, so that it can be assumed that the determined flow curves do not vary decisively due to the chemical composition.

Materials Research Proceedings 28 (2023) 149-158 https://doi.org/10.21741/9781644902479-17

Table 1. Chemical composition [wt.%] of the used 316L powder.

Alloy element	**Fe**	**Cr**	**Ni**	**Mo**	**Mn**	**Si**	**other**
Powder	67.7	17.5	11.3	1.6	1.2	0.6	0.1
Block 1 0° 3 mm	65.9	17.3	10.4	2.6	0.9	0.7	2.2
Block 1 0° 1.5 mm	66.3	17.5	10.7	2.5	1.0	0.8	1.2
Block 4 90° 3 mm	66.0	17.3	10.3	2.6	0.9	0.7	2.2
Block 4 90° 1.5 mm	65.4	17.2	10.5	2.7	0.9	0.7	2.6
Wall 0° 3 mm	66.3	17.4	10.5	2.7	0.9	0.7	1.5
Wall 0° 1.5 mm	65.9	17.5	10.8	2.5	1.0	0.7	1.6
Wall 90° 3 mm	65.7	17.4	10.4	2.6	0.9	0.7	2.3
Wall 90° 1.5 mm	65.5	17.3	10.2	2.6	1.0	0.7	2.7

Microstructure analysis.

Fig. 3 a) shows the microstructure of the specimens prepared in different orientations and initial geometries. To compare the grain sizes, three large grains were marked in each image. It can be seen that the grains in the samples eroded from the blocks are larger than those of the walls. The line intersection method was used to determine the average grain size, which was 27.0 µm for "Block 1 0°," 19.5 µm for "Block 4 90°," and 18.5 µm for "Wall 0°." Due to insufficient etching, the average grain size of "Wall 90°" could not be determined. A smaller grain size leads to an increased yield strength and improved ductility as a result of grain refinement strengthening [28].

Furthermore, it can be seen in Fig. 3 a) that the microstructure and grains of specimens fabricated in 0° orientation are stretched in the build direction and perpendicular to the compression direction, respectively. This results in anisotropy, with specimens fabricated in 0° orientation having lower tensile strength than those fabricated in 90° orientation [29]. Relative to the same specimen cross-section, the specimens printed in 90° orientation exhibit a more spherical grain structure regarding the x-y-plane. The direction of grain growth is influenced by the heat flux, which flows through the component to a large extent in the opposite direction of construction [30]. Therefore, the grains of the components produced by the LPBF method exhibit elongation in the build direction (Fig. 3 b)).

In all fabricated specimens, a cellular substructure is formed, with the dark core elements demarcated by light edge regions (Fig. 4). According to Prashanth et al. and Zhong et al., this substructure is formed by a local enrichment of heavy elements, such as molybdenum, due to a high solidification rate and associated effects of constitutional undercooling [31, 32]. In addition, the shell areas of the cells have a high dislocation density and thus increase the mechanical properties of the printed samples [33]. Due to the layered structure, the cells pass through several heating phases, which reduces the solidification rate, especially in areas far from the surface [30]. Therefore, larger cells are found on the surface.

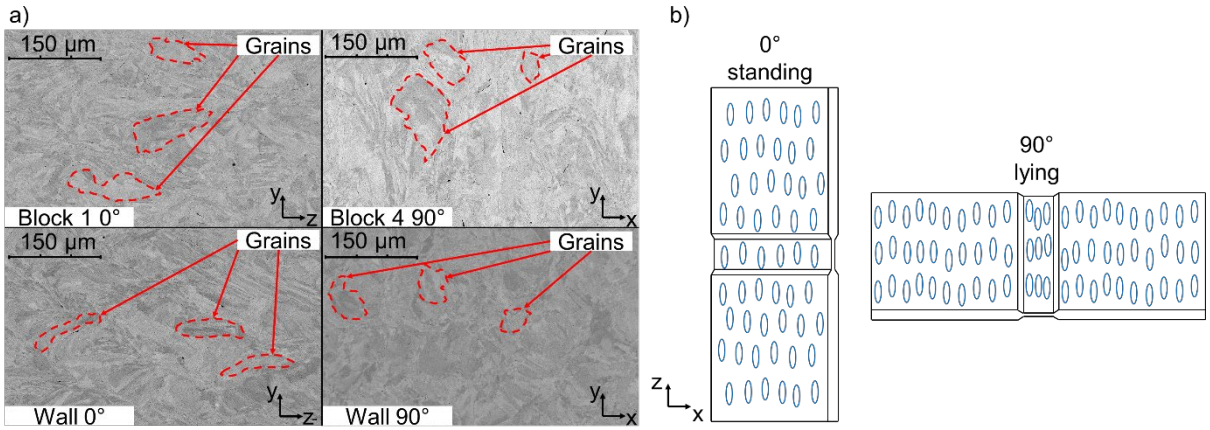

Fig. 3. Detected texture and grain sizes within SEM investigation of the a) Block 1 0°, Block 4 90°, wall 0° and 90° at a thickness of 3mm and b) stretching of the grains depending on the orientation of the printed samples.

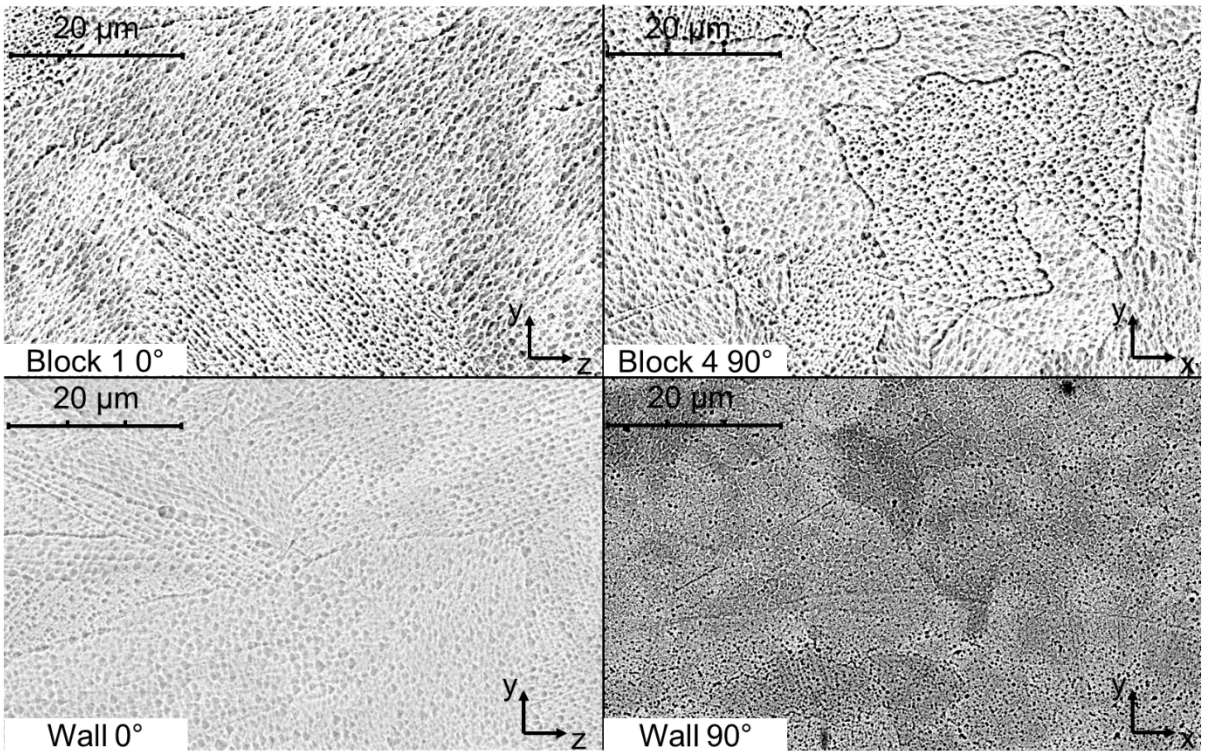

Fig. 4. Cellular substructure within SEM investigation of the a) Block 1 0°, b) Block 4 90°, c) wall 0° and d) wall 90° at a thickness of 3 mm.

Flow curves.

Finally, the qualitative difference in mechanical properties between thin and thick LPBF-manufactured specimens is shown. For this purpose, the repeatability of the compression tests is first presented using three flat compression specimens of equal thicknesses each made from three blocks in 0° orientation (Fig. 5 a)) and 90° orientation (Fig. 5 b)). In the figure, the influence of friction and shear due to the different ratio of punch width (constant) and specimen thickness (1.0, 1.5, 2, 3 mm) can be seen. The scatter increases with decreasing specimen thickness, so that the result for 1.0 mm is not included in the evaluation.

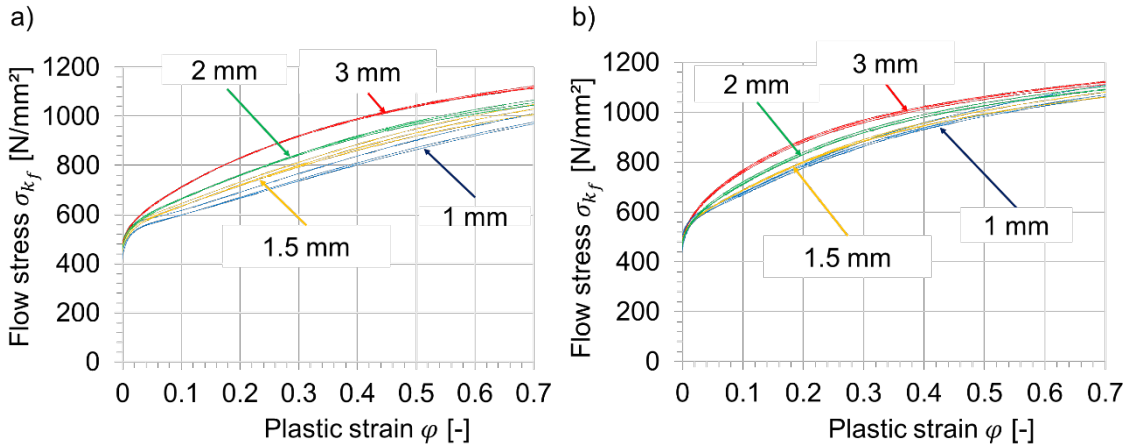

Fig. 5. Flow curves for specimens of thicknesses 1 mm, 1.5 mm, 2 mm and 3 mm taken respectively from blocks printed in a) 0° orientation and b) 90° orientation.

Fig. 6 shows the results for the directly printed walls, where the orientation again gives a clear difference in strength. However, as with the samples from the blocks, the same clear trend can be seen. In order to be able to make qualitative statements regarding the strength change due to the material properties exclusively on the basis of tests, the same specimen thickness from the block is compared with the printed specimen in the following.

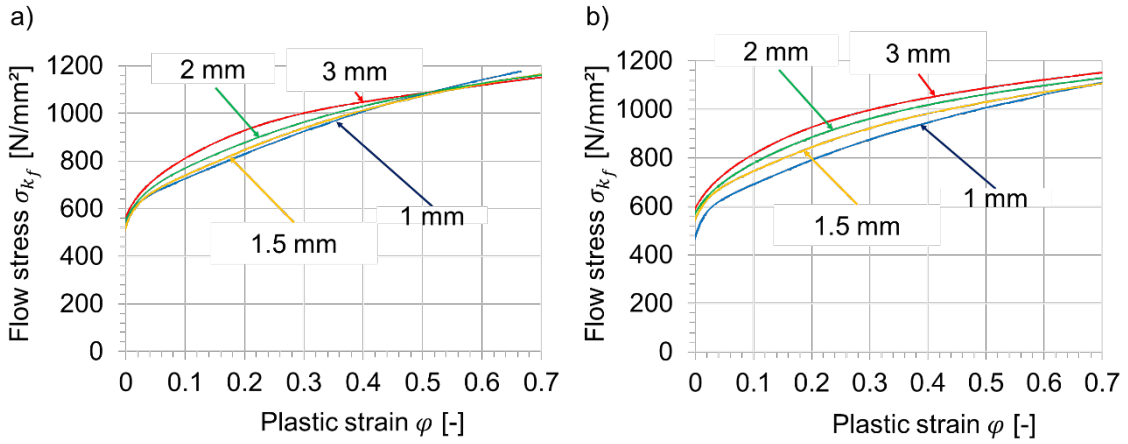

Fig. 6: Flow curves for as-printed plane-strain-compression-specimens at an orientation of the blocks of a) 0° and b) 90°.

Fig. 7 shows the flow curves for specimens with a thickness of 1.5 mm (a)) and 3 mm (b)) up to a plastic strain of 0.7. Both specimen thicknesses show higher flow stresses of the printed walls than the specimens of the same thickness from the blocks. The qualitative progression of the flow curves shows small differences, which are, however, not related to the material condition, but are rather seen in the test setup, or the specimen preparation.

The specimen printed in 0° orientation (block, 1mm) shows a lower slope than the specimen printed in 90° orientation up to a corrected plastic strain of approx. 0.25. From this value, the curves converge again up to the corrected equivalent plastic strain of 0.7. In contrast, the 1mm thick walls diverge from a plastic deformation of 0.2. It should be mentioned again that the grain growth of the specimen printed in 0° orientation was perpendicular to the punch width b_p and in 90° orientation parallel to the punch width b_p (Fig. 3 b)).

In the flow curves determined in the plane-strain-compression-test, this behaviour agrees only for the 1.5 mm thick walls. The flow curves of the 3 mm thick specimens from the block initially

show minor differences and finally meet at a yield stress of approx. 1110 N/mm². Thus, the analysis of the yield stress as a function of the compression direction or orientation in the build space leads to the result that no clear correlation can be identified. This result is confirmed in particular by the 3 mm thick walls.

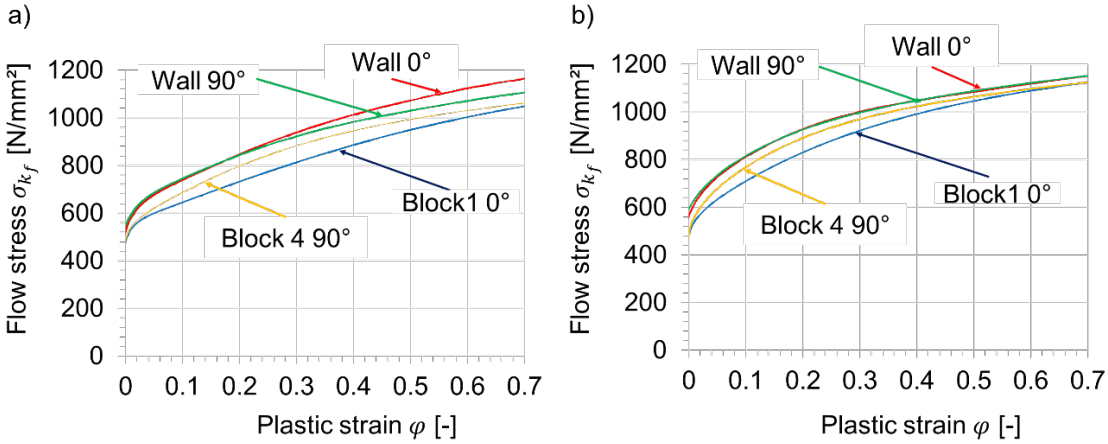

Fig. 7. Calculated flow curves for plane-strain-compression-specimens with a thickness of a) 1.5 mm and b) 3 mm.

Summary

In this work, the mechanical properties of different specimen geometries produced by the LPBF method were investigated in the plane strain compression test. The work shows that different mechanical properties can occur in components depending on the geometry. This results in a locally varying property profile for geometries with high complexity, which are usually produced by the LPBF method. Based on the research, the following conclusions can be drawn:

- The chemical composition of different LPBF specimen geometries is not significantly different.
- The grains are elongated along the build direction (for a specimen orientation of 0° perpendicular to the punch width and for a specimen orientation of 90° parallel to the punch width) and are larger for thick structures than for thin structures.
- The flow stress is significantly dependent on the component thickness and the orientation in the build space. The thinner the sample is printed, the higher the yield stress becomes compared to strips of the same thickness made from blocks. The influence of the orientation in the build space could not be clearly correlated.
- In areas close to the surface, a more pronounced cellular substructure develops due to a higher solidification rate, which also positively influences the mechanical performance.
- The plane-strain-compression-test is an effective test method to quickly obtain flow curves even from thin additive manufactured specimens. Thus, it is possible to estimate the effects of the local microstructure on the flow curve.

An industrial application is the consideration of these manufacturing-specific properties in the topology and structure optimization of components. However, further investigations are necessary for the practical application of the results in optimization programs. Accordingly, further geometries are to be considered in future investigations. In addition, a more detailed investigation of the phase composition and the resulting mechanical properties as a function of the manufacturing geometry is necessary.

Abstract. To improve process understanding and increase the numerical prediction quality of a wire arc additive manufacturing (WAAM) process, this paper focuses on determining the parameters of a numerical model that reproduces an experimental setup of a welding process, with particular attention given to the actual shape of the weld bead. The dimensions of the heat source (HS) model in a welding process are determined based on experimentally measured weld pool sizes as well as temperature history at selected points below and adjacent to a weld seam. The whole experimental setup is accurately reproduced within the Simufact.Welding software and an optimization procedure is applied to obtain the best possible agreement between experimental and numerical results. A validated numerical model with reliable parameters for two heat sources is later used to predict and observe material behavior during the WAAM process of more complex parts.

Introduction

The wire arc additive manufacturing process is becoming increasingly popular in many engineering industries due to its high deposition rate, low costs, nearly nonlimited build size, and near-net shape manufacturing of complex geometries. It enables the production of structurally efficient and free-formed shapes in a shorter time as compared to other AM processes. Moreover, varied materials can be applied together to obtain functionally graded materials [1,2]. The main advantage of WAAM is its ability to manufacture high-quality parts with strong structural and mechanical properties. All these and other advantages of the WAAM process are the reason for many research works focused on its applicability in aerospace, automotive, biomedical, or marine industries [3-7]. Most of the focus is concentrated on the microstructure and mechanical properties of the manufactured parts [8], controlling deposition shape [9], and analysis of the residual stress or distortions [10,11].

WAAM is executed by depositing subsequent layers of molten metal on top of each other until the expected geometry is created. Welding metals is a process that includes heating and cooling cycles, which strongly influences chemical-metallurgical reactions in liquid metal, phase transformations, grain growth, and therefore final material mechanical properties [12]. To better understand the mechanisms taking place during WAAM and to minimize the costs of experimental investigations at the same time, a simulation approach is eagerly applied, where not only finite element models [11,13-17], but also neural networks [16,18,19] or mathematical [20], recursive models [21] are increasingly used. However, to accurately simulate the final properties of the part obtained by the WAAM process, a realistic heat source shape and distribution is necessary [22].

Thus, to improve the understanding of the material behavior during a WAAM process, this work aims to determine the parameters of a numerical model that reproduces the welding process, with particular attention given to the actual shape of the weld bead. In this study, the dimensions of Goldak's heat source [23] model in a welding process are determined based on experimentally

measured weld pool sizes as well as temperature history at selected points below and adjacent to a weld seam.

Experimental Procedure

The welding experiments have been conducted with an Arc 605 WAAM system of GEFERTEC GmbH (Berlin, Germany). As welding material, AWS A5.18 with a wire diameter of Ø = 1.2 mm was chosen. The chemical composition of the welding material is stated in Table 1. To conduct the temperature measurement a DMC Plus measuring amplifier of HBM (Darmstadt, Germany) was used.

Table 1. Chemical composition of AWS A5.18 % weight.

C	Mn	Si	Cu	Fe
0.06 - 0.13	1.4 - 1.6	0.7 - 1.0	≤ 0.3	Rest

To ensure the reproducibility of the experiments and reproduce a real WAAM process concerning the thermal characteristics as far as possible a device was constructed as shown in Fig. 1a. All the parts are made of AISI 1045, which is considered to be sufficiently comparable to the AWS A5.18 and thus a real WAAM component of AWS A5.18 concerning the thermal characteristics. Since the measurement of the melt pool temperature is not possible during the welding, the temperature measurement took place at four relevant points near the welding seam via type K thermocouples. To improve the response time of the thermocouples, the thermocouples were spot-welded at the indicated positions. In detail, the temperature was measured at the upper substrate surface near the welding seam (TC 1), at the lower substrate surface directly below the welding seam (TC 2), and at two points within the base plate at different distances to the welding surface (TC 4 and TC 5), as seen in Fig. 1b.

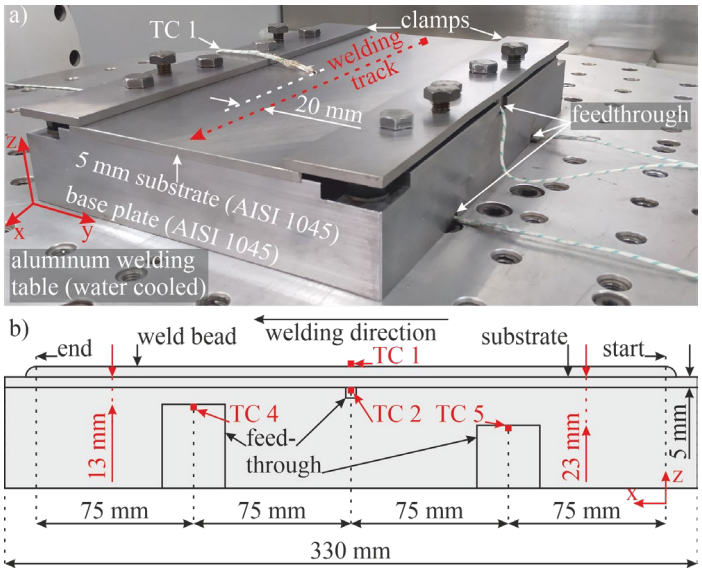

Fig. 1. Experimental setup for welding experiments with temperature measurement a) macroscopic image and b) cross-sectional sketch indicating positions of the thermocouples.

Since the melt pool characteristic is not stable when starting the welding process and thus not representative for the weld bead, the temperature measurement took place at least 75 mm after the starting of the welding process to ensure a quasi-static process state (Fig. 1b). With the device it is possible to perform welding experiments with and without preheating the substrate. The preheating of the substrate and the device enables the reproduction of the welding process of a real component in higher detail. In this case, preheating was not applied and thus the starting temperature of the

substrate was room temperature. Other relevant welding parameters are shown in Table 2. Subsequent scanning electron microscope (SEM) analyses of the welding seam were conducted with a Phenom XL G2 of ThermoFisher Scientific (Waltham, USA).

Table 2. Welding process parameter.

Welding mode [-]	CMT-process frequency [Hz]	Process gas [-]	Gas flow rate [l/min]	Current [A]	Voltage [V]	Feedstock velocity [mm/min]	Axis speed [mm/min]
Cold metal transfer (CMT)	3	Ar18CO$_2$	15	144	14.6	4,000	400

Results and Discussion

Temperature history plots show the highest recorded value (712°C) directly under the weld seam at the location of TC 2. The second highest temperature is noted by TC 1 – 180°C – on the top surface of the substrate. Thermocouples 4 and 5 record ca. 100 and 50°C as maximum values of observed temperatures (Fig. 2). Although TC 1 and TC 2 are in the same cross-section, the peaks of the respective temperature plots are temporally shifted to each other. TC 2 temperature plot represents the heat transfer from the electric arc, which is a moving HS, into the material by conduction. TC 2 temperature rises within a few seconds when the electric arc is passing the cross section above TC 2 and is falling shortly after the electric arc passed the relevant cross-section. TC 1 temperature history represents the heat transfer from the welding seam to TC 1 through the substrate by heat conduction. Thus, as long as the welding seam (TC 2) has a significantly higher temperature it acts as a stationary heat source regarding TC 1. Since TC 1 is 20 mm away from the welding seam and heat transfer by conduction takes time, the peak of TC 1 is delayed compared to TC 2.

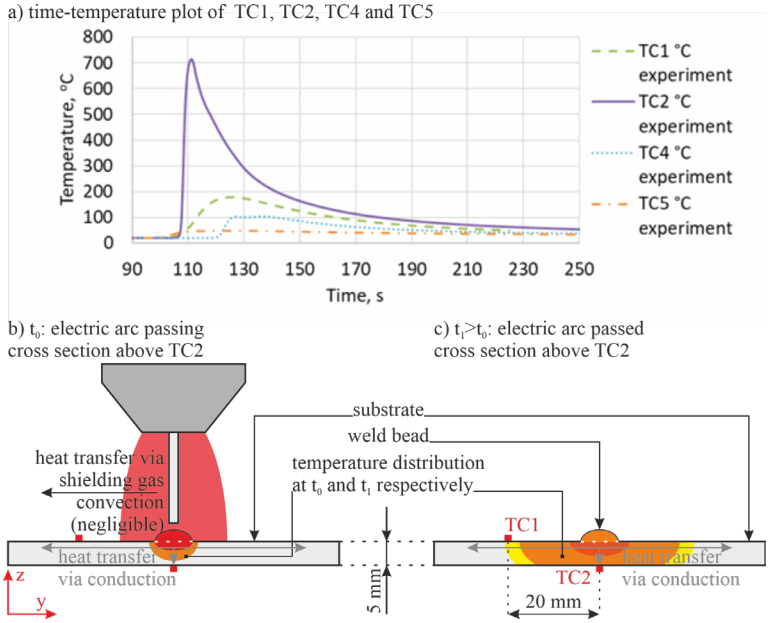

Fig. 2. a) Temperature history recorded by four thermocouples during the welding process of a single weld seam, b) schematic sketch of welding process at t_0 and c) schematic sketch of welding process at $t_1 > t_0$.

As is presented in Fig. 3a, SEM analyses are made in two locations: first at the cross-section in the middle of the weld seam (V1); second at the cross-section in the longitudinal direction at the end of the weld seam (V2). Fig. 2b shows that the depth of the fully melted zone of the base material

reaches ~1.41 mm during the welding process. A mixture of liquid and austenite phases existed till the ~1.9 mm level during the welding process. Lastly, the heat-affected zone reached a depth of ~3.5 mm. The longitudinal cross-section V2 enabled the estimation of the amount of material that overflows in the front and rear direction (Fig. 3c), which enabled the prediction of the initial values of the front and rear lengths of Goldak's heat source model. It is also visible there that the depth of the melted zone is not constant in a vertical direction and varies along the weld seam, which might be a result of the cold metal transfer mode.

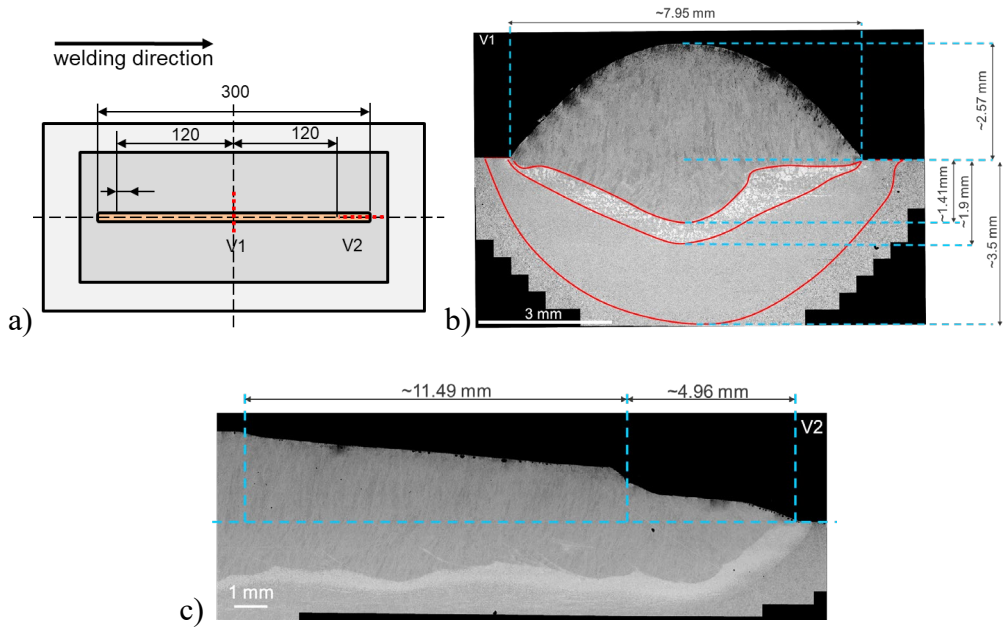

Fig. 3. a) Locations of the SEM analyses; b) in the middle of the seam, c) at the end of the seam in the longitudinal direction.

Numerical Simulation

To reproduce the experimental setup in a digital form, the Simufact.Welding 2021.1 software (Hexagon, Stockholm) is used, where a ground plate, substrate plate, and holding clamps are also included in the FE model (Fig 4a). To minimize the influence of the geometry of the weld seam on the quality of obtained results, a cross-section from metallography (Fig. 3b) was applied to represent the expected shape of the welding seam (Fig 4b).

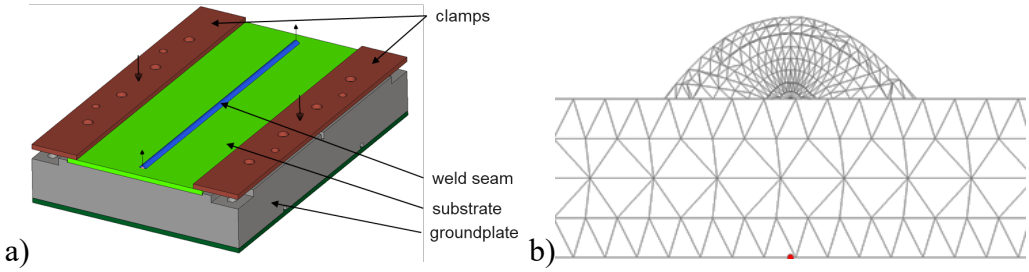

Fig. 4. FE model developed in Simufact. Welding software: a) full setup, b) cross-section of the weld seam.

Material properties of the AISI 1045 steel substrate, such as density and thermal capacity are taken from the literature [24, 25] (Fig. 5a, b), whereas thermal conductivity was measured with Linseis LFA 1000 Laser Flash test machine (Linseis Messgeräte GmbH, Selb, Germany) (Fig. 5c). Material properties of the AWS A5.18 wire are taken from the Simufact.Welding 2021.1 material database.

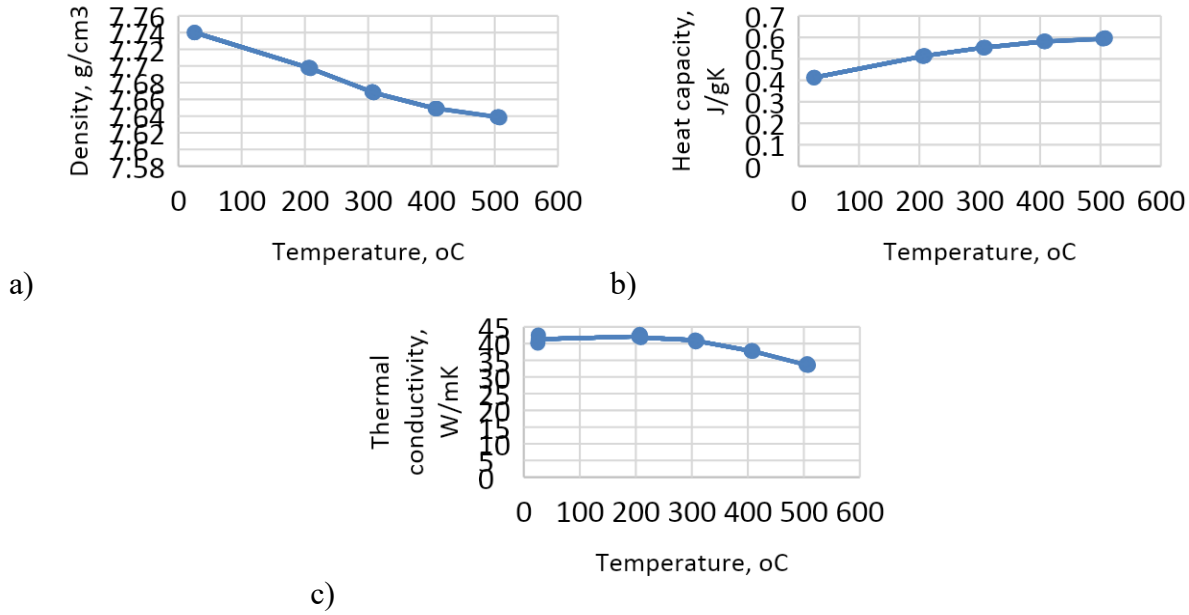

Fig. 5. Material properties of AISI 1045 as a function of temperature: a) density [24], b) heat capacity [25], c) thermal conductivity measured by Authors.

The convective heat transfer parameter h_{plate} in the function of temperature for a substrate (Fig. 6b), is calculated based on classical heat transfer equations characteristic for natural convection that is present over a flat surface facing up:

$$\beta = \frac{1}{T_f} \tag{1}$$

$$T_f = \frac{(T_s + T_\infty)}{2} \tag{2}$$

$$L_c = A_s/p \tag{3}$$

$$Ra_L = \frac{g\beta(T_s - T_\infty){L_c}^3}{v^2} Pr \tag{4}$$

$$Nu = 0.54{Ra_L}^{\frac{1}{4}} \tag{5}$$

$$h_{plate} = \frac{k}{L_c} Nu \tag{6}$$

where: A_s is the top surface area of the plate, p – circumference of the plate, Pr – Prandtl number (at T_f), Nu- Nusselt number, Ra_L - Rayleigh number, v – kinematic viscosity (at T_f), L_c - characteristic length, T_f - film temperature, k – thermal conductivity (at T_f).

The weld seam is treated as a horizontally placed cylinder, for which the natural convection parameter $h_{cylinder}$ is presented in Fig. 6a and calculated with the following equations:

$$Nu = \left\{ 0.6 + \frac{0.387{Ra_D}^{\frac{1}{6}}}{\left[1 + \left(\frac{0.559}{Pr}\right)^{\frac{9}{16}}\right]^{\frac{8}{27}}} \right\}^2 \tag{7}$$

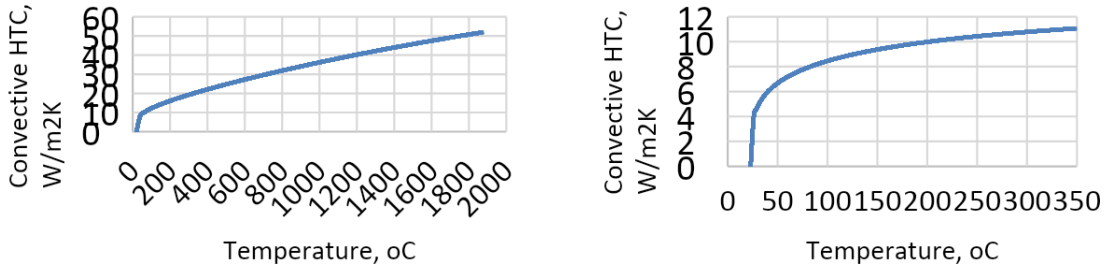
$$h_{cylinder} = \frac{k}{D} Nu \tag{8}$$

Properties of air at atmospheric pressure such as: kinematic viscosity v, thermal conductivity k and Prandtl number Pr are described as functions of temperature with following equations:

$$v = -0.000000000000001080028067777848\ T^3 + 0.000000000078431258717711 2\ T^2 + \\ + 0.0000009317235889175 73\ T + 0.0000131184421229409 \quad (9)$$

$$k = 0.000000000004641045635296 73\ T^3 - 0.000000025220464123877 6\ T^2 + \\ + 0.0000756242633211078\ T + 0.0236352337830901 \quad (10)$$

$$Pr = 0.000000000000000000025041212039251900\ T^6 - 0.000000000000000020791991918815 7\ T^5 + \\ + 0.000000000000067316897714983\ T^4 - 0.000000001097177506888 35\ T^3 + \\ +0.000000941818163402441\ T^2 - 0.000346614970760939\ T + 0.737371365505794 \quad (11)$$



a) b)

Fig. 6. Convective heat transfer coefficient as a function of the temperature of the a) weld seam, and b) substrate to air.

A single seam is welded digitally with the same speed (6.66667 mm/s), voltage (14.6 V), and current (144 A) as welding parameters applied during the real experiment. The air temperature and initial temperature of the wire are set to 23°C, the initial temperature of all plates is set to 21.5°C, and arc efficiency is assumed to be 80%.

Goldak's heat source model [23] was used to describe the volumetric heat flux density distribution, where a_f, a_r, b, d are parameters related to the shape characteristic of the welding arc (Fig. 7). Values of the front (4.96 mm) and rear (11.49 mm) length of the heat source one, are read from the microscopic analysis presented in Fig. 3c. Values of the width and depth parameters are established based on optimization procedure applied to obtain a similar picture of the melted zone between the simulation and experiment. During this procedure, an advantage of applying two heat sources was used [26], which enabled to improve results in terms of temperature history recorded during the real test, especially on the top surface of the substrate. A targeted adjustment of the parameters for both HSs was done at the same time, to compare the calculated shape of the fusion zone and temperature history to the experimental data shown in Fig. 2 and 3b. The final values of the obtained parameters of both heat sources are gathered in Table 3.

HS 2	0.1	0.1	0.3	0.3

Validation of the Numerical Simulation Results

The simulation results with 2 heat sources show a particularly good agreement with the available experimental data. The geometry and size of the melted zone visible directly below the weld seam agree well with the microscopic results (Fig. 8). Based on the phase diagram characteristic of AISI 1045 steel, the fully liquid phase is assumed to occur above 1525°C, a mixture of liquid and austenitic phases is observed at temperatures of 1425-1525°C, and only the austenitic phase is present at 770-1425°C. These temperature ranges are used to determine the calculated geometry of the melt zone during FE simulation. As shown in Fig. 8, the fully liquid phase can be seen to a depth of ~1.46 mm, austenite + liquid to ~1.7 mm, and the pure austenite phase to ~4 mm. In contrast, if only one heat source is used, neither the geometry nor the size of the melt zone visible directly below the weld seam is realistically calculated, as a comparison of Fig. 8b with Fig. 8c shows. Moreover, the calculated Root Mean Square Error (RMSE) (see Fig. 9) between measured and simulated temperature history (for using HS1 and HS2 together) at selected points equals 6.25, 44.6, 7.07, and 3.91°C at TC 1, TC 2, TC 4, and TC 5, respectively. Such well prepared and validated the numerical model with dependable Goldak's heat source parameters can be later used to predict and observe material behavior during the WAAM process of much more complex parts.

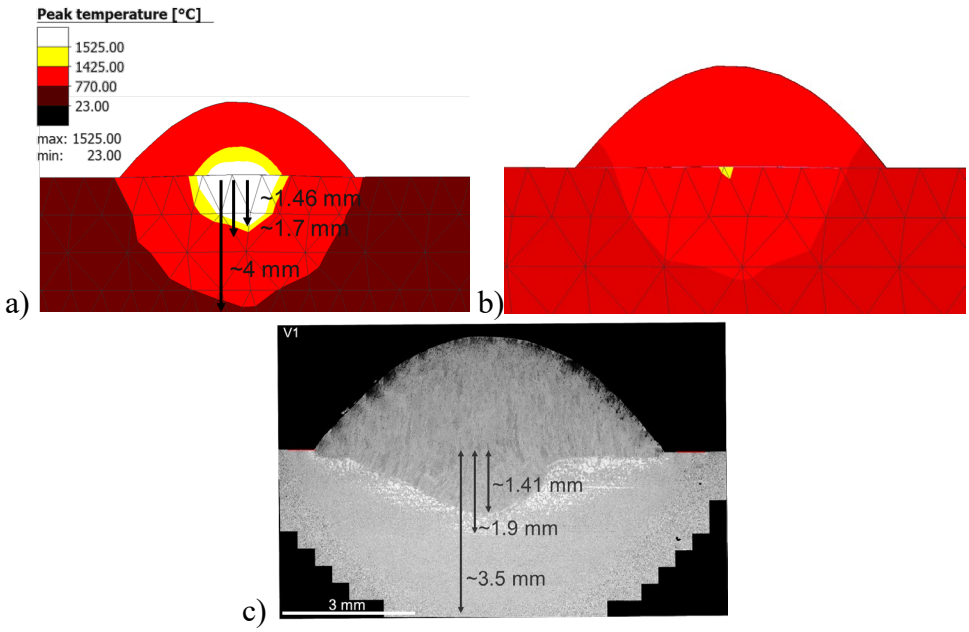

Fig. 8. Peak temperature distribution in the middle of the weld seam according to the simulation with a) 2 HSs; b) 1 HS; b)c) SEM-image of the weld seam indicating the temperature distribution during the welding process.

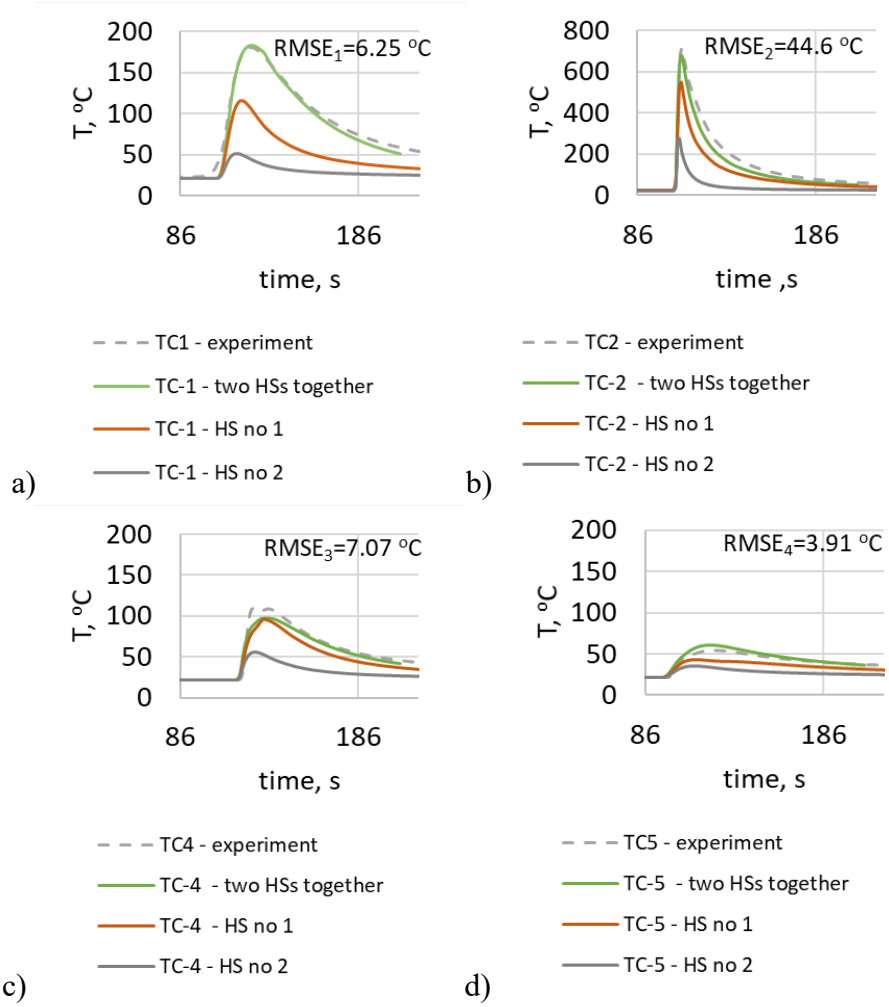

Fig. 9. Comparison between experimental (dotted lines) and numerical results (continuous lines) in terms of recorded temperature history in selected points: a) TC1, b) TC2, c) TC4, d) TC5.

For investigation purposes, also single HS models were calculated when only 1 Goldak's heat source was applied to weld a seam. Obtained results in form of temperature-time plots are presented in Fig. 9. As is noticeable, the application of the 2 HS model enables to obtain reliable temperature history at different locations of the base plate. Especially the prediction of temperature history on the top surface of the substrate is improved in comparison to the single HS model.

Summary

In this investigation, the parameters of Goldak's heat source model are determined based on experimentally measured weld pool sizes as well as temperature history at selected points below and adjacent to a weld seam. A single 300 mm long seam of AWS A5.18 wire is welded onto an AISI 1045 base plate. Four thermocouples are measuring temperature history: first on the top surface next to the weld seam, second directly under the weld seam, and two more thermocouples are placed under the base plate on two diverse levels. A microscopic analysis of the weld seam cut in the middle of its length gives information about the expected heat zone size and is also a hint for dimensions of the Goldak's HS. The whole experimental setup is accurately reproduced within the Simufact.Welding 2021.1 software and an optimization procedure is applied to obtain the best possible agreement between experimental and numerical results. In this case, a two-heat source model gives the most accurate results, where not only a melted zone of the material is accurately

predicted but also temperature history under the substrate, under the weld seam, and on the top surface of the substrate are very close to reality.

Keywords: Additive Manufacturing, FFF, Biopolymers, STL Generation, Trabecular Bone

Abstract. There are two types of structures in bone with different densities: cortical bone, a denser region, and trabecular bone, a porous part. Poly(lactic acid) - PLA, a biopolymer widely used in additive manufacturing (AM), can be applied for fabricate products for medical and dental applications since it is biodegradable and biocompatible to several mammalian cell lines. This article proposes a methodology for generating STL to produce by AM a structure with geometry similar to that of trabecular bone using a mathematical model that describes the population dynamics of bone cells. Bone density values obtained by solving the differential equations model with finite differences are used to develop a mesh surface. This surface is converted into a binarized mesh using a binary algorithm and, finally, the STL file is obtained by applying the multidimensional arrays tool from Matlab® software. The produced file is analyzed by BoneJ® using the same procedure currently applied for bone tomography to obtain some geometry parameters as trabecular thickness, trabecular separation, bone fraction and connectivity; and the degree of anisotropy. 3D Printed samples were successfully produced by Fused Filament Fabrication (FFF) using PLA filament. It was noticed that the produced structure is similar to the morphology of the trabecular part of the femoral head, comparing the different strategies of obtain STL and real bone tomography.

Introduction

Bone architecture can be classified as cortical or trabecular. Cortical bone is made up of a compact region of mineralized material, while trabecular bone has structures known as trabeculae, which are highly porous [1]. Bone is a mineralized conjunctive tissue that exhibits four types of cells: osteoblasts, osteocytes, osteoclasts, and bone lining cells [2]. Bone composition is given by 50-70% of inorganic material (hydroxyapatite), 20-40% of organic material (collagen I), and 5-10% of water and other materials, such as lipids and fibrillin [3].

The trabecular region of the bone is the most affected by fractures and is the area where bone weakening can happen with different carcinomas and pathologies. However, more facts need to be clarified about the characteristics of this tissue region, as well as the strategies to reproduce it aiming as a replacing bone tissue (bone tissue engineering) and technical-academic studies (orthopedic surgeries).

It is noticed many techniques to reproduce the trabecular bone structure as capture and image processing using computed tomography that stands out as a gold standard [4]. This process is relatively high cost and it need for real experiments, so the use of mathematical models as Wolff and Roux laws is an alternative to obtain this architecture as a digital image. These mathematical approaches describe the architecture of trabeculae as responses to mechanical stimuli [4]. Recent

progress has shown that this approach can be considered outdated since bone architecture can be related to cell effects [4] and bone cell remodeling [5].

A mathematical model developed by Komarova et al. [1] describes the dynamics of bone cells population, in view osteoclasts and osteoblasts in a basic multicellular unit. The authors explain the effect of local regulatory factors on cell production rates, employing a power law approximation. A system of differential equations is defined for variations in cell population (osteoblasts and osteoclasts) and bone mass. This model has been used in recent years in several studies to describe different phenomena and bone pathologies. Ayati et al. [6] adapted the mathematical modeling of Komarova et al. [1] to study the healthy cell population and those with tumor cells. In this paper, the cell diffusion and bone density were evaluated, with cell and bone density are described in one dimension. Valério et al. [7] investigated using the model to the anomalous (tumor) and healthy growth of the bone mass, considering disturbances in the origin, and applying the method of finite differences in two dimensions. Peyroteo et al. [8] studied the application of the finite element method to solve the remodeling equations and analyze the results in conditions of healthy bone and osteoporosis.

The work of Fernández-Cervantez et al. [9] applying the space-time adaptations of Ayati et al. [6] proposes to solve the system of differential equations using Euler's method for the temporal part and the finite difference method for the spatial part, to obtain a porous piece with a structure like the trabecular bone. Then, the authors used the 3D printing binder jetting technique to obtain printed pieces. The authors found patterns and profiles similar to those of trabecular bone morphology by assessing the image produced with the patterns of real trabecular bone.

In the image processing analysis of the trabecular bone structure, some parameters are important as defined by McGregor et al. [10]: Trabecular Thickness, Trabecular Separation, Bone Volume Fraction, Degree of Anisotropy and Connectivity. These parameters can be analyzed to mimic the trabecular structure, knowing that the study of Trabecular Thickness and Trabecular Separation dispersion in a certain range of values is important, since real bone does not have isotropic trabecular thickness and separation [11]. These characteristics of bone morphology may be key factors for tissue compatibility and regeneration when applied to tissue engineering scaffolds.

Filament Fusion Fabrication (FFF) is a simple 3D printing technique and relatively cheap when compared to other techniques that have greater precision [12]. In this technique, it is possible to obtain, with a 0.2 mm nozzle, structures that simulate a corresponding trabecular thickness of 0.2 mm. Most of the bones in the human body have thin trabecular, however, the femoral head bone has an average trabecular thickness of 0.19 mm, being the thickest documented [10]. Therefore, these structures have the potential to be printed by FFF, despite the relatively low accuracy of the technique compared to more robust AM techniques. Obtaining files that can be read by 3D printer software is essential for the operation of the technique, such as STL files that describe the surface with triangulation [12]. The present work seeks to apply the mathematical model proposed for cellular remodeling to obtain a STL that mimics the bone trabecular structure, for so it is analyzed the different bone parameters in comparison with real bone of femoral head in pieces printed by FFF.

Modeling the Bone Dynamics

Bone is a mineralized conjunctive tissue that exhibits four types of cells: osteoblasts, osteocytes, osteoclasts, and bone lining cells. This tissue performs important functions in the body, such as locomotion, support, and protection of soft tissues, calcium and phosphate storage, and bone marrow shelter. Despite its immobile appearance, bone is a highly dynamic organ. Bone material is continuously reabsorbed by osteoclasts and “rebuilt” by osteoblasts [8].

The model of bone remodeling proposed by Komarova et al. [1] takes into account that both osteoclasts and osteoblasts can produce local factors capable of activating or inhibiting themselves, or activating or inhibiting another cell type, i.e., signaling respectively autocrine and paracrine

factors. A simplified hypothesis considers that autocrine and paracrine factors only regulate the production rate of osteoclasts and osteoblasts and their removal rates are proportional to the current number of corresponding cells. Some growth factors were neglected, such as the action of the nuclear factor kappa β ligand-receptor activator (RANKL) and insulin (IGF) that can promote osteoclasts and osteoblasts survival. These assumptions reduced the number of parameters helping its implementation.

Equations (1) and (2) present the Komarova model describing the dynamics of cell populations for bone remodeling along the time (t). The main variables of the model are: number of cells of osteoclasts (C), number of cells of osteoblasts (B) and bone mass (ρ).

$$\frac{dC(t)}{dt} = \alpha_1 C(t)^{g11} B(t)^{g21} - \beta_1 C(t) \quad (1)$$

$$\frac{dB(t)}{dt} = \alpha_2 C(t)^{g12} B(t)^{g22} - \beta_2 B(t) \quad (2)$$

The constants α_i and β_i are called as cell production and removal activities, respectively, and $g_{i,j}$ represents the efficacy of autocrine or paracrine factors derived from osteoclasts (index 1) or osteoblasts (index 2).

Komarova model also propose Eq. 3 to calculate the bone mass $\rho\ (t)$ as a function of the cell population in steady state ($t \rightarrow \infty$), the constants are k_i that corresponds to the normalized activity of bone resorption (index C) and formation (index B). The term inside the parentheses in Eq. 3 corresponds to the number of cells that actively resorb or form bone, and the variables $\underline{C}$ and $\underline{B}$ indicate the values of number of cells in steady-state.

$$\frac{d\rho(t)}{dt} = -k_C(t) max\left(0, C(t) - \underline{C}\right) + -k_B(t) max\left(0, B(t) - \underline{B}\right) \quad (3)$$

To obtain estimates of the initial parameters, Komarova *et al*. used experimental data obtained from the histomorphometry analysis of bone sections [1].

A second model is proposed by Ayati et al. [6], an extended mathematical model adding a diffusion cells term (D_i), that it is multiply by the Laplacian of cell number, obtaining a field with cell population. The spatial distribution of C(t), B(t) and $\rho(t)$ is calculated using Eq. 4, 5 and 6, where u = (x, y, z). A numerical finite difference method can be used to solve this system.

$$\frac{\partial C(u,t)}{\partial t} = D_C \nabla^2 C(u,t) + \alpha_1 C(u,t)^{g11} B(u,t)^{g21} - \beta_1 C(u,t) \quad (4)$$

$$\frac{\partial B(u,t)}{\partial t} = D_B \nabla^2 B(u,t) + \alpha_2 C(u,t)^{g12} B(u,t)^{g22} - \beta_2 B(u,t) \quad (5)$$

$$\frac{\partial \rho(u,t)}{\partial t} = -k_1(u,t) max\left(0, C(u,t) - \underline{C}\right) + k_2 max\left((u,t) - \underline{B}\right) \quad (6)$$

Methodology for STL Surface using Cells Models

Two strategies (S1) and (S2) were developed in this article to produce the three-dimensional surfaces based on the presented models. The same cubic envelop was used for both strategies wherein bone and porous regions were produced, so a Basic Multicellular Unit, BMU. The first strategy used a 2D methodology for each layer and the second one calculated the regions in all envelop. The surfaces were transformed in STL file format for allowing 3D printing. The application of Matlab's tool *stlwrite* was used to export the surface volume produced with the two strategies.

Strategy 1 (S1).

This strategy is based on solving differential equations in two dimensions and applying the *isosurface* tool. Bone density values obtained by solving the differential equations model with finite differences are used to develop a mesh surface. This surface is converted into a binarized mesh using a binary algorithm and, finally, the STL file is obtained by applying the multidimensional arrays tool from Matlab® software. Strategy 2 (S2) solves the differential

equations in three dimensions, and with the obtained three-dimensional matrix, an *isosurface* similar to the one produced in S1 is created.

For two dimensions (x and y), applying finite differences in Eq. (4) and (5), Eq. (7) and (8) represents the model used for this strategy:

$$\frac{C_{i,j}^{(n+1)} - C_{i,j}^{(n)}}{\Delta t} = \frac{k_{i,j}C_{i+1,j}^{(n)} - 2C_{i,j}^{(n)} + C_{i-1,j}^{(n)}}{\Delta x^2}(D_c) + \frac{k_{i,j}C_{i,j+1}^{(n)} - 2C_{i,j}^{(n)} + C_{i,j-1}^{(n)}}{\Delta y^2}(D_c) + \alpha_1 C(u,t)^{g11} B(u,t)^{g21} - \beta_1 C(u,t), \quad (7)$$

$$\frac{B_{i,j}^{(n+1)} - B_{i,j}^{(n)}}{\Delta t} = \frac{k_{i,j}B_{i+1,j}^{(n)} - 2B_{i,j}^{(n)} + B_{i-1,j}^{(n)}}{\Delta x^2}(D_c) + \frac{k_{i,j}B_{i,j+1}^{(n)} - 2B_{i,j}^{(n)} + B_{i,j-1}^{(n)}}{\Delta y^2}(D_c) + \alpha_2 C(u,t)^{g12} B(u,t)^{g22} - \beta_2 B(u,t). \quad (8)$$

These meshes at different times can be "stacked" using the *Marching cubes algorithm* (*isosurface* tool from Matlab®) to obtain a three-dimensional surface. Using these meshes in Eq. 6, also a mesh is produced for bone mass. This strategy, called here as Strategy 1, would correspond to cell migration in the z direction that would continuously produce an extracellular matrix.

Strategy 2.

A second approach to obtaining an STL that mimics bone structure from bone remodeling would be to simply solve Eq. 5-7 in three dimensions applying finite differences. Strategy 2 (S2) obtained a three-dimensional matrix, an *isosurface* similar to the one produced in S1 is obtained with the Eqs. 9 and 10 for the population of osteoclasts (C) and osteoblasts (B).

$$\frac{C_{i,j,k}^{(n+1)} - C_{i,j,k}^{(n)}}{\Delta t} = \frac{k_{i,j}C_{i+1,j,k}^{(n)} - 2C_{i,j,k}^{(n)} + C_{i-1,j,k}^{(n)}}{\Delta x^2}(D_c) + \frac{k_{i,j}C_{i,j+1,k}^{(n)} - 2C_{i,j}^{(n)} + C_{i,j-1,k}^{(n)}}{\Delta y^2}(D_c) + \frac{k_{i,j}C_{i,j,k+1}^{(n)} - 2C_{i,j,k}^{(n)} + C_{i,j,k-1}^{(n)}}{\Delta z^2}(D_c) + \alpha_1 C(u,t)^{g11} B(u,t)^{g21} - \beta_1 C(u,t), \quad (9)$$

$$\frac{B_{i,j}^{(n+1)} - B_{i,j}^{(n)}}{\Delta t} = \frac{k_{i,j}B_{i+1,j,k}^{(n)} - 2B_{i,j,k}^{(n)} + B_{i-1,j,k}^{(n)}}{\Delta x^2}(D_B) + \frac{k_{i,j}B_{i,j+1,k}^{(n)} - 2B_{i,j}^{(n)} + B_{i,j-1,k}^{(n)}}{\Delta y^2}(D_B) + \frac{k_{i,j}B_{i,j,k+1}^{(n)} - 2B_{i,j,k}^{(n)} + B_{i,j,k-1}^{(n)}}{\Delta z^2}(D_B) + \alpha_2 C(u,t)^{g12} B(u,t)^{g22} - \beta_2 B(u,t). \quad (10)$$

Numerical Application

Parameters for bone dynamic model.

Table 1 shows the parameter values used in this article based in Ayati et al. [6]. The $g11$ value is different in a single cycle event, in this case is equal to 0.5 and for oscillatory changes the $g11$ value is equal to 1.1.

Table 1. Summary of parameters used in the model.

Parameters	Description	Value
α_1	Production rate of osteoclasts	3 [day^{-1}]
α_2	Production rate of osteoblasts	4 [day^{-1}]
β_1	Apoptosis rate of osteoclasts	0,2 [day^{-1}]
β_2	Apoptosis rate of osteoblasts	0,02 [day^{-1}]
k_C	Rate of bone's resorption	0,45% [day^{-1}]
k_B	Rate of bone's formation	0,0448% [day^{-1}]
D_C	Diffusion coefficient of osteoclasts	1x10^{-6} [bone mass mm^{-1}]
D_B	Diffusion coefficient of osteoblasts	1x10^{-6} [bone mass mm^{-1}]
$\underline{C}$	Cell population of osteoclasts in steady-state	1.06 [cell mm^{-1}]
$\underline{B}$	Cell population of osteoblasts in steady-state	212.13 [cell mm^{-1}]
$g11$	Autocrine signaling factor of osteoclasts	0.5 [single] 1.1 [osc.] [dimensionless]
$g21$	Paracrine signaling factor of osteoclasts	-0.5 [dimensionless]
$g22$	Autocrine signaling factor of osteoblasts	0.0 [dimensionless]
$g12$	Paracrine signaling factor of osteoblasts	1.0 [dimensionless]

Temporal Part Analysis - Single Remodeling Cycle. A separate function was created in auxiliary file to solve the Ordinary Differential Equations using adaptative Runge-Kutta method (ode45) in 150 days (t in days). The results are shown in Fig. (1).

Fig. 1a and 1b show that the addition of 10 active osteoclast cells led to a consequent increase in the number of osteoblasts, and consequently, the stabilization of the number of osteoclasts returns to a steady state.

Fig. 1c represents the evolution on percentage of bone mass: according to the role of the cells has an initial drop, related to the consumption performed by osteoclasts, and slow reformulation, related to the increase in the number of active osteoblastic cells.

Temporal Part Resolution - Periodic Remodeling Cycles. The literature points out that the change of osteoclasts parameters can be used to obtain the periodic cycles of remodeling. Komarova et al. [1] investigated the influence of each parameter on the stability and type of steady state obtained: the authors show the protagonist of the autocrine factor of osteoclasts (g_{11}); also, others authors point the same argument [14,15]. Low g_{11} values reproduced only one remodeling cycle, while values greater than 1.1 lead to a dynamic remodeling with oscillations with increasingly higher amplitudes. These results were therefore obtained in Figs. 1d, 1e, and 1f, below, where a progressive variation in cell number and mass is evident. Therefore, changing the model constants to obtain a non-stationary response applying the adaptative Runge-Kutta's method analogously can be seen in Fig. 1d, 1e and 1f.

The initial value problem for this ODE system can exemplify the bone remodeling mechanism. However, the bone mass distribution is only for a single BMU. Ayati et al. [6], Valério et al. [7] and Fernández-Cervantez et al. [9] solved the presented model by adding a diffusive term for cell population and bone mass shown in Eqs. 6-9.

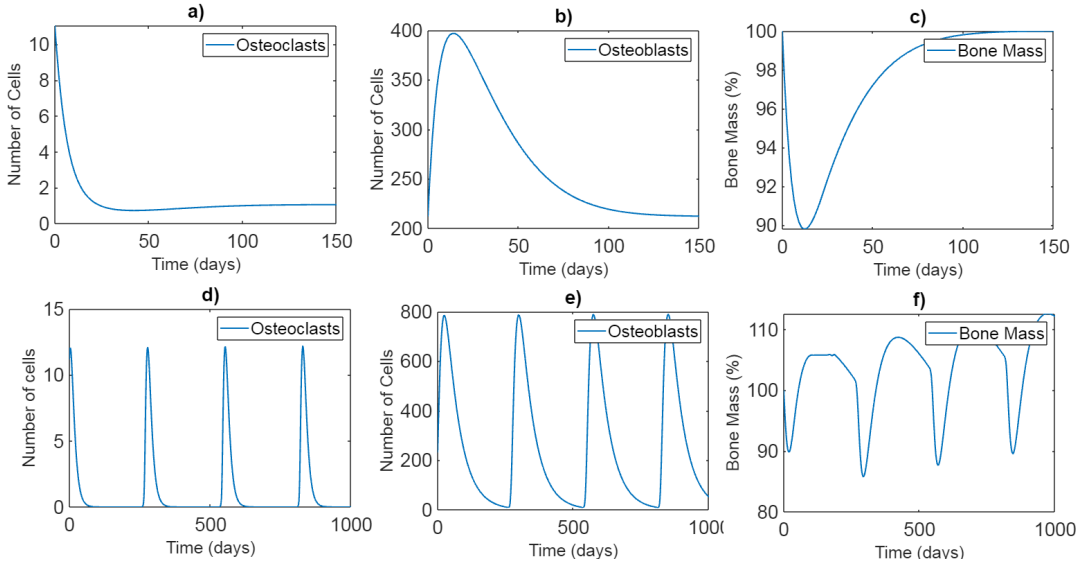

Fig. 1. Response to a bone remodeling cycle with the respective cellular behavior of osteoclasts (a), osteoblasts (b), and bone mass variation (c) and to periodic bone remodeling cycles with the respective cellular behavior of osteoclasts (d), osteoblasts (e), and bone mass variation (f).

Different BMUs were evaluated at each point of a given mesh or solid block. The approach of Valério et al. [7,9] and Fernandez-Cervantez et al. [9] were replicated below, in the respective Strategies 1 and 2. While in Strategy 1 the cell distribution is solved in x and y, in Strategy 2 it is solved in x, y and z. In order to obtain a three-dimensional block with the structure of trabecular bone, in the first form, therefore, it was necessary to apply the Multidimensional Matrices technique and the application of the *isosurface* tool after binarizing the data of each mesh x and y. In the second strategy, the matrix obtained already had orientations in three dimensions, which allowed the direct application of the *isosurface* tool, and binarizing the volume.

Resolution Space Part - Strategy 1.

The addition of a diffusive term to the bone cell remodeling model proposed by Ayati et al. [6] allowed the assessment of cell population distribution and bone mass. Therefore, the non-trivial steady-state conditions obtained in the temporal resolution (previous item) are defined for the temporal part of the model. The diffusive part is solved using finite differences, as follows. By defining a remodeling time in a series of meshes with different initial conditions the parameters are defined for a time of 150 days. Fig. 2 shows the distribution grids for the final time of 150 days for cell populations and bone mass. In this figure we can see the distribution of cells in different areas, that is, where there are osteoclasts there is less population of osteoblasts, Figs. 2a and 2b. Also, denser regions could be seen in Fig. 2c areas with presence of osteoblasts, and less dense regions could be seen in populated osteoclasts areas. A loop was used in this case, with dt = 0.01 days.

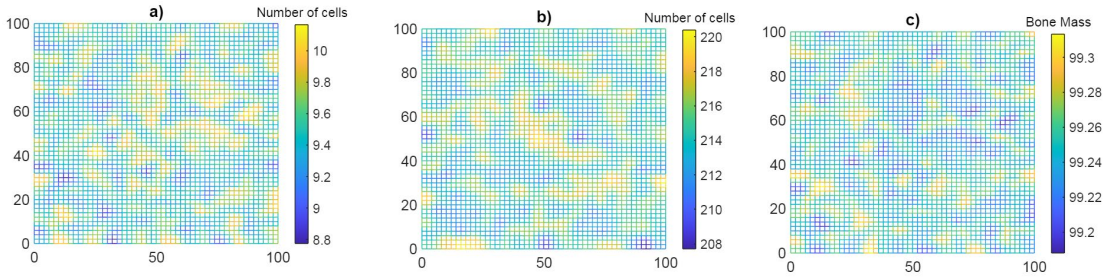

Fig. 2. Distribution of the cell population of osteoclasts (a), osteoblasts (b) and bone mass (c) with S1.

Resolution Spatial Part - Strategy 2.

Strategy 2 only proposes solving for x, y, and z dimensions and plotting an isosurface from the volumetric data produced at t = 150. It assumes the same conditions as Strategy 2: a series of meshes with different initial conditions (different amounts of cells).

The distributions of cell populations and bone mass can be obtained as shown in Fig. 3. This figure shows the three-dimensional distribution of cells and bone mass. As consideration of *isosurfaces* produced: the marching cubes algorithm connects areas with the same value (defined as *isovalue*). For this, the data was binarized (a 3D Matrix of zeros and ones) to produce the isosurface in Fig. 3c. The *stlwrite* algorithm in Matlab was applied in order to export the STL files.

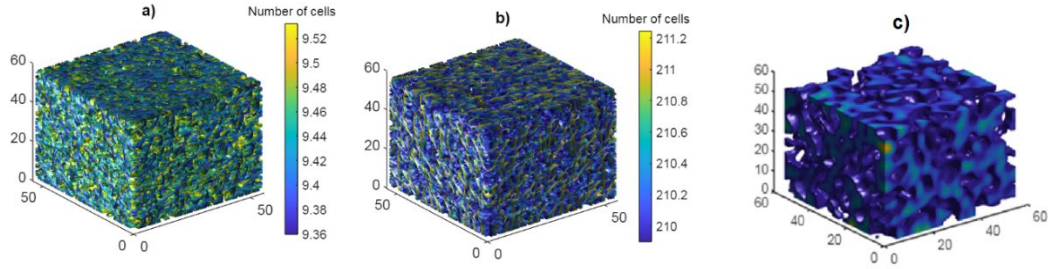

Fig. 3. Distribution of the cell population of osteoclasts (a), osteoblasts (b) and bone distribution (c) generated by Strategy 2 (dimensionless) in 150 days.

Analysis of 3D Printed Pieces

Experimental Setup.

The pieces were printed using the 3D Printer by FFF Dual Extruder N2 (Raise3D, Tesla, USA) for S1 and the Ultimaker 2+ for S2 (Ultimaker, Netherlands). The printing conditions were: nozzle temperature of 220°C, layer height of 0.15 mm, bed temperature of 60°C and printing speed of 5 mm/s (S1) and 60 mm/s (S2). The pieces were analyzed by microtomography using the equipment Easytom 130 (RX solutions, France) in Institut Clément Ader to obtain the microCT images.

Microtomography analyses.

The application of microtomography (microCT) of the printed pieces allowed the complete geometry of the manufactured workpieces. Fig. 4 shows the microCT images of the S1 (Fig. 4a), S2 (Fig. 4b) and of real bone (femoral head (FH) gently provided by the National Institute of Technology (INT-Brazil), Fig. 4c).

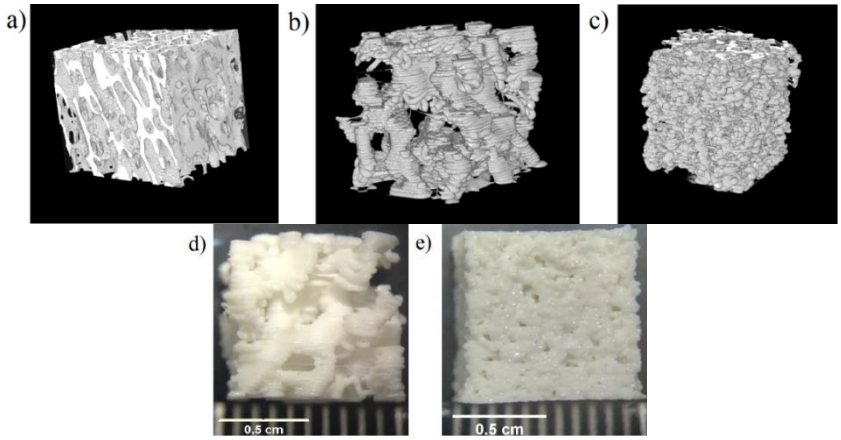

Fig. 4. MicroCT images obtained of the printed pieces with the different strategies: a) femoral head bone, b) S1, c) S2; the macrographs of the printed pieces: d) S1 and e) S2 obtained with magnifying glass (scale in cm).

The Bone J (ImageJ software plugin) was used in these analysis to obtain the parameters: trabecular thickness (TbTh, usually a mean value of thickness of the trabecula), trabecular separation (TbSp, the mean distance between the trabecula, it is similar to pore size), bone volume fraction (BV/TV, the fraction of material in the sample), degree of anisotropy (DA, it estimates how geometrically non-isotropic is the bone fraction), and connectivity (Conn, it gives an estimate of the number of connected trabeculae in the image) [11], [13].

The procedure to analyze the microCT images obtain were using the following image processing: no local means, unsharp mask, cropping image, binarize (Huang's method) and then use Bone J tool in the binarized images. For comparison, the microtomography of the femoral head (FH) bone also was characterized using the tool BoneJ. The choose of this kind of bone was because the parameters evaluated that could be printed by FFF was of this type of trabecular bone [10]. It is visible that pore size (TbSp) in S1 is greater than in real bone (FH). Some isotropy in z axes could be seen in Fig. 4a (FH). The morphology in S2 is closer of real bone, but the layers of 3D printing FFF technique misleading the accuracy.

Table 2. Bone parameters obtained with BoneJ of microCT images.

Strategy	TbTh (mm)	TbSp (mm)	BV/TV	DA	Conn.
S1	0.89±0.299	2.001±1.180	0.402	0.564	457.25
S2	0.418±0.165	0.946±0.432	0.323	0.657	2663
FH	0.213±0.072	0.552±0.217	0.2940	0.688	617

The real bone data, trabecular femoral head bone, is near that observed in the literature [10] as seen in Table 2. However, the comparison of the strategies shows that median values are greater than real bone. Peyroteo et al. [8] with the same mathematical model implemented an algorithm for density that could assess more precise thickness and separation between struts. Also, the distribution in the histogram in Fig. 5 can provide that the profile in the distribution of TbTh and TbSp in FH and S2 were closer. As seen in Fig. 5, the profile of distribution of TbTh and TbSp is closer than S1, and S1 has greater TbTh and TbSp. It is interesting to notice that DA in S2 is near of the real bone. Nevertheless, S1 seems different than the others probably because of the methodology of this strategy, a bone mesh growing in time and not on space.

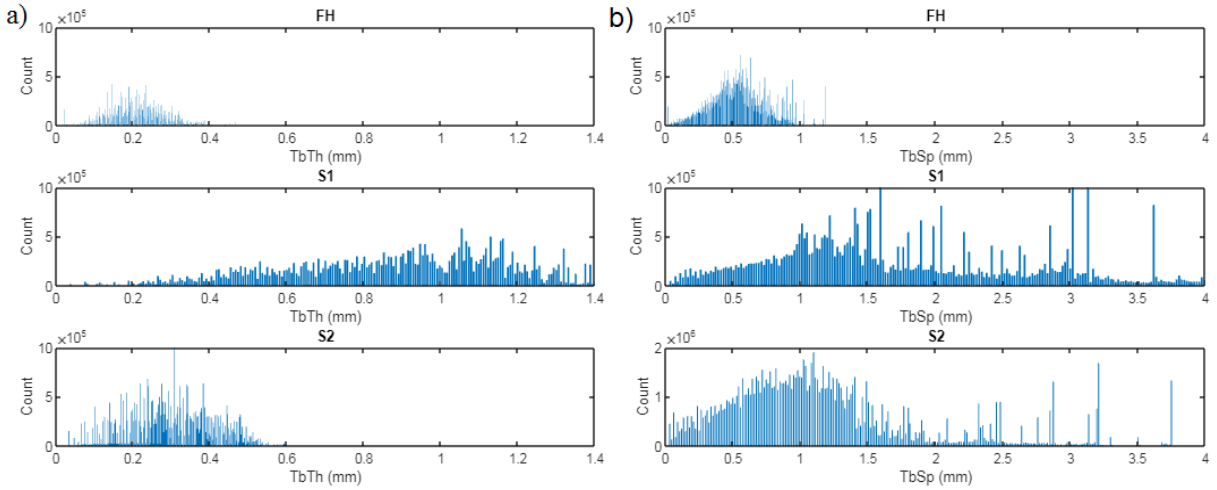

Fig. 5. Histograms for TbTh (a) and TbSp (b) for the different strategies and the femoral head bone.

Some modifications can be made in the algorithm proposed in methodology to reproduce exact profiles and morphological parameters, modifying some parameters in mathematical model and

printing conditions. But it is interesting to notice that porosity and pore size (related to TbSp parameter) greater than in real bone morphology it is necessary to provide angiogenesis [3] and permeability of nutrients in damage tissue [16, 17]. Future works can search the biological response in these printed pieces geometries, in comparison with the gold standard [17] of architecture scaffolds in Bone Tissue Engineering.

Summary

This work reproduced the structure of trabecular bone using the mathematical model of cell dynamics. Pieces with trabecular architecture were successfully printed by FFF technique, a cheaper AM kind of 3D printer. It was possible to evaluate the most influential parameters of the human bone and compare real bone parameters and printed pieces via micro-computed tomography. Comparing morphologies S1 and S2, the average TbTh in S1 is double of S2. S2 was similar to FH in terms of the TbTh and TbSp about the profile distribution, although high variability in S2. DA, an important parameter for the angiogenesis, was closer in S2 than in S1 compared with FH. Therefore, the results here presented suggest that S2 can be applied to future works along with the optimization of the mathematical model and the printing parameters.

Acknowledges

The authors are grateful to Dra. Cristiane Evelise Ribeiro da Silva, researcher in INT – National Institute of Technology (Rio de Janeiro – Brazil), for gently providing the microtomography of the femoral head. Part of this work was produced during the mobility of Rossana Thiré as a Visiting Professor financed by INSA Toulouse in October 2023.

Keywords: Crystal Plasticity, Size Effect, Additive Manufacturing

Abstract. In additive manufacturing processes, the resulting products might have highly anisotropic granular morphologies due to the complex thermal history. The most commonly observed morphology is columnar structure. The resulting morphology of grains is accompanied by the orientation alignment leading to plastic anisotropy. It has been shown in a recent study through local crystal plasticity calculations that the morphology evolution does not influence the mechanical behavior without considering the texture evolution [1]. However, the local frameworks do not consider the effect of the grain size which could be complicated due to high aspect ratio of the grains. This study aims to investigate the influence of the developed anisotropic grain structure on the macroscopic response through both local and non-local crystal plasticity frameworks to address the capacity of these models in capturing the realistic response. An additional subroutine is implemented (see [2]) into the crystal plasticity frameworks to obtain the slip resistance values at each material point based on grain geometries and misorientations. This allows the size dependent yielding of the crystals.

Introduction

Additively manufactured (AM) metallic alloy parts offer many benefits. The usage of additive manufacturing technology to create complex products has shown significant promise (see e.g. [3-6]). Through empirical studies over almost three decades, developments in additive manufacturing techniques have made them utilized in many industrial areas such as aerospace, automotive, construction. In these last decades, AM technology has become an important manufacturing methodology rather than a prototype production method. However, its application for manufacturing critical components is restricted by the inherent uncertainty associated with qualities, which frequently results from the variability in the manufacturing process itself (see e.g. [7]).

Some of the recent AM methods are based on melting and solidification of metallic powders during the process. Different kinds of microstructures can be resulted due to the complex thermal history of these processes which involve high temperature gradients and also high heating-cooling rates. This thermal history is highly dependent on the process parameters such as scanning strategy, hatch spacing, scan velocity. The high cooling rate in the complex heat transfer course during the AM processes results in the directional growth of grains. The thermal history influences not only the grain structure but also the grain orientation substantially (see [8]). Grain growth occurs along the direction of the highest temperature gradient where the solidification develops (see e.g. [9,10]). As a result, the final microstructures of AM products are observed to have anisotropic morphologies and consequent textures (see e.g. [11-13]). When additively made products are

examined, it becomes clear that crystal orientation alignment frequently occurs concurrently with the development of columnar grain structure (see e.g. [14-16]). Also, a common defect in AM products is their porous microstructure (see e.g. [17,18]). However, porosity is not examined in this study in order to solely focus on the grain and orientation alignment.

Additively manufactured parts show altered microstructures and mechanical properties with respect to the process parameters. Therefore, analyzing microstructures has importance for not only estimating their characteristics but also for adjusting the process parameters to achieve desirable mechanical properties.

In a previous study, the mechanical properties of microstructures consisting of elongated grain morphology are investigated through a rate dependent local crystal plasticity finite element framework (see [1]). In this paper, different crystal plasticity mechanisms are employed through different ABAQUS UMAT subroutines. First, simulations are conducted with only the local crystal plasticity framework. Then, a lower-order strain gradient crystal plasticity is implemented where, the impact of intrinsic size effects is addressed. A higher-order strain gradient formulation could also have been used as in [19,20] through a UEL, however it is omitted in the current study. A lower-order approach can be a good starting point for comparing different crystal plasticity mechanisms.

Along with the implementation of lower-order strain gradient crystal plasticity, a different mechanism is also studied to recalculate the initial slip resistance of each material point as in [2]. With this method, the slip resistance of each slip system for every material point is calculated considering grain orientations and the distance of points to grain boundaries.

The structure of this work is as follows. Firstly, the crystal plasticity frameworks used in the finite element simulations are described. Then, the method for determining model parameters and producing polycrystalline representative volume elements (RVEs) is provided. Orientation restrictions on the grains to obtain a more realistic grain alignment are given. Finally, the outcomes of crystal plasticity finite element method (CPFEM) simulations are shown and thoroughly explained for the three methods used.

Crystal Plasticity Frameworks

In the current study, first, a local finite strain rate-dependent crystal plasticity framework (see [21]) is adapted for the analyses of microstructures (see [22,23] for example applications of this framework). In this framework, the deformation gradient $\boldsymbol{F}$ is multiplicatively decomposed into elastic part $\boldsymbol{F}^e$ and plastic part $\boldsymbol{F}^p$**.** Plastic velocity gradient can be obtained by integrating the plastic slip rates $\dot{\gamma}$ overall slip systems as

$$\mathbf{L}^{\mathrm{p}}=\dot{\mathbf{F}}^{\mathrm{p}}\mathbf{F}^{\mathrm{p}-1}=\sum_{\alpha=1}^{\mathrm{N}}\dot{\gamma}^{\alpha}\,(\mathbf{m}^{\alpha}\otimes\mathbf{n}^{\alpha}) \tag{1}$$

where α defines the slip system. $\boldsymbol{m}^{\boldsymbol{\alpha}}$ and $\boldsymbol{n}^{\boldsymbol{\alpha}}$ are the slip direction and slip normal of the slip system respectively. In this work, an aluminum alloy is analyzed with all 12 slip systems of the face-centered cubic (FCC) crystal. All slip systems are active at all times, since a rate-dependent model is used. The slip rate of the slip systems $\dot{\gamma}^{\alpha}$ is governed by the power law

$$\dot{\gamma}^{\alpha}=\dot{\gamma}_0=\left|\frac{\tau^{\alpha}}{g^{\alpha}}\right|^{n} sign(\tau^{\alpha}) \tag{2}$$

where $\dot{\gamma}_0$ is the reference slip rate, τ^{α} is the resolved shear stress, g^{α} is the slip resistance and n is the rate sensitivity exponent. The slip resistance consists of statistically stored dislocations (SSDs) and geometrically necessary dislocations (GNDs) parts.

$$g^{\alpha} = \sqrt{{g_{ssd}^{\alpha}}^{2} + {g_{gnd}^{\alpha}}^{2}} \tag{3}$$

For local crystal plasticity simulations, only the hardening from SSDs is considered, which is described by the following relation,

$$\dot{g}_{ssd}^{\alpha} = \sum_{\beta=1}^{N} h^{\alpha\beta} \left|\dot{\gamma}^{\beta}\right| \tag{4}$$

where N represents the number of total slip systems and latent hardening is $h^{\alpha\beta} = q^{\alpha\beta} h^{\alpha\alpha}$, where $q^{\alpha\beta}$ is the latent hardening coefficient. Peirce and Asaro's (sech) self-hardening law is used for the self-hardening,

$$h^{\alpha\alpha} = h_0 \left|\frac{h_0 \gamma}{g_s - g_0}\right|, \tag{5}$$

where h_0 is the initial hardening modulus, g_0 is the initial slip resistance and g_s is the saturation slip resistance. The implementation of a lower-order strain gradient framework into the crystal plasticity subroutine enables the inclusion of additional hardening as a result of GNDs. This implementation allows an intrinsic length scale parameter to be defined and the size effects to be captured [24].

$$g_{gnd}^{\alpha} = g_0 \sqrt{l \eta_{gnd}^{\alpha}} \tag{6}$$

where $l = \frac{\alpha_T^2 \mu_s^2 b}{g_0^2}$ is the length scale parameter, α_T is the Taylor coefficient, μ_s is the shear modulus and b is the length of Burger's vector. Density of GNDs on a slip system α is defined as,

$$\eta_{gnd}^{\alpha} = \left|\mathbf{n}^{\alpha} \times \sum_{\beta=1}^{N} \mathbf{m}^{\alpha} \mathbf{m}^{\beta} \nabla \gamma^{\beta} \times \mathbf{n}^{\beta}\right| \tag{7}$$

Numerical Analysis

All the crystal plasticity simulations are conducted with the commercial finite element analysis software ABAQUS using brick (C3D8) elements. The material used in all finite element method (FEM) simulations is AA6016 in T4 condition. The hardening parameters are fitted in a previous study (see [1]). The hardening parameters are taken as initial hardening modulus $h_0 = 190\ MPa$, saturation slip resistance $g_s = 95\ MPa$ and initial slip resistance $g_0 = 47 MPa$. Cubic elastic coefficients for aluminum sheet are used as $C_{11} = 108.2\ GPa$, $C_{12} = 61.3\ GPa$, and $C_{44} = 28.5\ GPa$ [25]. Reference slip rate $\dot{\gamma}_0$ is taken as $10^{-3}\ s^{-1}$ and rate sensitivity parameter n is taken as 20. A strong latent hardening is assumed for aluminum and q is taken as 1.4. To observe the strain gradient effects clearly, the length scale parameter is taken as 500 μm in non-local strain gradient CPFEM simulations.

The user subroutine code (UMAT) based on [21] is modified to recalculate the initial slip resistance g_0. This modification will be referred as geometry-dependent slip resistance subroutine in the consecutive sections. With this subroutine, initial slip resistance is calculated by the distance of material points to grain boundaries and grain orientations. This theory aims to simulate the influence of dislocation piling up at grain boundaries. The details can be found in [2]. The aim of this method is to examine size effects based on Hall-Petch relation. Initial slip resistance is calculated as,

$$g_0^\alpha = \tau_0 + \frac{K\left(1-m^{\alpha'}\right)^c}{\sqrt{L^\alpha}} \quad (8)$$

τ_0 is taken as the critically resolved shear stress of a theoretically infinite crystal which is considered as zero. This value is taken as close to zero, which is 0.05 MPa. L^α is the distance of a material point to grain boundaries in the slip direction. K and c are empirical coefficients taken as 0.414 and 0.134. Their values are obtained by fitting the stress-strain curve of 300 grain RVE with 47 MPa initial slip resistance. $m^{\alpha'}$ is the Luster-Morris parameter for each slip system and is found from the misorientations of grains as $m^{\alpha'} = \left(\frac{\boldsymbol{m}_A^\alpha . \boldsymbol{m}_B^\alpha}{|\boldsymbol{m}_A^\alpha||\boldsymbol{m}_B^\alpha|}\right)\left(\frac{\boldsymbol{n}_A^\alpha . \boldsymbol{n}_B^\alpha}{|\boldsymbol{n}_A^\alpha||\boldsymbol{n}_B^\alpha|}\right)$ where $\boldsymbol{m}^\alpha$ and $\boldsymbol{n}^\alpha$ are slip direction and slip normal respectively. Subscripts A and B correspond grains A and B respectively.

Polycrystalline RVEs with 300 grains are generated through Voronoi Tessellation (see [26]). Each morphology represents different grain elongation levels and is named as Equiaxed, Needle1, Needle2, Needle3 in consecutive parts of the paper. Grain aspect ratios are (1,1,1), (0.5,1,0.5), (0.25,1,0.25) and (0.1,1,0.1) for Equiaxed, Needle1, Needle2, Needle3 respectively. Grain morphologies can be seen in Fig. 1.

10% displacement is given to RVEs as the loading condition with $10^{-3}\ s^{-1}$ strain rate. Boundary conditions are applied such that all surfaces are kept straight and it is ensured that the stress triaxiality value stays constant at 0.33 during the loading (see e.g. [27]).

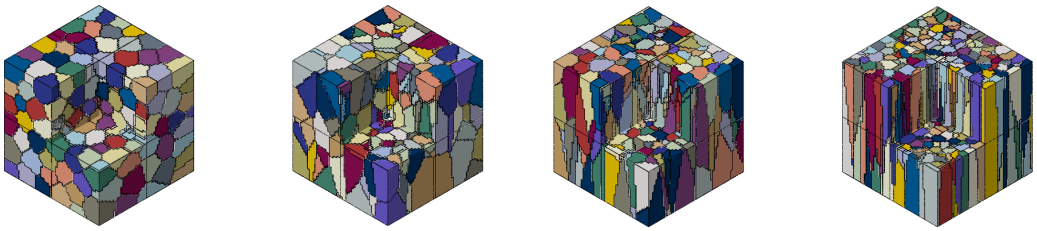

Fig. 1. Polycrystal RVE morphologies, from left to right: Equiaxed, Needle1, Needle2, Needle3.

Initially, all the RVEs are simulated at the same set of random orientations with the aforementioned crystal plasticity mechanisms separately. Following ZYX Euler convention, different orientation angle restrictions are assigned to corresponding RVEs. Crystals are tilted around the building direction (Y-axis) by restricting the X and Z rotations while the Y rotation is kept at zero. For restricted cases, [-90 +90], [-30 +30], [-10 +10] restricted intervals are assigned to Needle1, Needle2, Needle3 respectively. No restriction is applied for random orientation cases.

Numerical Results

Firstly, only the effects of grain morphologies are compared. All RVEs are assigned grains with the same set of random crystal orientations. A series of crystal plasticity finite element analyses using the three aforementioned mechanisms (i.e. local, strain-gradient, and geometry-dependent initial slip resistance subroutine in the local framework) are performed on every morphology by applying 10% strain in building-direction (Y axis) and the normal direction (Z axis) separately.

When there are no orientation restrictions on the grains (i.e., each one is randomly oriented), all three methods give very similar stress vs. strain responses. In Fig. 2a and Fig 2b, the results under the non-local crystal plasticity and geometry-dependent initial slip resistance modification are shown. Due to the presence of additional slip resistance from GND densities in the framework, higher amount of hardening with respect to the local framework is observed. However, beyond that, isotropic response is obtained for randomly oriented RVEs with all three methods.

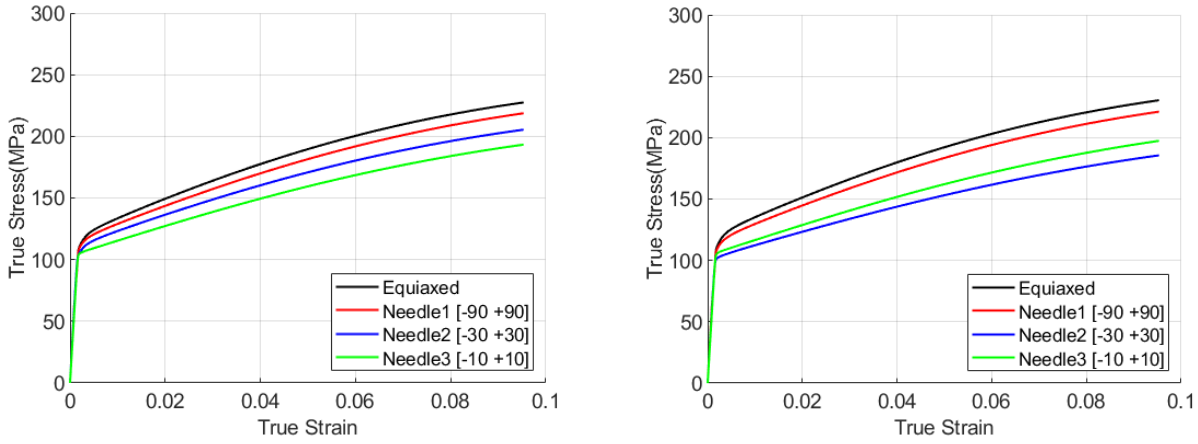
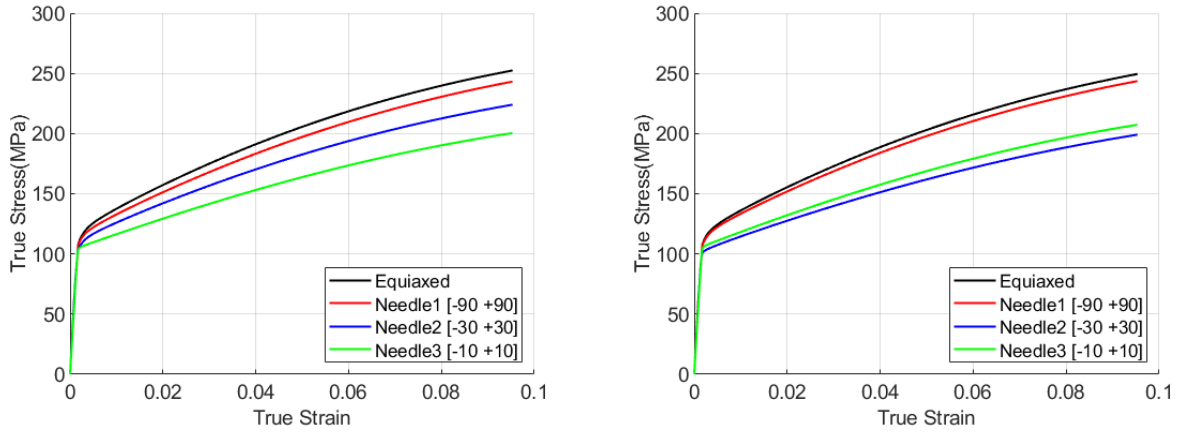
Fig. 2. Stress vs. Strain response of RVE finite element simulations with randomly oriented grains using different frameworks.



a) Building direction *b) Normal direction*

Fig. 3. Stress vs. Strain response of RVE finite element simulations with restricted crystal orientations using local framework with loading in building and normal directions.

To examine the results in a more realistic case, the crystal orientations of the grains have been increasingly aligned with the loading direction as the aspect ratio increases. The orientations of equiaxed grain morphology have been kept unrestricted. The rotations of crystals in X and Z axes have been restricted to previously mentioned intervals of Euler angles and the results are presented in Fig. 3. When the grains become more aligned, misorientations start to diminish gradually. Analyses in local framework have shown that, rather than the morphology, orientation has more impact on the mechanical response. A more anisotropic response is obtained for Needle2 case with [-30 +30] restriction compared to Needle1 and Equiaxed when the responses are compared in building and normal direction loading cases. However, the extreme case RVE with Needle3 morphology and [-10 +10] angle restriction does not show significant anisotropic response. This is because the misorientations between the grains are so small that it behaves as if there is a crystal symmetry between the grains.



a) Building direction *b) Normal direction*

Fig. 4. Stress vs. Strain response of RVE finite element simulations with restricted crystal orientations using non-local framework with loading in building and normal directions.

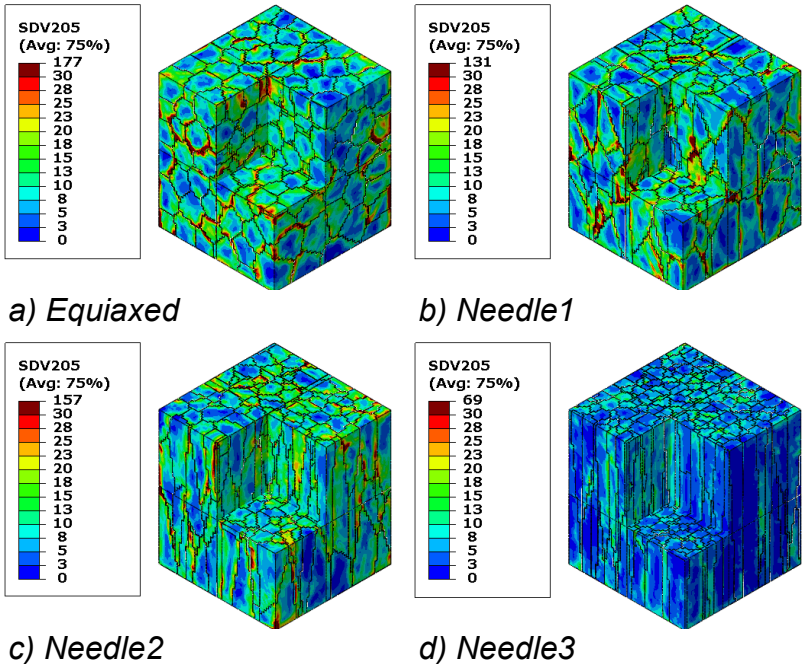


Fig. 5. Distribution of GND densities [1/mm] in RVEs from strain gradient framework simulations after loading in building direction with restricted orientations.

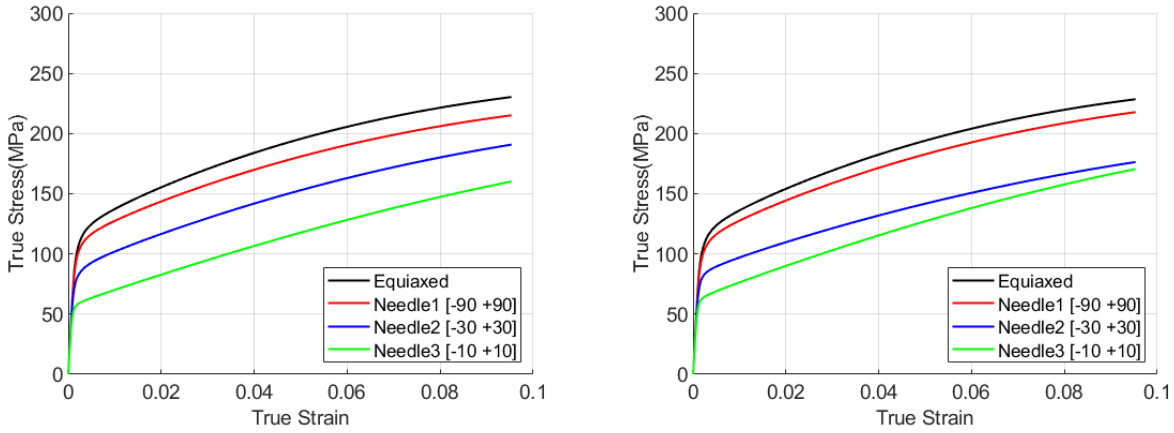
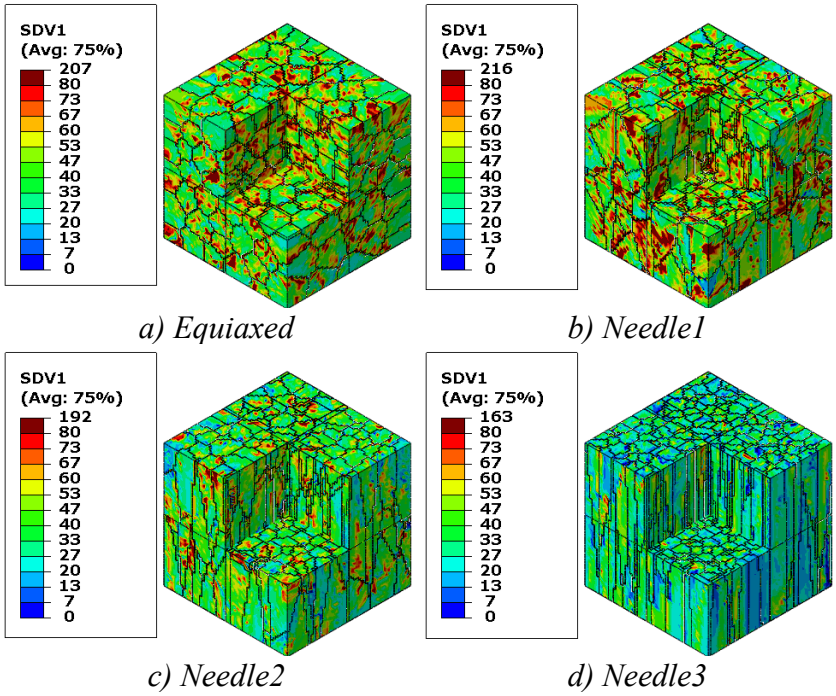
Fig. 4 shows the results of the same simulations through the strain gradient crystal plasticity framework. Needle2 shows highly anisotropic behavior compared to other morphologies similar to local framework. General trend of decrease in stress results stays same as the orientations become more restricted. However, there is an increased gap between the stress response of RVEs. This is a result of reduced misalignment between the grains causing GND densities to exist in smaller quantities. This can be seen in Fig. 5 as well, where the distributions of GND densities of all morphologies are shown. GNDs are most prominent at the grain boundaries. As the grains become more oriented in a particular direction (in this case, the building direction), the density of GNDs and their contribution to hardening begin to decrease.



a) Building direction *b) Normal direction*

Fig. 6. Stress vs. Strain response of RVE finite element simulations with restricted crystal orientations using modified after loading in building and normal directions.



a) Equiaxed *b) Needle1*

c) Needle2 *d) Needle3*

Fig. 7. Distribution of the modified initial slip resistance g_0 in RVEs with restricted orientations.

The stress vs. strain results of simulations using the geometry-dependent initial slip resistance calculation subroutine are shown in Fig. 6. The most important factor here is that both of the previous methods do not affect the yielding point of the material significantly. This is because the initial slip resistance of the material is taken as constant. However, when the influence of morphology and orientation on the initial slip resistance is taken into account, overall yielding points of the RVEs also differ. As the grain orientations become more aligned, the yield stress of the RVE decreases as a result. In Fig 6b, it can be seen that stress values of Needle2 and Needle3 become closer when they are loaded in normal direction as opposed to building direction. This is a result of modifying the initial slip resistance. In both previously examined methods (i.e. local and non-local cases), Needle3 shows a higher stress response for normal direction loading. However, modifying the g_0 decreases the yield point so much that the stress value of Needle3

becomes lower than that of Needle2 at the end of displacement. This is a different result compared to ones obtained with other frameworks, since Needle2 shows the weakest response in normal direction in both local and non-local methods. Similar in other methods, anisotropic behavior is the strongest in Needle2.

The distribution of initial slip resistance calculated from the grain geometries and orientations are shown in Fig. 7. The randomly oriented Equiaxed morphology and the [-90 +90] restricted Needle1 morphology shows a similar distribution. This is also seen in Fig. 7 from their yield stress distributions being similar. On the other hand, when the misorientation between grains decreases in Needle2 and Needle3, there are fewer points with high initial slip resistance.

Summary

In this paper, anisotropic granular morphologies which developed in additive manufacturing techniques are examined with different crystal plasticity frameworks. Grains are elongated step by step for different RVEs.

Firstly, only the effect of morphology is examined with different crystal plasticity frameworks. It has been observed that when the strain gradient framework is taken into account, morphology without providing the proper texture does not significantly change the outcomes as in the prior study [1]. However, using a non-local model has benefits in terms of locating the GND density accumulations, especially at the grain boundaries. The influence of texture on GND densities is discussed and results have proven that lower-order SGCP can be a useful framework for the recognition of dislocation pile-ups in additive manufacturing products.

Different stress responses are obtained for different loading directions when grain orientations are restricted. Even though the lower-order SGCP framework contributes to hardening and makes stress responses stronger, it does not change the general trend observed in the previous study. In Needle1's case, a large range of possible orientations does not yield an anisotropic response regardless of the framework used in simulations. Needle2, on the other hand, shows a highly anisotropic response from the results with all frameworks since orientation restrictions on the grains is much narrower compared to Needle1. While Needle3 is assigned with most narrow orientation restrictions, the material shows less anisotropic behavior than Needle2. This is a result of building and normal directions lying on the symmetry axes of FCC crystal. Heavily aligning all grains with the loading direction causes the material to act similar to a single crystal specimen since grain misorientations become small. Without a modification of the initial slip resistance of grains, Needle3 displays a stronger response compared to Needle2 in normal direction. However, by modifying its initial slip resistance based on grain geometries and orientations, the yield stress of Needle3 is predicted to be lower than all other morphologies in normal direction.

Abstract. As an easily processable Al alloy, AlSi10Mg manufactured by Laser Powder Bed Fusion (LPBF) has received a lot of attention so far. However, it is well known that microstructural heterogeneities at the scale of the melt pool – in particular the weaker Heat Affected Zone whose microstructure evolves during the deposition of the next layer – exert a strong detrimental effect on the ductility of AlSi10Mg LPBF. In this work, a 2D Finite Element (FE) model is developed in order to tackle this issue and help in guiding the optimisation of LPBF process parameters. The model is calibrated using experimental measurements of the melt pool height. Furthermore, to allow for the efficient simulation of 5 successive layers, a remeshing procedure is implemented. No heat accumulation is observed during the deposition of these 5 layers. The thermal history of the HAZ can thus be studied with a thermal model for one layer.

Introduction

The Laser Powder Bed Fusion (LPBF) of Al alloys has been the subject of extensive work for almost a decade, dating back to the pioneering work of Thijs et al. [1] and Olakanmi et al. [2]. Among the wide variety of available Al alloys, the hypoeutectic AlSi10Mg alloy has received a particular attention in view of its good castability and weldability, its high melt fluidity and low shrinkage upon solidification [3-5]. However, microstructural heterogeneities at the scale of the melt pool remain a matter of concern, by compromising the ductility of AlSi10Mg LPBF components [6,7]. Indeed, the Heat Affected Zone (HAZ) whose microstructure evolves during the deposition of the subsequent layer has been shown to play an essential role in the tensile fracture of AlSi10Mg LPBF. The Si eutectic precipitates that are originally finely distributed in a cellular structure, tend to coarsen and globularize under the influence of the heat input associated to the deposition of next layer, as can be seen in Fig. 1. As a result, the fine cellular structure is broken, thus creating a weaker zone for damage initiation [6]. The microstructural homogeneity and the ductility of AlSi10Mg LPBF components may be restored to some extent by thermal or thermo-mechanical post-treatments but this improvement in ductility is achieved at the cost of a loss in strength [7-9]. As an alternative to post-treatments, optimisation of the processing parameters with the aim of minimizing the thickness of the HAZ appears as a viable option [10]. Physically based and validated Finite Element (FE) models are essential tools in that respect.

In this work, a 2D FE model is developed in order to tackle this issue and help in guiding the optimisation of LPBF process parameters. Two different calibration procedures were tested i.e. using experimental measurements of (1) the cell size or of (2) the melt pool height. Furthermore, to allow for the efficient simulation of 5 successive layers, a remeshing procedure is implemented.

Materials and Methods

Sample fabrication.

In order to obtain experimental data for the calibration and validation of the FE model, two sets of AlSi10Mg LPBF samples, named as set A and set B, were fabricated under very distinct processing conditions. Samples of set A were processed using a MTT SLM 250 machine. The building parameters were as follow: a laser power of 175W, a scan speed of 195 mm/s, a powder layer thickness of 60 µm and a pre-heating temperature of 200°C. Samples of set B were fabricated using an EOS SLM equipment and the following processing parameters: a laser power of 370W, a scan speed of 1300 mm/s and a powder layer thickness of 40 µm without pre-heating i.e. considering a building platform temperature of 35°C. Both sets of samples were fabricated in the vertical direction. The processing parameters of set A were chosen to enhance the thickness of the HAZ, as opposed to the processing parameters of set B. More details may be found in [6,8,10].

Characterization.

Samples for microstructural characterization were ground and polished following standard practices and then etched using Keller's reagent (95 vol.% distilled water, 2.5 vol.% HNO_3, 1.5 vol.% HCl and 1 vol.% HF). Scanning electron microscopy was carried out using a Philips XL30 microscope. Image analysis was performed using the ImageJ software to determine the Al Cells size in the MP fine, MP coarse and HAZ (Fig. 1). The melt pool height was only measured on the last deposited layer, since the melt pool of the previous layers are overlapped due to the systematic re-melting of the underlying layer during the deposition of each new layer.

Finite Element model.

A 2D thermal finite element model of the LPBF process has been developed as follows. The temperature evolution in the part is given by the non-linear equation for an isotropic material:

$$\nabla . k\nabla T + Q = \rho c_p \frac{\partial T}{\partial t} \quad (1)$$

where ∇ is the gradient operator; k is the thermal conductivity, Q the power generated in the part, ρ the density, c_p the heat capacity and t the time. The enthalpy of fusion and vaporization are included in the heat capacity that is thus defined as an apparent heat capacity.

The boundary condition at the free surface for the heat exchange is defined as:

$$-k\nabla T.n = q_{laser} - h(T - T_{amb}) - \mathcal{E}\sigma\left(T^4 - {T_{amb}}^4\right) \quad (2)$$

where n is a unit vector normal to the surface; T_{amb}, the ambient temperature, h, the convection coefficient (taken as 20 W/m^{2}K); σ, the Stefan-Boltzmann's constant (5.67×10^{-8} W/m^{2}K^4), $\mathcal{E}$, the emissivity and q_{laser} the laser heat source. The laser is modeled by a Gaussian heat source:

$$q_{laser} = \frac{2AP}{\pi R^2} exp\left(\frac{2r^2}{R^2}\right) \quad (3)$$

where P is the laser power (i.e. 175 W or 370 W); R, the laser beam radius (40 µm); A, the laser absorbed energy; r, the radial distance from the beam centre.

The thermophysical properties are considered temperature dependent. These properties are obtained from [11] for the base plate made from aluminium alloy 2024, and from [8] for the AlSi10Mg powder bed and consolidated part. The laser absorbed energy A is chosen as a tuning parameter of the 2D FE model and is obtained through calibration based on experimental observations. In this study, two different calibration procedures have been tested: (1) based on experimental measurements of the cell size and (2) based on experimental measurements of the melt pool height. The academic finite element code LAGAMINE is used. It is developed since 1984 at the University of Liege [12-15]. To switch between the desactivated elements, the unfused powder, to the bulk material and vary the bulk properties, element birth and death technique is employed. The mesh of the system and boundary conditions are summarized in Fig. 2.

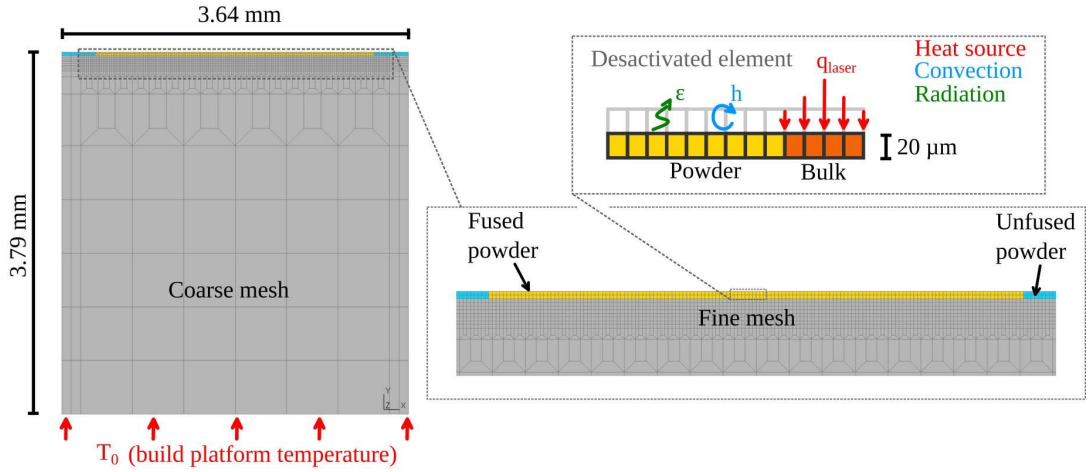

Fig. 2. Finite element domain with the boundary conditions: laser heat source, heat loss by convection, radiation, and build platform temperature. Desactivated elements are illustrated to highlight the birth and death technique.

The dimensions of the studied domain are 3.79 mm in height and 3.64 mm in width, that is large enough for the melt pool to reach a thermal steady state and to reproduce the heat drain effect of the build platform and previous solidified layers. The domain is discretized with 2D quadrilateral elements. Furthermore, the domain is divided in two zones: a fine meshed zone of size ranging from 40 µm to 2.5 µm where the laser is applied, fine enough to capture the steep thermal gradient, and a coarse zone below to save in number of elements and computation time.

In particular, a 2D multilayer simulation of the LPBF process was performed in this work, in order to investigate the effect of the number of fused layers on heat accumulation and thus on the thermal history of LPBF AlSi10Mg components. To reduce the computational costs of this

Materials Research Proceedings 28 (2023) 189-198 https://doi.org/10.21741/9781644902479-21

multilayer model, that can be high even in 2D, a remeshing strategy has been developed in order to keep the number of node constant independently of the number of layers under consideration. It consists in picking the temperature field at the end of the simulation for the first layer and set this temperature as an initial nodal condition for the second layer. This operation is then repeated for the third layer and so forth… As shown in Fig. 3, the change in powder bed height with the number of fused layers is incorporated in the coarse part of the mesh while the fine part remains the same. This approach allows to perform multilayer simulations while keeping the computation time reasonable.

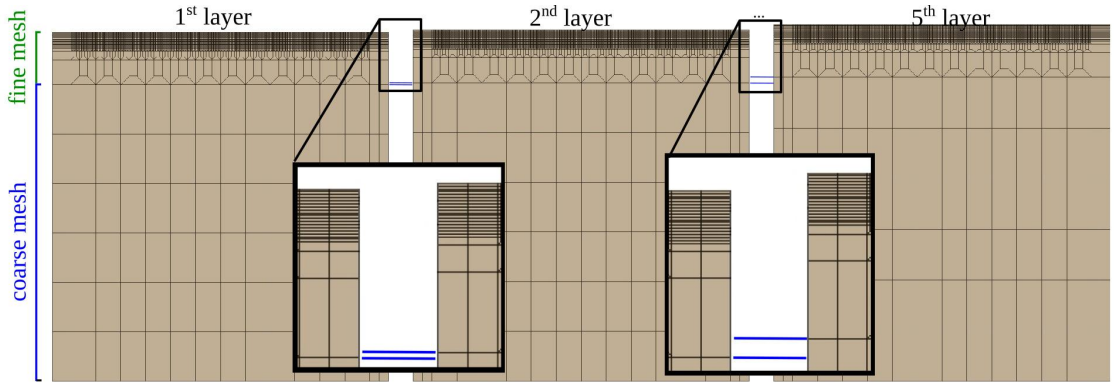

Fig. 3. Meshed domains for the first, second and fifth layer. The number of elements remain constant between the domains. The fine mesh part are the same between the domains while the coarse part changes.

Results and Discussion

Sensitivity to the mesh size.

Convergency was tested based on the size of the fine mesh zone ranging from 40 µm to 5 µm in Fig. 4. Based on the analysis of the line profile in Fig. 4(b) extracted from the temperature maps of Fig. 4(a), mesh convergency is shown. A mesh size of 10 µm offers a good compromise between accuracy and computation time. This is also demonstrated when analyzing the melt pool area with the laser beam travel time in Fig. 4(c). We should notice that it takes 1.8 ms for the melt pool to reach a steady state where its size no longer changes. Therefore, the size of the model is large enough to study the thermal history in the heat affected zone.

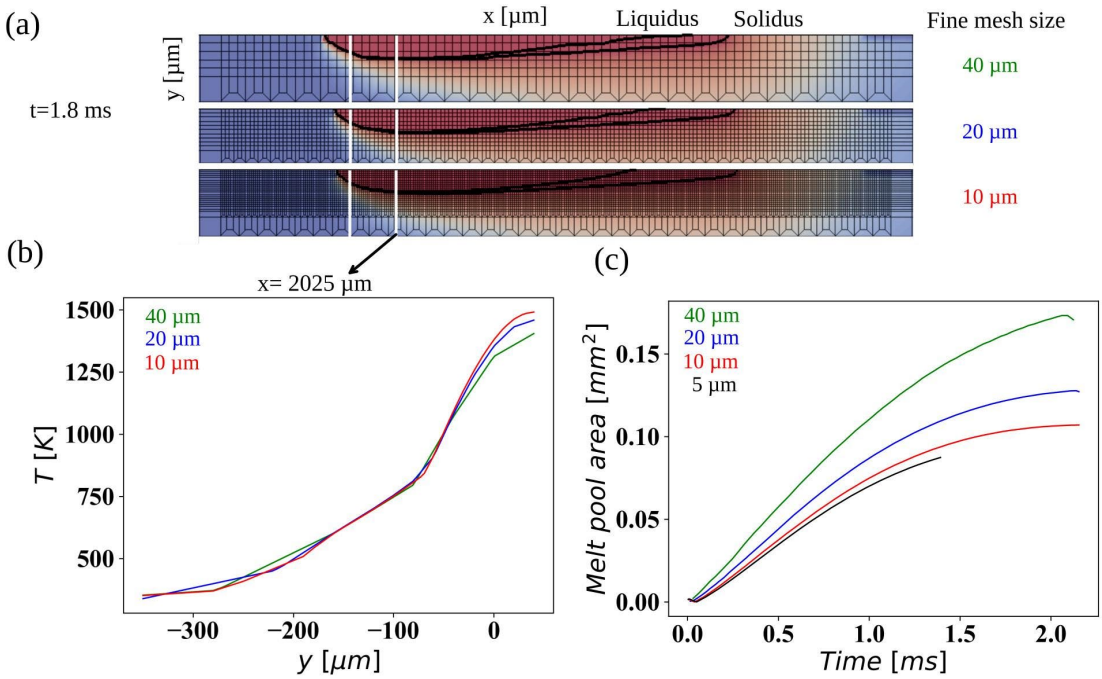

Fig. 4. (a) Temperature map of the melt pool taken at t=1.8 ms for different mesh refinements. (b) Corresponding temperature line profile at x = 2025 µm position and (c) melt pool area with the laser beam travel time.

Model calibration.

The results of the calibration of the 2D thermal model under the processing parameters of set B are shown in Fig. 5(a) for the calibration based on the melt pool height and in Fig. 5(b) for the calibration based on the cell size that can be computed from the cooling rates extracted at the liquidus isotherm line [6,8,10,16]. Fig. 5 shows a remarkable result in that the 2D FE model can only be calibrated against the melt pool height. Indeed, the cell size values computed from the FE model are systematically larger than the experimental values. This is a marked difference to previous reports concerning analytical model as e.g. Rosenthal's model [6,10,16] for which calibration based on cell size may be preferred in view of its greater flexibility as cell size may be measured at any location within the sample contrarily to the melt pool height that is only accessible in the last deposited layer.

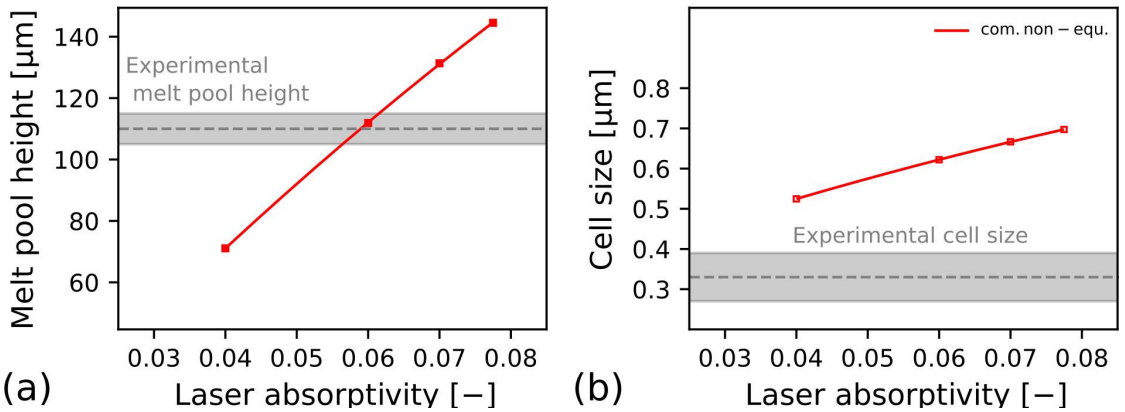

Fig. 5. (a) Melt pool height and (b) cell size calibration for the 2D thermal FE model.

This observation can be understood considering that the cell size is computed from the cooling rate that depends in turn on the thermal gradient. The heat flux transmitted by conduction in the part is also proportional to the thermal gradient. However, in the present 2D FE model, the heat flux is not evacuated through a surface but through a line. In this case, fewer paths are available for these fluxes. Therefore, the 2D model systematically experiences a lower thermal gradient compared to a 3D model. The 2D FE model will thus always overestimate the cell size.

The effect of the number of fused layers for samples of set B is studied by analyzing the thermal history of three points of interest (POIs) in Fig. 6. These POIs are located in such a way that their respective spacings correspond to 2 times the powder bed thickness, i.e. 40 µm. In this way, the thermal history can be compared between the fused layers. As can be seen in Fig. 6, the thermal history of POI1 exhibits five peaks corresponding to the five fused layers. The first peak corresponds to the maximum temperature experienced during the direct application of the heat flux of the laser. In view of the location of the three POIs, the maximum temperature of POI2 is then reached during the fusion of the third layer while the maximum temperature of POI3 is reached for the fifth layer. When comparing the temperature of the first peak for the three POIs, it can be seen that they have the same value around 2700K. In a similar way, the second and the third peaks of POI1 and POI2 match each other with values around 1750K and 1350K, respectively. The good match between the peaks for the three POIs indicates that they is no rise in temperature as the successive layers are fused. Furthermore, this observation is confirmed qualitatively by looking at the temperature distribution around the melt pool in Fig. 6(b-c). Indeed, the temperature distribution and the melt pool size obtained for the first layer (Fig. 6(b)) and for the fifth layer (Fig. 6(c)) are very similar. The cold area at the right-hand side of Fig. 6(c) corresponds to unfused powder.

This observation that the heat accumulation remains negligible during the deposition of five successive layers can be explained by considering both the thermophysical properties of AlSi10Mg and the processing conditions. Indeed, LPBF AlSi10Mg exhibits a high thermal conductivity with values ranging between 110 and 130 $W*m^{-1}*K^{-1}$ [8]. These values are much higher than those reported for LPBF Ti6Al4V (5-34 $W*m^{-1}*K^{-1}$)[17] or stainless steel 316L (14-34 $W*m^{-1}*K^{-1}$) [18] for which heat accumulation is observed. The high thermal conductivity of LPBF AlSi10Mg thus allows the rapid evacuation of heat from the melt pool and its vicinity towards the top surface of the part where it can be dissipated first through radiation just after the laser is switched off and later through convection. Moreover, the high laser scan speed (1300 mm/s) combined with a medium laser power (370W) used for the processing of set B samples result in relatively low heat input when compared to the processing parameters of [17] and [18], which also contributes to the negligible heat accumulation.

Microstructural observation of the HAZ dimensions along the whole sample height brings further confirmation of the above finding. Indeed, the HAZ has been found to exhibit a constant width throughout [8], thus also suggesting that the average temperature in the part remains constant. This result implies that the thermal history of the HAZ in LPBF AlSi10Mg processed under relatively low heat input is independent of the number of fused layers, and that it can be studied using one layer FE thermal model.

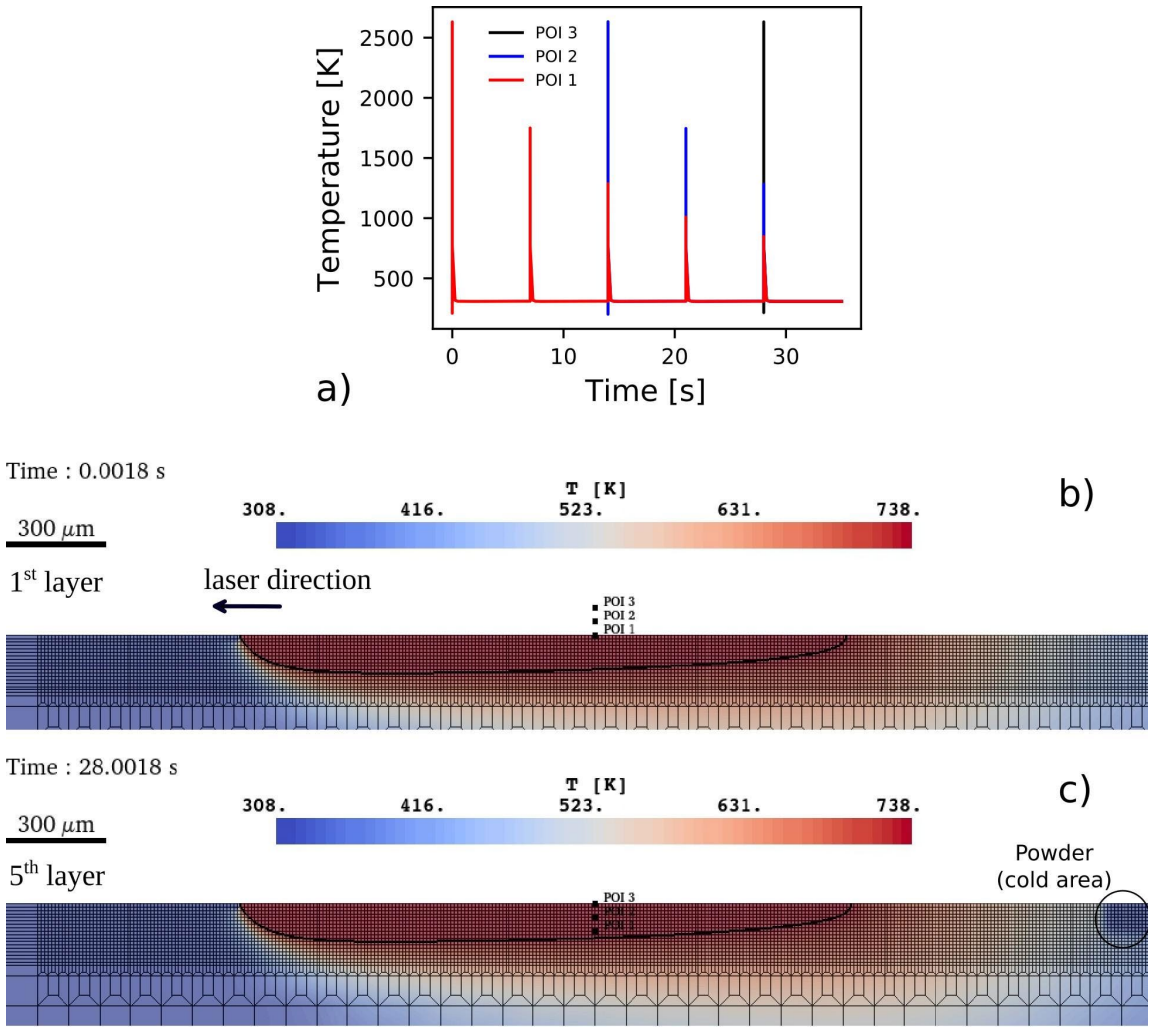

Fig. 6. (a) Thermal history of three POIs; temperature maps (b) for the first layer and (c) for the fifth layer.

The influence of the processing parameters on the thermal history of the HAZ is studied by comparing the result of FE simulations for the two sets of processing parameters A ("Sirris", with a relatively low laser power of 175W, a slow scan speed of 195 mm/s and build platform temperature of 200°C resulting in a relatively high heat input) and B ("Anyshape", with a laser power of 370W, a high laser scan speed of 1300 mm/s and build platform temperature of 35°C resulting in a relatively low heat input). These two parameters sets have been selected as (1) they are far enough from each other to expect different thermal histories and (2) the corresponding microstructures have been characterized in details [8].

The thermal histories in the HAZ for the two sets of processing parameters are plotted in Fig. 7(a). For set B (Anyshape), a peak of temperature is observed at 650K lasting for 1.5 ms. For set A (Sirris), on the contrary, the peak is wider, lasting over 2.5 ms. In the latter case, the end of the peak is not clearly visible as the temperature of the peak does not fall back to 473K, that is the build platform temperature, within the frame of the simulation.

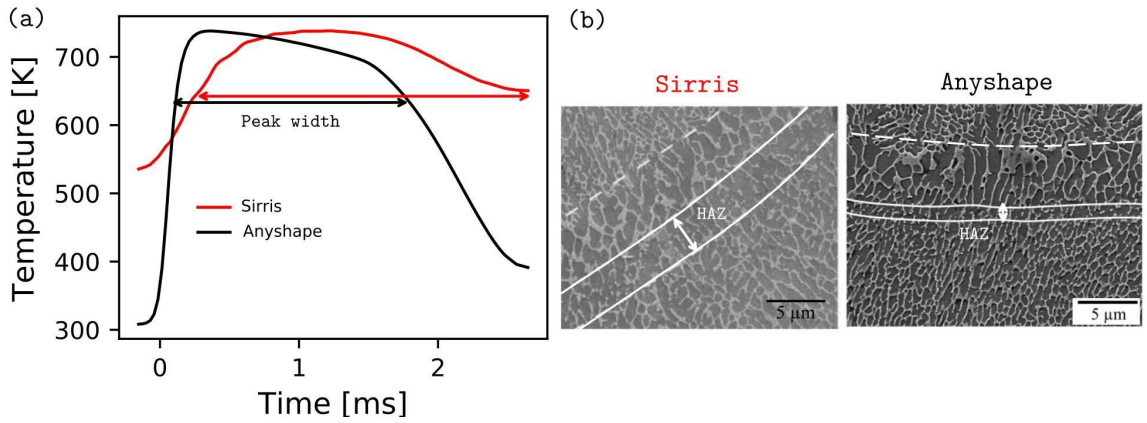

Fig. 7. (a) Thermal history of the HAZ and (b) corresponding SEM micrographs for set A (Sirris, average HAZ size: 5 µm) and set B (Anyshape, average HAZ size: 1.3 µm).

The difference observed between the duration of the peaks of temperature for the two different sets of processing parameters can first be explained in terms of the input energy. This energy is equal to A921 $J.m^{-1}$ for set A (Sirris) while it is A284 $J.m^{-1}$ for set B (Anyshape) (here, the A coefficient stands for the laser absorptivity). The excess energy injected under the processing parameters of set A takes longer to be evacuated from the part, giving way to a large temperature peak. Moreover, the build platform temperature also plays a role: a higher build platform temperature (set A) leads to smaller thermal gradient and consequently to a decrease in heat conduction, which again tends to increase the width of the peak. These observations are in agreement with the experimental HAZ size shown in Fig. 7(b). The results from the FE simulations are thus consistent with the experimental observations.

Summary

A 2D FE model for the thermal history of LPBF of AlSi10Mg is developed and calibrated using experimental measurements of the melt pool height. In order to allow for the efficient simulation of the deposition of five successive layers, without incurring excessive computational cost, a remeshing procedure is implemented by keeping a constant number of nodes independently of the number of fused layers. The results from the multilayer FE simulations highlight that no heat accumulation is observed in LPBF AlSi10Mg under processing conditions corresponding to relatively low heat input. In this case, the thermal history of the HAZ is independent of the number of fused layers, and it can be studied using a thermal FE model for one single layer. Indeed, the influence of two different sets of processing parameters on the thickness of the HAZ is correctly predicted by single layer FE simulations.

Keywords: Aluminum-Matrix Composites (AMCs), Direct-Vacuum-Casting (DVC), Direct Energy Deposition (DED), Additive Manufacturing (AM)

Abstract. Aluminum-Matrix Composites (AMCs) are particle-reinforced aluminum matrix composites that are well-established in high-performance lightweight components in the automotive and aerospace industries. So far, the use of AMC materials has been limited to components manufactured using casting technology (e.g. brake discs). The adaption of AMC materials in Additive Manufacturing (AM) processes, such as powder feedstock for Direct Energy Deposition (DED), is dependent on the availability of the corresponding semi-finished product. An approach for the production of such a semi-finished product is presented in the current work. This study presents, how powder as semi-finished product for the DED processes, is produced from cast ingots manufactured by Direct-Vacuum-Casting (DVC). The novel DVC process allows a SiC_P particle content of up to 35%, whereas conventional AMC casting processes can only achieve a fully embedded SiC_P particle content of up to 20%. Particular attention is paid to ensuring that the SiC_P particles remain completely embedded in the aluminum matrix after the semi-finished product has been produced. However, there is currently not an extensive literature existing on semi-finished products from AMC materials in AM processes. Therefore, in these investigations, ultrasonic atomization technology was used to produce of AMC powder with an average size of 80 µm as a feedstock material. The microstructure analysis of this powder demonstrated the presence of primary SiC_P particles with non-optimal distribution. Nevertheless, the AMC powder was used in the subsequent DED process studies. It was possible to develop the fundamentals for the deposition processing of AMC powder. As demonstrated by microscope techniques, secondary SiC_P particles were precipitated in an aluminum matrix with complete embedding during deposition, pointing the way forward to develop AMC powders as semi-finished products in AM processes.

Introduction

Aluminum matrix composites (AMCs) are composed of two material systems situated in one material. The aluminum alloy represents a matrix that utilizes low density and corrosion resistance. Ceramics are a possible reinforcement component of the hardness and wear resistance. Due to this unique combination of properties, AMCs are pertinent in various industrial sectors, such as the automotive and aerospace industries [1]. Conventionally, solid or liquid processing routes are available to produce AMC parts, such as sintering, stir casting, and squeeze casting [2]. These processes enable the production of AMC parts with completely embedment and an even distribution of ceramic particles in the matrix. The performance of AMC parts can be further enhanced by increasing the fraction of ceramic particles in the matrix. Therefore, the novel casting processes as Direct-Vacuum-Casting (DVC) allow a SiC_P particle content of up to 35%, whereas

conventional AMC casting processes can only achieve a fully embedded SiC_P particle content of up to 20% [3]. However, the disadvantages of conventional processes are high tooling costs, limited component geometry, and size. Therefore, AM technologies are currently being developed, enabling the production of AMC components without the tooling and lead-time required in conventional processes [4].

The processing of AMCs using AM is still in the initial stage due to the lack of technologies to produce feedstock materials, especially AMC powders. The appropriate morphology, size, and chemical composition of AMC powders are crucial for the AM technologies, such as Laser Powder Bed Fusion (L-PBF) or Direct Energy Deposition (DED), to obtain fully dense components. Also, the uniform distribution of the reinforcement phase within/around the alloy powder particles is significant to achieve the desired mechanical performance of AMC components. The available methods to fabricate AMC powders are ball milling [5] or gas atomization [6]. During the ball milling, AMC powders arise mechanically by the collides of powder particles. The powders produced by this method exhibit, e.g. less sphericity and a mismatch between the reinforcement and the matrix. The more desirable approach to fabricating AMC powders is gas atomization, where the initial material is melted in a crucible and then sprayed by high-pressurized gas jets. This method ensures the production of spherical AMC powders with a uniform distribution of ceramic particles in the matrix. However, a prerequisite to fabricating such powders is a sufficiently long homogenization (by separately added ceramic particles) during melting to avoid segregation. Therefore, using a previously homogenized AMC material, e.g. by a novel DVC, could reduce the processing time of powder production and ensure good powder properties.

The current work presents an approach to the production of AMC powder. An AlSi9Mg aluminum alloy reinforced with 20 vol% SiC_P particles (SiC_P /AlSi9Mg) was considered. The initial material SiC_P /AlSi9Mg was manufactured by DVC and then atomized into SiC_P /AlSi9Mg powder using a novel ultrasonic atomization (UA) technology. In subsequent DED process studies, it was possible to develop the fundamentals for the deposition processing of SiC_P /AlSi9Mg powder. The microstructure evolution of SiC_P /AlSi9Mg powder and as-deposited SiC_P /AlSi9Mg material were investigated using different microscope techniques to determine the presence of SiC_P particles and their embedment behavior in the matrix.

Material and methods

Initial material.

AlSi9Mg aluminum alloy reinforced with 20 vol% SiC_P particles (SiC_P /AlSi9Mg) manufactured by the DVC process [3] was used in this work. The average size of SiC_P was 9.3 µm (=F600). The chemical composition of the aluminum matrix AlSi9Mg is listed in Table 1.

Table 1. Chemical composition of AlSi9Mg alloy in [wt.%] according to the EN AC-43300.

Si	Mg	Fe	Cu	Mn	Zn	Ti	Pb	Al	Others
9.0 - 10.0	0.25 – 0.45	<0.19	<0.05	<0.1	<0.07	<0.15	<0.03	Balance	0.1

Powder fabrication.

The SiC_P /AlSi9Mg powder was produced in the company 3DLab on the ATOLab+ machine using UA technology. In this method, the feed rods are gradually melted by the welding arc, creating a melt pool on the vibrating platform. The droplets are separated from the melt pool by ultrasonic vibrations and discharged by the inert gas flow. During the discharging stage, the formed droplets are solidified leading to the production of powder particles. The atomization process of investigated material was carried out in an atmosphere of pure argon (>99.998%) with a flow rate of 15 – 20 $Lmin^{-1}$. A significant process parameter was the vibration frequency of 35 kHz, the

amplitude of 80%, and the arc current of 130 A. Finally, the atomized SiC_P /AlSi9Mg powder was sieved with a mesh size of 100 µm.

Specimen manufacturing.

DED is performed with a laser metal deposition (LMD) system, Lunovu e-LMD. The LMD system consists of a 2.5 kW solid state laser power source, a coaxial nozzle corresponding powder feed unit, a 5-axis kinematics and a scanner (see Fig. 1). Laser wavelength and spot diameter are 960 – 1080 nm and 1.6 mm, respectively. Argon is used as a shielding gas with a 12 $Lmin^{-1}$ flow rate to avoid the atmospheric contamination. The nozzle uses a 3 $Lmin^{-1}$ powder gas flow rate to carry the powder to the melt pool. Substrate – nozzle distance is 13 mm to focus the laser and powder, simultaneously. The rotation of substrate is chosen between 5 – 10° angle to prevent the reflection (see Fig. 1b).

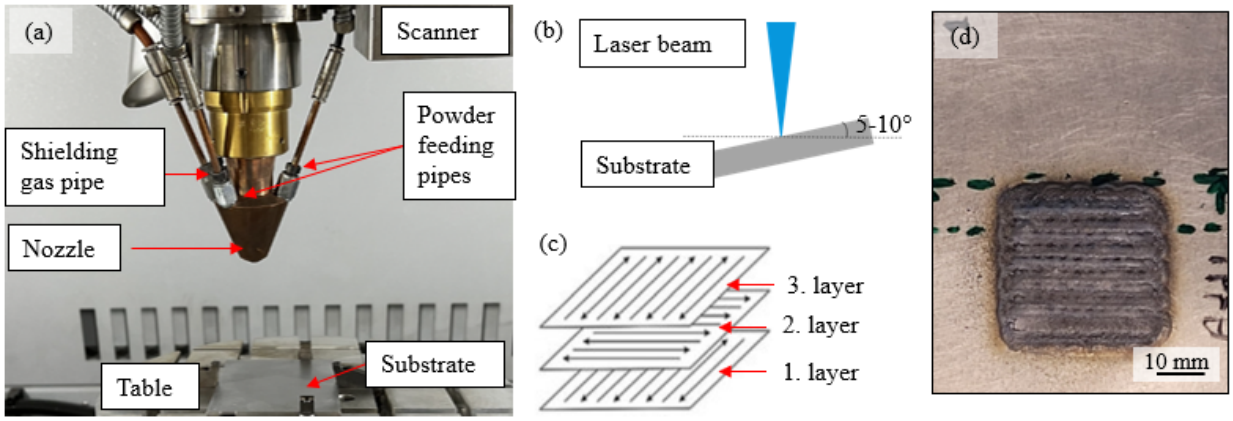

Fig. 1. (a) LMD system components, (b) demonstration of the rotation of substrate and (c) deposition strategy of the additively manufactured part.

The cuboid (length 30 mm, width 30 mm, high 2 mm) was deposited with a bidirectional scanning strategy (with a rotation of 90° to the scanning direction) (see Fig. 1c). The process parameters for the deposition of this part are listed in the Table 2. The distance between parallel track lines was defined as the hatch distance and was approximately 1.7 mm. The number of layers was 6. The overview of the additively deposited part is presented in Fig. 1d.

Table 2. Parameter setup for the manufacturing of the cuboid by DED process.

Laser Power, [W]	Scan Speed, [mms^{-1}]	Powder feed rate, [$gmin^{-1}$]
1750 (1. Layer) 1800 (Upper Layers)	500	1.3

Powder analysis.

To investigate the morphology (=sphericity) and distribution size of powder particles, scanning electron microscope (SEM) (Phenom XL, Thermofisher Scientific), equipped with a Secondary Electron (SE) detector was used. The imaged powder particles were analyzed with the integrated software ParticleMetric in the SEM to determine the distribution size and sphericity, represented as aspect ratio. The aspect ratio is an index for sphericity, where an aspect ratio of 1 equates to ideal powder sphericity. Approximately, one hundred powder particles were analysed.

For the microstructure analysis, the powder particles were ground using silicon carbide grinding papers with 1200 grit size and oxide polished (0.05 µm silica solution, Struers OP-S Suspension) using a vibratory polishing machine. The Digital Microscope (DM) VHX-7000 (Keyence Deutschland GmbH) was used to investigate the presence, size, morphology, and embedment behaviour of particles in the matrix of powder particles. The size of the particles was measured

with the integrated software in the DM on approximately 25 particles. The chemical composition of particles was measured by SEM using the energy-dispersive X-ray spectrometer (EDX) to determine their type.

Analysis of as-deposited specimen.

To investigate the porosity and microstructure of the as-deposited specimen, the cuboid was sectioned lengthwise to the deposited direction. The sectioned sample of this cuboid was then ground on silicon carbide grinding papers with grit sizes from 240 to 2500, polished using three steps diamond suspension (6 µm, 3 µm and 1 µm), and oxide polished (0.05 µm silica solution, Struers OP-S Suspension). The determination of porosity was carried out using the integrated software in the DM. The microstructure analysis of the as-deposited specimen was carried out in the same way as in the case of powder.

Results and discussion

Initial material.

SEM image of initial microstructure of as-cast SiC_P /AlSi9Mg is presented in Fig. 2. This microstructure exhibited a uniform distribution of SiC_P (primary) particles in the aluminum-based matrix.

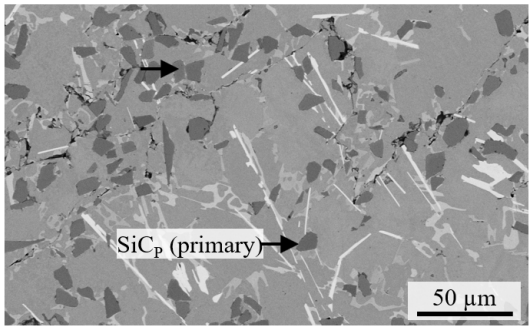

Fig. 2. SEM BSE image of initial microstructure of as-cast SiCP /AlSi9Mg.

Powder analysis.

SEM SE image of powder particles of SiC_P/AlSi9Mg is shown in Fig. 3 a. The powder particles were spherical and free of satellite particles. The size distribution and the aspect ratio (=sphericity) of powder particles in cumulative frequency are depicted in Fig. 3 b,c. The results have shown that the average size (d50) of powder particles was 80 µm. The particle size distribution (between d10 and d90) ranged between 63 µm and 92 µm that was suitable for DED process. The powder particles exhibited very good sphericity, only 10 % of all particles had an aspect ratio below 0.98 (d10) (see Fig. 3 c).

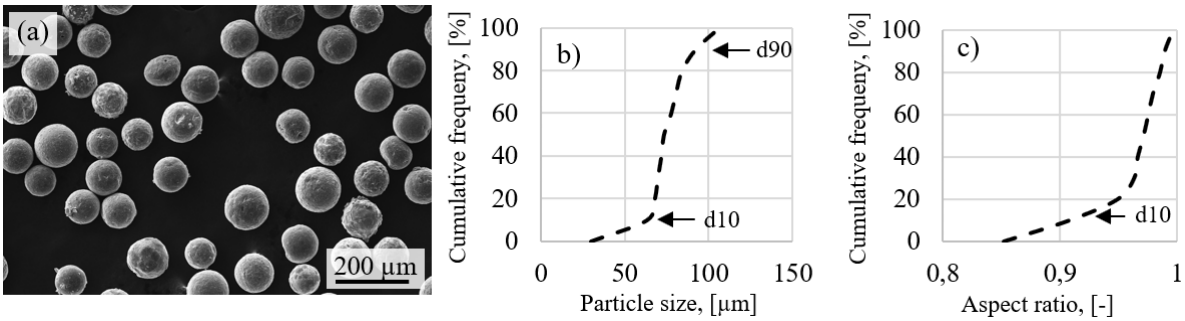

Fig. 3. (a) SEM SE image, (b) particle size distributions and (c) aspect ratio of SiCP /AlSi9Mg powder.

DM images of powder particles of SiC_P /AlSi9Mg in cross-sections are presented in Fig. 4. The powder particles exhibited three predominant types of particles. Their chemical composition was locally determined using EDX analysis (see Table 3), indicating the presence of SiC_P (primary), Al-Si-C and Al-C particles.

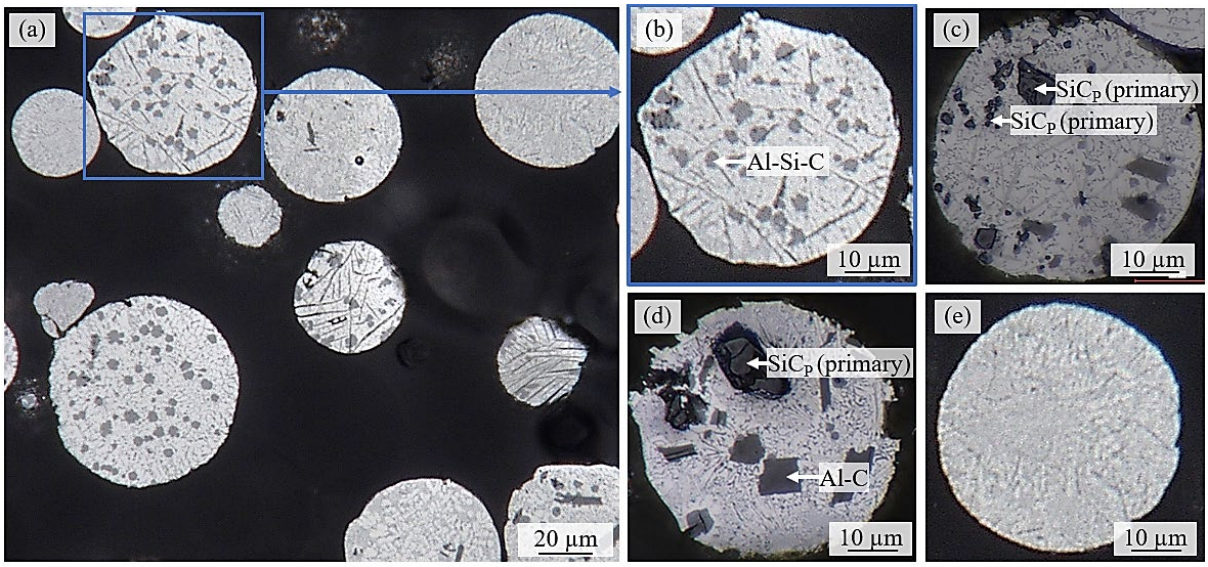

Fig. 4. DM images of particles of SiCP /AlSi9Mg powder in cross-section.

The similar morphology of the detected SiC_P particles in the powder particles, such as in the initial material, suggests that these particles exhibited resistance during welding arc melting (atomization process) and were transferred into the powder without re-melting. Therefore, the SiC_P in powder particles were determined as primary. However, their average size decreased from 9.2 µm (as-cast) to 4.5 µm (powder), which indicates their partial dissolution. Some primary SiC_P particles had internal cracks due to high thermal stress during the rapid solidification of droplets into powder particles. Furthermore, voids were formed at the interface between these SiC_P particles and the aluminum-based matrix, indicating the non-optimal embedment of these SiC_P particles in the matrix. The presence of primary SiC_P particles was not determined in every particle, indicating their non-uniform distribution in powder particles. The Al-Si-C particles were formed by the reaction of molten aluminum alloy and SiC_P particles [7,8]. The average size of these particles was 8.5 µm. Al-C particles were formed by the similar reaction, depending on the different local temperature and composition [7]. The low oxygen content in these particles indicates their reaction with oxide layer Al2O3 on the surface of initial material [9]. Moreover, some powder particles were formed without any precipitated particles.

Spectrum 3: Al-C	79.4	12.3	2.8	5.5

Analysis of as-deposited specimen.

The internal porosity of the as-deposited cuboid is 6.0%, and the pore size ranges between 5 µm to 120 µm. The formation of such high porosity in the as-deposited samples indicates the contamination issues as the result of moisture uptake in aluminum powders [10] or oxygen trapped in SiC_P particles powders processed by atomization process. Nevertheless, the as-deposited SiC_P /AlSi9Mg material was used for the analysis to investigate the presence, morphology and chemical composition of SiC_P particles and their embedment behavior in the matrix.

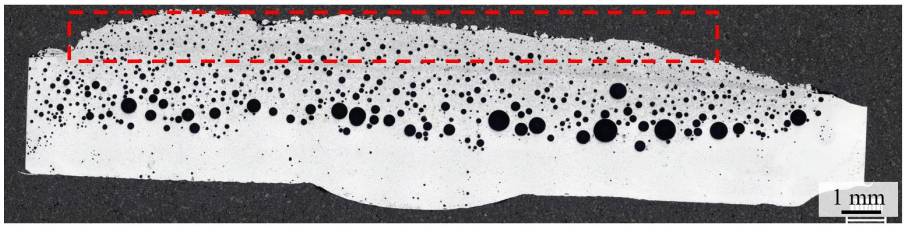

Fig. 6. DM image of the as-deposited cuboid from SiCP /AlSi9Mg in the longitudinal section.

The microstructure of as-deposited cuboid consisted of uniformly distributed and well-embedded particles in the aluminum alloy matrix. The microstructure from different areas within this part was found to have similar characteristics (see Fig. 7). However, the size of particles was finer at the bottom of the part (Fig. 7 c) as compared to the top/center and edge (Fig. 7 a,b).

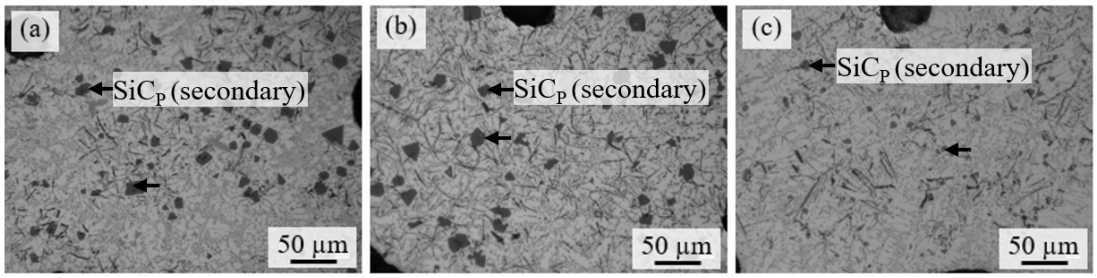

Fig. 7. DM images of microstructure of as-deposited cuboid from SiCP /AlSi9Mg: (a) at the edge, (b) at the top/centre and (c) at the bottom/centre.

The microstructure of as-deposited cuboid exhibited two predominant types of particles. Their chemical composition was locally determined using EDX analysis (see Table 4), indicating the presence of SiC_P and needle-like Al-Si-C particles (see Fig. 8). The size of the SiC_P was between 22 and 26 µm at the top of the part and 13 µm at the bottom. The shape of these particles was almost angular. Compared to SiC_P (primary) in powder particles, the SiC_P particles in the as-deposited part exhibited a different morphology (larger size and almost angular shape) and were uniformly distributed. That indicates the formation of these SiC_P particles during deposition via mechanism of complete dissolution of powder structure (e.g. primary SiC_P) and their precipitation. Therefore, the SiC_P in powder particles were determined as secondary. The in-situ formation of

SiC_P is thermodynamically possible and can result from the reaction of e.g. Al-C with Si in the melt [7]. In addition, needle-like Al-Si-C particles were formed and uniformly distributed in the microstructure of the as-deposited part. The oxygen content in these particles indicates their reaction with oxide layer Al2O3 on the surface of powder particles [9].

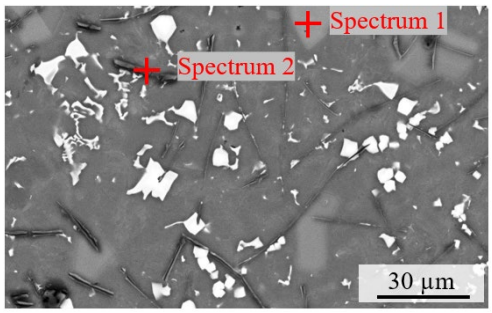

Fig. 8. SEM BSE image of as-deposited cuboid from SiCP /AlSi9Mg (top/centre).

Table 4. Chemical composition (at.%) of the measured spectrums in the microstructure of as-deposited cuboid from SiCP /AlSi9Mg (top/centre).

Spectrum	C	Al	Si	O
Spectrum 1: SiC_P (secondary)	36.1	1.8	60.3	--
Spectrum 2: Al-Si-C	9.6	53.2	9.2	28.0

Conclusions and outlook

In this work, SiC_P /AlSi9Mg powder was produced via ultrasonic atomization technology from the SiC_P /AlSi9Mg manufactured by the DVC process. The produced SiC_P /AlSi9Mg powder was then processed in the DED process. The investigations of the SiC_P /AlSi9Mg powder and as-deposited SiC_P /AlSi9Mg material with the focus on the microstructure analysis were carried out. The following conclusions can be drawn:

- The SiC_P /AlSi9Mg powder exhibited a particle size distribution between 63 µm and 92 µm and high sphericity, indicating its suitability for the processing with the DED process.
- In the microstructure of SiC_P /AlSi9Mg powder, three predominant particles: SiC_P (primary), Al-Si-C and Al-C were determined. The primary SiC_P particles were not uniformly distributed in powder particles and their embedment in the matrix was non-optimal.
- The porosity of the as-deposited sample from the SiC_P /AlSi9Mg powder was 6.0%, indicating moisture uptake in aluminum powders or oxygen trapped in SiC_P particles powders processed by atomization process. Nevertheless, the as-deposited part was used to study the evolution of the microstructure during deposition.
- In the microstructure of the as-deposited SiC_P /AlSi9Mg material, two predominant particles were determined: SiC_P and needle-like Al-Si-C. The different morphology (shape, size) of these SiC_P particles compared to the primary SiC_P particles (whether in powder or initial material) suggested their formation via the mechanism of dissolution and precipitation (as secondary SiC_P). The distribution of secondary SiC_P was uniform in the as-deposited material with the well-embedding.

Future work will focus on reducing porosity in the DED-processed SiC_P/AlSi9Mg material. Therefore, it is necessary to realize measures, such as drying the powder before the AM process, increasing the control of the gas atmosphere during the atomization process, or ensuring appropriate conditions for powder storage are needed to avoid of powder contamination.

Abstract. This study aimed to explore the capability of different additive manufacturing (AM) or 3D printing technologies to rapidly manufacture mold inserts for injection molding as well as to evaluate the performance of the printed mold inserts and the quality of the injection molded parts. Fused filament fabrication (FFF), stereolithography (SLA), and multi-jet fusion (MJF) 3D printing technologies were used to produce the mold inserts, whereas a cosmetic compact base was selected as the case study part. The results obtained show that it is possible to use the mentioned technologies to manufacture tool inserts for rapid prototyping or low volume production of cosmetic compact bases using injection molding. When using the FFF mold inserts, the cosmetic compact bases produced were not of the best quality and surface finish but still acceptable for prototyping purposes only. The vertically printed SLA mold inserts as well as the MJF mold inserts produced cosmetic compact bases with no flashes and the best surface finish. The MJF mold inserts had excellent thermal properties so that apart from HDPE, a higher melting temperature ABS was also successfully molded. Also using the MJF mold inserts, the highest production number of 80 cosmetic compact bases of a good quality could be achieved.

Introduction

Rapid Tooling (RT) is a rapid production of tools or molds using additive manufacturing (AM) also as known as 3D printing technology, which were introduced a couple of decades ago [1]. Additive manufacturing is a layer-by-layer process using only one machine, which is capable of joining materials to manufacture a desired three-dimensional object. This technology is the opposite of traditional manufacturing, where an object is carved by removing the unwanted extra material [2]. In other words, rapid tooling is the use of AM technologies to produce tools, molds, or dyes, in order to produce parts using a subsequent manufacturing technique such as injection molding to produce parts or prototypes instead of using an AM technology directly, which may take longer and cost more if a certain quantity is required [3-5]. Although the process and technology used for rapid tooling is the same as the ones used in AM, the purpose is different. Using rapidly and additively manufactured tools/molds, the final products or prototypes are expected to be better since the parts can be molded from the desired molding material and fully dense.

RT could save time and money in the injection molding industry since the designer can analyze the performance of the AM tool and confirm that the tool has met its objectives before starting the long and expensive process of manufacturing the conventional tool steel mold. This will save a company months of work and tens of thousands of euros [6,7]. On the other hand, if a rapid tool will be used for the actual production of finished parts and not only to produce several prototypes to test the tool and its expectations, then surface finish will also be an issue and a very good quality product is expected [8]. In rapid manufacturing/rapid prototyping process, surface finish is not that of an issue since these technologies have a free form nature [1].

RT can be divided in two categories, namely direct and indirect tooling. These two categories are further divided into other two categories which are soft tooling and hard tooling [10]. Hard tooling is used when high production runs are required. Normally for hard tooling tool, steels are applied using metal AM technologies such as, laser beam powder bed fusion process (LB-PBF). On the contrary, soft tooling is mostly used for a few runs. Therefore, this process could make use of thermoplastic materials, epoxy resins, and low melting temperature metallic alloys using AM technologies such as fused filament fabrication (FFF) and stereolithography apparatus (SLA).

This study aimed to explore the capability of different AM or 3D printing technologies to rapidly manufacture soft tools for injection molding as well as to evaluate the performance of the 3D printed soft tools and the quality of the injection molded parts.

Materials and Methods

Case Study Part.

A small Terra cosmetic compact of Toly Product Ltd. Malta was selected as the case study which consists of a lid and base. For this study, only the base was considered, as can be seen in Fig. 1, which is mass produced from a mixture of acrylonitrile butadiene styrene (ABS) and styrene acrylonitrile (SAN) polymers. The injection mold used in the actual mass production process had two sliders, one at the front and another at the back. The back section has sliding cores to form holes on each side of the cosmetic base to accommodate two metal pins, which are used as a hinge to allow the user to open and close the lid of the cosmetic compact. At the front side of the base, a protruded bump is formed using another slider which is used as a snap-fit join to lock or release the lid, Fig. 1a. The part was injected from the center on the bottom side, using a 2-cavity hot runner mold. The injection point can be easily observed on the center bottom of the original part, while the four ejector pins are located in the well sections of the part, as can be seen in Fig. 1b.

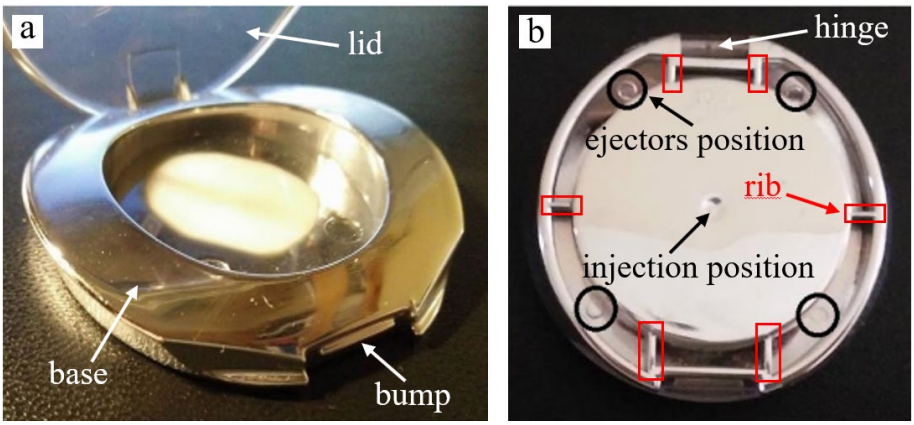

Fig. 1. Small Terra cosmetic compact top view (a) and its base's bottom view (b).

Part Design Simplification.

The design of the cosmetic base required slight simplifications so that the cosmetic bases could be produced without the above-mentioned sliders using a cold runner mold instead of the hot runner mold as in the actual mass production. The holes for the hinge metal pins and the snap-fit bump to lock the lid both of which are formed by the sliders were eliminated. On the bottom side, the base had six ribs in its recess to give the part extra rigidity and strength. Two of these ribs, one on each side, were eliminated to decrease part complexity and also at the same time to give space for ejector pins. The remaining four ribs which are close to the hinge and snap-fit areas are slightly thickened since they were considered to be weak so that it was not ideal for the tooling/mold inserts which are to be manufactured using additive manufacturing. The last necessary simplification was

to alter the parting line, which also determines the design of the core and cavity inserts as well as the position of the gate, as can be seen in Fig. 2.

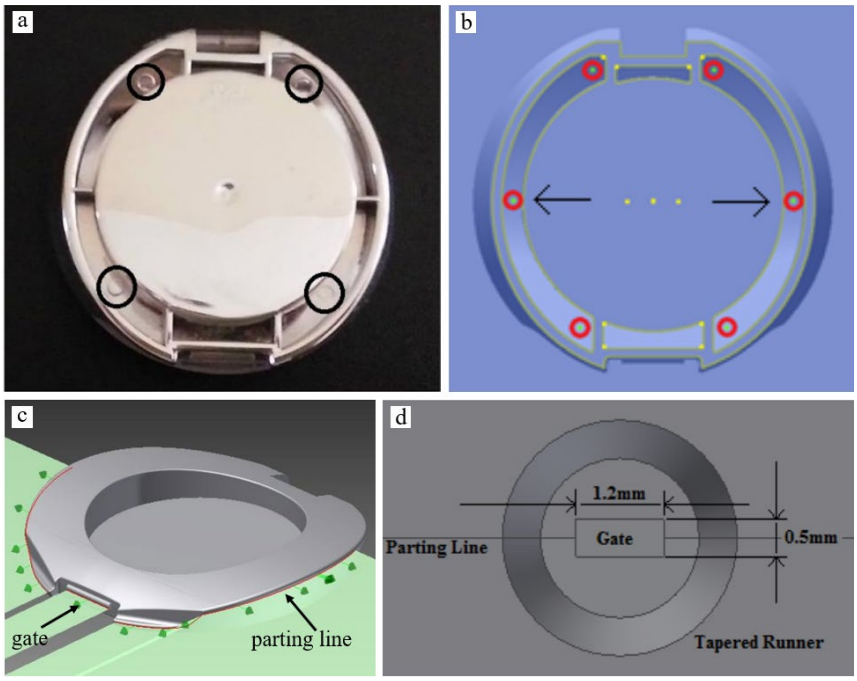

Fig. 2. Ejector pins position on old (a) and new (b) part design; new parting line and gate position (c,d).

Mold Design and Manufacture.

The mold designed for this study was a 2-plate, 2-cavity cold runner mold, without sliders as previously explained. The mold design started from a complete mold base including the mounting and cavity plates, locating ring, riser/spacer block, the locating sleeves, ejector pins, ejector retainer plate and support plate, etc. The cavity plates from both injection and ejection sides have a pocket for a metal insert on which two pockets on each side were machined to accommodate the 3D printed or additively manufactured (AM) mold inserts, as shown in Fig. 3.

Other mold components or features such as runner system, gate type and size, ejection forces including the number and position of the ejector pins, cooling time including the cooling channels were calculated or designed according to guidelines given in Kazmer [11] and Menges et al. [12], although they are for conventional mold design. However, since the aim of this study is not to achieve high production rates and the shortest of cooling or cycle time as well as the printed mold inserts are manufactured from polymer materials with a low heat conductivity, these calculations were not given a great deal of importance. They serve mainly as starting points of the mold design and to ensure that the deviation in the injection molding process including the molding results comes from the 3D printed mold inserts.

In deciding the gate type, the type of runner system, the desired method of de-gating, the allowable level of shear rates through the gate, the resulting flow that is desired as well as the material used in injection molding were all considered. A tab gate is usually used for a simple cold runner type characterized with a manual de-gating, moderate melt shear rates and radial flow. These characteristics were all desirable for this study, and thus, a tab gate, with dimensions as shown in Fig. 2, was designed. The shear rates and the pressure drop at the gate as well as the gate freeze time were also calculated according to Kazmer [11].

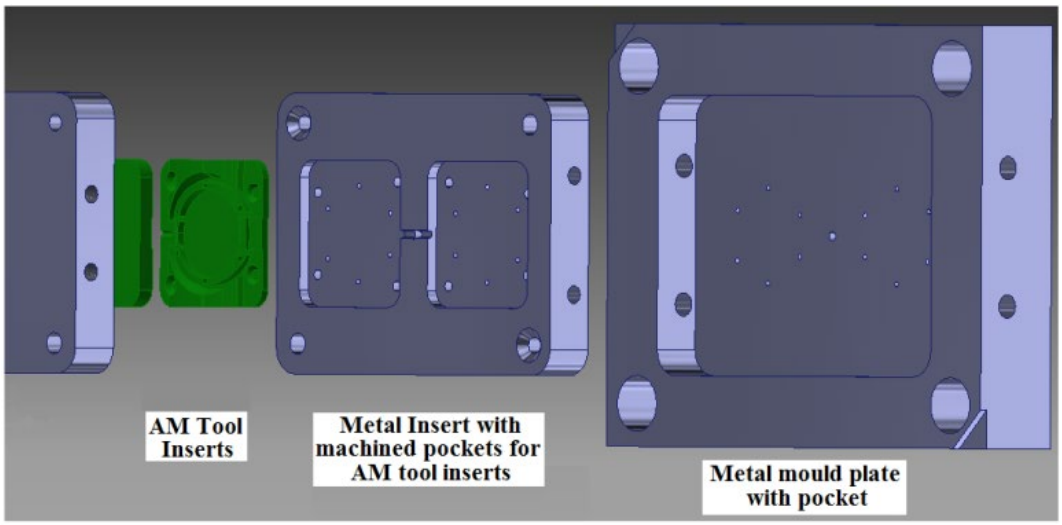

Fig. 3. Metal mold plate, metal insert, and 3D printed (AM) mold insert of the ejection side.

Although the cooling system and its efficiency is of great importance, it was kept simple not to compromise and complicate the machining of the channels. The cooling channels layout in the metal inserts can be seen in Fig. 4. Each cavity had its own U-shaped cooling line. The cooling channels were 46 mm apart on the ejection side and just 27 mm apart on the injection side as shown in Fig. 4a-b. On the ejection side, the cooling channels could not have been machined closer due to the ejector pin holes, while on the injection side there are no such restrictions, the cooling lines were made closer for increased efficiency, higher cooling and thermal dissipation rates. The flow direction of the coolant with a temperature of 19˚C, is indicated by the arrows in both Fig. 4a-b.

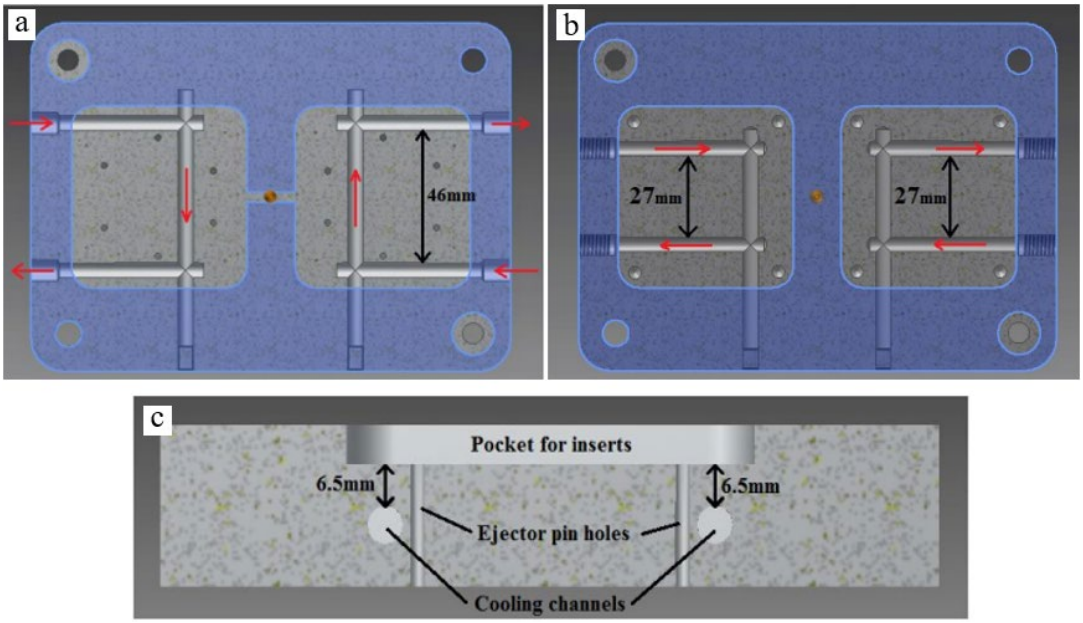

Fig. 4. Cooling channel layout on ejection (a) and injection side (b) of the mold as well as the cross-sectional view of ejection side (c).

In this study, three polymer additive manufacturing or 3D printing technologies were used to print the mold inserts, namely fused filament fabrication (FFF), stereolithography (SLA), and multi-jet fusion (MJF). Two desktop FFF 3D printers (Up Plus 2 and Zortrax M200) were used to manufacture the mold inserts using acrylonitrile butadiene styrene (ABS). ABS was selected based on its overall good properties for mold inserts such as good heat resistance, relatively high heat deflection temperatures, hardness, and toughness. For SLA technology, the mold inserts were printed with Formlabs Form 1+ printer using its standard resin and with Viper Si2 printer using its Accura Xtreme resin. Regarding the MJF technology, ProJet 3500 together with VisiJet M3-X material was used to build the mold inserts.

Fig. 5 shows an example for a mold insert that was manufactured using the FFF 3D printer Zortrax M200 before and after the removal of support material, and Fig. 6a shows another example for SLA mold inserts manufactured using Viper Si2. Fig. 6b and Fig. 6c show the final mold setup from the ejection and injection side which has two pockets and, on each of which, 3D printed mold inserts can be mounted, in this case two different FFF mold inserts 3D printed using UP Plus 2 printer.

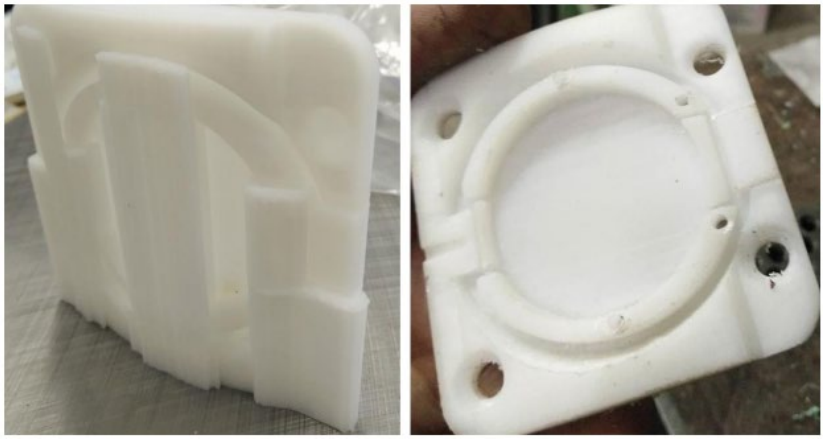

Fig. 5. An example for mold inserts FFF 3D printed on the Zortrax M200 before and after the removal of support material.

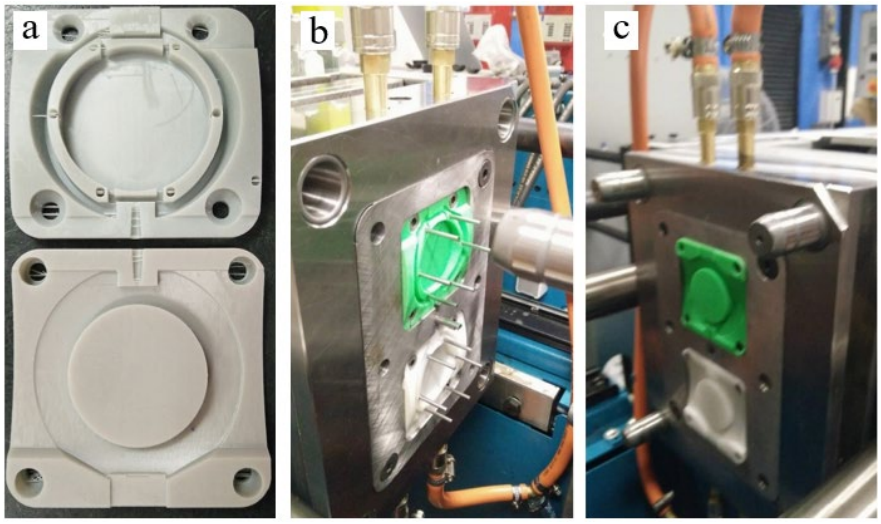

Fig. 6. SLA 3D mold inserts manufactured using Viper Si2 (a), ejection side (b) and injection side (c) of the 2-cavity mold with two different FFF mold inserts 3D printed using UP Plus 2.

Injection Molding Experiments.

The experiments were carried out on Boy 22E injection molding machine. Considering the fact that the mold inserts are printed from polymer materials, the selection of the molding materials was based mainly on a low processing temperature range. For the main injection molding experiments, high density polyethylene, HDPE HMA 016 from ExxonMobil Chemical, was used to produce the cosmetic compacts with the main processing parameters as shown in Table 1. Apart from HDPE, molding experiments using acrylonitrile butadiene styrene (ABS) were conducted to test the mold inserts printed using high temperature materials.

Table 1. Injection molding parameters for HDPE.

Temperature		Injection			Holding		Cooling
Melt	**Mold**	**Pressure**	**Speed**	**Time**	**Pressure**	**Time**	**Time**
165°C	19°C	800 bar	15 cm³/s	1.5 sec	342 bar	3.5 sec	35 sec

Results

Mold Inserts Temperature and Cooling Time.

Using an infrared camera, the temperature of the mold inserts as well as the parts upon mold opening can be observed as can be seen in Fig. 7 (left). The temperature of the parts and the cavity of the mold inserts was around 100˚C. Thus, after ejection of the part, further cooling of the mold inserts is required before closing them again to start a new molding cycle. In the case of Zortax mold inserts, further cooling time (open mold) of 240 s was required, which resulted in a total cycle time of 280 seconds including the injection time, the holding time, cooling time (with the mold closed) and the further cooling time with the mold open. Although the temperature of the mold inserts increased after each molding cycle, the desired mold temperature could be reached approximately at the same time as can be seen in Fig. 7 (right).

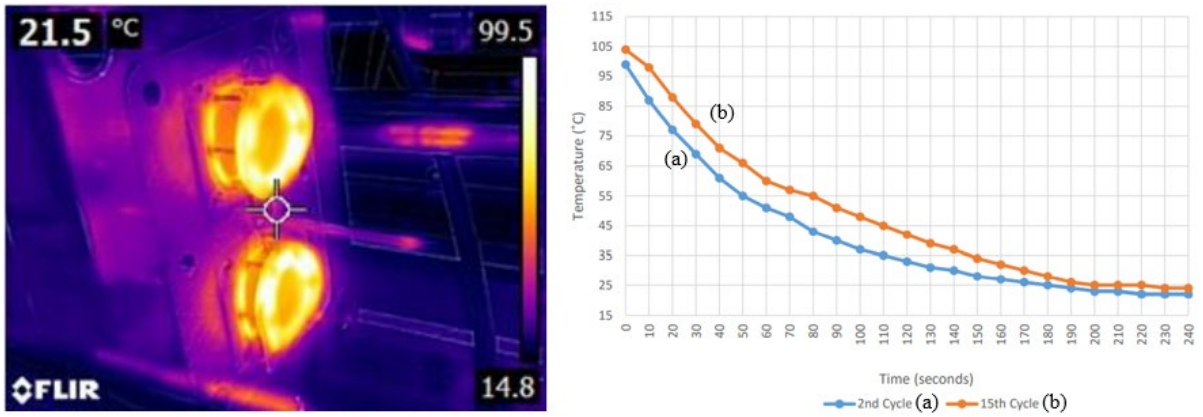

Fig. 7. IR thermal image of part (left) and parts' temperature decrease during further cooling after the mold is opened (right).

Evaluation of Molding Process and Molded Parts Quality.

Using the FFF printed mold inserts, several molding problems occurred especially during demolding e.g. puncturing of the parts by the ejector pins as the parts tended to stick onto the cavity surface of the mold inserts due to the relatively rough surface of the mold inserts as well as some flashes formed on the molded parts. This was solved by further decreasing the part temperature before demolding, the application of mold release agent, and the reduction of the ejection speed. Even though the mold inserts were printed with 100% infill, certain areas had voids, which collapsed slightly inwards during the first molding cycles. This was replicated on the molded parts. Overall, the cosmetic compacts were not of the best quality and surface finish but they are acceptable to produce prototypes with molding quality and from the desired molding material.

In contrast to the desktop FFF printed mold inserts, the quality and surface finish of the mold inserts printed with SLA Viper Si2 using Accura Extreme were excellent. However, the inserts printed horizontally showed steps on the top curved surfaces of the mold inserts which were replicated on the molded parts and also caused a formation of small and thin flashes, as shown in Fig. 8.

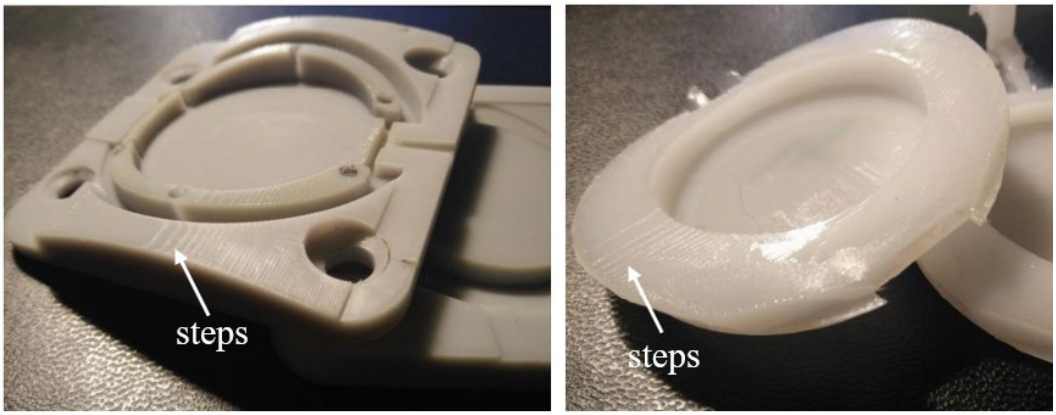

Fig. 8. Viper Si2 SLA horizontally printed inserts using Accua Extreme (left) and the molded cosmetic compact base (right).

The problems related to the above step and flash formation was eliminated by printing the mold inserts vertically. A finer surface finish of the curved sections of the mold inserts could also be achieved. This resulted in very few flashes only after the 15th molding cycle, while all front features of the molded parts were clearly replicated. A total of 27 molding cycles were carried out with a relatively good quality of the produced cosmetic compact bases, as can be seen in Fig. 9a.

Similar to FFF mold inserts, the tab gates of the SLA mold inserts lasted only a couple of molding cycles before breaking off. However, the strength and hardness of these SLA inserts were better compared to the FFF inserts. The rest of the mold features sustained the heat and pressure from the injected melt. The protruding sections of the mold inserts including the core on the injections side turned brownish in color as can be observed in Fig. 9b.

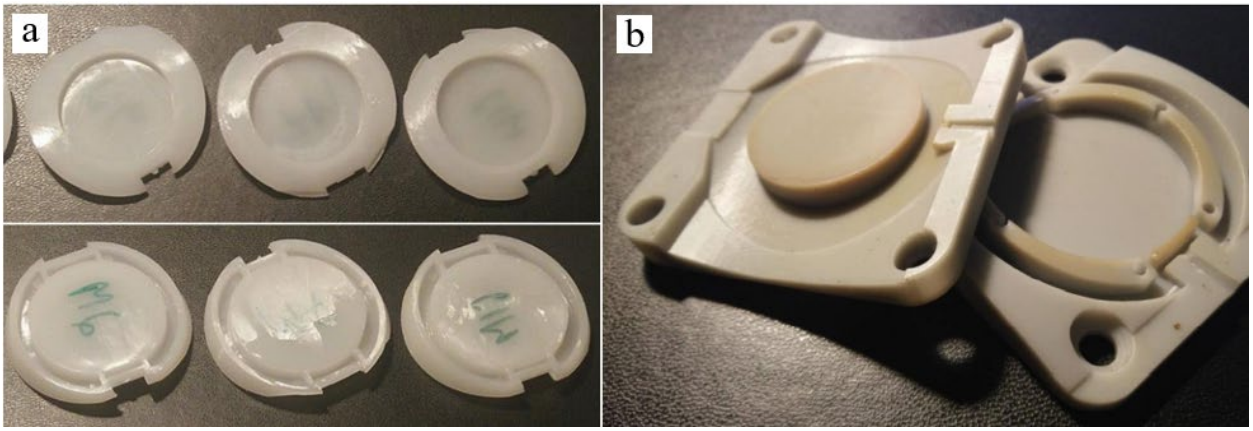

Fig. 9. Molded cosmetic compact bases (left) and used SLA mold inserts vertically printed using Viper Si2 and Accua Extreme resin (right).

The MJF mold inserts manufactured on a PolyJet 3500 printer using VisiJet M3-X material had excellent thermal properties. These inserts should be capable of withstanding temperatures up to 350˚C after annealing. Therefore, apart from molding using HDPE, ABS, which has a much higher processing temperature of around 200˚C, was also successfully used to mold a few parts at the end of the experiments using these mold inserts. No part puncturing occurred in the entire molding experiments and no flashes were formed up to the first 22 molding cycles. The parts produced show the best surface finish compared to ones molded using other mold inserts, Fig. 10.

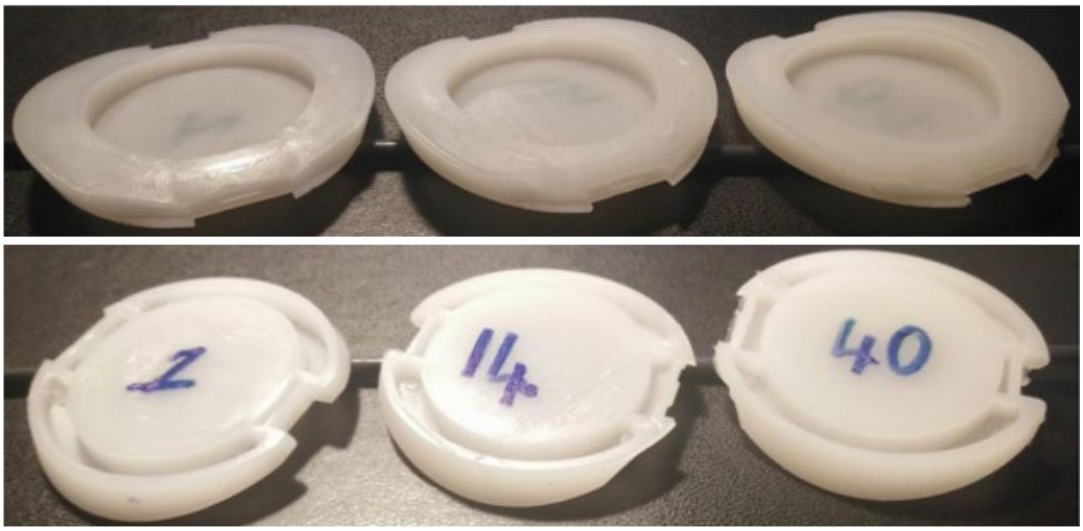

Fig. 10. Cosmetic compact bases top and bottom view molded using MJF mold inserts.

Fig. 11. MJF mold inserts with cracks after 40 molding cycles using HDPE and other 6 successful molding cycles using ABS as the molding material.

The MJF inserts performed excellently and, in contrast to other mold inserts additively manufactured using FFF and SLA 3D printers, the gate of the MJF mold inserts was not broken. The only drawback was that these inserts were discovered to be quite brittle and after a considerable amount of number of cycles, they cracked as shown in Fig. 11. These cracks initiated from weak areas such as the mounting holes. Other points of crack initiation were the ejector pin holes. These cracks kept propagating and getting bigger in size and depth, and after 40 molding cycles using HDPE and other 6 successful molding cycles using ABS. Despite the cracks, parts could be still injected but slight flashes were formed through the cracks formed.

Summary

Although there were some molding problems in the first runs when using the FFF mold inserts and the cosmetic compact bases produced were not of the best quality and surface finish, these could be substantially improved in the next runs. When using the vertically printed SLA mold inserts as well as the MJF mold inserts, the results obtained were excellent since no flashes were formed in the first few molding cycles and a good surface finish was also achieved. The MJF mold inserts had very good thermal properties so that apart from HDPE, ABS was also successfully molded which is the main material for the actual mass production of the cosmetic compact bases. The SLA inserts were considerably less thermal resistant, but a total of 27 molding cycles were easily accomplished producing 54 good cosmetic compact bases. The maximum production number of 80 cosmetic compact bases could be achieved using the MJF mold inserts. This proved that, using advanced materials available today, some of the AM technologies which are normally used for rapid prototyping, rapid manufacturing, and soft indirect rapid tooling applications, can also, easily be used, in hard direct tooling. This saves time and resources, which could give companies a competitive advantage, since development and manufacturing time are substantially reduced.

Abstract. Fiber-metal-laminates (FML) provide excellent fatigue behavior, damage-tolerant properties, and inherent corrosion resistance. A 2017-developed single-step process that combines deep-drawing with simultaneous infiltration (in-situ-hybridization) yields promising results. However, Fluid-Structure-Interaction (FSI) between the hybrid stack and the fluid pressure complicated the defect-free processing of double-curved parts. In this work, a Finite Element (FE) simulation approach for modeling the in-situ hybridization of FMLs is expanded to incorporate a both-sided (strong) FSI, aiming to facilitate apriori virtual support for process- and part development. Using Terzaghi's effective stress formulation, the proposed framework can predict metal sheet buckling and resin accumulation resulting from local fluid pressure during infiltration of the textile interlayers on part level. Different conditions are simulated, outlining the high relevance of considering strong FSI during process simulation. The part-level results are compared with experimental findings. Modeling challenges are discussed, along with suggested future enhancements of the simulation approach.

Introduction

The aerospace industry has driven the processing and application of Fiber Metal Laminate (FML) in recent decades [1,2]. Combining the best features of metals and composite materials, FML provides excellent fatigue behavior, damage-tolerant properties, inherent corrosion resistance, and good fire resistance [3,4]. Product examples are GLARE (Glass-Fiber Reinforced Aluminum Laminates) or ARALL (Aramid-Reinforced Aluminum Laminates). Beyond flat structures, defect-free manufacturing of three-dimensional curved FMLs with a high degree of automation still proves difficult and is extensively investigated in the literature [1,5, 6]. Despite experimental trials, several numerical models with varying focus and scale have been proposed and validated, enabling a prediction of potential wrinkling, fracture, or strains with metal sheets or fibers [6–10]. A strong FSI during in-situ hybridization has not been modeled so far. The classical manufacturing process using an autoclave is time-consuming, expensive, and the achievable geometric complexity of the components is very low [11]. In this regard, Mennecart et al. [12] suggested and developed, among others [13,14], an alternative manufacturing process by combining deep drawing with thermoplastic resin transfer molding, called hybrid liquid composite molding (HyLCM).

A schematic illustration of the principal process steps is given in Fig. 1. The stack is positioned between a matching punch and a die. The stack is clamped during the whole process using circumferential blank holders. In the first step, the hybrid stack is only slightly deformed, temporarily sealing the outer rim. Subsequently, reactive resin is centrally injected through a hole in the lower metal layer while deep drawing proceeds. The fluid pressure can bend the metal top

layer during injection, as illustrated in Fig. 1. During the last 20% of the tool stroke, the resin is forced outward and infiltrates the core GF layers. The heated molds enforce isothermal curing.

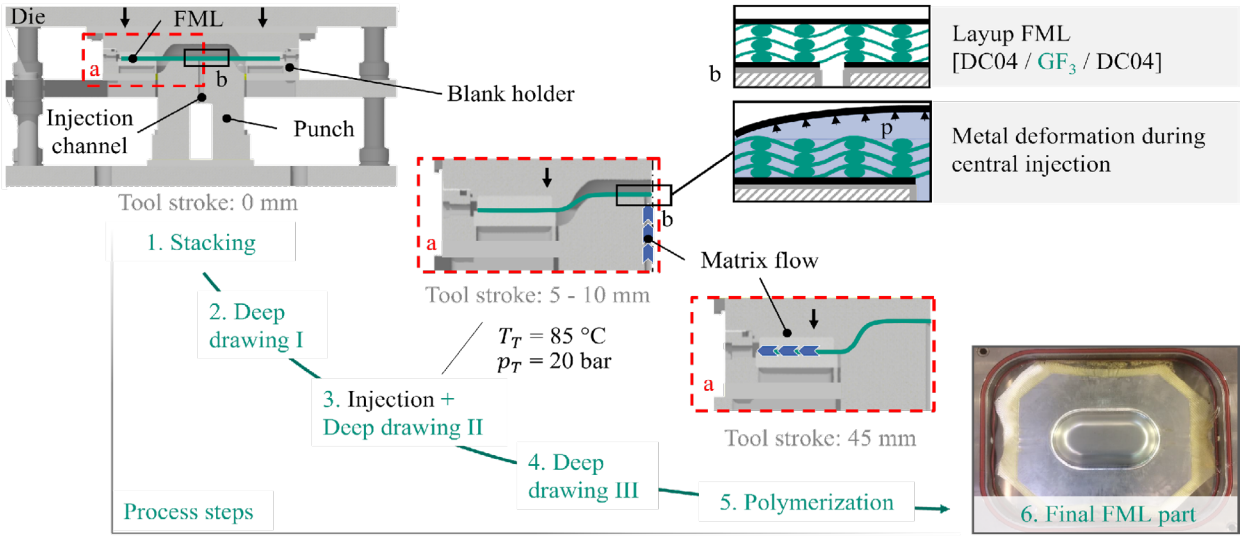

*Fig. SEQ Figure * ARABIC 1. Visualization of the combined deep-drawing and LCM process (HY-LCM) from Stacking (1.) to intermediate injection (3.) and final polymerization*

Objective

In a previous work [10], the authors presented a macroscopic process simulation model for the outlined process, which allows modeling the deep drawing of the FML stack, including transverse compression of the textile core layers and the simultaneously arising fluid progression. The deep-drawing model was verified with close-to-process trials. However, the presented model only incorporated a weak Fluid-Structure-Interaction (FSI). Local deformation was considered during fluid progression, but fluid pressure-related deformation was neglected.

As experiments and available literature show that an accurate prediction of potential defects requires modeling a strong FSI, this paper aims to implement and investigate a both-sided coupling between FML material deformation and fluid progression.

Exemplary Processing Results

Process trials are conducted at Leuphana University Lüneburg (Germany) with different parameter settings combining two DC04 metal sheets (1 mm) with six core layers made from a glass twill fabric (280 g/m^2, INTERGLAS 92125 FK800) [15]. A thermoplastic matrix (Arkema Elium® 150), with an initial viscosity of 100 mPas, mixed with 2.5 % hardener, is injected.

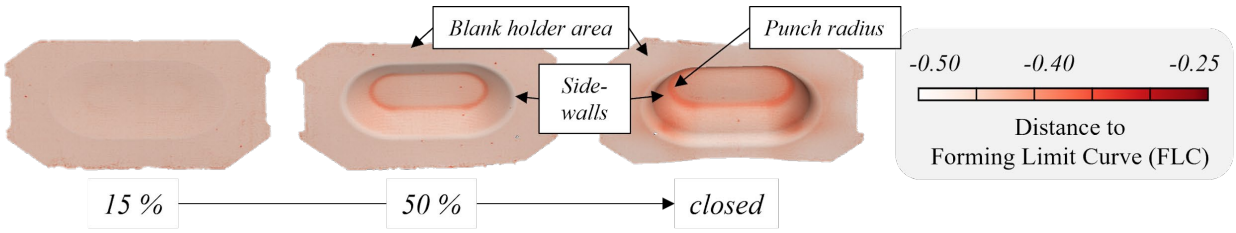

Fig. 2. Shaping and distance to the Forming Limit Curve, data obtained with GOM ARGUS measurements.

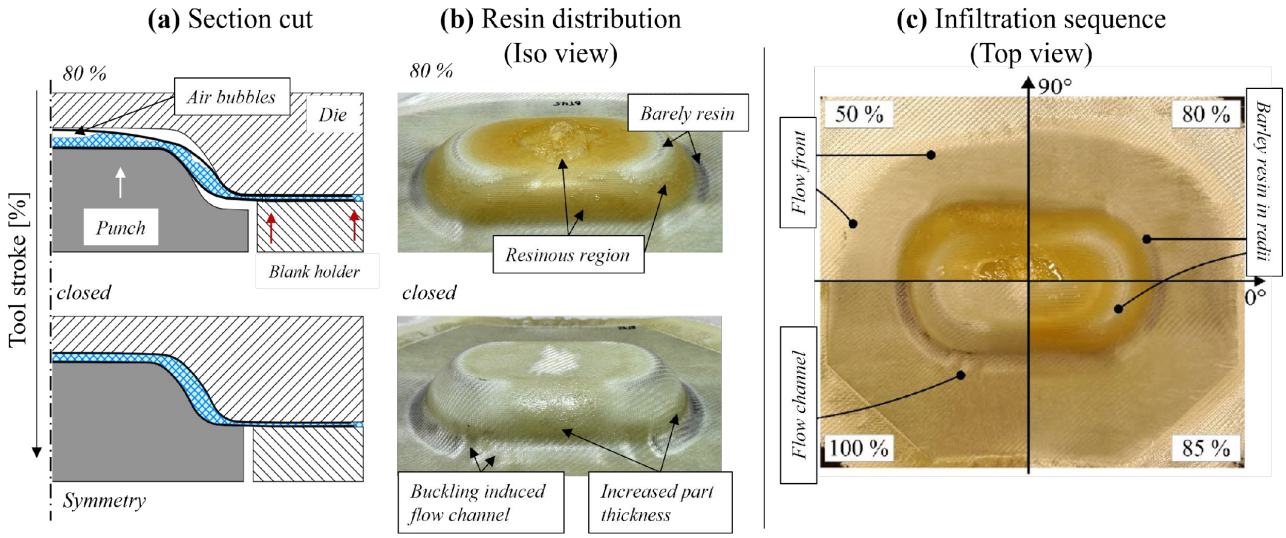

Fig. 3. Visualization of the FSI during FML processing; (a) Schematic section cut; (b) Photos illustrating the resin distribution; (c) Infiltration sequence and observed effects.

Fig. 2 summarizes a shaping of a part during the tool stroke and the distance to the Forming Limit Curve (FLC). The distance to the FLC indicates forming margin before failure. During dry forming trials, the FML stack is deep-drawn without buckling, as no additional fluid pressure is present, and other parameters are adjusted suitably. This changes when injecting the reactive resin. Driven by the fluid pressure between the metal sheets, bending of the metal sheet is observed close to the injection port and later towards the side walls of the geometry.

These observations are schematically illustrated in more detail in Fig. 3 (a,b). The resin first accumulates between the metal sheets, especially near the inlet and the side walls. The blank holder seals this region and prevents fluid-induced deformation in the flange area. Fig. 3 (b,c) shows that the fluid is forced through the flange during subsequent tool closure. Fluid is pushed out of the bottom area and other regions where high compressive stress is induced by the deep drawing of the metal, such as the punch radius or the side walls. These exemplary results illustrate the high relevance of strong FSI modeling for reliable virtual product- and process design for in-situ hybridized FMLs.

Process Simulation Model

This work's applied process simulation model originates from WCM modeling [16, 17], which has been expanded and verified to account for hybrid FML forming and weak FSI [10]. A schematical overview of the macroscopic FE-based simulation framework is given in Fig. 4.

Two fully-coupled submodels provide the core part of the model to describe the intra-ply behavior of the textiles (a). The FE-based draping submodel captures the macroscopic deformation mechanism, such as membrane, bending, or compaction behavior. A superimposed FE/CV-based fluid submodel describes the fluid progression and pressure field using Darcy's law for porous media flow. This approach implies that the fluid is modeled homogenized and purely liquid regions cannot be modeled discretely. Both submodels are formulated three-dimensionally, enabling a local prediction of fiber orientation, FVC, and modeling of squeeze flow as well as infiltration in the thickness direction. Despite that, the framework comprises a material model for the metal sheets, see Fig. 4b, and an interface model which describes the dry and infiltrated contact behavior during processing (cf. Fig. 4c).

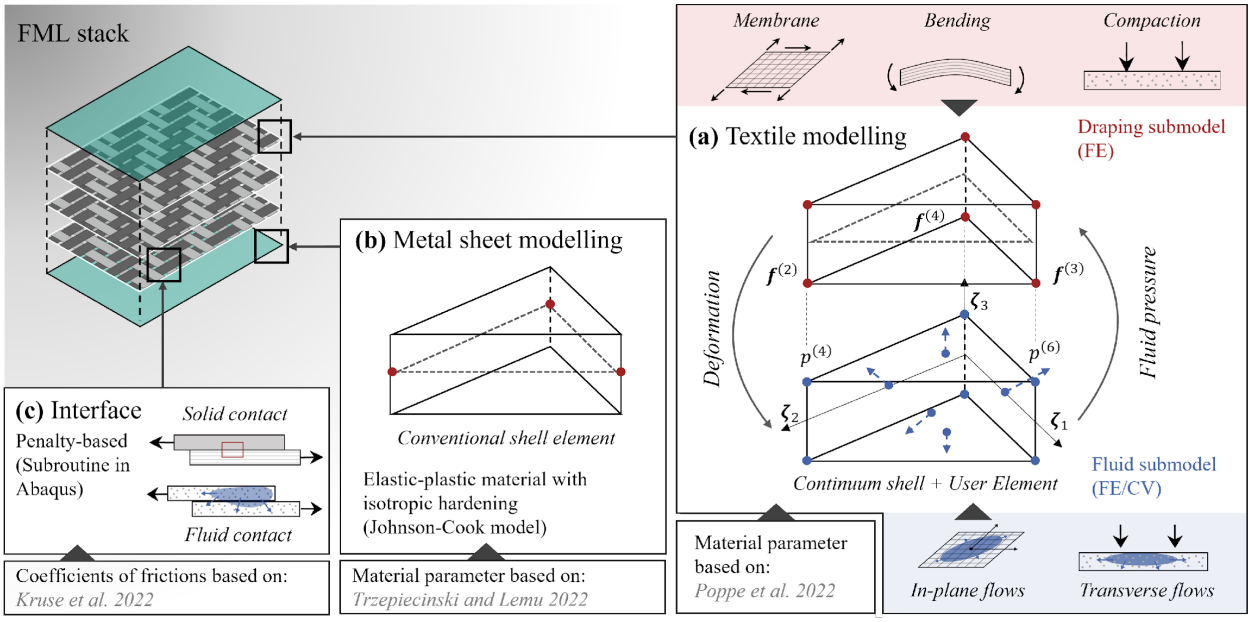

Fig. 4. Process simulation modelling framework in ABAQUS, clustered according to interface, metal sheet and textile modelling.

Draping submodel.

The relevant deformation modes of the glass fiber textile are in-plane shearing (membrane), out-of-plane bending, and compaction. They are implemented through a superimposed reduced-integrated continuum shell (SC6R) and a hyper-elastic material formulation (St. Venant-Kirchhoff material) in a thickness direction within a user element, see Fig. 4a. This approach neglects the required decoupling between the membrane and bending behavior [16]. In the case of the FML modeling, an overestimated bending stiffness can be accepted as the bending stiffness of the stack is dominated by the metal sheets. For a description of transverse compaction modeling, including identified material parameters, the reader is referred to our last year's contribution [10].

The hypervisco-elastic in-plane *membrane model* [18] has not been explicitly characterized for the here applied glass fiber textile. Yet, its prediction on the here-applied geometry has been compared to a membrane model designed for the used material [19]. A pre-study showed comparable fiber orientation, which is reasonable as the geometry is relatively simple and does not induce defects or shear looking. The former model was chosen as it proved more robust in combination with active strong FSI.

A transverse shear stiffness of $\kappa_{GF,11}, \kappa_{GF,22} = 1.0$ N/mm² is used to adapt the *out-of-plane bending* stiffness within the continuum shell. Based on these parameters and the underlining

Materials Research Proceedings 28 (2023) 219-230 https://doi.org/10.21741/9781644902479-24

membrane model, the model overestimates the textile's bending stiffness by approximately 100. However, compared to the bending stiffness supplied by the metal sheets, the bending stiffness of the textile is negligible.

Fluid submodel.

Darcy's law, in combination with mass conservation, is applied in a transient explicit formulation and is embedded in the superimposed user element (cf. Fig. 4a) to solve the pressure field and model flow front progression [17]

$$\int_{V_k} \rho C_{hyd}\, \dot{p}\; dv = \frac{\boldsymbol{K}(\phi)}{\eta \cdot \varphi} \int_{V_k} \mathrm{div}(\mathrm{grad}(p) - \rho g)\, dv \tag{1}$$

Using Eq. 1, a transient single-phase flow based on an explicit time integration scheme can be modeled. Here, $K(\phi)$ is the permeability tensor as a function of the current FVC ϕ. The viscosity is given by η, and $\varphi = 1 - \phi$ is the porosity.

The in-plane permeability values are given by

$$K_{11}(\phi) = 0.009 \cdot e^{-11.3 \cdot \phi}, K_{22}(\phi) = 0.004 \cdot e^{-11.8 \cdot \phi}, K_{33}(\phi) = 0.01 \frac{K_1(\phi) + K_2(\phi)}{2}, \tag{2}$$

and the permeability in the thickness direction, which has not been measured for the material yet, is estimated using a downscaling factor of 100 based on the results of a comparable material [20]. This estimation in the thickness direction is not a critical assumption as the fluid is contained between the sheets, and pressure-relevant flows are in-plane.

Based on the pressure field within the saturated domain, fluid progression is implemented using the flows across every element surface at the flow front in combination with element-based saturation values. The saturation values are updated in every increment, and saturated elements are added to the transient domain governed by Eq. 1.

Strong FSI.

To this point, a one-sided (weak) FSI is presented in the model as the deformation drives the pressure field and fluid progression in the textile. Terzaghi's effective stress, according to MacMinn et al. [21], is implemented to consider the fluid pressure and drag forces acting on the porous medium. As Eq. 3 shows, this yields two new nodal force terms that add up with the material reaction forces.

$$\hat{\boldsymbol{f}}_{\mathrm{R}}^{\mathrm{Node}} = \hat{\boldsymbol{f}}_{\mathrm{R}}^{\mathrm{Mat}} + \hat{\boldsymbol{f}}_{\mathrm{R}}^{\mathrm{p}} + \hat{\boldsymbol{f}}_{\mathrm{R}}^{\mathrm{d}} \quad \text{with } \hat{\boldsymbol{f}}_{\mathrm{R}}^{\mathrm{p}} = -\det(\boldsymbol{J})\, p \boldsymbol{I} \quad \text{and} \quad \hat{\boldsymbol{f}}_{\mathrm{R}}^{\mathrm{d}} = \det(\boldsymbol{J})\, \varphi \boldsymbol{N}\, \mathrm{grad}(p) \tag{3}$$

The first one represents the reaction forces $\hat{\boldsymbol{f}}_{\mathrm{R}}^{\mathrm{p}}$ caused by the fluid pressure within the skeleton structure of the deformable porous medium, and the second one representing the fluid drag $\hat{\boldsymbol{f}}_{\mathrm{R}}^{\mathrm{d}}$ between flow and fabric. In Eq. 3, $\boldsymbol{I}$ is the second-order unit tensor, and $\boldsymbol{N}$ represents the element shape function. Using the permeability values in Eq. 2, the method can be applied to the glass woven fabric without further adjustments. This formulation has been validated in [22].

Metal sheet.

The model comprises an elastic-plastic material model with isotropic hardening based on the built-in Johnson-Cook model for the metal sheets using conventional shell elements with a constant thickness (cf. Fig. 4) parameterized by Trzepiecinski and Lemu [23] for the same material. A comparison between experiments and the simulation on a single metal sheet yields a good agreement of the obtained reaction forces and deformations [10].

Interface. Contact behavior between ply and tool interfaces is modeled using penalty-based contact algorithms in ABAQUS/explicit, cf. Fig. 4. In the case of dry friction (solid contact), coulomb friction is modeled using coefficients of friction (CoF) that have been identified by Kruse et al. [24] ($\mu_{Tool,Metal}$ = 0.2, $\mu_{Tool,Textile}$= 0.253, $\mu_{Textile,Textile}$= = 0.334). Due to the metal sheet, high contact stresses of 2000 N/mm^2 are necessary to prevent excessive contact penetration. A damping of 1 N/s mm is used to reduce contact oscillations. In case of an infiltrated contact, hydrodynamic friction is used in combination with maximal tangential contact stress of $\tau_{t,max} = 1 \cdot 10^{-4}$ N/mm². Arising contact slips of several millimeters prevented the proper usage of cohesive zones during draping.

Small-Scale Application

Before part-level application, the outlined simulation approach is applied to a small slice of the final geometry to investigate the impact of infiltration during a processing sequence, see Fig. 5 (a,b). Similar to the physical process (cf. Fig. 1), an initial dry deep drawing phase is followed by a central injection phase within further punch movement, see Fig. 5c. Afterward, the partly pre-infiltrated stack is draped into the final shape without additional injection.

The tools are modeled as rigid surfaces, and displacement boundary conditions drive the blank holder and the punch. The stack is modeled as outlined above. The three textile core layers are homogenized into a single instance with an initial thickness of 1.2 mm. A constant pressure of 5 bar is applied to the inlet nodes between 0.5 and 4 seconds. Each metal sheet has an initial thickness of 0.5 mm. The tool geometry is derived from a deep-drawing configuration, resulting in a non-constant cavity in the closed state. A velocity of 100 mPas is assumed.

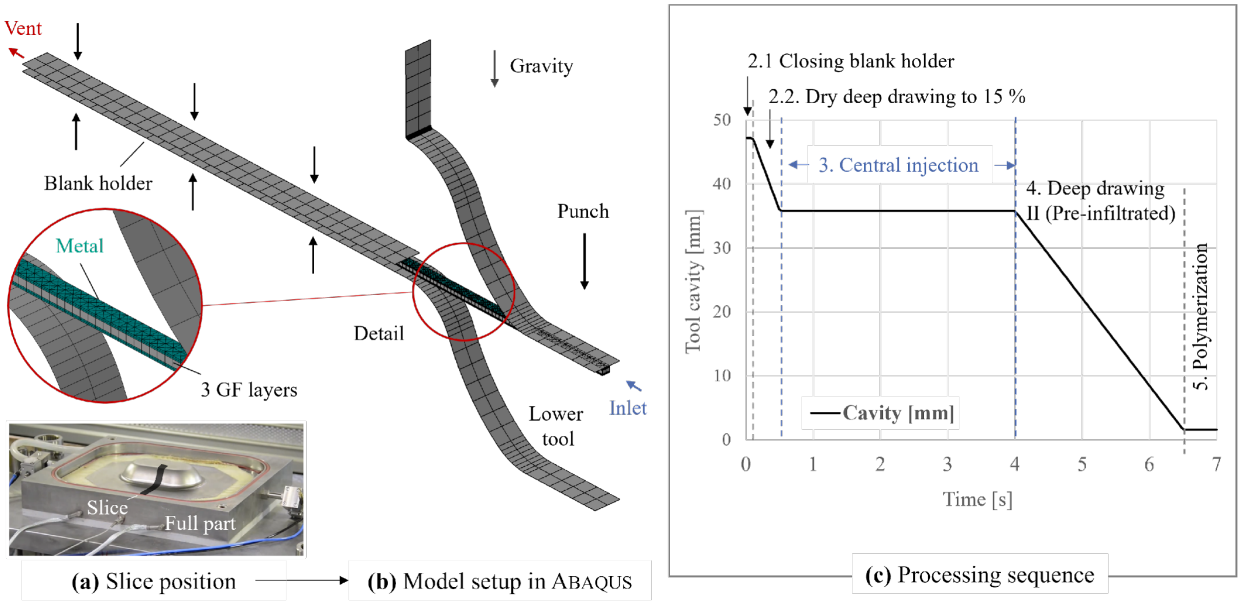

Fig. 5. Small scale demonstrator: (a) Slice position; (b) Setup and (c) Processing sequence.

To assess the impact of fluid progression along with strong FSI during processing, Fig. 6a comprises results for a dry deep-drawing reference. It shows that during a solely dry forming, the fabric layers are squeezed between the metal sheets, leading to significant compaction in the thickness direction below the blank holder and on the radii (cf. Fig. 6a). As deep-drawing of the metal sheets induces substantial in-plane strains, the textile layers are also compressed in the not

directly contacted side-wall region, recall Fig. 2. Consequently, the cavity is not entirely occupied by the FML laminate after the tool has closed completely.

Considering the injection and resulting FSI between fluid pressure and FML stack, see Fig. 6b, allows for predicting the above-made experimental observations. Injection leads to a severe increase in stack thickness towards the inlet. During the pre-infiltrated deep-drawing face (4.), the resin is forced through the side wall regions and eventually the blank holder. The fluid pressure prevents comparable high FVCs during processing and enforces a more homogeneous distribution. In this regard, the average FVC for the dry setup is predicted at 51.3 %, compared to only 40 % in the case of strong FSI consideration.

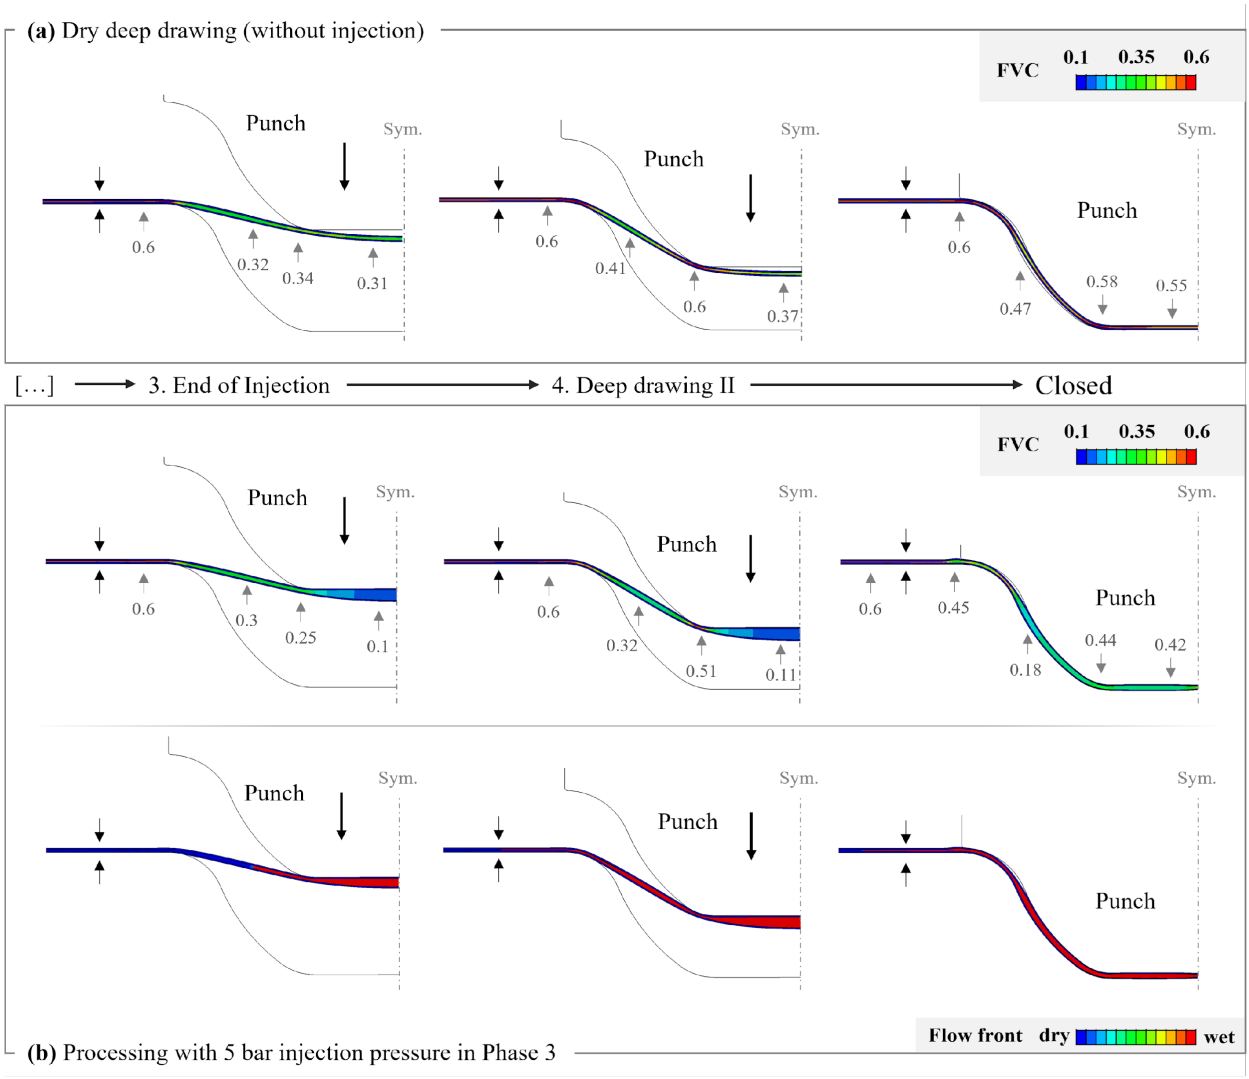

Fig. 6. Small demonstrator results: (a) Dry conditions; (b) Conditions according to Fig. 5 (c).

Part-scale Application

Finally, the outlined model is deployed on part level using the same geometry as for the physical process illustrated in Fig. 1. The modeling setup, comprising the FML stack, punch, lower tool, and blank holder, is shown in Fig. 7. Model settings are identical to the small-scale simulation trials, yet the simulation starts with a pre-saturated area, not matching the exact processing sequence, see Fig. 7b.

This adaption was necessary to reduce the required computational effort. The nonlinearity of implemented, interacting physical effects and the substantial stiffness differences between the fabric layers and the metal sheet requires a relatively small stable time increment during time integration in ABAQUS/explicit. A fluid amount of 100 ml is prescribed for the model (100 mPas). The outlined setup is simulated with both configurations to assess the impact of a one-sided (weak) and a both-sided (strong) FSI. The comparison of predicted punch reaction forces in Fig. 7 shows that significant differences only arise within the last 30% of the tool stroke when the available space of the metal sheets to evade the fluid pressure reduces to the cavity.

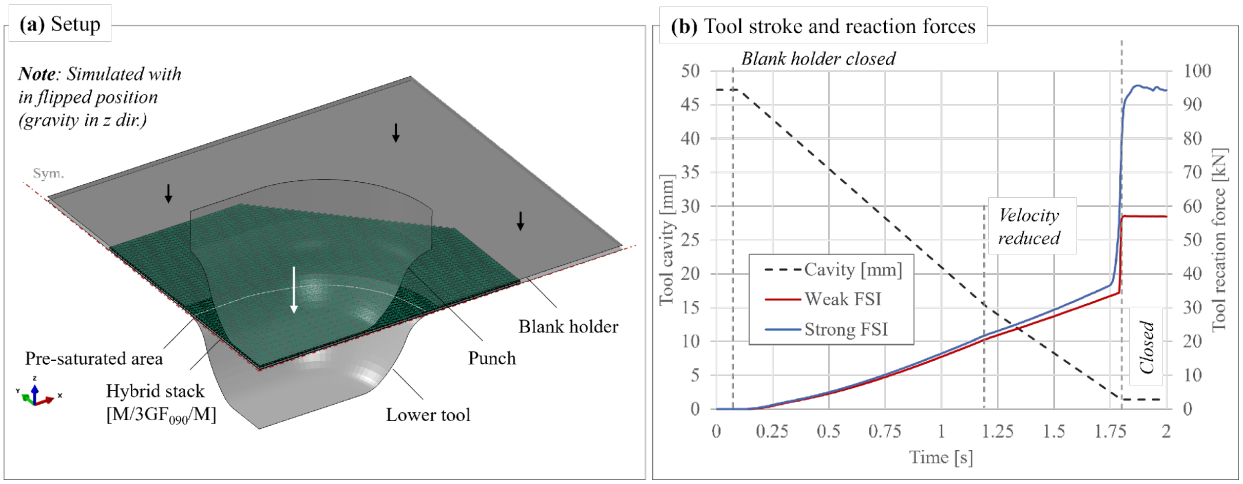

Fig. 7. Process simulation on part level; (a) Setup and (b) Tool stroke and obtained reaction forces during partly pre-infiltrated conditions using weak or strong FSI settings.

In contrast, significant differences arise early during processing when comparing the spatial distribution of the flow front, see Fig. 8, and the resulting FVC (cf. Fig. 9). Due to the local increase in the part thickness, less fluid is pushed toward the circumferential blank holder region. As a result, the flow front progression is overpredicted by the weak FSI approach.

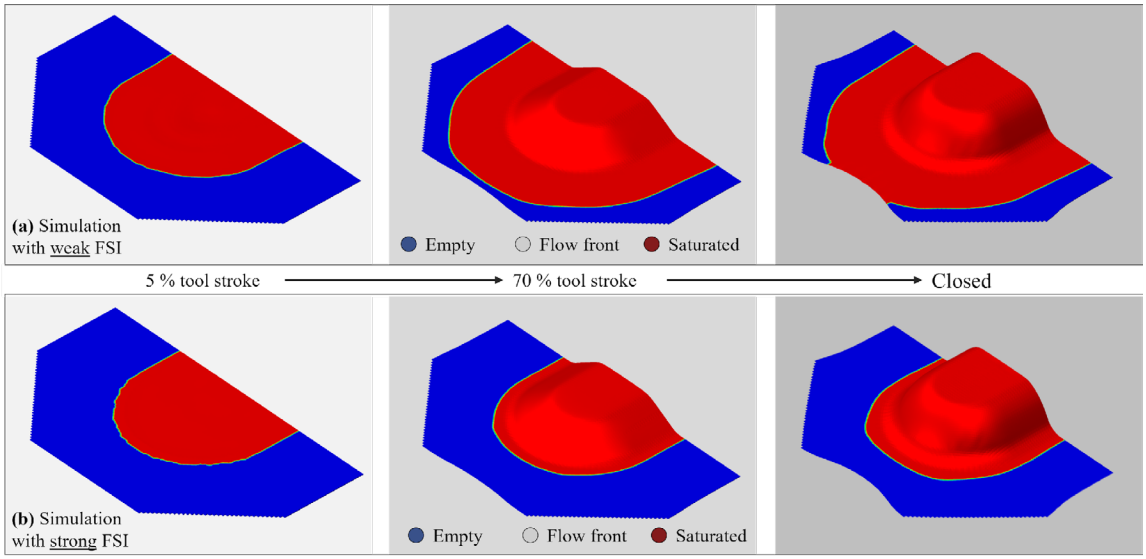

Fig. 8. Impact of FSI on flow front progression: (a) One-sided (weak) FSI, fluid pressure is not considered; (b) Both-sided (strong) FSI, fluid pressure leads to material deformation.

Fig. 9 summarizes the resulting FVC distribution and thickness for different regions of the geometry during 25, 70, and 100 % of the tool stroke. Regarding FSI consideration, comparable interactions to the small-scale demonstrator are present. As before, the compaction of the fabric results in increased part thickness in regions not directly contacted by the tool surfaces. This applies to both configurations.

Moreover, strong FSI increases the local stack thickness significantly as the fluid pressure beads the metal layers surrounding the fabric stack. Consequently, severe differences are predicted already at 25 % during processing. These differences reduce towards the end of the tool stroke as the FML stack is squeezed into the cavity, yet the average FVC for the weak FSI configuration is still 4% higher (55.8 % weak, 51.8 % strong).

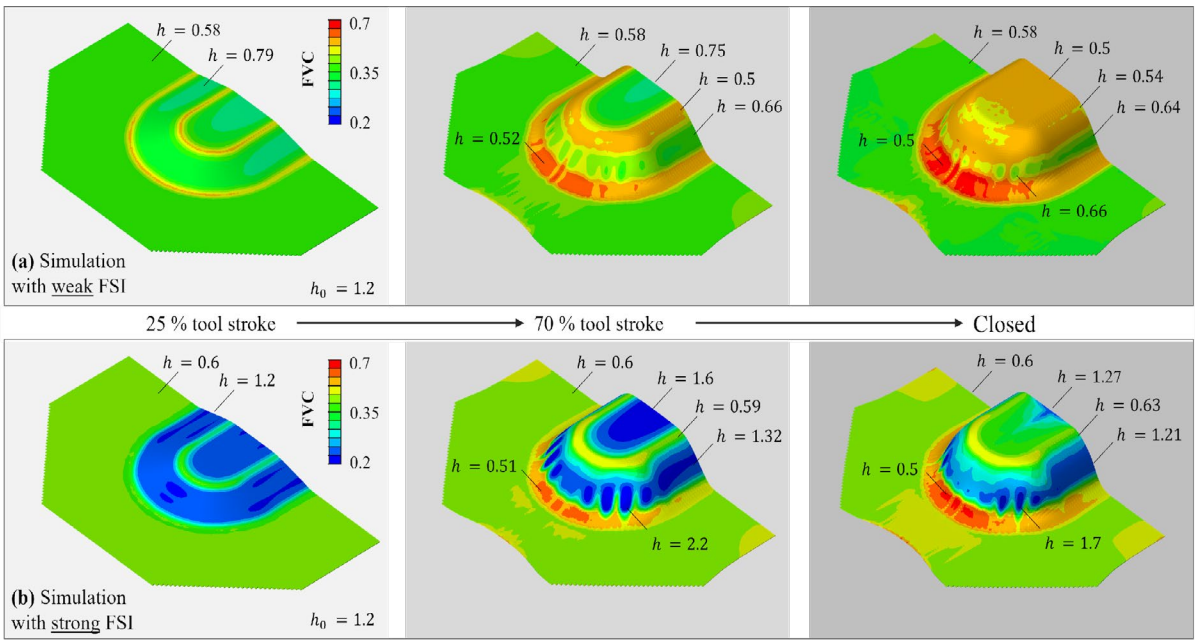

Fig. 9. Impact of FSI on FVC and part thickness (h) during partly pre-infiltrated forming.

Comparison with experiments.

Comparing the strong FSI results outlined in Fig. 8b and Fig. 9b with the above-introduced experimental observations, see Fig. 3, it becomes apparent that several effects can be predicted correctly. Although the single-phase-based modeling approach cannot predict pure resin areas, it can give a good prediction of where fluid accumulates during forming and in the final state. Moreover, fully-coupled interaction modeling between fluid, fabric, and metal sheets allows for predicting the onset of buckling of the metal sheets in the corners of the dome geometry. This buckling leads to flow channels similar to experimental observations, reducing the area's local FVC.

Summary

A fully-coupled macroscopic process simulation model for modeling producing in-situ hybridized, double-curved FML is presented. Experimental observations in the literature and on the here investigated FML process indicate a strong interaction between fluid pressure and forming of the FML stack. Reported defects such as buckling of the metal sheets, dry spots, or resin accumulations in corners could not be comprehensively numerically predicted so far, which hinders process- and part development.

Using an FE-based simulation approach combined with a control volume-based fluid progression model, the arising FSI can be considered directly via additional nodal reaction forces at the element nodes. Simulation trials on a slice of the actual geometry comparing a solely dry configuration with one that matches the processing sequence, including central injection, underline the importance of considering strong FSI in process simulation. Simulations on the part level confirm these observations and show that the simulation approach can predict the experimentally identified effects, such as resin accumulation and metal sheet buckling.

Outlook

For now, a relatively small time increment of 1E-07 is necessary to stabilize the simulation, resulting in substantial computation times on the part level. An improved interface modeling technique and stable time increment algorithm are assumed to improve the model's performance. Beyond that, a two-phase flow model would allow for predicting air entrapments and resin-rich regions. However, a two-phase model presumably requires a non-monlytic approach by coupling a proper-fluid solver with the proposed draping submodel. Heat transfer and resin kinetics should also be implemented into the proposed framework to increase prediction accuracy and support process parameter identification.

Keywords: Tailored Fibre Placement, Forming, Finite Element, Orthotropic Design

Abstract. Forming of conventional reinforcements to manufacture 3D fibre-reinforced composite parts with complex geometries is limited by the architecture of the reinforcement made of initially straight fibres. On the opposite preforms obtained by Tailored Fibre Placement (TFP) are made of curvilinear fibre tows maintained on a backing material through stitching. In theory, the degree of freedom offered by TFP allows to form doubly-curved parts from preforms whose designs are determined from the desired final fibre orientations. In practice, it requires numerical tools to determine the design of the flat TFP preforms from the desired 3D parts, known as flattening. However, flattening is a virtual process which cannot be validated directly. Besides, the behavior of TFP preforms during forming has never been studied. Consequently, developing a numerical model to predict the formability of TFP preforms was considered as of first importance. Moreover, numerical forming can be required in a flattening algorithm [1]. Based on the Finite Element Method, a TFP preform is modelled at the fibre tows scale using 2-node beam elements. The stitching yarn, which ensures the cohesion of the layers, is modelled implicitly using an embedded element approach. The backing material is removed. A full-scale simulation of forming is experimentally validated. A tetrahedral shape, which corresponds to a corner bracket, is used to demonstrate the potential of TFP preform forming. An orthotropic design of the final part is achieved without defects using a simple forming device, which represents important progress in the field [2].

Introduction

Forming of conventional reinforcements to manufacture 3D fibre-reinforced composite parts with complex geometries is inherently limited by the architecture of the reinforcement made of initially straight fibres. As opposed to regular fabrics, fibrous reinforcements made by Tailored Fibre Placement (TFP) are made of curvilinear fibre tows maintained on a backing material through stitching. In theory, the degree of freedom offered by TFP allows to form doubly-curved parts from preforms whose designs are determined from the desired final fibre orientations. The flattening step which consists in determining the flat pattern from the desired final part is virtual and can only be computed numerically for complex parts. However, developing such a numerical tool would require prior knowledge of the behavior of a TFP preform during forming (or unforming). Therefore, it is of primary importance to investigate the forming behavior of TFP preforms before focusing on the flattening step. Moreover, Sun et al. [1] shows the option to use a forming numerical tool as a step of the flattening operation to determine the reverse trajectory to be imposed to the final configuration in case of double diaphragm forming. This is why this work focused on developing a numerical tool to model the behavior of TFP preforms during forming.

Previous work on TFP investigated the advantages of aligning fibres with the principal stress directions in 2D parts [3-5]. For instance, the stress concentration in notched plate can be removed by using curvilinear path circumventing geometric discontinuities [6-9]. The work by Uhlig et al. [10] compared the strength of TFP and Non-Crimp Fabrics (NCF) open-hole laminates using cyclic and tensile tests and showed similar performances. Examples of work focusing on the manufacturing of 3D shapes using TFP is quite limited. Takezawa et al. [11] manufactured a car hood from two distinct layers with optimal orientations based on Gaussian curvatures considerations. Rihaczek et al. [12] determined optimized flat pattern to form a stool by bending. This work follows a double objective. The first one is to demonstrate the ability of manufacturing 3D orthotropic parts from specifically designed flat TFP preforms which cannot be achieved by forming conventional textiles and will therefore represent a major improvement in the field of fibrous reinforcement forming. The second one is to propose a first efficient model to simulate the forming of TFP preforms. Validation of the proposed modelling strategy is addressed by experimental and numerical forming on a tetrahedral shape. This shape has a highly double curvature and corresponds to a corner bracket widely used to design composite structures. The forming of conventional reinforcements on this shape has been largely studied [13,14] and showed the complexity of manufacturing such a shape without defect.

This paper is organized as follow. The second section describes the experimental work on TFP preform forming on a tetrahedral shape with quantitative measurements. The next section introduces the finite element modelling strategy. Finally, the last section presents the results of the forming simulation and its comparison with the experimental forming.

Experimental Forming on a Tetrahedral Shape

TFP preform architecture.

A TFP preform is built from a continuous fibre tow deposited on a flat backing material along curvilinear trajectories and maintained in place through a zig-zag stitching pattern as illustrated in Fig. 1. The thickness of the preform is achieved through stacking of several layers. When manufacturing a TFP preform, the stitch length, width and tension can be varied. Depending on the layout pattern, intra-layer and inter-layer overstitching create additional bonding between the fibre tows in a layer and between layers. The numerous interactions between the different components of a TFP preform, namely, the backing material, the fibre tows and the stitching yarn, inherently make its realistic modelling difficult. Moreover, depending on the nature of the backing material, the formability of the TFP preform can be limited. When using a thermoforming process, a non-woven polymer film which will add polymer in the final part is a good choice. However, in this work the forming experiment are carried-out at ambient temperature. Since the cohesion conferred by the stitching yarn between the layers was deemed sufficient, the backing material was removed prior to forming.

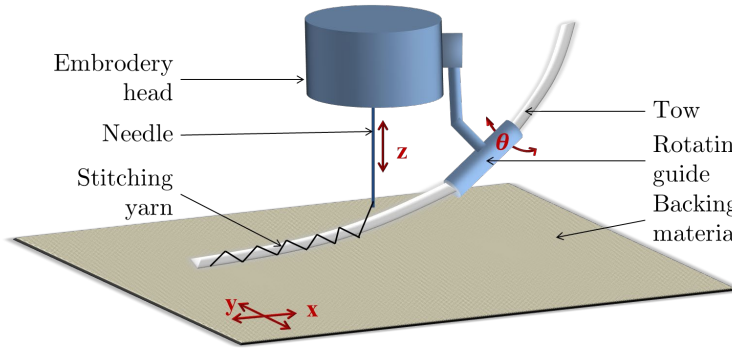

Fig. 1. TFP principle [2].

Material and manufacturing of the TFP preforms.

The TFP preforms where manufactured at IRT Jules Verne using the TFP ZSK © CMCW 0200-900D-2500 embroidery machine. A PolyVinyl Alcohol (PVA) water soluble film was used as backing material and removed by washing. Then, the TFP preform were dried in an oven at a temperature of 60◦C. The 2690 tex PET/E-glass continuous tow (from P-D-Glasseiden GMBH,

Oschatz, Germany) was stitched onto the PVA film (Gunold® Solvy film 80, Stecker) using a 24 tex PET stitching yarn (Serafil fine, Amman). The stitching length and width were set to 2.5 mm and the stitching tension to 5 10^{-2} N.

TFP preform design.

The objective is to obtain an orthotropic configuration in the final tetrahedral part. In practice, the determination of the flat pattern from the desired final configuration, namely, the flattening step, would require a numerical tool for complex geometries [1]. However, for the case of a tetrahedral shape, the flat pattern was determined analytically based on the assumption of the fibre tows inextensibility. Fig. 2 (a) shows the desired configuration of a 2-layer TFP preform. On each face of the tetrahedral shape, a 0/90° orientation is achieved. Since fibre tows are aligned with the three edges which converge through the vertex of the tetrahedron, their length must be conserved in the flat configuration. These constraints are satisfied with an angle of 120° between the edges in the flat configuration Fig. 2 (b). Therefore the fibre tows have initially an angle of 120° between the two layers on each face. During the forming step, a uniform in-plane shear deformation characterized by an angle of 30° is expected. Fig. 3 shows the flat pattern with is split into two layers. It should be noticed that several combinations of 2-layer lead to this flat pattern. As it will be highlighted at the end of this section, it was noticed to late that the chosen one was not optimal.

Forming device.

The forming device shown in Fig. 4 is composed of a tetrahedral punch mounted on the cross head of a universal testing machine (AGXplus by Shimadzu). Two transparent square plates (550 mm × 550 mm × 10 mm) made of poly(methyl methacrylate) are used as blank-holder. One plate is fixed within a metallic frame and the other lies directly onto the preform and only applies its self-weight. A pin system prevents the movable plate of the blank holder from moving in the plane. The tetrahedral part of the punch is 120 mm high and on top of a 20 mm thick base. The stroke punch stroke is 140 mm with a speed of 15 mm/min.

Quantitative measurements.

Optical measurements were carried out to compare the results with the forming simulations presented the last section using a camera positioned along the displacement axis of the punch which takes a picture every 2~mm. This setup allows visualizing the 2D displacement field orthogonal to the punch displacement. Moreover, at the end of the experiment, a picture of one face of the punch was taken to measure the inter-layer angle. Red-ink markers were drawn on the TFP preform in order to compute the 2D displacement field and a python script based on the open-source image-processing library OpenCV was used to track the position of these markers. This 2D displacement field allows extracting the preform contour for comparison with the simulation results in the last section.

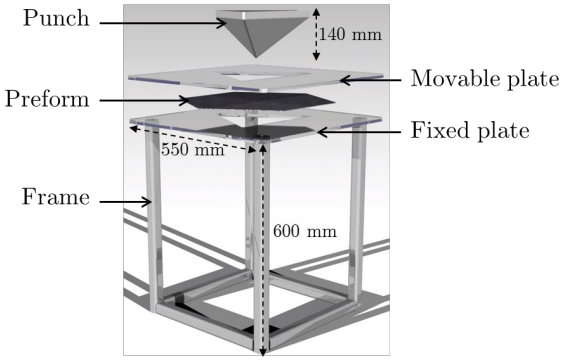

Fig. 4. Forming device.

Results.

The final configuration of the forming process as well as the force-displacement curve is shown in Fig. 5. No apparent defects such as wrinkles or fibre tow slippage were noticed. The force-displacement curve shows a first phase with a slow increase until 120 mm before increasing rapidly once contact with the thick base (120-140 mm) is established. Therefore, the minimal blank-holder used was sufficient to obtain a final configuration free of defects. Concerning the final inter-layer orientation, from the picture taken on one face, the trajectory of the fibre tows was extracted manually by drawing curves using Inkscape and saved as a svg file for post-processing. Then a python script extracted the curves representing each fibre tow and the angle at the intersection of two fibre tows was computed. Fig. 6 (a) shows the extracted trajectories and while Fig. 6 (b) presents a nice distribution of the inter-layer angle around 90°. Considering a normal distribution of the angles, a mean angle of 90.72◦ with a standard deviation of 4.31◦ is obtained. However, it must be noticed that due to the choice of the layers to obtain the flat TFP pattern, the fibre tows are parallel along the symmetry line of the faces. Another choice for the layer layout which eliminates this orientation defect was noticed too late.

Finite Element Model of a TFP Preform

Modelling strategy.

The model developed to simulate the forming of a TFP preform without backing material is based on the finite element method. Since the backing material is removed prior forming in this work or in a melted state when a thermoforming process is used, its contribution is neglected. To take into account the flexibility offered by the TFP technology in the preform design, it was chosen to use a semi-discrete approach where the preform is modelled at the scale of the fibre tows.

Hypothesis.

In this model, the fibre tows are considered to be quasi-inextensible. Although the backing material is removed prior forming, the stitching yarn is assumed to ensure the cohesion between the layers thanks to inter-layer overstitching.

Fibre tows.

The fibre tows are modelled as a continuum medium using 2-node shear-flexible beam element. The initial formulation of this type of element can be found in [15-17]. Since fibre tows cannot be considered as a perfect continuum medium, the section moduli, which relate the cross-section forces and moments to its deformation and curvatures, are considered to be independent. A high value of the tensile modulus ensures a weak enforcement of the quasi-inextensibility constraint.

Stitching yarn.

The stitching yarn is the component of a TFP preform whose contribution is the most difficult to take into account. To avoid burdensome computations implied by a realistic modelling of the stitching yarn and its interactions with the fibre tows, it is modelled implicitly as an embedded constraint between crossing fibre tows of adjacent layers. In other words, the stitching yarn is assumed to act as a perfect bond between fibre tows of adjacent layers which intersect. The embedding constraint principle is illustrated in Fig. 7 where two fibre tows intersect. To apply this constraint a node is required at the intersection between the elements of the lower fibre tow and those of the upper fibre tow. On the kinematic side, the displacement of this node is computed as function of the displacements of the lower beam element it is embedded in (host element). As a consequence, forces which are computed at this embedded node are transferred on the nodes of the host beam element. To take into account the resistance to rotation between crossing fibre tows, a linear torsional spring is added at each intersection. The vertical offset between the two crossing fibre tows in Fig. 7 is only for visibility purpose.

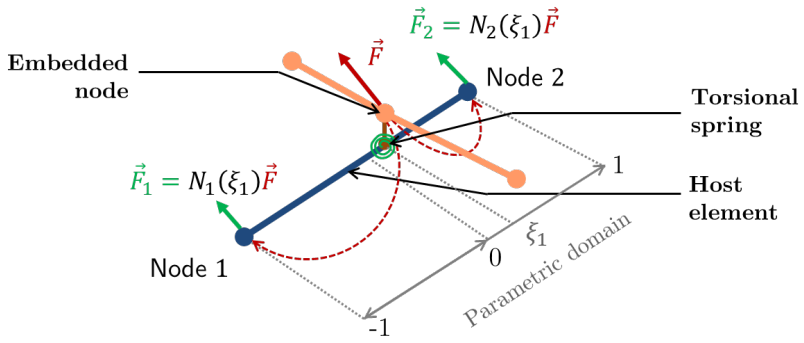

Fig. 7. Embedding constraint principle: Transfer of forces from an embedded node to the nodes of its host element.

TFP preform model.

Therefore, in this work, a 2-layer TFP preform without backing material is considered where the fibre tows are modelled explicitly using 2-node shear flexible elements and the stitching yarn is modelled implicitly through an embedding constraint where the fibre tows of adjacent layers intersect each other. The resistance to in-plane shear is taken into account through a linear torsional spring at these intersections.

Numerical Forming on a Tetrahedral Shape

Material parameters.

The model requires six independent material parameters for the beam elements corresponding to the six independent deformation modes (one for tension/compression, 2 for transverse shears, 2 for flexions and one for torsion). An additional parameter is required for the resistance to rotation between crossing fibre tows. No characterization of these material parameters was carried-out and their estimation is given in Table. 1.

Table. 1 Values of the material parameters for the beam elements and the torsional springs.

Modulus	**Tensile**	**Transverse shear 1**	**Transverse shear 2**	**Flexion 1**	**Flexion 2**	**Torsion**	**Torsional spring**
Value	1400	700	700	1	0.1	1	1
Unit	kN	kN	kN	kN mm²	kN mm²	kN mm²	N mm

Finite element solver.

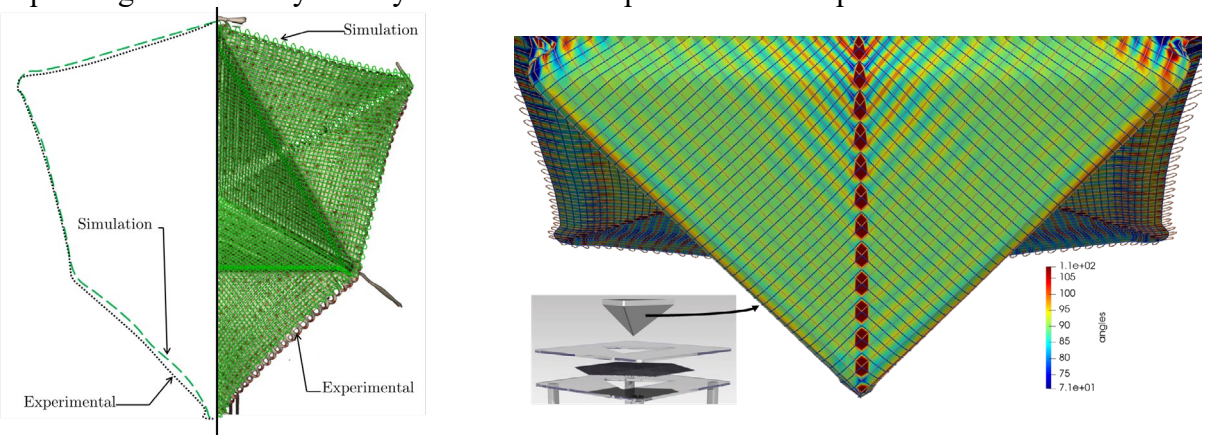
A research code based on an explicit scheme is used to simulate the forming process with a time step of 10^{-4}s. The contact interactions between the TFP preform and the tools, namely, the tetrahedral punch and the blank-holders are solved using a forward increment Lagrangian multipliers method.

Finite element model.

The first layer is composed of beam elements of 2.5 mm. The second layer is meshed with the same element size but nodes additional nodes are required at intersections with the elements of the first layer. These additional nodes are embedded in the corresponding host elements of the first layer. The total number of beam elements is 22190 and the simulation runs in 12 h using four cores of an Intel(R) Core(TM) i7-8750H CPU 2.20 GHz processor. A friction coefficient of 0.2 between the fibre tows and the forming tools was chosen for simplicity even though it might be different since the blank-holders are made of different polymers. A displacement of 140 mm is imposed to the punch. Concerning the blank-holder, the fixed part is clamped and the movable part can only move along the punch axis as in the experiment. Rigid surfaces are used to model the tools.

Results.

A comparison between the experiment and the simulation is shown in Fig. 8 (a). In this figure, the contours of the preform in the experiment and in the simulation are superposed on the left part and shows good agreement. In Fig. 8 (b), the inter-layer angle field on one face of the punch is displayed. The colormap shows a distribution of the inter-layer angle around 90° as expected, except along the line of symmetry of the face as explained in the experimental section.



(a) (b)

Fig. 8. Superposition of the preform contour in the experiment and simulation (a), inter-layer angle field on a face of the punch (b).

Summary

This work demonstrates the ability to form a 2-layer TFP preform on a doubly-curved part with a final orthotropic configuration. Only a minimal blank-holder setup was needed to form the preform without defects. The orthotropic orientation in the final configuration shows great improvement compared to forming of regular fibrous reinforcements. The design of the flat TFP pattern was obtained analytically by considering the inextensibility of the fibre tows. A first finite element model was proposed to simulate the forming of TFP preform without backing material. Based on a semi-discrete approach, the fibre tows are modelled explicitly using 2-node shear-flexible beam elements while the stitching yarn is modelled implicitly using an embedding constraint. It assumes the stitching yarn to act as a perfect bond between crossing fibre tows of adjacent layers. Additional linear torsional spring take into account the resistance to in-plane shear of the reinforcement.

In future work, the development of a numerical tool to determine the flat pattern of more complex parts is of interest. Besides, a model which takes into account the backing material is currently developed.

Keywords: Flat-Knitting, CBS, Simulation, On-Demand, FEM

Abstract. Though the level of machine digitization in flatbed-knitting (FBK) today is high, the design and development of knittable data sets are still currently very time-consuming, digital simulations methods are calculation expensive and insufficient in terms of accuracy of fit and technical properties. Knitting process retrofitting activities are executed mostly manually by an operator on the basis of the operator´s experience. This circumstance makes it more difficult to use the diverse potential for flexibility and on-demand purposes in future-networked-production for lightweight constructions for Automotive, Aerospace and aviation or Medical-Products. New easy-to-learn, intuitive, calculation inexpensive digital augmented workflows for the planning of knitted objects with complex 3D-shapes are needed. With regard to the requirements of composite forming, the aspects of wrinkling, slip and permeability are of particular importance. However, flatbed-knitted fabrics are subject to different requirements in some cases, which implies different questions from those posed by research in the area woven textile composites. In order to address a few of the questions raised by previous research on textile composites, this paper covers some of the current research topics in the field of 3D-knitted flatbed-knitting fabrics and shows references as well as potentials to already researched problem fields of textile reinforced composites. In doing so, the author strongly refers to the topics of the summarizing publication "Advances in composite forming through 25 years of ESAFORM" by P. Boisse et al. [1].

Introduction

To give a first impression of the current possibilities and concepts in the development of three-dimensional shaped flatbed-knitted textiles, a brief summary of current geometry-based approaches follows. The approaches presented currently show their greatest potential at the level of purely plastic-shape reproduction. Special consideration of material parameters to extend the product properties of the planned object are given little attention here. However, the presented methods could be suitable to derive FEM-calculable models on macro-scale level. A standardization towards certain restricted geometric variables is emerging. Most noticeable is the representation of a knittable geometry in quad and partial triangle meshes (Fig. 1).

The formation of these types is described in the following. Furthermore, technical knitted fabrics with different property zones in particular are currently a major focus of the author’s work. The mutually influencing material and stitch properties generally lead to results that are difficult to predict in the initial development stages. In the field of today's "craft / non-simulation-based" planning and individualization of 3D-knitted-technical-textiles, these property zones play a major role. On the one hand, mesh ratios are used to influence the plastic-shape and, on the other hand, to design zones with references to external forces. Different mesh-loop ratios often result from technical knitting/binding variations for loop formation. These are also not considered in depth here. In Yordan Kyosev's publication from 2019 entitled "Topology-Based Modelling of Textile Structures and Their Joint Assemblies", these are considered in more detail. Specifically, starting on page 100 of the aforementioned publication, the framework for FEM calibrations at the meso-scale level is described.

Depending on the yarn properties at the micro-scale level, for example, the stitch height in combination with the pre-tensioning by yarn feeders has an influence on the strength of the knitted fabric under pressure and tension on macro-scale or product-scale level. The product scale level can be seen as the sum of all parameters acting on the entire textile-product. In order to be able to represent property changes at this level, additional geometry-based calculation models are required in addition to all the other levels mentioned above. Therefore, at the end of this paper, the author presents a new approach with reference to the mentioned influences of the stitch ratio on product-scale level.

In addition to the basic principles introduced below for the development of geometric standards, the author considers the field of research (varying ratios) to be one of high priority for technical design using digital simulations.

As illustrated, different stitch ratios have a major influence on the technical properties, shape contours and surface finish of 3D knitted technical textiles. The basic technical possibilities for influencing shape and thus important design criteria for three-dimensional technical textiles are, in addition to the stitch ratios: Darts and Notches, short- and Long-Rows with decreases and increases. In all these areas, elastic yarns and yarns with different properties can have a strong influence on the prospective shape. Knitted fabrics also have a highly indiscreet structure. This reality assumption makes it difficult to calculate distortions or other plastic and material property changes using FEM methods. Taken together, this forms a complex set of requirements for future tools for digital simulation, especially with regard to industrial use.

FEM-Simulations

Y. Kyosev sums up this challenge in textile technology in general as follows: during the modelling with FEM, the real system (…) has to be idealized first in order to achieve a somewhat simplified physical system. This first step is the building of the physical model, where certain assumptions have to be made [2].

To address the problem of abstracting real complexity in the field of flatbed-knitting, the author proposes the reduction of complexity in the form using of discrete Knit-Meshes. These digital Knit-Meshes in the form of stitch-ratio-proportion quad-meshes and partly triangulated quads can be used for dynamic-FEM calculation. Similar to the digital simulation of woven surfaces, the properties on the three levels: micro-, meso-, and macro-scale level give important parameters for the calculation. For the calculation method proposed in the paper, the author follows Y. Kyosev's statement: "The macro scale is the most important for the applications. It deals with the mechanical behaviour of the structure as a continuum membrane or plate with known properties" [ibid.]. Furthermore, Kyosev describes that there are several methods to obtain the properties at the macro-scale level, which are mostly derived on the specifications of the meso-scale. Most often, various mechanical tests with material samples are used [ibid.].

Despite the necessary connection of the different property levels described by Kyosev, the author devotes himself for the time being only to the macro level. This serves to set up a digital simulation model for deriving the internal forces at different stitch ratios within a knitted fabric.

In addition to the references to the field of textile composites outlined in the further text, the large medical technology companies and their customers in particular would have great advantages from further process innovations in the digital design of flat-knitted products. Since the author's previous focus has been on consumer products and medical devices, the demonstrator of the paper for the purpose of illustrating the process, in dealing with varying ratios, will be a bandage.

By using 3D CAD data from 3D scans and FEM calculation methods, the processes in the individualization of bandages could be further simplified in the future. In particular, specific body parts with high concave and convex plasticity (e.g., popliteal fossa, crook of the arm, kneecap) can

benefit from the use of scan data and semi-automatic data set optimization. Prosthetic applications would also be conceivable with reference to textile composites.

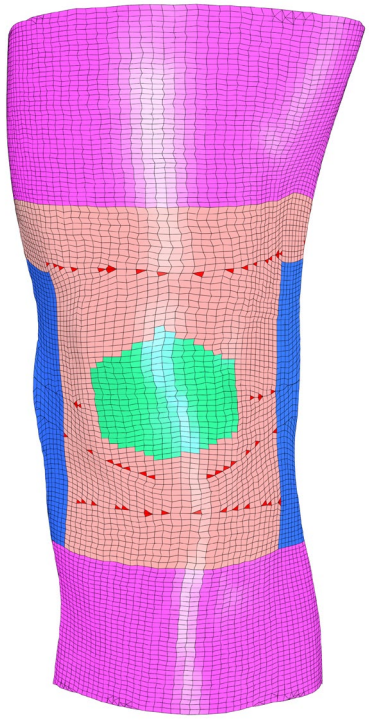

Fig. 1. Function zoned and topography optimized knit mesh.

Knit-Meshes

Several methods are currently known for creating knittable mesh topologies. K. Wu et al. describe in their publication "Wearable 3D Machine Knitting: Automatic Generation of Shaped Knit Sheets to Cover Real-World Objects," 2021, the following approach. The first step is to convert the cut mesh into a quad-dominant mesh where there are only triangles, quadrilaterals, and pentagons exist and all faces have the same size and the and have the same ratio between the edge lengths of course and wale [3].

Furthermore, they describe that the directions of course and wale are already determined during a surface cutting procedure. In two referenced earlier works, previous developments are introduced. Herein they also describe, on one hand, a vektorfield-oriented anisotropic remeshing pipeline and, on the other hand, the use of a local anisotropic parameterization method in conjunction with an extraction approach to generate an anisotropic quad-dominant mesh with relatively few triangles and pentagons [ibid.]. Through this form/step of categorization and modularization, they achieve an anisotropic quad-dominant mesh. In particular, this geometric property supports a later good calculability in the form of FEM calculations.

G. Nader et al. described another, partly similar, process in their 2021 published Work “KnitKit: A flexible system for machine knitting of customizable textiles”. The construction of the knit mesh starts here with a parameterization which generates orthogonal stripes with equal distances. It is followed by a remeshing step, which generates an adequate quad-dominant Knit-Mesh. The edges of this mesh are consistently aligned with the knitting direction and are divided into two groups: course-edges and wale-edges [4].

To create the wale and course contours/curves, they use a unit vectorfield-based analysis of the surface of an input mesh at each node/vertex. At each vertex of the input triangular mesh, they start by computing $\vec{v}$c as the rotation of $\vec{v}$w by π /2 in the respective local tangent plane. From

this cross-field ($\vec{v}c$; $\vec{v}w$) there is an orthogonal, equally spaced stripe pattern computed using Knoppel et al.'s [2015] method [ibid.]. In another concept, first published in 2019 by Mariana Popescu, a graph-theoretic foundation is set. Basically, a 3D geometry, Mesh or NURBS-Surfaces, is needed. A gauge edge and a knit-end-edge are marked with curves or surface edges. Between two more "left-side" & "right-side" bounding edges, an intermediate frequency curve (tween curve) or contouring curve series is created. These are subsequently subdivided in weft-direction in the height dimension of the planned stitch-ratio [5]. To create the warp lines of the knitting pattern, the vertices must be connected by edges. Resulting Edges describe the directions of the knitting pattern and represent the weft and warp directions of the knitting pattern. In the stitch creation step, only "weft" edges are added. Before the edges are added, for each vertex a set of potential connection points is defined. Two sets of at least four closest vertices on the adjacent contours are added to a list for the later Wire Frame-Mesh. If the four nearest points fall on the same coordinate, the knit-mesh will show a decrease or an increase. Through these superposed points the ends of a warp-line-segment will build a common end-point. This constructs a triangle as shown in red in Figure 1. This symbolizes a decrease or increase within the resulting mesh.

In a thesis published in 2020, Max Eschenbach summarizes various approaches, but especially M. Popescu's graph-based computational basis of knit meshes and knittable paths in a compendium. Part of his work is the publication of Cockatoo, which is a prototypical open-source software toolkit for generating (3d) knitting patterns from NURBS surface and mesh geometry [6].

Due to the comprehensibility of the latter approaches, the same categorization/modularization is applied in the further process. It is assumed that both the computability by kinematic-FEM-Computation and the basic structure of the mesh by quad-dominance and decrease/increase-triangles are well suited for the evaluation and simulation processes presented in the following.

The basic design features of an FEM-compliant geometric calculation basis are derived from the general remarks on textile FEM calculation by L. Girdauskaite et al. and interpreted for the present focal field of technical flat knitting. Girdauskaite et al. describe the basic method in an article summarizing on textile physical tests [7].

The crossing points of weft and warp lines represent the joints for a kinematic FEM calculation explained later. Between the crossing points, constructed lines behave like rods with constant or limited flexible length. This flexibility allows a later consideration of constituent material properties. However, these are not yet considered in the present paper. An outlined concept for linking the macro-scale-knit-meshes with the meso-scale-binding-variants is touched upon under headline Experimental measurement.

The purpose of the presented process is the evaluation of form-giving cut features and the subsequent fit optimization by means of additionally entered different stitch ratios. However, as described, an accurate distribution of forces at the macro level requires further linkage with property models at the meso-scale level. These will be considered in further studies.

Simulation Differences for Woven Textiles

At this point, the research results presented so far will serve as a comparison between digital simulation of woven and knitted textiles. Due to the technical characteristics of the structure and the machine binding logic of both textile-production-methods (Knit & Woven Fabric), fundamental differences arise. These differences create very different geometric assumptions at the macro- and meso-scale levels for calculating shear and other material properties such as the effects of stress and strain on the textile.

Measuring Textile Composites, Knitted & Woven Materials

Analysis and modelling of the deformation behaviour of fabrics, textile composites and prepregs can be performed more or less at one or more of three scales: (1) microscopic, (2) mesoscopic, and (3) macroscopic. In terms of scale, simulations of flat-knitted three-dimensional textiles are

Materials Research Proceedings 28 (2023) 239-248 https://doi.org/10.21741/9781644902479-26

currently mostly subjected to macroscopic analyses of the behaviour of the entire mesh shell/geometry (continuum membrane; Kyosev:2019), similar to the summary publication mentioned above regarding woven textiles by P. Boisse et al [8]. Since simulation methods at the macro level for three-dimensional flat knitting have so far been little standardized and are often very application-specific, (1), (2) and (3) are currently usually considered separately or a link is neglected.

Another complicating factor is that there are no generally valid calculation concepts for the shear behaviour of the individual stitch loops, taking into account different ratios, or the many different combinations for stitch loop/mesh formation and various knitting techniques (e.g., plating, weft insertion). Compared to woven fabric, the complexity of derivation increases here. This is because a stitch loop has multidirectional intersections and connections, as shown below.

Experimental Measurement

Experimental measurement for woven materials relates in part to the derivation of different shear angles. P. Boisse et al. describe essentially two different methods. One is the picture frame test and the other is the bias extension test [ibid]. Whether these two test methods are usable for the three-dimensional flatbed- knitting has to be evaluated in experiments. Furthermore, the researchers state earlier in 2017 that two relationships are required to analyse the results of an in-plane shear test [9]. A kinematic relationship that relates the in-plane shear angle to the extension of the Sample. For flatbed-knitting, the second dependence might be different and a third is required. For example, instead of shear angles, the focus of a question could be directions vectors related to truss centres resulting from the construction properties for stitch/mesh-loops at the meso-scale level. A mesh loop on the meso-scale level is described by a quad cell (polygon) in the digital model on the macro-scale plane. The centre of a truss can be related to one another cell-truss-centre. Changes in the positions of any node i in certain directions $\overrightarrow{vn}$ can be analysed. The resulting direction vectors can be used to optimize an FEM-based deformation analysis. The forces applied in warping experiments would then be expressed in "flow directions" within the knitted fabric. The third dependency can be achieved through investigations at the micro-scale level. Here we are concerned with the forces acting within the mesh loop elements at the yarn level. These can be represented in global coordinates by the relationships between the internal nodal forces and nodal displacements [10] within the truss:

$$F = Ku \tag{1}$$

Analyses could take the form of deviation measurements in applied 2D samples. This form of quality determination and analysis of visual warpage behaviour is today part of the craft practice in the development of three-dimensional knitted fabrics (for e.g.: car seats.). Color-coded zones or knitted-in measuring points could be detected and assigned with the aid of invariant moments (e.g.: Hu moments). This enables a point or area-accurate comparison between textile at rest and distortion.

Digital Augmented Experimental Measurement

Another possibility arises from taking 4D scans. With the help of the evaluation of different recording frames, the exact distortion behaviour in motion could be investigated. In the author's experience, point cloud data is also very well suited for machine learning-based analyses of the behaviour of specific clusters.

Colours, patterns or point-groups can be used as invariant moments or invariant geometries. Knitted-in position-sensors would also be conceivable.

DIC, Invariant Moment & Geometries (3D-Scan)

The described procedures have similarities to the digital image correlation (DIC) which was described by Boisse et al. The DIC method is divided into a two-dimensional & a photogrammetric three-dimensional analysis method for pattern recognition.

The mentioned Hu-moments are rather used for shape recognition of geometries as a whole with closed contours. It hereby forms an important foundation in AI-assisted shape recognition. Based on the briefly described different approaches of image and geometry analysis, further methods can be designed which can be adapted for flat-knitting-/ and woven-textile-/ -based-composites. The experimental and digital augmented measurements and evaluations of deviations or errors will be important here in the future in order to achieve further simulation concepts for adequate computation.

Reengineering 3D-Scans and Remeshing

To obtain a computable mesh shell of a 3D scan or a 3D model, e.g., of a knee, the approaches presented above (Knit-Meshes) are partially applicable. Behind each of the approaches is the assumption that certain geometric properties are given. Therefore, the approaches can be described as application-specific. A generalistic approach for the construction of knit meshes is currently not known to the author. Therefore, each approach has advantages and disadvantages when applied to an arbitrary geometry. The author uses a workaround of proprietary software processes and commercial applications. These are described briefly below to provide a summary at the end of the paper with respect to the process foci described above (slip, wrinkling and permeability) in the development of textile-composite materials.

Knitting Technicians Best Praxis

The concepts presented for knit mesh creation have, as mentioned, in part very application-specific advantages & disadvantages. The author considers the lack of possibility to influence the position of darts or gores & notches to be the biggest disadvantage. In practice, these are used by knitting technicians in addition to changing the stitch ratio in order to influence the shape and material properties. The author therefore focuses on the removal and insertion of material quantities in certain cut sections with excess material or excessive stretch. Cut material-areas are adjusted at the edges and provided with the triangular shapes described above (increase/decrease) Afterwards the mesh is joined at row transitions. This is followed by the calculation of the internal warpage behaviour by means of kinematic calculation (Fig. 2).

In order to ensure a quantitative evaluation of the results, a geometric invariant is used. In addition to the visually observable effects, this gives another possibility to evaluate the shape accuracy after given adjustments.

Knit Mesh Preparation

A feature of the commercial NURBS modelling software Rhinoceros 3D is used to create the quad mesh. The integrated quad mesh tool allows a homogeneous quad recalculation of given NURBS or polygon geometries. The generated quad geometry is relatively uniform and quad-dominated. The ratio deviations from the actual mesh ratio are readjusted by dynamic relaxation. Here, as shown below, all segments dS are equated and relaxed in the knit-mesh ratio.

Dynamic Relaxation

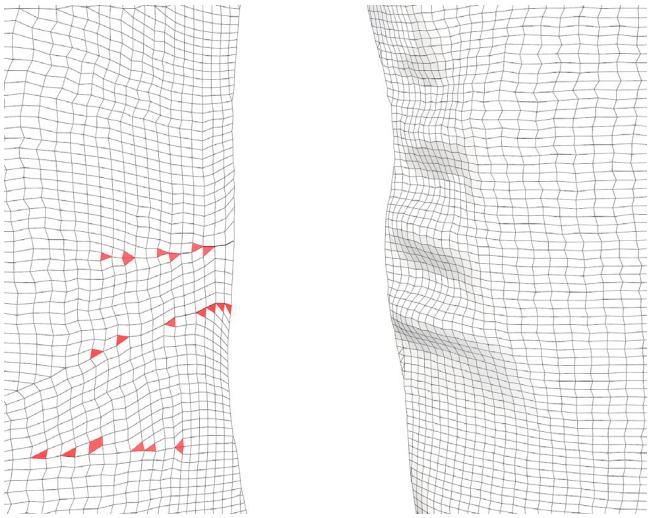
The dynamic relaxation method is based on discretizing the continuum under consideration by lumping the mass at nodes and defining the relationship between nodes in terms of stiffness. An iterative process is followed by simulating a pseudo-dynamic process in time, with each iteration based on an update of the geometry [11]. Considering Newton's second law of motion in the x direction at the i^{th} node at time t:

$$R_{ix}\,(t) = M_i\,A_{ix}\,(t) \tag{1}$$

The forces generated by the expansion of each edge segment led to a realignment of the whole mesh due to the internal references of the discrete structure.

According to the principle of equilibrium of forces, the relationship between the residuals and the geometry can be determined:

$$R_{ix}(t + \Delta t) = P_{ix}\,(t + \Delta t) + \sum \frac{T_m\,(t+\Delta t)}{l_m\,(t+\Delta)} \times \left(x_j(t + \Delta t) - x_i(t + \Delta t)\right) \tag{2}$$



The sum must cover the forces in all the connections between the node and other nodes. By repeating the use of the relationship between the residuals and the geometry, and the relationship between the geometry and the residual, the pseudo-dynamic process is simulated. Residuals $T_m(t), R_i(t)$are computed until the structure is in static equilibrium [ibid.].

Reducing Wrinkles

Fig. 2 shows the comparison of a relaxed mesh-shell to an author-edited mesh-shell. The wrinkles that appeared after the material was relaxed into a uniform knittable mesh-ratio were achieved by removing material and changing the mesh proportions in certain areas. This process is described below.

FEM – Calculation

To simulate the shape accuracy of a knitted fabric, taking into account the knitted fabric weave and stitch ratios, three main laws can be required for the modelling of mechanical systems – kinematic, constitutive (material) and equilibrium [12].

Only kinematic equations were used to calculate the following patterns. Since textile kinematics assumes that relationships between the movement of individual nodes in a mechanical system consisting of nodes and connecting edges lead to internal deformations, a readability of a deformation due to external and internal force influences in the knit mesh can be assumed. The algorithms used are based on the basic algorithm of the kinematic model. All points $\vec{x}$ on a doubly curved geometry surface can be parametrically represented with surface coordinates u_i:

$$\vec{x} = \vec{x}\,(u_1, u_2) \tag{3}$$

The elementary length dS of a surface segment, between two closely spaced points/nodes (i, j) is given by the initial prepared Knit-Mesh and its constituent uniform mesh ratios. The stitch ratios

correspond to the selected stitch ratios of a knitted fabric. In this case, an initial stitch ratio of 1.47 mm width and 1.1 mm height was chosen. For faster simulation calculation, the stitch ratio was multiplied by a factor of two (2.94 mm x 2.2 mm). The lower number of nodes (i, j) and edges speeds up the calculation.

$$dS^2 = G_{ij} du_j du_i \tag{4}$$

An angular threshold is used to define the possible shear inside each triangular face of the triangulated simulation quad-meshes. This threshold value is basically present. It is represented by the given initial angle of the triangular legs of each face. This determination thus represents a part of the Stiffness matrix, where K is the stiffness matrix of the system, u is the vector with the nodal displacements and F represents the external forces.

$$K \cdot u = F \tag{5}$$

In addition, internal forces act. The external forces pull the Knit-Mesh against a given avatar, which acts as a collision object. While the internal forces are generated by the one recurrence of the inner triangles edges(diagonals). These represent a simplified truss. This form does not give exact results, but serves as a necessary variable for the computational model. The virtual external work is due to the external forces described and can be represented by Eq. 1.

The equilibrium state is reached when the nodal displacement u_i = is less than 0.01mm/s for given forces δW_i.

The material constitutive parameters were disregarded for the time being, since a large number of experimental measurements are necessary for this. T. Pusch sums up that: due to the strong anisotropy of continuous fibre fabrics, the material properties depend on the type of loading. This requires a high level of testing for a complete experimental analysis. In general, the directional properties can be investigated in tension, compression, bending, and shear tests by experimental measurements on knitted material specimens fabricated for survey purposes [13]. Yarn elongation and/or stretching are considered to be neglected for the time being in the descriptions of deformation shown. Truss and Quad-Edges behave roughly stiffly.

Geometric Invariants

In a digital simulated polygonal representation of a knitted fabric (zoned Knit-Mesh, Fig. 1), geometric invariants are required in order to draw conclusions about the shape reproduction of knitted fabric (shape-fidelity) due to compressive, tensile and relaxation stress. In this case, invariance can be related to physical reality. However, this requires a high level of testing for a complete experimental analysis as mentioned above. Invariance describes a property that remains unchanged after operations or transformations of a certain kind have been applied to objects. The author hypothesizes that on the one hand distance deviations between the simulated knit geometry and a 3D-Scan-avatar-model may be suitable for a) predicting shape-fidelity from given deviations and b) enabling optimized parameter sets for repeated FEM simulation. On the other hand, area deviations in the quad faces and length deviations of the warp-/ and weft-, truss-lines or of the edges of the faces could be used to evaluate strongly overstretched areas. The method proposed extends the previous experimental measurements and proposes a purely digital computational model for virtual simulation. In further research, this digital data can be enriched with real measurement data to obtain a material property (micro-/ & meso-scale) database. This database may then be used to inform future simulations of knitted fabric. Furthermore, it may serve as training data for machine learning algorithms.

Used Geometric Invariants

To evaluate the kinematically calculated distortions resulting a) from the cutting treatment and b) from altered mesh ratios, a distance deviation between the 3D scan and the approximated knitted mesh structure is used as a geometric invariant for quantifiable quality determination.

Distance-Map

In order to display the deviations of the generated knitted fabric quantitatively, a point cloud of the 3D scan is compared with the calculated knitted topography. For this purpose, a tool for distance analysis of geometry and point clouds in the Rhinoceros 3D software is used. Four different additionally applied mesh ratios were calculated. The deviations and *Input-zones* are shown in Table 1.

Table 1. List of deviation und ratio variants.

Deviations	Example 1	Example 2	Example 3	Example 4
Mean	0.3021334 mm	0.2793425	0.2868251	0.2223705

Ratio Plot				

Summary

At the beginning, the special requirements and challenges for working with woven-based composites were outlined. These can be found in: wrinkling, permeability and slippage.

From the author's point of view, the basic assumptions for calculation and analysis models behave somewhat differently. This is mainly related to the more complex material-internal force relationships. Nevertheless, the surveying apparatuses can be used to analyse the material behaviour under other implications. These were listed under the heading "Experimental Measurement" and "digital augmented experimental measurement".

Keywords: Compression Molding, Fiber Content, Process Development, Lightweight Design

Abstract. Due to an increasing volume of shipments, there is a significant need for more delivery vehicles. One approach to reduce the associated increase in carbon dioxide (CO_2) emissions is a new light weight design approach involving the substitution of conventional materials with glass fiber mat-reinforced thermoplastics (GMT) based on polypropylene (PP). The application of GMT by compression molding is a widely used process in the automotive industry. However, application in the commercial vehicle sector requires much larger dimensions, making it necessary to clarify whether the manufacturing process and material are suitable for semi-structural applications on this scale. To find this out, two replacement geometries are abstracted in this study and manufactured by varying the main manufacturing parameters. The feasibility can be demonstrated by recording and analyzing the resulting process variables and measuring the formed fiber distribution. At the end of the paper, recommendations are given for the production of GMT structures on the scale of commercial vehicles.

Introduction

Background.

Current studies on the development of parcel services clearly show that national and international shipment volumes have risen sharply in recent years and continue to rise further. While 2.4 billion shipments were delivered in Germany in 2011, the total increased to 4.5 billion in 2021. Compared with the previous year 2020, this represents an increase of 11.2 %. By 2026, the volume of shipments is forecast to reach around 5.7 billion [1]. To cope with the growing volume of shipments, significantly more delivery vehicles will be needed. In addition to high investments, the increasing volume of traffic also leads to greater strain on the infrastructure in inner-city traffic. This in turn results in longer idle times for all road users and increased emissions of greenhouse gases, which are crucial to climate change. For this reason, it is a necessary consequence to reduce the emission of climate-damaging combustion gases such as CO_2.

Two thirds of the vehicle fleet of parcel services consists of light commercial vehicles. These include commercial vehicles with a gross vehicle weight of up to 7.5 tons [2]. Current floor assemblies for box bodies of these light commercial vehicles consist of numerous individual parts, which entails many manufacturing and assembly steps. This is not only time-consuming but also cost-intensive. Furthermore, the lightweight potential of such bodies is limited and therefore requires a new and systemic development approach.

Project approach.

In this project, a process is to be developed that allows the modular subdivision of the loading floor for light commercial vehicles. For this purpose, an integral design with materials not commonly used for this area will be applied. By reducing the vehicle weight, the mass-dependent driving resistances correlating with CO_2 emissions can be minimized and the assembly effort for the floor structure can be kept to a minimum [3]. On the other hand, the lower unladen weight of the vehicle means that more parcels can be moved with a single vehicle, so that in total fewer delivery vehicles need to be used to cope with the increasing volume of parcels (cf. Fig. 1a).

Within the scope of the project, the floor modules will be manufactured from GMT, which is processed by compression molding (cf. Fig. 1b). The PP based material offers excellent weight specific mechanical properties, outstanding cost efficiency and a high degree of design freedom. The advantages over thermosets are based on shorter process times, almost unlimited recyclability and higher toughness [4-6]. Compression molding is well established and has been used in the automotive industry for many years. The heated GMT cuttings are pressed into cavities at forming pressures of up to 200 bar, so that complex structural components can be produced via flow movements of the material [4, 5]. Furthermore, due to the higher fiber length compared to fiber-reinforced granules in injection molding, higher mechanical strengths can be generated [6].

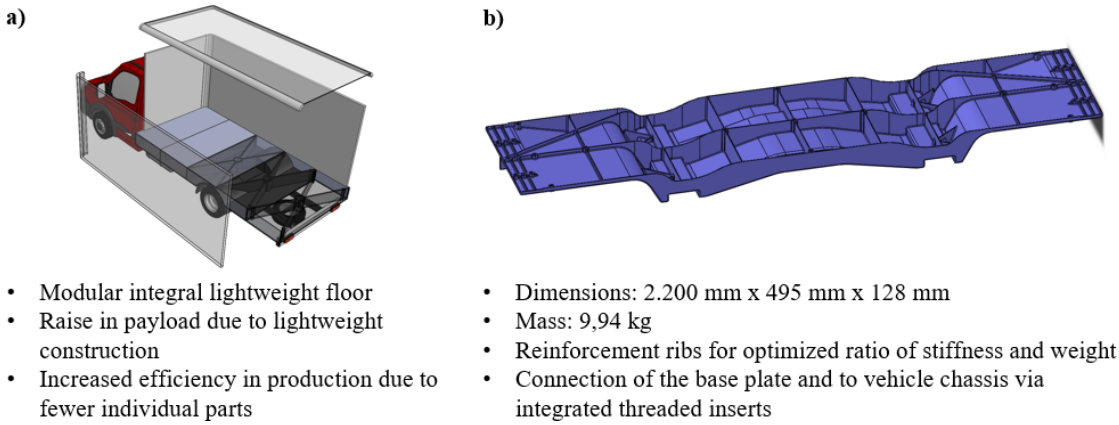

Fig. 1. a) Illustration of a commercial vehicle up to 3.5 t with box body and the associated project goals b) Design model of the floor module based on GMT.

Fig. 1b) shows the current design status of the topology-optimized CAD model of the floor module. The opposing requirements for stiffness and minimum weight can be met via reinforcement ribs. By stringing together eight modules, the entire store floor of the delivery vehicle is represented. A base plate can be mounted using threaded inserts integrated in the compression molding process. On the underside, the modules can be connected to the different geometries of the vehicle manufacturers underbodies.

Experimental Approach

To validate the process concept, it is necessary to investigate whether compression molding of GMT is suitable for the large dimensions of commercial vehicle sector in terms of mold filling and homogeneous fiber distribution. As shown in [4], the filling of the cavity in the course of the material flow movement can lead to accumulation of glass fibers in some places and thus to voids in other places of the component. These phenomena correlate with the final mechanical properties of the component. Rubio et. al. [5] found that the simpler the geometry, the more homogeneous the resulting properties are. Pöhler [7] investigated the fiber content of compression molded reinforcement ribs with a length of 90 mm as a function of the geometric design parameters. With a nominal fiber content of about 52 %, the fiber content in the rib tip was reduced up to 30 %. For

a compromise between lightweight construction and homogeneous cavity filling, Pöhler defined a demolding angle of 1.0 °, a minimum rib width of 3.0 mm and an insertion radius of 6.0 mm [7].

Rib geometry.

Since no comparable work is available for rib lengths greater than 90 mm, two different rib lengths are considered in this study and need to be investigated. As the final geometry of the floor module had not yet been determined at the time the tests were carried out, the rib lengths 87 mm and 200 mm were selected in order to be able to analyze a clear influence of the rib lengths. The rib length L, which is more than twice as long, is compensated by an increased demolding angle α and width W at the uppermost point. The minimum rib thickness is identical. Since a modular compression molding tool is used, other main dimensions of the rib are identical (cf. Fig. 2 a-b) and Fig. 3 a-c). A list of all different parameters is given in Table 1.

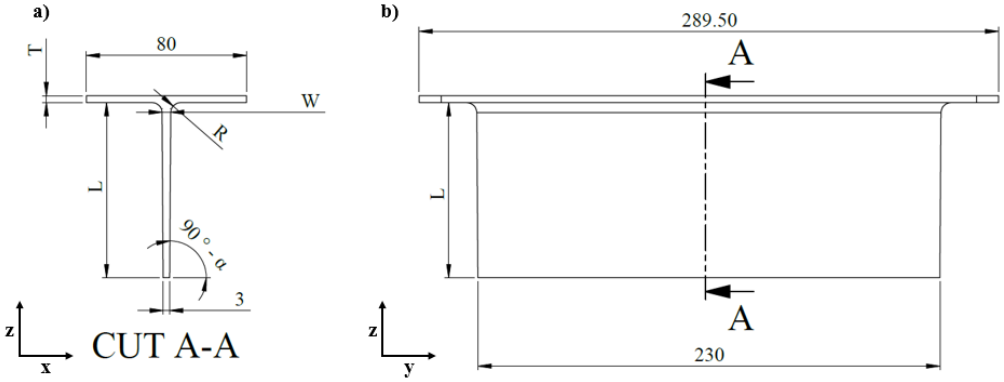

Fig. 2. Dimension of investigated ribs with a) cut view and b) longitudinal view.

Table 1. Parameters of "Rib 87 mm" and "Rib 200 mm".

Parameter	**Rib 87 mm**	**Rib 200 mm**
Rib length L	87 mm	200.0 mm
Insertion radius R	5.0 mm	6.0 mm
Rib width top W	4.3 mm	9.8 mm
Demolding angle α	0.4 °	1.0 °
Flange thickness T	Depending on material insert and mold filling (1.7 mm – 11.5 mm)	

Process technology.

The used compression molding tool can hold various cavities due to the pocket in the lower mold plate. Temperature regulation up to 95°C is enabled via a water-based temperature control unit. A cutout of the same size as the face of the cavity is provided in the upper mold plate, so that sealing of the process via vertical flash faces is possible (cf. Fig. 3 a).

Holes for piezoelectric pressure sensors are recessed at various positions within the cavities so that the resulting pressure in the cavity can be measured. In the cavity for the shorter rib length, holes are also provided for temperature sensors at the same position on the opposite cavity wall. In both cavities, two temperature sensors are positioned at the lowest point parallel to the direction of material flow in order to be able to measure the temperature of the melt shortly before the mold is completely filled (cf. Fig. 3 b-c).

As in Stallmeister et. al. [8], piezoelectric load cells are used to record the resulting press force and a draw-wire sensor is used to detect the press stroke. The data from the pressure sensors, the load cells and the draw-wire sensor are recorded simultaneously, so that no time offset has to be considered in the analysis.

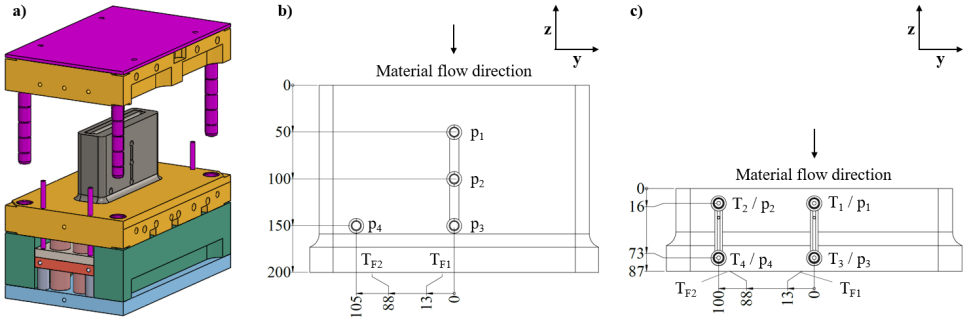

Fig. 3. a) Compression molding tool and b) – c) cavities with the respective geometric positions of the sensors.

Materials.

A widely used PP-based GMT with a fiber mass fraction of 52 % from Mitsubishi Chemicals Advanced Materials (MCAM) is used for the majority of the tests. According to the manufacturer, the material has good flow properties, a very homogeneous fiber distribution and is applied for semi-structural applications. A GMT with 33% fiber mass fraction from MCAM is used to analyze the flow behavior as a function of the fiber content. The main properties can be found in Table 2.

Table 2. Material properties of the GMT used according to MCAM.

Material properties	**GMT PP-GF52**	**GMT PP-GF33**
Thickness (laminate)	4.8 mm	5.4 mm
Density (laminate)	1.34 g/cm³	1.12 g/cm³
Density (molded)	1.40 g/cm³	1.16 g/cm³
Tensile strength	145 MPa	70 MPa
Tensile modulus	8600 MPa	4600 MPa
Melting point	165°C	166°C

Process sequence.

GMT cuttings with the dimensions of 260 mm x 50 mm are used for specimen production. To achieve a defined mass for the specific trial, smaller sheets are added until the desired weight is reached. Fig. 4 a-d) shows the following process steps.

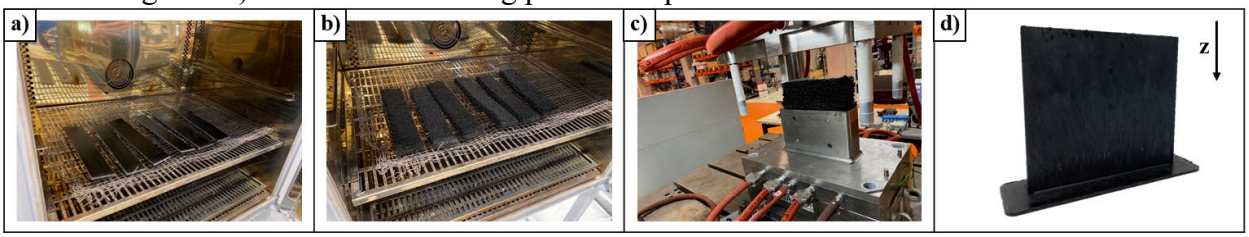

Fig. 4. Process sequence: a) GMT in furnace, b) heated GMT, c) GMT stack on cavity, d) manufactured rib.

The cuttings are placed next to each other in a 250°C convection oven and are heated for 10 minutes (cf. Fig. 4 a-b) Before transfer to the compression molding tool, the sheets are stacked in the oven to minimize temperature loss to the ambient air. After the GMT stack is centered on the cavity, the press stroke of a hydraulic forming press with a maximum press force of 50 tons is immediately actuated to form the rib (cf. Fig. 4 c-d). Closing speed of the press is about 30 mm / sec. The press force F is calibrated based on the desired forming pressure p, which is calculated from the press force F and the projected area of the cavity A_{cav}, before the test (cf. Eq. 1).

Forming pressure p is maintained for a time s of approx. 60 seconds. After completion of the pressing process, the rib is ejected via the ejector unit of the tool.

$$p = \frac{F}{A_{cav}} \tag{1}$$

Process Parameters.

In order to obtain various information on mold filling and fiber distribution in the ribs, applied forming pressures (100, 150 and 200 bar), mass of the inserted material (approx. 450-650 g) and temperature of the cavity (25°C and 90°C) for GMT PP-GF52 are systematically varied. The cavity temperatures 25°C and 90°C are marked T_{25} and T_{90} in the following. The investigations are mainly concentrated on the 200 mm long rib type and are occasionally carried out for the 87 mm long rib type (approx. 350 g – 400 g of GMT). Furthermore, the influence of a reduced fiber mass fraction (33 %) is investigated for defined test points. Each test point is performed at least twice.

Analysis methods.

To evaluate the quality of the ribs, the complete shape was visually inspected. In this context, it is useful to determine the resulting flange thickness by measuring the local thickness in at least three places and then calculating an average value. Furthermore, the resulting pressures in the cavity are analyzed as a function of the geometric position in the cavity. By means of the temperature measurements within the tool, it is possible to estimate the flowability of the GMT melt.

In order to gain an insight into the resulting fiber contents and distributions, X-rays of the ribs and point density measurements as a function of cavity depth are performed. While 2D X-ray is very well suited for the detection of fiber accumulations and voids, density measurement allows a quantitative and time-saving measurement of the resulting fiber content, since a determination of fiber content via ashing method according to DIN ISO 1172 [9] is too time-consuming for the large number of samples (up to 120 specimens). PP has a density of approx. 0.9 g/cm³ and E-glass fibers of approximately 2.6 g/cm³ [4]. Considering the specification for the pressed laminate, fiber accumulation or voids can be classified numerically (cf. Table 2). This is done by measuring the mass of the sample in ambient air (m_{GMT}) and under complete coverage with a known fluid (m_F). The difference between the masses is the mass of the displaced fluid. By dividing with the known density of the fluid ρ_F (in this case ethanol), the volume of the displaced fluid and thus the volume of the specimen V_{GMT} can be determined. Afterwards, the density ρ_{GMT} of the body can be calculated (cf. Eq. 2) [10].

$$\rho_{GMT} = \frac{m_{GMT}}{V_{GMT}} = \frac{m_{GMT}}{\frac{m_{GMT} - m_F}{\rho_F}} = \frac{m_{GMT} * \rho_F}{m_{GMT} - m_F} \tag{2}$$

Results

Mold filling.

In the following, only the results for complete shaped ribs with a length of 200 mm and the material PP-GF52 are considered, since mold filling for the 87 mm long rib is already state of the art. The heated GMT stack has an approximate temperature of 200°C before insertion, which was determined in advance with an infrared camera. At a forming pressure of 100 bar and a low cavity temperature (T_{25}), the mold filling can be improved with increased GMT mass (450-660 g), but a complete mold formation is not possible (cf. Fig. 5 a-c). Instead, the resulting flange thickness grows with increasing material input (up to 8.2 mm). If the temperature of the cavity is increased (T_{90}), complete mold formation is already possible from an inserted mass of 450 g. For this material input, the resulting flange thickness is reduced from approx. 3.2 mm (T_{25}) to 2.0 mm (T_{90}).

At a forming pressure of 150 bar, mold formation is possible from a GMT mass of 490 g (T_{25}). A positive influence on mold formation can be observed due to the lower flange thickness (2.1 mm

at 450 g GMT mass). Once again, complete mold formation is possible with a mass of 450 g when the cavity is heated up (T_{90}).

If the forming pressure is increased to 200 bar, complete ribs are possible in some cases from a mass of 450 g (T_{25}). Reliable mold filling can also be achieved starting from a mass of approx. 490 g (cf. Fig. 5 d). Variations between individual test points may be due to different transfer times and resulting temperature losses.

Basically, it can be stated that mold tempering is very advantageous for complete mold formation. It is also advisable to increase the forming pressure and the insertion mass. However, it must be considered that the increased GMT mass can lead to an undesirably high wall thickness in real components.

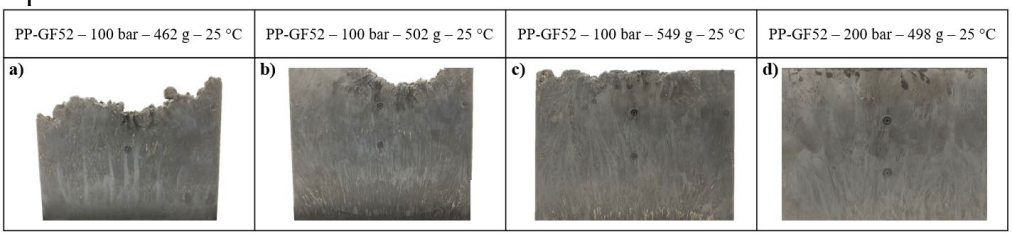

Fig. 5. Mold filling of the 200 mm long rib for selected process parameter combinations a) – d).

Process Monitoring.

Fig. 6 shows the recorded process parameters for the rib geometry with a length of 200 mm produced from GMT PP-GF52. The calculated forming pressure p, the measured values of cavity pressure p_1 – p_4 and the temperature T_{F1} – T_{F2} in the base of the rib as a function of time t are presented for two different combinations of process parameters (cf. Fig. 6 a-b). Since the calculated forming pressure p is proportional to the press force F, the force is not shown separately (cf. Eq. 1). Furthermore, the recorded press stroke changes only minimally as soon as the maximum press pressure has been applied, so this is also not shown. The process start is defined as soon as the measured force rises.

Forming pressure.

In both diagrams it is visible that forming pressure drops minimally after a steep start. Subsequently, the desired forming pressure level is reached with a reduced gradient. This phenomenon is due to the fact that the stacked GMT layers are initially compressed and start to enter the cavity since the mentioned threshold value is reached. After a compression time of at least 60 seconds, the process is terminated.

Cavity pressure.

With a small time offset, which is based on the distance between the insertion radius and the 1st pressure sensor, the cavity pressure at sensor p_1 increases with a similar slope. It is noticeable that the maximum pressure in the cavity is clearly below the calculated forming pressure. Furthermore, it is visible that the pressure p_1 does not remain constant and decreases over time. The qualitative trend of the sensors p_2 - p_4 corresponds essentially to the described trend of p_1. However, there is a premature pressure drop with increasing cavity depth (p_2, p_3/p_4) and nearness to the outer wall (p_4). This effect will be due to the thermal shrinkage of the GMT, as the material thickness decreases with increasing cavity depth, allowing the heat to dissipate faster. Furthermore, the heat can be dissipated even better at the outer edges of the cavity, so that full pressure drop occurs first at sensor p_4 (cf. Fig. 6 a-b).

Furthermore, a fundamental difference can be observed in the characteristics of the cavity pressures for different process parameters. While the cavity pressures p_1-p_4 at a forming pressure of 150 bar for a high cavity temperature (T_{90}) start almost simultaneously and reach a common maximum (cf. Fig. 6 a), a clear time offset in the pressure rise and a difference in the respective maxima can be seen at a pressure of 100 bar and a low cavity temperature (T_{25}). In addition, the

cavity pressures are maintained for a significantly shorter time and are significantly lower in relation to the calculated pressure (cf. Fig. 6 b).

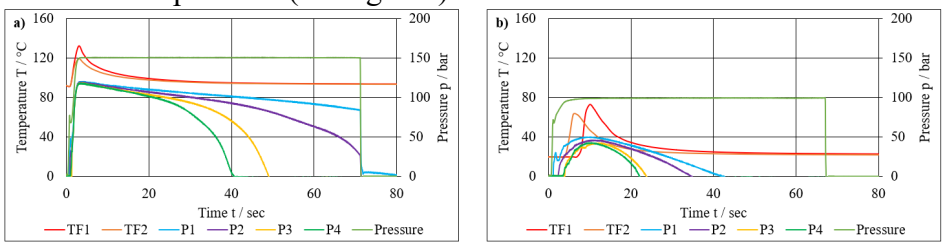

Fig. 6. Process diagrams with parameter combinations a) 150 bar, 649 g, T_{90} and b) 100 bar, 662 g, T_{25}.

Temperatures.

Examination of the resulting temperature in the base of the rib at two positions provides information about the temperature of the melt - and thus the flowability of the GMT - and about the geometric characteristics of the flow front. In the case of Fig. 6 a) both sensors reach their maximum almost simultaneously. However, the temperature at the sensor with the smaller wall distance is about 10 K lower. Compared to the set cavity temperature, there is an offset of 30-40 K. In comparison with other forming pressures and GMT masses, no significant differences can be observed.

In the second example (cf. Fig. 6 b), the maxima of the temperature sensors occur with a time offset. Here, the melt seems to first hit the sensor in the outer areas of the cavity wall. Compared to T_{25}-cavity wall, the maximum temperature offset is 40-50 K. At a maximum of 70°C, the temperature of the material is significantly below the melting temperature of the material, so that a clearly poorer flowability can be concluded.

For temperature sensors T1-T4, which are aligned orthogonally to the press direction of the 87 mm long rib, temperature offset of the GMT is even lower to the prevailing temperature in the tool (cf. Fig. 3 c). If the cavity is not heated, the maximum measured temperature is 40°C. If the cavity is heated to 90°C, the temperature of GMT is 100°C. It can be concluded from this that the outermost layer of material solidifies immediately on the cavity wall and the molding is driven from inside the structure.

Further analysis of cavity pressure.

As can be seen in Fig. 6, the measured cavity pressure sometimes differs significantly from the calculated forming pressure p. Insufficient pressure within the cavity can result in the GMT not being properly compacted. As a consequence, air pockets and fiber accumulations could result, since the pressure is not high enough to push fibers all the way to the bottom. In order to investigate this in more detail, the maximum ratio of the acting pressure ratio $p_{r,max}$ was determined for all test points for the pressure sensor p_1 (cf. Eq. 1 and 3).

$$p_{r,max} = \frac{p_{1,max}}{p_{max}} \tag{3}$$

Fig. 7 below shows this ratio as a function of inserted GMT mass, rib length, glass fiber content and cavity temperature for both rib types. Low values for a 200 mm long rib for a cavity temperature of 25°C (cf. Fig. 7 a) are due to insufficient mold filling. It can be observed that the ratio can be increased up to 0.75 when the forming pressure and GMT mass are increased. A further increase is possible with a tempered cavity, but the maximum is at a value of about 0.85 (cf. Fig. 8 b). The above-mentioned ratios can be achieved with a reduced fiber content (PP 33) even with significantly lower GMT masses (cf. Fig. 7 a-b).

Much less mass is required for the mold filling of the 87 mm long rib. Specimens prepared show that ratios of up to 92 % can be achieved even at low forming pressures and when using

GMT PP-GF52 (PP 52). At cavity temperature of 90°C and use of GMT PP-GF33 (PP 33), even a ratio of 1.0 is possible (cf. Fig 7 a-b).

From the results, it is concluded that the moldability of GMT is more advantageous with lower fiber content and shorter ribs. This is justified by the lower flow resistance due to reduced fiber content and shorter material flow paths. The impact of a reduced pressure ratio on the mechanical properties must be determined by separate investigations.

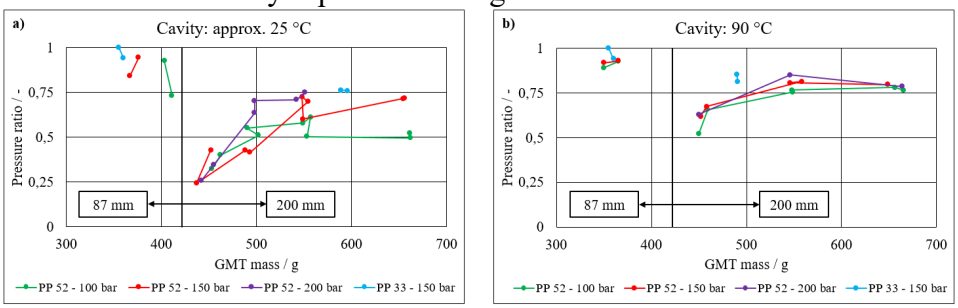

Fig. 7. Maximum pressure ratio of sensor p_1 as a function of process parameters for a) cavity temperature of approx. 25°C and b) cavity temperature of 90°C.

Qualitative fiber distribution.

A low pressure ratio could mean that a homogeneous fiber distribution might not be present for a rib length of 200 mm. To investigate this in more detail, the results of the X-ray images of the ribs are presented and analyzed below.

When analyzing the X-ray images of the 200 mm long ribs (cf. Fig. 8 a-e), it is noticeable that for the most part there is a very homogeneous fiber distribution. Only at a forming pressure of 150 bar and a low material loading of 488 g there are larger voids (cf. Fig 8 a). Smaller voids in the base of the ribs cannot be completely eliminated for PP-GF52 by increasing forming pressure, GMT mass and cavity temperature (cf. Fig. 8 b-c). In comparison, there appear to be fewer voids for a PP-GF33 (cf. Fig. 8 d). Increasing the temperature to 90 °C almost completely eliminates them (cf. Fig. 8 e).

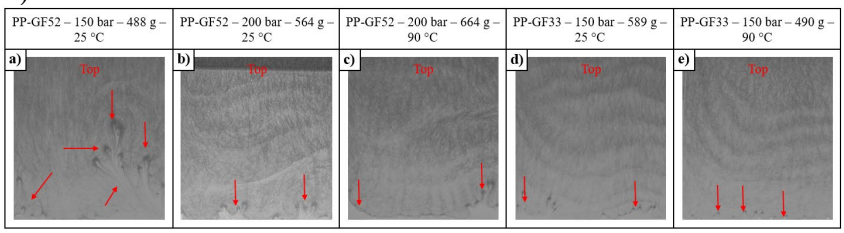

Fig. 8. X-rays of the ribs with a length of 200 mm for different parameter combinations a)-e). The full height (200 mm) and approx. half of the width (145 mm) are shown starting from the cavity wall.

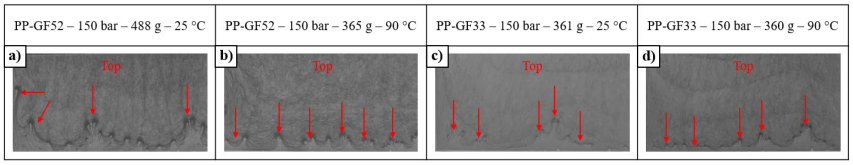

Fig. 9. X-rays of the ribs with a length of 87 mm for different parameter combinations a)-d). The full height (87 mm) and approx. 75% of the width (217 mm) are shown starting from the cavity wall.

In relation to the total rib length, the voids are significantly more pronounced in the 87 mm ribs (cf. Fig. 9 a-d). For PP-GF52, minimization is possible by increasing the cavity temperature

(cf. Fig. 9 a-b). For PP-GF33, the voids are again smaller, but complete elimination is not possible by tempering the cavity (cf. Fig. 9 c-d).

Quantitative fiber distribution.

To determine the density, the ribs are divided into rectangular test pieces. For ribs with a length of 200 mm, the test pieces have a size of 20 mm x 20 mm and for ribs with a length of 87 mm a size of 10 mm (parallel to flow direction) x 20 mm. For comparison, an average value is calculated for each height row (cf. Fig 10 a-b).

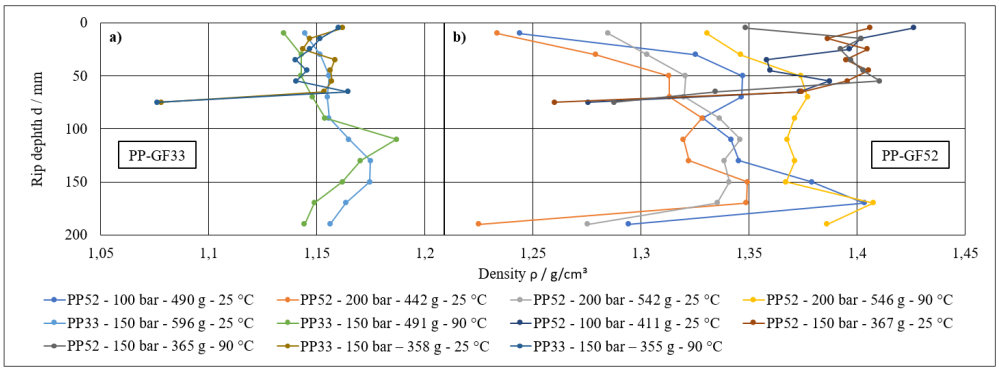

Fig. 10. Density measurements for both rib types with materials a) PP-GF33 and b) PP-GF52.

For rib length 200 mm, it is noticeable that the density, despite decreasing cavity pressure, rises continuously with increasing rib depth. When using PP-GF52, the density is many times below the value from the data sheet for the starting material. It is possible that the prevailing pressure is not sufficient to cause enough compression for the large wall thicknesses. A lack of glass fibers is unlikely at this point (cf. Fig. 10 b). For PP-GF33, the density is more homogeneous, with a tendency to increase as well (cf. Fig. 10 a).

In the deepest row, the density for PP-GF52 is significantly lower than in the penultimate row for many ribs. This will be due to the voids detected in the X-ray image. In contrast, for a high forming pressure and a tempered cavity, almost no drop is observed and the density value corresponds to the data plot for molded GMT. Obviously, an increased forming pressure, a sufficient amount of GMT and a tempered cavity leads to a satisfying compression and fiber distribution in the material (cf. Fig. 10 b).

For the 87 mm long rib, the value for compressed GMT from the data sheet is achieved (almost) for all specimens in the first row. With decreasing rib depth, this remains relatively constant and decreases again more strongly in the last row. In this application, a strong decrease is also observed for PP-GF32 (cf. Fig. 10 a-b). Basically, the findings made correlate well with the X-ray images and the certain pressure ratios. Voids occur only in the lowest areas and are more pronounced in the geometry of an 87 mm long rib. This can be answered by the low demolding angle. Furthermore, the increased pressure ratios for the GF-PP33 and the 87 mm long rib result in improved compression. This can be compensated for a 200 mm long rib by a high forming pressure and tempering of the cavity. A sufficient amount of GMT is also essential.

Summary

In the research project, floor modules for delivery vehicles should be produced from GMT using the compression molding process. Due to the dimensions prevailing in the commercial vehicle sector and a topology optimization carried out, reinforcing ribs up to a length of 200 mm may be required to meet the mechanical requirements. This goes beyond the previous state of the art, so that it was necessary in this study to abstract two substitute geometries of the floor module and to

test the process for its suitability for this application scenario by varying the most significant process parameters (e.g. forming pressure, mass, temperature of cavity, fiber content).

By analyzing the mold filling, the resulting process parameters (e.g. resulting pressures and temperatures in the cavity) and methods for qualitative and quantitative determination of the fiber distribution, a basic feasibility for the application in the commercial vehicle sector can be demonstrated. To prevent voids without any fibers, it must be ensured that the demolding angle of the cavity is greater than or equal to 1 °, sufficient amount of GMT is used (≥ 450 g), high forming pressure (≥ 150 bar) is applied and that the tool is heated (≥ 90 °C).

The knowledge gained will be used for further design of the floor module. Nevertheless, further mechanical tests will have to be carried out to confirm the study carried out. Moreover, a process simulation with the 3DTimon software will be validated on the basis of the recorded measurement data. This is to be used in the final stage to predict the manufacturing process of the whole floor module.

Acknowledgement
The research project is funded by the German Federal Ministry for Economic Affairs and Climate Action as part of "Technologietransfer-Programm Leichtbau". Thanks are due to all project members not mentioned by name. Special thanks go to Dr. Manel Ellouz of Bielefeld University of Applied Sciences for her support in the preparation and discussion of the X-ray images.

Keywords: Fibre Metal Laminates, Magnesium Alloy, Forming, Compaction Behaviour

Abstract. This research presents a methodology for the compaction characterization of thermoplastic prepregs with a twill weaving style under a range of parameters typical of the thermoforming process applied to magnesium alloy-based fibre metal laminates (FMLs). The compaction tests were conducted making use of a plate-to-plate mode testing setup. The through-thickness and transverse width of the prepregs were evaluated on the FML specimen cross-section at varying compaction force and temperature. Significant deformations were observed at the lowest compaction force above the prepreg polymer melting point, whereas a further increase in the compaction force led to gradually smaller through-thickness and in-plane deformations. Additionally, a higher decrease in thickness and increase in width of the prepregs were detected at higher temperatures.

Introduction

Nowadays, the aerospace and automotive industries are facing more and more environmental and economic challenges to manufacture parts that have to meet the requested high standards. In particular, the energy efficiency in transportation can be enhanced by reducing the weight of their structures. FMLs, as a hybrid material system interlacing metallic and fibre-reinforced polymer (FRP) sheets (hereafter called prepreg), show high potentials for that thanks to the high strength-to-weight ratio they offer, combined with good fatigue and impact [1] performances.

The manufacturing of the FML components usually involves the forming of the metal and prepreg sheets into the designed shape individually, followed by the bonding of the two parts with adhesives [2,3]. However, this process chain necessitates a long time and use of several dies, which, overall, increase the manufacturing costs. On the contrary, thermoforming, as a single step forming technique, facilitates the manufacturing process since the forming and bonding of the metal and FRP sheets are carried out simultaneously at elevated temperature.

It is worth underlining that, being the FML a hybrid system, the inhomogeneity in the metal and prepreg characteristics exacerbates the challenges of quality control during both the manufacturing step and subsequent in-service life of the formed component [4]. Therefore, a more comprehensive understanding of the metal and FRP sheets deformation mechanisms during forming becomes mandatory, also in the view of improving the FML formability. Among the deformation mechanisms arising during forming, the transverse flow of the prepreg significantly affects the performances of the formed component, especially in case of parts having a doubly-curved shape and high thickness [5]. During deformation, the prepreg transverse flow may be induced by an uneven distribution of the normal pressure at the bending areas, where the polymer matrix is squeezed outwards transversely. As a result, a change in the fibre volume fraction is also obtained [6].

The FML part thickness variation during the fabrication process significantly depends on the part geometrical features. In the stamping process of hat-shaped parts, a reduction of the thickness

was observed at the radii at the bottom as a consequence of high compaction forces [7]. Under a uniform normal pressure, the polymer matrix is squeezed transversely from the high-pressure region toward adjacent areas facing a lower load. Similar results were also presented in the [8] when stamping cup-shaped components: material accumulation was found in the bottom and side walls adjacent to the radii areas.

Another potential driver behind the thickness variation of FML parts is the structure of the fibres within the prepregs. For uniaxially oriented, namely unidirectional (UD), prepregs, since the fibre can migrate with the resin along the transverse direction, only the matrix is squeezed along the longitudinal direction due to the inextensibility of the fibres [9]. While for the cross-plied UD or woven fabrics, even if the transverse behaviour can be limited to some extent due to the pin-joint structure [5], the influence of a normal pressure gradient on the nonuniform distribution of thickness cannot be neglected.

The polymer matrix of the prepregs used in existing FMLs is either thermosetting or thermoplastic. Thermosetting polymers, such as the epoxy resin, have been widely used, such as the FMLs named GLARE [10]. However, their forming cycle is quite long due to the time needed for the thermosetting polymer curing process [11]. On the other hand, thermoplastic polymers represent an alternative solution thanks to some benefits such as good recyclability, outstanding toughness, and shorter forming time [12]. The thermoforming process applied to FMLs with thermoplastic resin-based prepregs has to be carried out at temperatures higher than the melting limit of the thermoplastic resin. Due to the high mobility and flow characteristics of the polymer matrix at elevated temperatures, its thickness dynamically varies at varying process parameters. After forming consolidation takes place, during which the molten polymer matrix transfers into a solid state by cooling down below its glass transition point. The compaction behaviour of cross-plied UD carbon fibre reinforced thermoplastic tapes (CF/PPS and CF/PEEK) at different temperatures and normal pressures was investigated in [13]. Above their melting points, the thermoplastic polymers exhibit dramatic deformations, with higher in-plane deformations and gradually smaller through-thickness displacements as the temperature rises.

To gain a comprehensive understanding of the deformation mechanisms arising during the thermoforming process applied to magnesium alloy-based FMLs with a PA6 thermoplastic polymer matrix, the compaction behaviour of the prepregs was experimentally investigated at varying thermoforming parameters.

Materials and Methods

Materials.

The FMLs investigated in this study are made of two layers of AZ31B magnesium alloy sheets (thickness 0.5 mm) as skins and one layer of glass fibre-reinforced PA6 consolidated prepreg (Tepex® 102-RG600 (2)/47% Type B, thickness 1 mm) as core. The mechanical characteristics of the magnesium alloy sheets and prepregs in the as-received condition were determined by carrying out standard tensile tests (ISO-6892) on a 50 kN MTS™ 322 hydraulic dynamometer, see Table 1. The main material data of the prepregs are presented in Table 2.

Table 1. Mechanical properties of the AZ31B sheets and prepregs.

AZ31B sheets		**Prepregs**	
Elastic Modulus	45 GPa	Tensile modulus	18 GPa
Yield Strength	158±2 MPa	Tensile strength	380±5 MPa
Tensile Strength	248±4 MPa	Strain at break	2.3%
Shear Modulus	16.7 GPa	Flexural Modulus	16 GPa
Poisson's Ratio	0.35	Flexural Strength	300 ±5 MPa

Table 2. Main characteristics of the prepregs.

Layup	**Value**		**Unit**
	Longitudinal	**Transversal**	
Fibre	E-Glass		
Weaving style	Twill 2/2		
Area weight (dry fabric)	600		g/m²
Yarn count	1200		tex
Yarn density	2.5	2.5	1/cm
Weight rate	50	50	%
Fibre content	47		Vol-%
Thickness per layer	0.5		mm
Laminate density	1.8		g/cm³

Compaction tests.

To assess how the prepregs behave during the thermoforming process, compaction tests with the above-mentioned material system were conducted on the testing apparatus shown in Fig. 1 (a). The prepreg is positioned in the centre of the AZ31B sheets, as shown in the sketch of Fig. 1(b). The width of the AZ31B sheets (40 mm) is twice that of the prepreg (20 mm), which facilitates the observation of the change in the width of the prepreg. The tests were performed on the MTS™ 322 hydraulic dynamometer equipped with the MTS™ 651 environmental chamber for heating up the specimen to the testing temperature. To achieve a uniform temperature distribution, the apparatus is heated up for 1 hour before assembling the specimen. Afterwards, the metal sheets and prepreg stacked according to the sketch of Fig. 1 (b) are placed on the lower punch for 5 minutes to assure they reached the target temperature (*Tt*). The force *F* is applied to the specimen in a controlled way when the upper and lower punches touch both the surfaces of the FML specimen, in a plate-to plate configuration. The normal pressure *p* can be calculated from Eq. (1), where *A* is the contact area of the prepreg with the metal sheets.

$$p = \frac{F}{A} \tag{1}$$

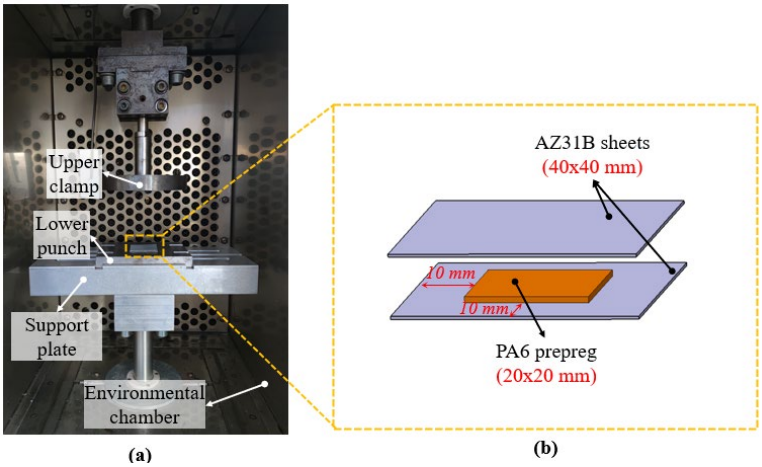

Fig. 1. Compaction tests: (a) testing apparatus, and (b) sketch of the employed FML sample.

Three levels of testing temperatures were selected to assess the effect of temperature on the compaction behaviour of the prepregs, namely 215°C, 235°C, and 255°C. Among them, 235°C and 255°C are both above the PA6 melting temperature, which is 220°C, while the 215°C testing temperature was selected to have a comprehensive evaluation of the prepreg compaction behaviour both below and above the melting point of the polymer matrix. To investigate how the FMLs behave differently under various levels of compaction force, the compaction tests were carried out at each testing temperature applying different forces, namely 40 N, 120 N, 200 N, 600 N,1000 N, and 2000 N, which is equivalent to the normal pressure varying from 0.1 MPa to 5 MPa. To be consistent with a typical thermoforming cycle, a ramp-dwell loading method was used as shown in Fig. 2: the force rises at 10 N/s to the target force (*Ft*) in the ramp period, followed by its holding in the dwell period for 240 s, after which the specimen is left to cool down to room temperature (*Tr*) still with the force applied to finish the consolidation process. For each testing condition, three tests were performed to assure the repeatability of the results.

The tested specimens were saw cut along the A-A and B-B planes as shown in Fig. 3 (a), and then these two cross-sections were polished. The through-thickness and transverse width of the prepreg within the FML were measured by making use of a microscope.

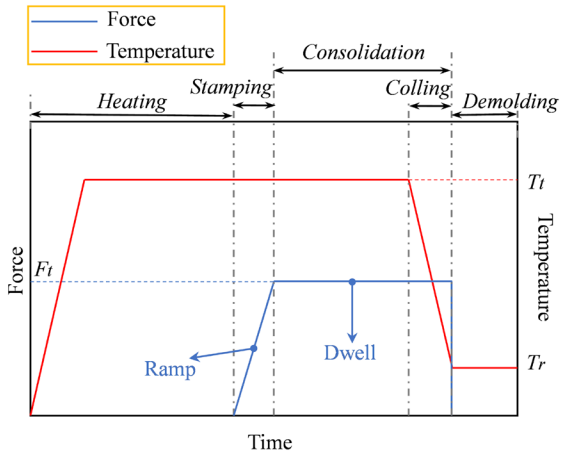

Fig. 2. Experimental procedure of the compaction tests.

Results and Discussion

Thickness variation.

After the consolidation process at different forces and temperatures, the thickness of the prepregs was measured on the cross-sections shown in Fig. 3. Fig.4 reports the normalized thickness t/t_0 versus the compaction force F for the three levels of testing temperature. Overall, the measured thickness changes dramatically at temperatures below and above the melting point of the PA6 polymer matrix. At 215°C, the thickness reduction is very limited, regardless of the compaction force, as the solid state of the polymer matrix at this temperature imparts thermally stable properties to the prepreg, resulting in an almost elastic response [11]. When testing above the PA6 melting point, the polymer matrix viscous response induces a more obvious decreasing thickness at increasing loading. For both the testing temperatures above the PA6 melting point, the prepreg thickness decreased dramatically when the applied compaction force was lower than around 600 N, then it remained stable at increasing compaction force.

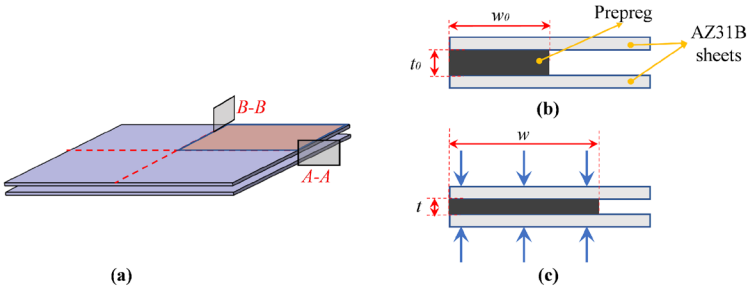

Fig. 3. Scheme of the prepreg thickness measurement method: (a) selection of the cross-sections, (b) before and (c) after consolidation.

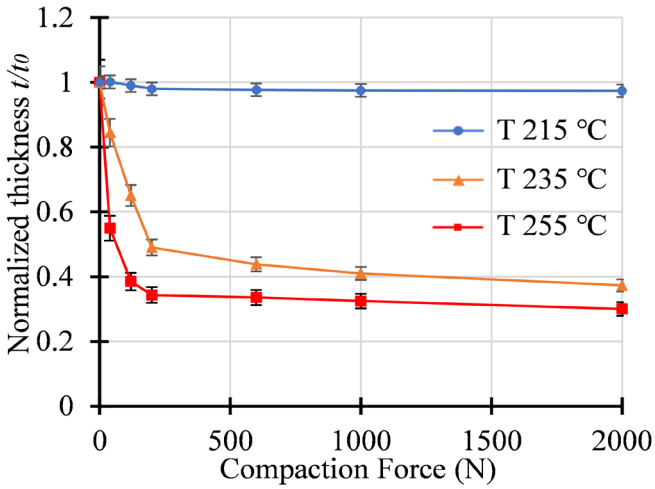

Fig. 4. Normalized thickness of the prepregs at varying compaction force.

Fig. 5 shows the morphology of the FMLs in the cross-section when tested at 235°C under 40 N, 600 N, and 2000 N compaction forces. When a compaction force of 40 N is applied, the warp and weft fibres within layer 1 and layer 2 are separated by the polymer matrix present in a high amount between them. At increasing compaction force, the gap between the warp and weft fibres becomes narrow as more polymer matrix together with some fibres is squeezed towards the adjacent areas; the warp fibres within layer 1 touch the weft fibres within layer 2 when the compaction is 600 N, which is shown by the neglectable gap between them in Fig. 5 (b). Fig. 6

shows the micrograph of the edge of the FML at 600 N compaction force. The concurrent pattern of squeezing flow, also known as shear flow (namely the resin pushes the fibres transversely), and bleeding flow (namely the resin bleeds out without shifting the fibres) enables the high compressibility of the prepregs. At the same time, the undulation of the weft yarns is gradually flattened at increasing compaction force, inducing a more uniform distribution of the warp fibres between these two plies of weft fibres. As more warp fibres in the middle area along the thickness direction are squeezed out, the gap between the two plies of weft fibres becomes narrower. When there are not enough warp fibres separating these two plies of weft fibres, two plies of weft fibres with the same orientation meet each other thus acting as an individual ply with a larger thickness as shown in Fig. 5 (c), which is relevant to 2000 N compaction force. Due to the PA6 lower viscosity at 255°C than at 235°C, the higher flow and mobility of the polymer matrix facilitate the squeezing flow of the resin together with the fibres from the centre to the edge areas, which causes a further reduction of the prepreg thickness for the same loading conditions.

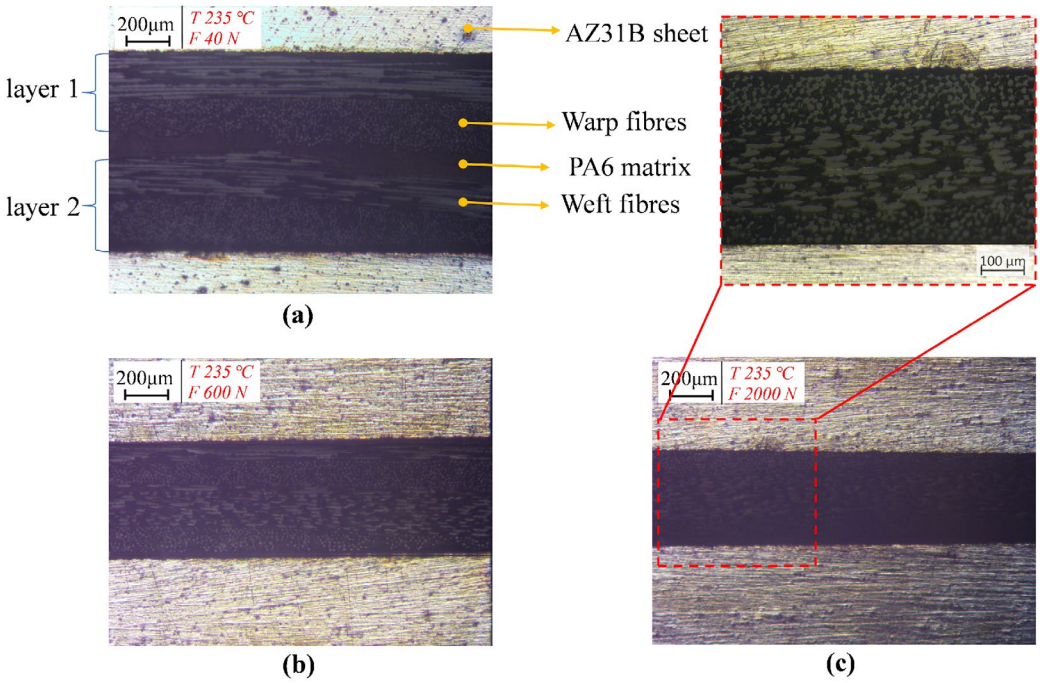

Fig. 5. Morphology of the FMLs on the cross-section tested at 235°C under (a) 40 N, (b) 600 N, and (c) 2000 N compaction force.

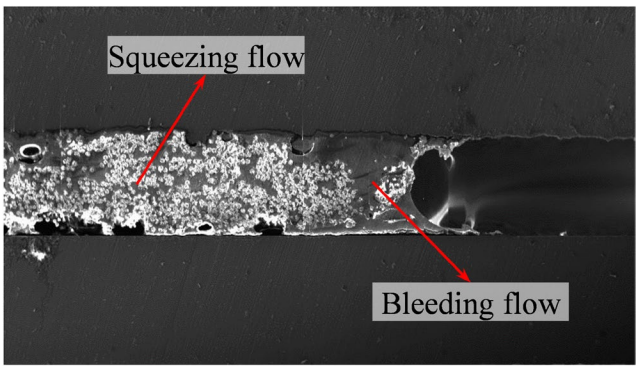

Fig. 6. SEM image of the edge of the FML at 235 °C under 600 N compaction force.

Width increase.

The compaction force promotes a redistribution of the fibres and matrix via a transverse squeezing that influences the prepreg width. Fig. 7 shows the normalized width *w/w0* versus the compaction force *F* for the three levels of testing temperature. As expected, like the through-thickness compaction behaviour, no changes in the prepreg width can be observed at 215°C testing temperature, regardless of the applied compaction force. When the testing temperatures are above the PA6 melting point, the normalized width increases at increasing compaction force, but for values lower than 600 N, whereas, for higher compaction force values the normalized width reaches a steady state. The transverse widening observed in experiments was shown to grow in tandem with the increase in temperature. As a result of its lower viscosity at these temperatures, the molten polymer matrix is able to transfer the load to the fibres, which permits an increased motion of the polymer matrix and fibres.

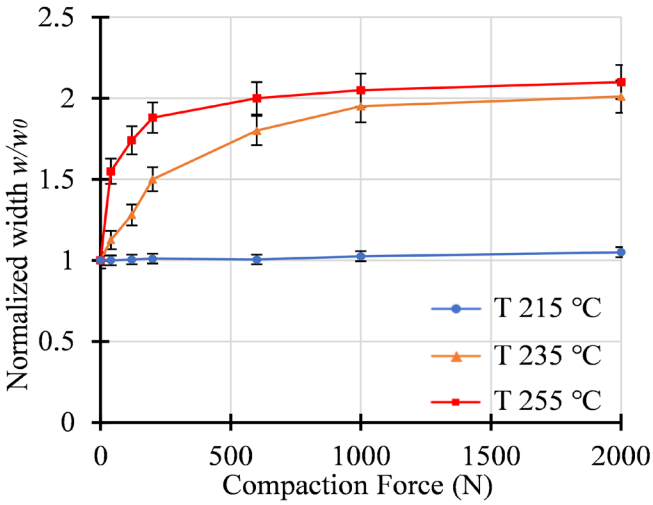

Fig. 7. Normalized width of the prepregs at varying compaction force.

Summary

In this research, the compaction behaviour of thermoplastic prepregs with a twill weaving style under a range of parameters typical of the thermoforming process applied to magnesium alloy-based FMLs was investigated. By conducting compaction tests, the through-thickness and transverse width of the prepregs within the tested FMLs at different loading conditions were measured and compared. The main findings can be summarized as follows:

- When testing below the melting point of the polymer matrix, the prepregs exhibit no significant variations in the thickness and width. Above the melting point of the polymer matrix, a dramatic decrease in the thickness and an increase in the width of the prepregs were observed.
- Most of the compaction occurred when the compaction force was below 600 N, above which a compaction limit was reached with just slight variations in the prepreg thickness and width.
- Moreover, the lower viscosity of the polymer matrix at higher temperatures allows for a greater compaction.

The results of this experimental research of this study are the basis for the analytical modelling of the compaction behaviour of the PA6-based prepregs with a twill 2/2 weaving style at elevated temperatures, which will be further implemented into FEM to predict the thickness distribution of thermoformed FMLs with doubly-curved shapes.

Abstract. Process simulation software for hot press forming is a vital tool for the development of complex continuous fiber-reinforced thermoplastic parts for structural applications. The simulation tools need to be accurate to truly facilitate the design stage, which in turn requires accurate material characterizations and constitutive models. The material forming behavior is composed of different deformation mechanisms, one of which is the separation of adjacent plies or delamination. Currently, the resistance against delamination or ply-ply adhesion is modeled as a constant tensile stress that needs to be overcome, the value of which is based on an educated guess. To date, no standard exists to characterize this material property for thermoplastic matrix composites (TPC) in melt. Hence, we discuss and evaluate several methods to measure ply-ply adhesion of TPCs. The most promising approach, a so-called probe test, was further pursued and a setup was designed and manufactured for the use in a rheometer. Subsequently, we measured the required normal force to separate two C/LM-PAEK tapes in melt. Repeated tests on the same specimen resulted in an increasing adhesive peak force, which we relate to a change in the amount and distribution of the matrix material at the ply's surface. The peak force increased also with increasing compression time and pressure. We found a reasonable correlation of the average measured peak force with the values currently assumed in simulation software.

Introduction

Hot press forming is an attractive technology to manufacture small to medium-sized parts from continuous fiber reinforced thermoplastic blanks through remelting and reshaping. The process is rapid, cost-effective, and automatable. Complex parts can be produced with tailored lay-ups based on unidirectional (UD) fiber reinforced tapes using automated fiber placement (AFP) or automated tape laying (ATL) processes [1]. Moreover, thermoplastic matrix composite (TPC) parts can be welded to create large structural components [2]. However, the development of a proper production line becomes increasingly difficult with more complex parts and materials, as defects like forming-induced wrinkles could occur.

The development stage of a new part is facilitated by process simulation software that provide design engineers the tools for virtual design iterations and, with that, reduce trial-and-error costs [3,4]. The predictions of these simulations need to be accurate, especially on defect generation, to truly enable first-time-right defect-free manufacturing. In turn, accurate predictions require accurate material characterization and constitutive modeling to properly describe the material behavior during forming. Hence, different deformation mechanisms that occur during forming are

commonly considered, which can then be characterized and modeled separately to capture the material's forming behavior.

One of the considered deformation mechanisms is delamination [5], which describes the separation of adjacent plies during the hot forming process. The resistance against delamination, or the ply-ply adhesion, is currently often described as a constant tensile stress based on an educated guess [3] or as a certain adhesion stiffness [6]. Moreover, the adhesive tension (normal direction) as used in numerical simulations indirectly affects the friction between adjacent plies (tangential direction) through the use of a penalty method that models the normal pressure in the ply-ply contact [5]. In our recent work [7,8], we investigated the ply-ply friction response to improve the constitutive friction modeling, for which the coupling with ply-ply adhesion of TPC in melt needs to be investigated in more detail as well. A standard to characterize the ply-ply adhesion for TPC in melt is to the best of our knowledge not defined.

The study of Mulye et al. [9] seems to be the only one that dealt with characterizing the ply-ply adhesion of TPCs in melt. These authors used a DMA with only the molten matrix material to measure the polymer melt strength as function of the debonding rate, which was subsequently used in a forming simulation for a fiber-reinforced PA-66 part to improve the prediction of local discontinuous plies (patches). Although the prediction of the patch's position and orientation improved, characterization of only the matrix material itself could result in an overestimation of the ply-ply adhesion, especially for plies with high fiber volume fractions. Contrary, the fibers were included in studies on the characterization of ply-ply adhesion of thermoset composites [e.g. 10-13], using different methods.

Given the above, this research aims to develop a setup and method to measure the required normal force to separate TPC tapes in melt for the characterization of ply-ply adhesion.

Background

The mechanisms and factors influencing ply-ply adhesion of TPCs will be presented in this section together with a brief description of some experimental methods to measure adhesion.

Ply-ply adhesion.

The creation of a bond between two molten TPC plies that are brought into contact develops through two mechanisms [14,15]. First, intimate contact or sufficient wetting needs to be established, meaning that the polymer chains of both surfaces are in close physical contact. Secondly, at locations with intimate contact, the polymer chains interdiffuse over the interface to form an entangled network, a process referred to as healing.

The formation of intimate contact is hindered due to the asperities on the ply's surface. Hence, the degree of intimate contact can be enhanced by applying a normal pressure. A lower viscosity of the polymer also promotes intimate contact formation. Thus, the time required for intimate contact depends on the applied pressure and polymer viscosity. The presence of fibers at the surface leads to local dry fiber-fiber contacts, which do not contribute to the formation of a strong bond. Therefore, Çelik et al. [16] proposed an effective intimate contact, considering only the intimate contact of matrix-rich areas in a study on contact development of UD C/PEKK tapes with AFP. Squeeze flow and percolation of matrix material increase the effective intimate contact.

The healing process starts once the polymer surfaces are locally in intimate contact. The polymer chains diffuse and form entanglements across the interface, leading to a fully entangled network comparable to the one in the bulk. The time required to establish this state depends on the polymer dynamics, for which generally de Gennes' theory of reptation is used [17]. A typical time in this theory is the reptation time, which denotes the required time for a certain polymer chain to escape from its initial configuration and, with that, form new entanglements with neighboring chains. According to Wool et al. [14], the strength of an interface grows through interdiffusion with time to the power ¼ and a fully entangled structure is achieved at a timescale comparable to

the reptation time, which is probably in the order of less than a second for the polymer melt considered here [18].

The timescales involved in ply-ply bonding of TPCs are, however, not so straightforward, as experimental studies found hundreds of seconds for healing [15,19] or intimate contact formation [20]. Polymer degradation, reducing the chain mobility, could have affected the healing process in the study of Avenet et al. [15], while the relatively long timespan for intimate contact formation found by Levy et al. [20] is probably due to the low consolidation pressure applied (1.34 kPa).

Adhesion test setups.

Adhesion was frequently characterized for thermoset composites for a variety of purposes as well as for the performance of (pressure-sensitive) adhesives. An overview of the different methods found in literature is visualized in Fig. 1 [21,22]. Crossley et al. [22] designed a setup to peel prepreg tape off a surface (Fig. 1a). A comparable test method is the T-peel test (ASTM D1876) [23], the fixed arm peel test [23], and the floating roller peel test (ASTM D3167), as visualized in Fig. 1b-d, respectively. For all four tests, the adhesion is quantified by gradually peeling surfaces from each other. Other techniques for adhesion characterization are the probe [10,12] and loop test (ASTM D6195), schematically illustrated in Fig. 1e and 1f, respectively. An interface is created by bringing the surfaces into contact and the formed adhesion can subsequently be measured by pulling. The probe and loop test are based on a more direct separation of the surfaces in normal direction, though the loop test actually features a combination of peeling and pulling.

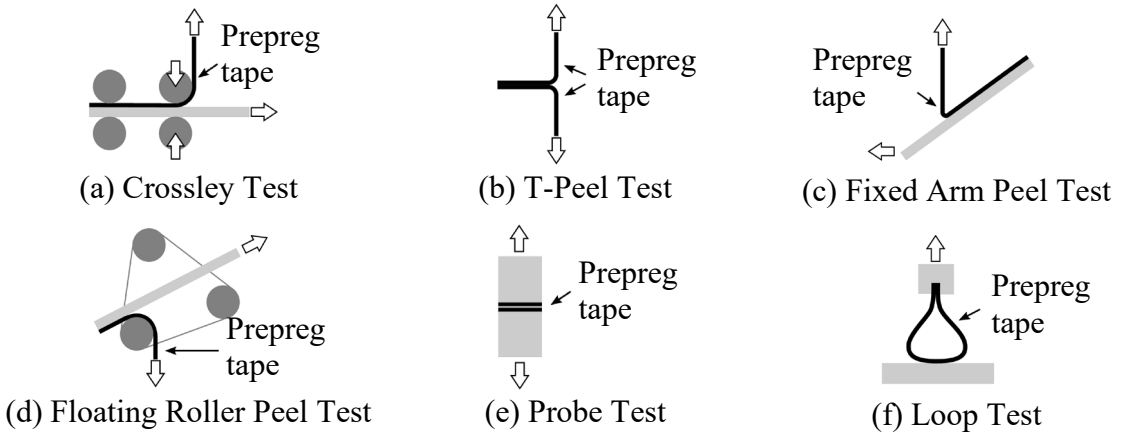

Fig. 1. Schematic illustration of several testing methods to measure adhesion [21,22].

Design of the Test Setup

A brief concept evaluation will be presented first followed by the final design of the test setup.

Concept evaluation.

From the four peel methods (Fig. 1a-d), we expect that the T-peel test (Fig. 1b) would suit the best for the use with TPCs, as it avoids the use of moving or rolling parts and the specimen can be pre-consolidated to form the ply-ply bond, closely resembling the situation in actual hot press forming. Contrary, the formed contact with the loop test (Fig. 1f) is not predefined and the stiffness and geometry of the loop will affect the measurement. The probe test will be more robust regarding contact formation and probably results in a more straightforward separation by pulling compared to the loop test.

Preliminary experiments were conducted with both the T-peel and probe method to determine the best suitable approach. During testing with the T-peel method, unwanted movement of the specimen due to slight misalignments and/or the convective heat flow in the oven resulted in variations in the pull force. Further, this measured force is a combination of adhesive failure and

bending of the specimen. Contrary, the pull force measured with the probe test can directly be used to calculate an apparent tensile stress for adhesive failure, as considered in simulation software for hot press forming. The probe tests was also slightly easier regarding specimen mounting and test cycle time. However, we observed slippage of the specimen in the clamps during the probe tests and specimens tended to bend in the force direction. These effects need to be minimized to reduce variations and to obtain a pure ply-ply adhesion measurement. All in all, the probe test was found the most promising.

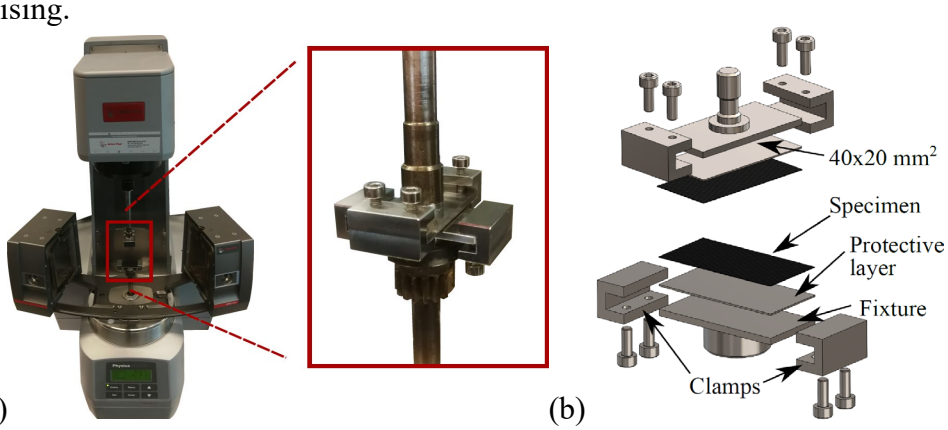

Fig. 2. Test setup mounted in an Anton Paar MCR501 rheometer (a) and (b) exploded view of the test setup with top and bottom fixture featuring direct connections for the rheometer.

Setup design.

The probe test fixture as used for the preliminary tests was further developed. The final setup mounted in an Anton Paar MCR 501 rheometer is shown in Fig. 2a. An exploded view of the designed setup, consisting of a top and bottom fixture out of stainless steel with direct connections for the rheometer is shown in Fig. 2b. The clamps at either side of the fixtures can be used to fix the TPC tapes. The usable surface area of each fixture is 40x20 mm^2, resulting in an overlap area of 20x20 mm^2 in case of a 0°/90° interface. Protective layers out of steel, measuring 40x20x1 mm^3, were used to shield the fixture from the molten polymer and served as a backing material for the TPC tape (see Fig. 2b), as will be discussed in the next section.

Experimental Work

Materials.

The composite material used in this research consisted of a unidirectional (UD) carbon-fiber reinforcement with a pre-impregnated LM-PAEK thermoplastic matrix. The tape, known as TC1225 C/LM-PAEK, was manufactured by Toray Advanced Composites. The melting temperature equals 305°C, according to the manufacturer.

Specimen preparation.

The tape material was supplied in 12 inch rolls, from which 39x18 mm^2 strips were cut with the fibers in the longitudinal direction. The strip width was chosen slightly smaller than the width of the fixture to ensure that the whole specimen was supported. The matrix material at the ends of the strips was removed using a blow torch to improve the clamping of the specimen in the setup. Next, a co-consolidation step was used to bond a strip to the protective metal plate. A bond between the metal plate and the tape material stronger than the ply-ply adhesion avoids parasitic bending of the specimen during testing, i.e. the metal served as a rigid backing material. Strips were placed on the protective layers in an oven at a temperature of 330°C under a slight pressure (around 50 kPa) for 10 minutes. The specimens were dried overnight before testing.

Test procedure.

Two co-consolidated strips were clamped in the top and bottom fixture of the test setup (see Fig. 2b) to form a test specimen. The fixtures were then mounted in an Anton Paar MCR501 rheometer and the oven was set to the test temperature T_t. A nitrogen flow was applied to avoid degradation during testing. A schematic illustration of the experimental procedure is shown in Fig. 3. The tapes at the top and bottom fixture were brought into contact with a controlled compression force F_c, resulting a normal pressure p, for a compression time t_c. After t_c, the force was put to zero for a short period of time t_x to ensure a force reading equal to zero at the start of the measurement. Subsequently, a constant upward displacement rate $\dot{\lambda}$ was applied to the top fixture to separate the plies, yielding a peak force F_{max}, as illustrated in Fig. 3. Besides the force, the time t and displacement λ were logged as well with a sampling frequency of 200 Hz. The measured data was smoothed with a Gaussian filter with a 50 points window to suppress the high-frequency scattering.

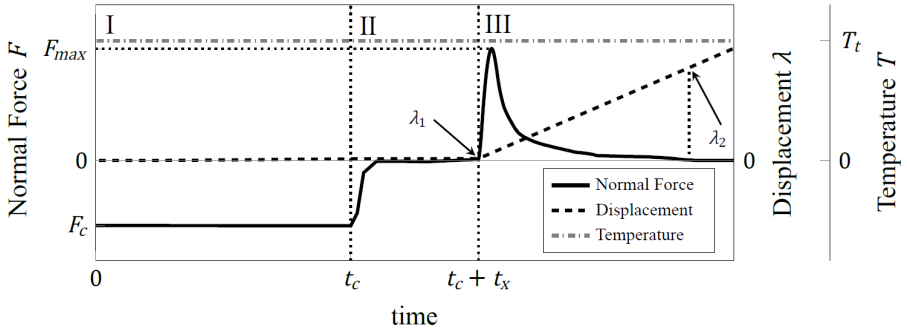

Fig. 3. Experimental procedure used to measure ply-ply adhesion.

Experiments.

All tests were performed at a temperature of 340°C and a displacement rate of 0.05 mm/s. In a first series of experiments, the effect of repeated testing of the same specimen on the peak force was investigated. Repeated tests on the same specimens, under different conditions, greatly reduces the experimental time required for a full characterization of the ply-ply adhesion. A normal pressure of 15 kPa was applied for 120 s followed by separation of the plies, which was repeated for ten times and performed for three specimens.

In a second series of tests, we investigated the effect of the compression phase on the subsequent ply-ply adhesion force by varying the compression time and pressure as listed in Table 1. The measurements were conducted in triplicate and a fresh specimen was used for each test. The longer compression times marked with an asterisk were only measured with a pressure of 15 kPa.

*Table 1. Test matrix for the second series of tests to investigate the effect of the compression phase. Compression times marked with * were tested only with a pressure of 15 kPa.*

Parameter	Input	Unit
T	340	°C
$\dot{\lambda}$	0.05	mm/s
p	3, 15, 31	kPa
t_c	10, 30, 60, 120*, 240*, 480*	s

Microscopy.

The ply's surface in the contact area was analyzed using a Keyence VHX-7000 digital microscope before and after testing to investigate whether the test invoked changes in the surface morphology of the tape. Micrographs were made from tapes in pristine state and after being measured for 3 and 12 times.

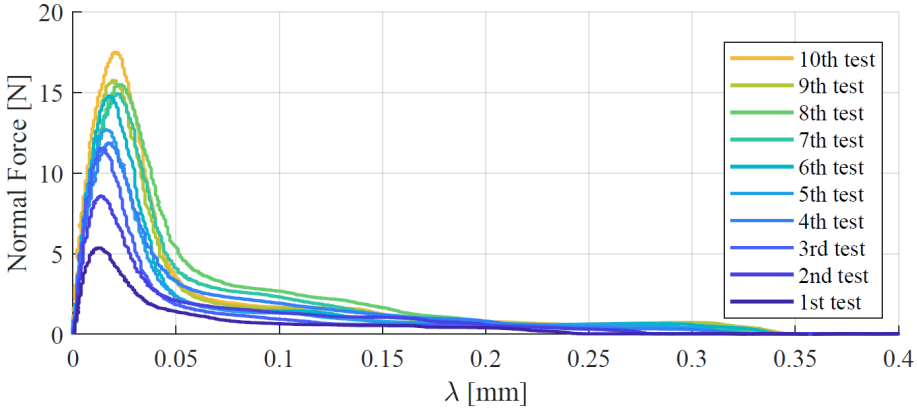

Fig. 4. Normal force versus displacement curves for a single specimen measured ten times with a compression phase (time of 120 s and pressure of 15 kPa) between each run.

Results

The normal force-displacement curves of a specimen tested repeatedly for 10 times are shown in Fig. 4. A clear peak adhesion can be observed followed by a gradual decrease in force towards zero at full separation around 0.3 mm. The peak force F_{max} gradually increases with increasing number of repetitions. The average trend of F_{max} over three specimens as function of the number of tests is shown in Fig. 5a. The error bars denote the standard deviation, indicating a large spread between the specimens. The increase in F_{max} with succeeding tests is further visualized in Fig. 5b, in which F_{max} is normalized with the first measured peak force for each of the three specimens.

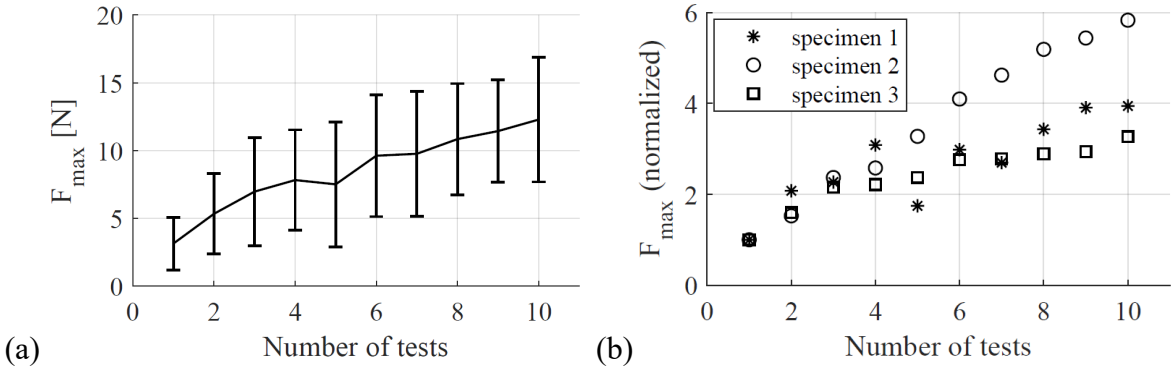

Fig. 5. Average peak force with number of repetitions (a) with the error bars denoting the standard deviation over three specimens and (b) normalized peak force with repetitions for each of the thee specimens measured.

The effect of the compression phase on the measured peak force is shown in Fig. 6a and 6b through varying the compression time and applied pressure, respectively. A longer compression time or higher pressure resulted in a higher F_{max}. Within the chosen experimental window, the peak force continued to grow without showing a sign of an asymptotic value. Even for the tests conducted with an extended compression time at a pressure of 15 kPa (see Fig. 6a), a limiting value for the peak force was not reached.

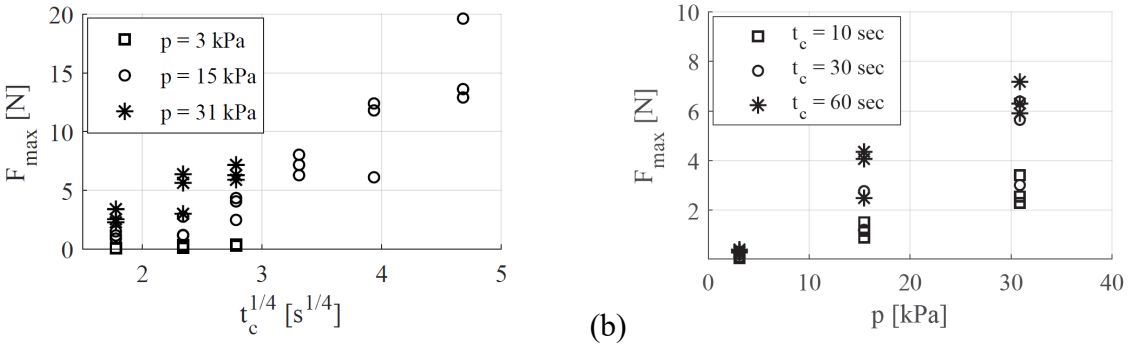

Fig. 6. Effect of the compression phase on the measured normal peak force through (a) the compression time and (b) the applied pressure.

Micrographs of the surfaces of the plies before and after testing are visualized in Fig. 7. The pristine state, shown in Fig 7a, clearly shows the fiber direction with matrix material distributed over the whole surface, shown by the lighter shade areas in the micrograph. The matrix material tended to form clutters in the contact area on the ply's surface after three repeated adhesion tests, as visualized in Fig. 7b. We observed a partition on the ply's surface, as highlighted in the micrograph by the red line, with contact (left) and non-contact (right). With more repetitions, the clutters formed into larger patches of matrix material, as visualized in the micrograph of a ply's surface tested for 12 times (see Fig. 7c). Note that the micrographs only show a small part at the boundary of the ply-ply contact, though the observations outlined above a more general and apply to the whole contact area.

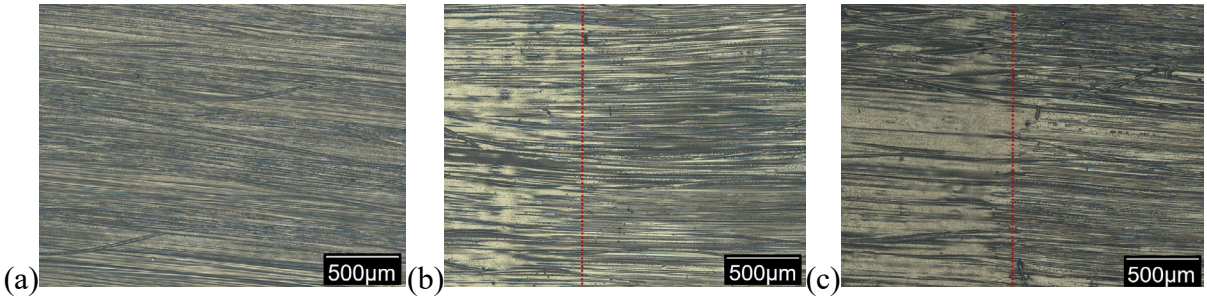

Fig. 7. Micrographs of the ply's surface (a) in pristine state and after tested for (b) 3 times and (c) 12 times. The red line approximately corresponds to the border between contact (left) and non-contact (right). The matrix material is visible by the lighter shade color.

Discussion

Repeated tests.

The peak force increased with the number of repetitions on the same specimen (see Fig. 5), meaning that reconsolidation of a specimen in the setup affects the subsequent ply-ply adhesion. The change in adhesion after repeated reconsolidation suggests to measure a specimen only once, consequently increasing the experimental time required for a full characterization of the ply-ply adhesion. More importantly, this reconsolidation effect disputes the representativity of the initial consolidation to simulate the actual ply-ply bond during hot press forming. Based on the experimental observations and the micrographs of the ply's surface as shown in Fig. 7, we believe that the force increase relates to a change in the amount and distribution of the matrix material in the contact area after repeated testing. The formation of clutters and larger patches of matrix material may be due to polymer strings between the top and bottom ply. These polymer strings tend to pull matrix material towards the ply's surface during a ply-ply adhesion test. Once a polymer string fails, the polymer settles in clutters on the ply's surface. With more repetitions, more matrix material gathers at the surface, forming larger agglomerates and increasing the

subsequent peak adhesive force. A change in the matrix material itself through degradation was found less probable to explain the increase in ply-ply adhesion based on control tests without nitrogen and DSC measurements.

Besides the increase in adhesion with repeated testing, quite a large spread was obtained on the measured peak force F_{max} as indicated by the error bars in Fig. 5a. This variation could be attributed to local variations in the fiber volume fraction at the ply's surface, leading to different effective intimate contacts between the specimens. Preliminary tests with an additional layer of matrix material in the ply-ply interface substantiated this idea of a change in effective intimate contact, as we measured a lower spread in F_{max} (not shown here).

Effect of the compression phase.

In the second series of tests, the effect of the compression phase on the measured peak force was investigated using fresh specimens for each test (see Fig. 6). The peak force increased with increasing compression time and pressure, as expected from literature. A higher pressure enhances the formation of effective intimate contact, resulting in a higher adhesion [15,16]. The timespan at which we observed an increase in ply-ply adhesion is also comparable to findings in earlier research on TPCs [15,19,20]. It remains unclear which mechanism, either intimate contact formation or healing, dominates this behavior. A ¼ power relation between force and time seems to appear at longer compression times, suggesting a healing process, though more experiments are required to validate this trend.

An apparent tensile stress σ_{max} can be computed through dividing the measured peak force by the total surface area of 18x18 mm^2, which can be used in process simulation software to describe the ply-ply adhesion. The maximum apparent tension values for different compression times and pressures are listed in Table 2, which are of the same order of magnitude as considered elsewhere. For example, Haanappel [5] estimated an adhesive tensile stress of 100 kPa for forming simulations with C/PEEK using the software package AniForm [4]. Recently, the tensile stress was lowered in an update on AniForm based on advancing insight. Lastly, Mulye et al. [9] found an average tensile stress of 6.2 kPa in their research on a thermoplastic composite with a PA-66 matrix.

The compression phase in the ply-ply adhesion tests was necessary to create a bond between the two ply's surfaces that were brought into contact. Ideally, the created ply-ply bond mimics the one present in pre-consolidated blanks or in layups produced with AFP or ATL to properly simulate the actual hot press forming process. However, the exact time and pressure that should be used for the compression phase remains unclear. Future research could be to investigate which values for the compression time and pressure should be used to mimic a certain process or the use of pre-consolidated specimens could be considered.

Table 2. Maximum apparent tensile stress σ_{max} in ply-ply adhesion for different compression times t_c and pressures p computed from the measured peak force and the surface area.

σ_{max} [kPa]		t_c [s]					
		10	30	60	120	240	480
p [kPa]	3	0.3	0.7	1.1	-	-	-
	15	3.7	5.3	11.2	22.1	31.2	47.5
	31	8.5	15.5	19.9	-	-	-

Summary

A setup was designed and manufactured to measure the required normal force to separate two plies, or the ply-ply adhesion, of thermoplastic matrix composites (TPC) in melt. The design is based on a so-called probe test, as used in adhesion tests for thermoset composites, and can be mounted in a rheometer. TPC tapes were brought into contact for a certain compression time under

a controlled pressure, after which the formed bond was separated with a constant upward displacement rate while measuring the normal force. Repeated adhesion tests on a single specimen with a compression phase between each run resulted in an increase of the normal peak force, implying that a fresh specimen needs to be used for proper ply-ply adhesion characterization. The increase in force was attributed to the formation of clutters and patches of matrix material in the contact area on the ply's surface, increasing the peak force after each adhesion test.

Increasing the compression time and applied pressure resulted in an increase of the peak force. A higher pressure is expected to increase the formation of intimate contact, consequently increasing the ply-ply adhesion. The compression time could affect the peak force through both the formation of intimate contact and the healing process. The latter mechanism might prevail as the force versus time curve seems to follow the typical ¼ power law relation, though the data is not conclusive enough on this aspect. Future work is to determine suitable parameters for the compression phase to mimic the ply-ply bond as formed in pre-consolidated blanks or after the AFP or ATL process.

Keywords: XCT, Knitted Textiles, Synthetic Meshes, Abdominal Wall Hernia Repair

Abstract. Abdominal wall hernia repair mostly involves the implantation of a synthetic mesh material. The link between the mesh microstructure, mechanical behaviour and clinical outcome is still not fully understood, complicating the selection of a suitable patient-specific mesh. Here, we created a parametric 3D model of a synthetic mesh based on X-ray microfocus computed tomography (XCT) images. The model was implemented in a *TexMind* Warp Knitting Editor software and then exported for finite element model (FEM) analysis. This model allows better understanding of the mechanical behaviour of the mesh and identifying the influence of single structural parameters that are essential for the design of the mesh. We also used the XCT-based filament paths to directly build a FEM, representing all 3D structural details of the as-produced product. Whilst the mechanical analysis of the mesh is feasible, important difficulties are identified, related to the initial relaxed mesh contacts configuration and necessity of the mesh pretension in experiments and calculations.

Introduction

An abdominal hernia is a medical condition in which an internal organ partially protrudes through the surrounding structures, i.e. the musculofascial layers of the abdominal wall. There is a lifetime risk for inguinal hernia of about 27% for men and 3% for women. Consequently, abdominal wall hernia repair is among the most frequently performed surgeries, and it is mostly performed on adults younger than 65 years old [1]. Hernia repair involves in most cases the implantation of a synthetic mesh material to substantially reduce the rate of hernia recurrence [2,3]. Nowadays, a wide range of mesh types is available for the surgeon to choose from in terms of polymer type (degradable or not), fibre structure (mono- vs. multifilament), textile structure (woven vs. knitted), strength, stiffness, elasticity, pore size, weight per area, etc. [4]. Depending on the manufacturing process, synthetic meshes can be divided in woven, non-woven or knitted (weft or warp).

Nowadays, however, most commercially available meshes are fabricated by warp-knitting since it allows to achieve the desired mesh properties, both structurally and biomechanically [5].

Clinical outcome and postoperative quality of life are strongly influenced by the structural and biomechanical properties of the mesh, [6]. Biomechanically, the mesh should ideally behave in a similar manner to the native tissues of the abdominal wall, whilst being able to withstand the *in vivo* mechanical loads, as internal abdominal pressure can reach values up to 20 kPa [7]. Current mesh designs generally can withstand the high forces within the abdominal wall, but often have anisotropic characteristics concerning elasticity. In that case, mesh positioning should conform to the elasticity of the abdominal wall. However, many of the biomechanical tests used in vitro for the mechanical characterization of synthetic meshes currently still lead to inconsistent and non-robust results. Only scarce information is available on the biomechanical behaviour of the meshes after implantation, which if present strongly relates to the biocompatibility of the material and consequent tissue ingrowth. There is, hence, a need for better understanding of the structural changes during loading and the in vivo effects on mechanical properties of the meshes to be able to improve their design.

State-of-the Art of Warp-Knitted Meshes Modelling and Mechanical Characterisation

The warp knitting technology provides a unique possibility to produce structures, which satisfy all technical requirements for hernia repair [8, 9]. Especially the mesh type fabrics produced by fine mono-filaments have excellent seam slippage characteristics – the longer chains of loops remains stable during deformation [10]. At the same time knitted meshes provide a reduced contact area with a foreign body, hence decreasing the risk for granuloma bridging and providing sufficient open space for tissue ingrowth [11].

The mechanical response of surgical warp-knitted meshes is studied in [12-15]. The mesh biaxial tension and shear mechanical response is studied experimentally in these papers (including *in-vivo* measurements). In [16] the mechanical response of the mesh represented as a membrane is modelled, which advances this work towards a model of a warp-knitted loops in a mesh structure. These developments are included in a general "landscape" of geometrical and mechanical models of warp-knitted fabrics [17-20]. The available geometrical models create an idealized 3D sketch of the fabrics, which does not represent the relaxed state of the material and has to be refined using mechanical modelling with finite element method (FEM).

X-ray Microfocus Computed Tomography (XCT) provides the opportunity for direct observation and modelling of the 3D geometry of textiles [21], including knitted fabrics [22] in a relaxed or loaded state. In the present paper we compare parametric FEMs of a warp-knitted surgical mesh created using the *TexMind* software [20] and a "digital twin" of the real mesh, with an XCT-based FEM. These fine-tuned parametric models would allow optimization of the surgical mesh in future work.

Developments of the XCT-based geometrical models and simulation of their mechanical behaviour is well-aligned with similar studies of the composite reinforcements under forming [23].

Materials

A DynaMesh®-CICAT Visible mesh (FEG Texiltechnik, Aachen, Germany) was used in this study. This mesh is designed for the extraperitoneal repair of primary ventral (umbilical, epigastric) and incisional hernias [24]. This anisotropic large pore surgical mesh is a monofilament (+/- 100 μm) polyvinylidene fluoride (PVDF, grade SOLEF 1008 of Solvay Solexis) mesh with black orientation strips (Fig. 1a) that act as guides in the correct positioning of the implant during surgery, for conforming to the elasticity of the abdominal wall. Moreover, the black orientation filaments, are impregnated with iron oxide for allowing MRI visibility of the mesh. The PVDF filaments provide good biocompatibility, as they induce less granuloma formation and are less affected by degradation and embrittlement when compared to their polypropylene-based

counterparts [25, 26]. The warp-knitting pattern used in this mesh is the key to tear propagation resistance and provides the desired high porosity of the mesh.

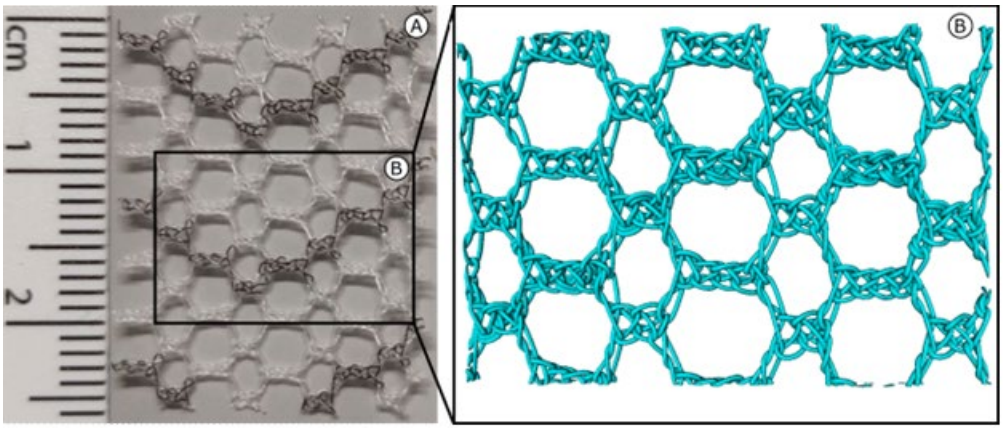

Fig. 1. The surgical mesh DynaMesh®-CICAT: (a) a photo; (b) XCT 3D rendering.

XCT Registration and Analysis of the Mesh 3D Image

A 2 cm by 2.5 cm piece of the DynaMesh®-CICAT surgical mesh was placed in between two half-cylinder Styrofoam parts to keep the fabric straight, while preserving a relaxed state. The assembly was slid into a polysulfone (PSU) sample holder and mounted on the rotation stage of a Bruker SkyScan 1172 scanner, equipped with a closed Hamamatsu 100 kV/10 W microfocus X-ray tube, and a 12-bit detector of 4000 × 2700 pixels. The acquisition parameters are listed below (Table 1). Cross-sectional imaging reconstruction was performed by applying a filter back-projection algorithm in the BRUKER SkyScan software NRecon, with a post-alignment filter to optimize the center of rotation value and a median filter to improve the signal to noise ratio.

Table 1. XCT acquisition parameters.

Tube Voltage [kV]	37	Detector Rows	1332
Tube vCurrent [µA]	234	Detector Columns	2000
Tube Power [W]	8,7	Exposure timing (ms)	215
Hardware filter	None	Voxel size (µm)	8,94
Rotation step [deg]	0,4	Frame Averaging	3
Sector scan [deg]	180	Random movement	ON
Detector binning	2x2		

XCT-based 3D voxelized structures are not suitable as input for mechanical modelling as the voxels create stepped surfaces, which result in an unrealistic and erroneous mechanical behavior in the modelling. Therefore, the aim was to perform a finite element meshing of each individual filament in the surgical mesh structure, extracted using the Avizo XFiber module (Fig. 1b), allowing to obtain smooth filament surfaces.

Transformation of the XCT Dataset Into a FE Model

The transformation of the XCT dataset into a parametric FEM started with the processing of the filament segment nodes and points, by visual inspection of the location and interpenetrations. The original points that represent each filament segment are replaced with interpolated points, with an inter-point distance of 178 µm. This distance allows representing the filament segment without

over-constraining the spline or losing information. The distance is controlled by the smaller radius of curvature, where more points are needed.

With the new equidistant points, a spline is created that serves as the base for a path pultrusion, allowing the creation of each individual yarn. It is possible that for some tight curvature radii, a spline can be created, but a pultrusion of the specified fibre diameter will not provide realistic results, as it generates self-penetrating fibres. Here, having the equidistant points comes in handy, as it is possible to manually edit the points in question and reduce the curvature radius.

To reduce the required computational resources, a general element size of 100 µm was used in the model. One fibre had a high curvature, forcing to reduce the element size to 20 µm, to avoid negative volumes (Fig. 2a, inset). The boundary conditions were set for biaxial tension (Fig. 2b).

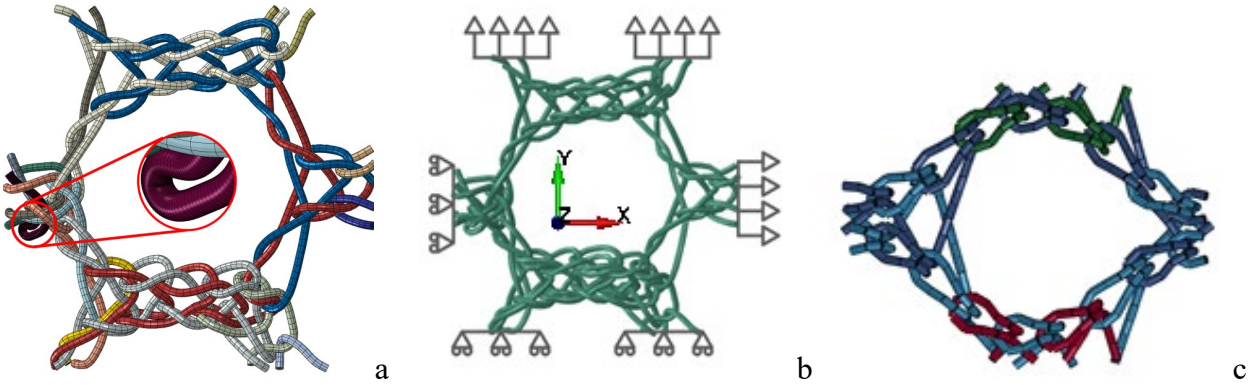

Fig. 2. FE models based on the XCT image, Abaqus (a), with boundary conditions for biaxial tension (b), and exported from TexMind for LS Dyna (c).

Parametrical Modelling of the Warp Knitted Structures

Fig. 3 shows the knitting pattern and the idealised geometrical model of the warp-knitted mesh. Depending on the run-in settings on the machine (derived yarn length per 480 loops) and the bending stiffness of the monofilament yarns the loops will be formed with different geometry. A more stiff filament, at sufficiently large yarn length, forms wider loops, while lower yarn length per loop, and material with lower bending rigidity, forms narrow loops. The yarn length per loop influences the possibility for slippage of the yarn during deformation, and in this way wider and larger loops will result in a larger initial elongation and a lower elasticity modulus.

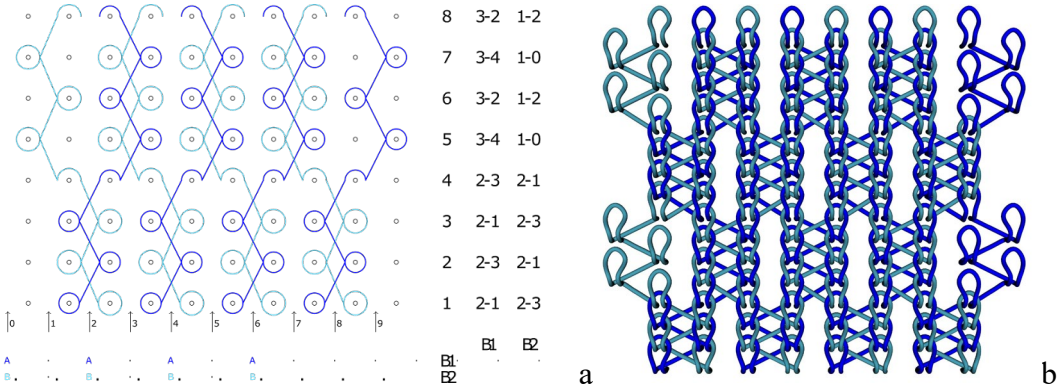

Fig. 3. Pattern of common warp knitted fabrics for production of hernia mesh, lapping and threading notation (a), idealised geometrical model (b), by TexMind Warp Knitting Editor [20].

The idealized geometrical model can be refined by adjusting the loop centre position in the horizontal direction, based on the sum of the horizontal projections of the resulting forces of all

yarns during the knitting process, the flexibility or stiffness coefficient and a scaling factor [19]. Fig. 4 represents the reconstructed FE geometry of one unit cell of the investigated mesh structure, compared with the parametrically modelled one. From the XCT image the yarns can be well-recognized. The loops move not only around the horizontal axis, but they rotate as well under the influence of the yarn tension. Such a rotation of the knitted cells is not implemented yet in the parametrical model, but this can be an extension of the model in the future, in a similar way as the correction of the horizontal loop centre position.

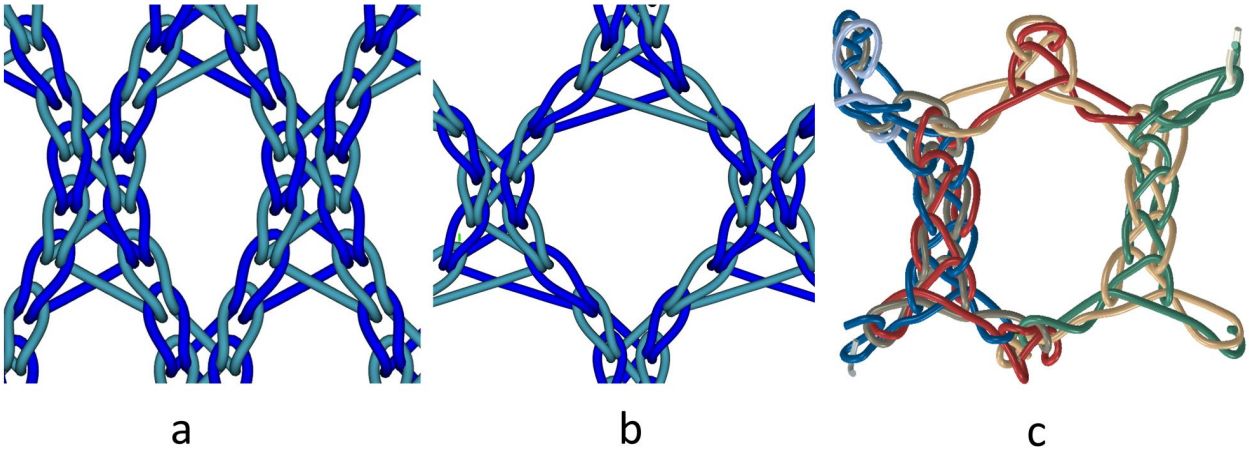

Fig. 4. Comparison of the parametrically modelled structure, two different machine gauges (a,b) with the one obtained by XCT analysis (c).

The parametric modelling of the warp knitted structure is performed without information about the available yarn length per loop. Two figures with different machine gauge (spacing between the needles) and level of side deformation are visualised at Fig. 4a and 4b and they still have different configurations than the reconstructed geometry Fig.4c. The reconstructed geometry shows longer loops in the transition areas between the single linear elements, which can be achieved as well with larger run-in for these steps on computer-controlled machines. For the proper modelling in such case an iterative process with variation of the loop length per each loop and comparison of the simulated and extracted geometry is required, but its implementation is a complex procedure.

The modelled warp knitted fabrics store the coordinates of the single yarns in the memory and as files with lists of 3D coordinates. During the application of explicit FEM software for the modelling process, the element length influences the integration time step. In order to keep all elements with equal length, the curves of the yarn paths are fitted with cubic splines, and then starting from the first node of each yarn, the next node for export for FEM is located from the yarn path so, that the element length remains constant to the value, specified by the user (0.25 mm in this case). The computed nodal coordinates are saved as a text file for LS-Dyna or Abaqus, with the required format as nodes, and then elements between these are placed by interpolation. The complete process is implemented as C++ library, using The Visualization Toolkit (VTK) for visualisation and processing. The model exported in LS Dyna is shown in Fig. 2c.

Modelling of the Biaxial Tension of the Mesh

Biaxial tension on X and Y directions with the equal displacements U_0 on the two axes was applied in LS Dyna to the FE model, exported from *TexMind* and in Abaqus for the XCT-based model. Fig. 5 shows the calculated displacement – force diagrams. The initial regions with low resistance are corresponding to the regime of unbending of the filaments and transition of the loops to the locked condition. In XCT-based model, Fig. 5a, this region exhibits certain resistance to loading, albeit low. For the loading in X direction this low stiffness behavior continues till the end of the

calculation. The inset in Fig. 5b shows details of this region for *TexMind* model. The jumps and negative force values correspond to the resolving of contacts caused by the sliding of the yarns. The forces in this region in this model should be taken as zero. After the loops are locked, the resistance is given by the elongation of the yarns.

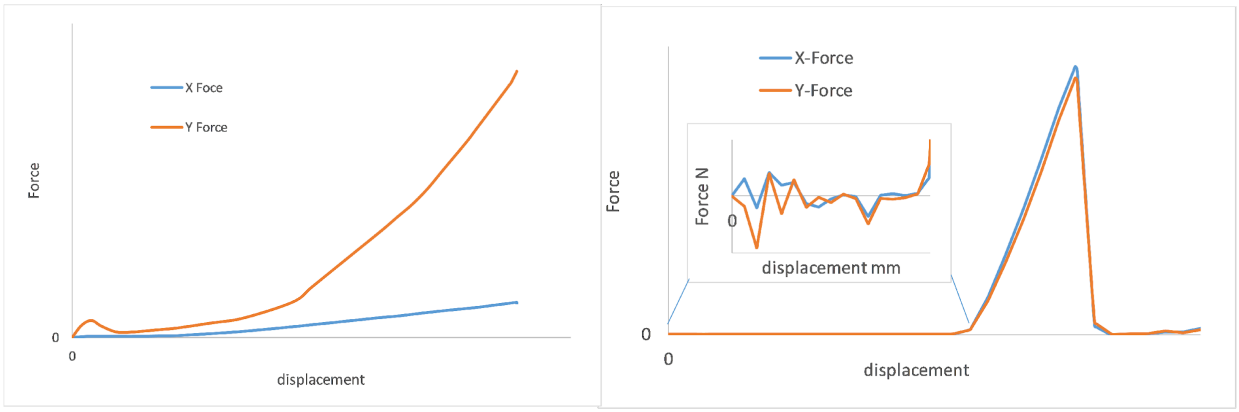

Fig. 5. Biaxial tension diagrams, calculated for the XCT-based digital twin in Abaqus (a) and for the idealised model in LS Dyna (b).

The graphs in Fig. 5 are plotted without specification of the absolute values of force and displacement, because in the present calculations FE convergence problems have forced us to use quite arbitrary values for the filaments and contact properties, based on the FE convergence requirements rather than on the physics. However, the present results allow making certain observations, which highlight difficulties in achieving true-to-life calculations.

The transition-to-locking regime depends very much on the fabric conditions and pre-tension (not accounted for in the calculations). This most probably explains the fact that in *TexMind* calculations, the force is the same in both directions: *TexMind* model operates with ideal distances between the filaments in the loop contacts. In the XCT-based model apparently the fabric is looser in X than in Y direction, which also corresponds to the behavior described by the manufacturer (dyna-mesh.com) The pre-tension will be “the must” for the experimental measurements and for the future modelling, as it allows stabilization of the initial tension conditions.

Summary

We have created geometrical and mechanical models for warp-knitted abdominal wall meshes. The models are built as “digital twins” with the help of 3D imaging with XCT, and using design of 3D mesh structures with *TexMind* software. XCT represents exact knitting pattern, so should theoretically result in the most accurate simulations. *TexMind* possesses the ability to virtually tweak the knitting pattern and, in that way, to optimize the pattern in terms of mechanical behavior. As such, we would able to optimize current mesh designs, or even come up with new mesh patterns that more closely resemble the mechanical behaviour of native fascia tissue.

We developed a methodology of 3D image acquisition of surgical abdominal meshes with XCT and methods and routines for creation of FE models for the real meshes on micro-level. The analysis of the mechanical behavior of a complex mesh under biaxial tension is feasible, whilst important difficulties are identified for development of true-to-life finite elements modelling. In future work, the limitations of the present study will be tackled to obtain models of the larger part of the mesh (as in Fig. 1b), a more precise reproduction of the knitting pattern and an experimental validation of the mechanical properties.

Keywords: Biaxial NCF, Hyperelastic, Meso-Scale Model, Unit Cell

Abstract. Understanding the mechanical properties of carbon fiber reinforcements is necessary for the simulation of forming processes. A unit-cell mesoscopic model provides a tool to implement virtual material characterizations which can be served as an input for macroscopic modelling, avoiding complex experimental tests and significantly reducing calculation time. Meanwhile, the occurrence of some local defects during the forming process, such as the gapping, would be easier to be detected through a mesoscopic approach. In this research, a novel mesoscale model for biaxial non-crimp fabric is developed based on the geometry measured from the results of X-ray tomography. A hyperelastic constitutive law is applied to the fiber yarns which are considered as a continuous medium. One type of unit-cell model is chosen and validated through a comparison with experimental tests and its in-plane shear behavior is studied.

Introduction

Biaxial non-crimp fabric (Bi-NCF) is increasingly used nowadays due to its higher lightweight potential and lower cost of manufacturing in various areas such as aeronautics and automotive [1]. Unlike a woven fabric, its fiber yarns in both directions are straight without any undulations and each of them is bound with a stitching loop along a specific direction that can be adapted to a desired formability [2]. Different stitching patterns strongly effect the final mechanical properties and drapability of the Bi-NCF [3,4]. Some optical observation methods were carried out by many researchers in order to better understand the internal geometry of NCFs, which is a critical step for the mesoscopic modelling [5,6].

In the literature, macroscopic approaches are commonly used to predict the forming behavior of fibrous reinforcements [7-10]. However, such an approach may encounter difficulties when predicting some local defects, such as the gapping which occurs when the two adjacent yarns move away from each other and leave an empty zone without fibers. These gapping defects are often detected through a numerical result of the in-plane transverse strain at this macroscale [7,11]. Furthermore, yarn-yarn and also stitch-yarn slippage, which usually occur in non-crimp-fabrics, is hard to be seen via a macroscopic continuum approach. An alternative is using microscopic approaches, where each filament of the fiber yarn is modelled by beam or solid elements. This micro-model is realistic but complex and time-consuming. Therefore, mesoscopic approaches are much more used on the Biaxial-NCF or even UD-NCF [12,13].

Mesoscopic modelling considers each fibrous yarn as a solid medium and the surrounding stitches are modelled by finite beam or bar elements. The contact behavior between the stitches and yarns are considered as well. Therefore, the local deformation of NCFs, such as the yarn's compression, the slippage between yarns and stitches, as well as the development of gap, is visible

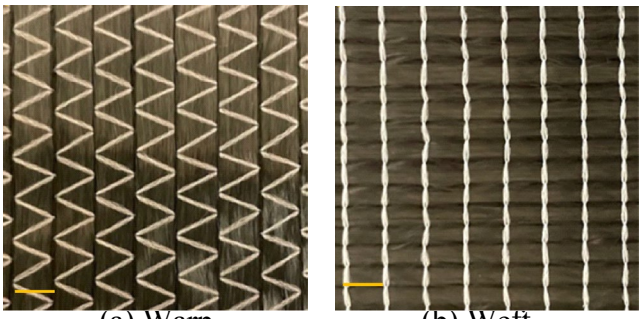
at this scale. This work aims to develop and introduce a unit cell mesoscopic model in commercial software Abaqus, on which virtual material characterization can be conducted and different stitching pattern can be analyzed.

Unit Cell Mesoscopic Model

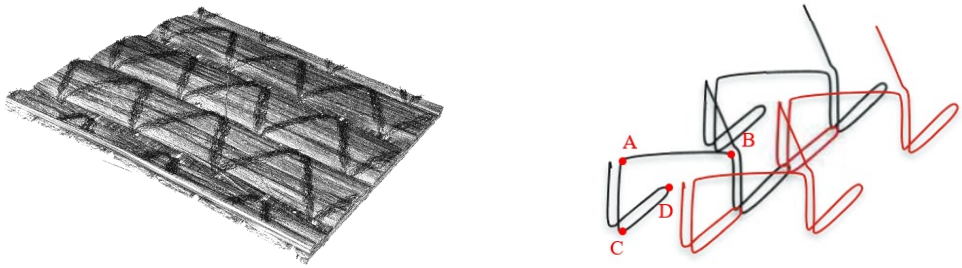
In this research, a $0^{\circ}/90^{\circ}$ carbon fiber biaxial NCF with a polyester tricot stitching is selected. The two layers are bound together during the production process with loop formation in the warp direction. The fiber yarns in the warp direction which are characterized with a "Z" stitching pattern are shown in Fig. 1a, and the weft fiber yarns are shown in Fig. 1b. Its areal weight is 600 g/m^2.



(a) Warp (b) Weft

Fig. 1. carbon biaxial non-crimp fabric architecture.

In order to better understand its internal geometry, an X-ray tomography was firstly carried out, as shown in Fig. 2a. Several geometrical parameters, such as the width and thickness of weft and warp fiber yarns, the knitting position (where the stitch passes through the two layers of fiber yarns), the initial gap between fiber yarns, were measured to serve as input for the mesoscopic model.



(a) (b)

Fig. 2. Geometry of NCF (a) X-ray tomography (b) tricot stitching pattern schema [24].

The cross-section shape of the fiber yarns was assumed to be circular, flat, elliptic or biconvex in several researches [14-16]. In this study, the yarn's section was built as a half elliptical shape and the yarn is considered to be straight as an ideal initial configuration. The tricot stitch pattern is shown in Fig. 2b. It is complex to observe the stitch geometry since some of stitch yarns are hidden between the fiber yarns. Researchers use tracer fiber techniques to extract the stitching path [6] and define mathematical equations to describe these explicitly [17]. For an example of stitching loop shown in Fig. 2b, the A, B, C and D points are the knitting position where the stitch yarn goes through the two layers of fiber yarn. Their locations can be confirmed from tomography results. From A to B and C to D, two elliptical equations are respectively used to describe the stitch yarn to wrap around the weft and wrap yarn. From A to C is a straight line to describe the piercing stitch. Through repeating these steps, the whole stitching pattern can be generated. After assembling the fiber yarns and stitches, a simulation of the shrinkage of the stitch is carried out in order to tighten the initial loose structure and realize the interaction between the yarn systems [18].

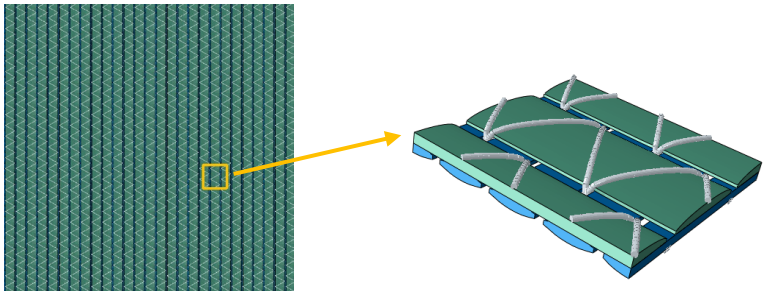


Fig. 3. Modeling of biaxial NCF.

One selected type of unit cell model is shown in Fig. 3. It has the smallest size to contain at least one entire stitching loop and is able to represent the entire mechanical properties of the NCF. A half yarn position is chosen as this model's boundary rather than the gap position because it will not break the stitching loop connection (which is point D in Fig. 2b). Otherwise the separation of stitches may happen which requires additional boundary conditions.

Boundary Conditions and Periodicities

It is assumed that the biaxial NCF is a periodic medium if the internal slippage is neglected and in order to guarantee this periodicity, appropriate kinematic boundary conditions need to be imposed on the unit cell so that it can represent the mechanical property of entire fabric [19]. The displacement field $\underline{\varphi}(\underline{X})$ of the structure can be split into two parts, as shown in Fig. 4: the macroscopic displacement field $\underline{\varphi_m}(\underline{X})$ which is known since it is the input of the simulation and the periodic local displacement $\underline{w}(\underline{X})$ which is unknown [20,21].

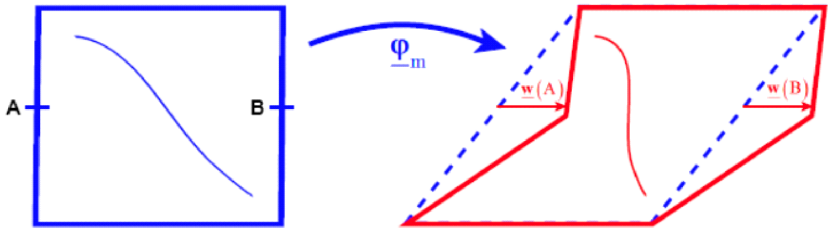

Fig. 4. Initial and deformed periodic structure, displacement field.

This can be expressed as:

$$\underline{\varphi}(\underline{X}) = \underline{\varphi_m}(\underline{X}) + \underline{w}(\underline{X}) \tag{1}$$

To ensure the periodicities, it is necessary to make sure that the local displacements of two opposite sides $\underline{X^+}$ and $\underline{X^-}$ are equal

$$\underline{w}(\underline{X^+}) = \underline{w}(\underline{X^-}) \tag{2}$$

Then the boundary conditions can be obtained as:

$$\underline{\varphi}(\underline{X^+}) - \underline{\varphi}(\underline{X^-}) = \underline{\varphi_m}(\underline{X^+}) - \underline{\varphi_m}(\underline{X^-}) \tag{3}$$

Materials Research Proceedings 28 (2023) 285-292 https://doi.org/10.21741/9781644902479-31

Mechanical Behavior of the Fiber Yarn and Stitch

In this study, the polyester stitch was modelled by two-node beam elements and was considered as a linear elastic material. A traction test was carried out to measure its tensile stiffness. A hyperelastic constitutive law which had been proposed by A. Charmetant [22] was used for the carbon fiber yarn.

Hyperelastic constitutive law.

The fiber yarn is specific as it contains thousands of filaments of carbon fibers, giving it high tensile stiffness and relatively low shear stiffness. From the cross-sectional images at the microscopic scale, the two-point covariance, which represents the probability that two points separated by a distance x to belong to the same phase of the fiber, looks similar along the width and thickness of each fiber yarn [20]. Thus, it can be assumed that the spatial distribution of these filaments inside the yarn is isotropic and the fiber yarn is considered to be transverse isotropy. Four deformation modes are used to describe the fiber yarn's behavior, which are the elongation along the fiber direction, the compaction of the cross section, the transverse shear (distortion of the cross section), and the longitudinal shear along the fiber direction, as shown in Fig. 5.

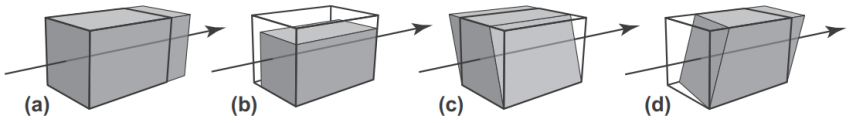

Fig. 5. Four deformation modes of fiber yarn (a) elongation (b) compaction of cross section (c) transverse shear (d) longitudinal shear.

Thus, the deformation gradient tensor, $\underline{F}$, which allows the transformation of fiber yarn from its initial position $\underline{X}$ to its deformed position $\underline{x}$, can be split into four matrixes associated with these four deformation modes.

$$\left[\underline{F}\right] = \left[\underline{\underline{F_{elong}}}\right] \vdots \left[\underline{\underline{F_{comp}}}\right] \vdots \left[\underline{\underline{F_{dist}}}\right] \vdots \left[\underline{\underline{F_{sh}}}\right] \tag{4}$$

The hyperelastic equation defines the material's elastic strain energy potential based on the strain state. Four physically based invariants I_{elong}, I_{comp}, I_{dist}, I_{sh} are defined as a function of the classical invariants I_1 to I_5 of the right Cauchy Green strain tensor $\underline{\underline{C}}$ and then used to describe these different deformation modes.

These classical invariants are expressed as:

$$I_1 = trace(\underline{\underline{C}}),\ I_2 = \frac{1}{2}(trace\left(\underline{\underline{C}}\right)^2 - trace(\underline{\underline{C}}^2)), I_3 = det(\underline{\underline{C}})$$

$$I_4 = \underline{\underline{C}} : \underline{\underline{M}}, \qquad I_5 = \underline{\underline{C}}^2 : \underline{\underline{M}} \tag{5}$$

where $\underline{\underline{M}}$ is a structural tensor defined by a unit vector of preferred direction $\underline{M}$, i.e. the fiber direction:

$$\underline{\underline{M}} = \underline{M} \otimes \underline{M} \tag{6}$$

The four physically based invariants are introduced in [22] and expressed as:

$$I_{elong} = \frac{1}{2} ln\, ln\, I_4\,,\; I_{comp} = \frac{1}{4} ln\, ln\, (\frac{I_3}{I_4})\,,\; I_{dist} = \frac{1}{2} ln\, ln\, (\frac{I_1 I_4 - I_5}{2\sqrt{I_3 I_4}} + \sqrt{(\frac{I_1 I_4 - I_5}{2\sqrt{I_3 I_4}})^2 - 1})\,,\; I_{sh} = \sqrt{\frac{I_5}{I_4{}^2} - 1} \quad (7)$$

Then, the deformation energy is assumed to be the sum of the energies of these four deformation modes:

$$w(\underline{\underline{F}}) = w_{elong}(I_{elong}) + w_{comp}(I_{comp}) + w_{dist}(I_{dist}) + w_{sh}(I_{sh}) \quad (8)$$

The second Piola-Kirchhoff stress tensor is defined as

$$\underline{\underline{S}} = 2\frac{\partial w}{\partial \underline{\underline{C}}} = 2(\frac{\partial w_{elong}}{\partial I_{elong}}\frac{\partial I_{elong}}{\partial \underline{\underline{C}}} + \frac{\partial w_{comp}}{\partial I_{comp}}\frac{\partial I_{comp}}{\partial \underline{\underline{C}}} + \frac{\partial w_{dist}}{\partial I_{dist}}\frac{\partial I_{dist}}{\partial \underline{\underline{C}}} + \frac{\partial w_{sh}}{\partial I_{sh}}\frac{\partial I_{sh}}{\partial \underline{\underline{C}}}) \quad (9)$$

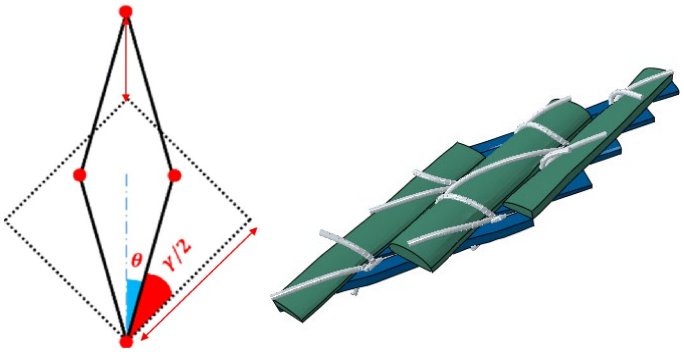
Experimental tensile tests and compaction tests on woven fabric and single fiber yarn were carried out in several previous researches [22,25]. Since the studied Bi-NCF is also made of carbon fibers, the same material parameters are temporarily used and are shown in Table 1.

Table 1. Parameters of the constitutive model for the yarn.

Deformation mode	Strain energy function	Material parameters
Elongation	$w_{elong}(I_{elong}) = \frac{1}{2} K_{elong} {I_{elong}}^2$	K_{elong}=108500 N
Compaction	$w_{comp}(I_{comp}) = \lvert K_{comp} {I_{comp}}^p \quad 0 \;\; if\; I_{comp} > 0$	K_{comp}=1.25 Mpa $P = 1.84$
Transverse shear	$w_{dist}(I_{dist}) = \frac{1}{2} K_{dist} {I_{dist}}^2$	K_{dist}=0.6Mpa
Longitudinal shear	$w_{sh}(I_{sh}) = \frac{1}{2} K_{sh} {I_{sh}}^2$	K_{sh}=2Mpa

Numerical Study

The virtual tests such as the elongation tests or compaction tests can be done on the unit cell model. In this study, an in-plane shear simulation was carried out to validate this unit cell model through comparing the deformed geometry and the shear force with the experimental results, after assuming that the shear deformation is uniformly distributed. Fig. 6a shows the in-plane shear deformation schema. The nodes at the bottom corner were fixed and the nodes at the top corner were stretched. The unit cell length was 10 mm, and the displacement of the stretched nodes was set up as 5 mm. The deformed configuration of this unit cell is shown in Fig. 6b. During the shear deformation, it can be seen that one segment of stitch is always stretched and another one is compressed. The fiber yarns are also compressed by the tightened stitches. In order to validate the deformed geometry, the yarn's width as well as the gap are measured. They all show a good agreement with the experiments.



(a) (b)

Fig. 6. (a) Schema of an in-plane shear deformation [26] (b) Deformed unit cell model.

The shear angle during this deformation can be expressed as:

$$\gamma = \frac{\pi}{2} - 2\theta = \frac{\pi}{2} - 2(\frac{\sqrt{2}L+D}{2L}) \quad (10)$$

where L is the unit cell length and D is the displacement.

In order to compare with the experimental results, the reaction force F which is measured at the fixed nodes is normalized by the frame length [23]:

$$F_{nor} = \frac{F \cdot L}{\sqrt{2}L+D} / L \quad (11)$$

The simulation results of normalized shear force and shear angle are shown in Fig. 7, showing a good agreement with the experimental results.

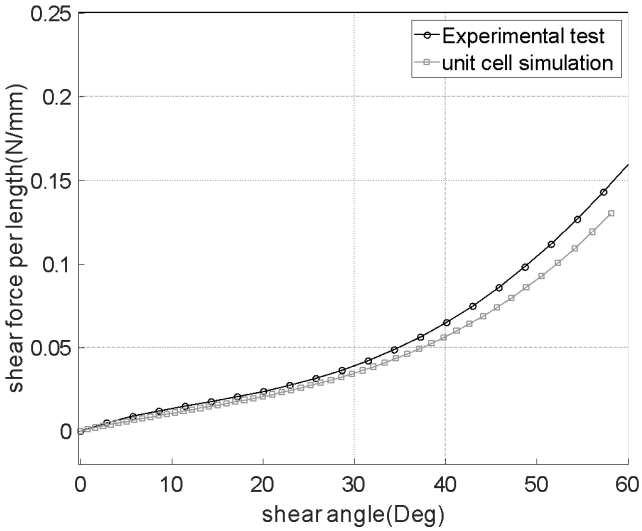


Fig. 7. Shear force normalized vs. shear angle.

Summary

A unit cell mesoscopic finite element model with explicitly described geometry of fiber yarns and stitches is proposed in this study. This model is validated through an in-plane shear simulation, where the shear force and the deformed geometry are in good agreements with experimental results. It shows that this model is able to conduct virtual material characterization and significantly reduce the necessary amount of experimental tests. Furthermore, the geometry of stitches and yarn's section can be easily adjusted which allows for the analysis of different stitching patterns, with the opportunity to develop tailored NCFs with optimized deformation behavior for specific applications.

The hyperelastic constitutive law that is applied on carbon fiber yarns in this study does not consider the bending behavior which is necessary when conducting forming simulation and analyzing gapping defect. The generalized continua approach is needed to be developed and implemented in the future work.

Abstract. Validation of composites forming simulations is essential to improve simulation predictions. Detailed validation requires reliable and well-controlled forming processes with precise methods for comparison to simulation results. This study presents some preliminary results from press forming experiments with cross-ply laminates shaped over a dome geometry. The material studied is a unidirectional carbon-fiber reinforced thermoplastic composite. The forming experiments were combined with a deformation measurement technique based on photogrammetry to measure the in-plane deformation on the surface of the laminate after forming. The obtained full-field deformation measurements allow for a direct and quantitative comparison with simulations. The accuracy and precision of the methodology are discussed in detail. The combination of a versatile forming experiment and a detailed analysis method as presented in this article could enable a more precise validation of composite forming simulations.

Introduction

The development of composite forming simulation models based on finite elements has already resulted in various commercial implementations to date. [1] These high-fidelity design tools can be used to address challenges in the complex relation between part design, process design and the occurrence of defects through the prediction of deformation and stress during processing. In this way, virtual design iterations using simulations allow engineers to mitigate some of the risks associated with production delays, unforeseen costs and wasted material.

However, like any model, composite forming simulations will have inherent limitations in terms of accuracy and precision. Moreover, because simulations are generally an ideal representation of reality, they cannot always account for material variability or uncertainties in boundary conditions. The prediction of wrinkling is a particular challenge in composites forming, because these defects can be relatively small compared to the overall geometry and the physical buckling phenomenon underlying this defect is sensitive to the aforementioned variabilities and uncertainties. Therefore, validation efforts are required to evaluate the limitations of current simulation models. Knowing the discrepancies properly can serve as a basis for future improvements to composites forming simulations.

This article follows up a previous publication [2] where a dome was used to study wrinkling with changing laminate geometry and layup on a simple generic toolset. Wrinkles were observed more easily by not closing the press fully and careful choice of the boundary conditions allowed the material behavior to dominate over handling influences in the result. Those results already taught a lot about the material's limitation in forming. However, for validation, the wrinkling can

mainly be used as a qualitative measure, limiting the accuracy due to subjective interpretation. Wrinkling quantification may be possible through measurement of the laminate surface and an appropriate wrinkling metric, such as local curvature as featured in the work of Dörr et al. [3] Nevertheless, a quantitative comparison of wrinkles may still be complicated due to the variability in exact shape, size and location of individual wrinkles and folds. Hence, despite wrinkling being the predominant defect of interest, it only allows for an indirect way to validate many of the complex inputs (e.g. material models) to the simulation.

In a related field of study, sheet metal forming, a well-established technique to validate simulations is the measurement of the deformations. Hence, professionalized and automated implementations of such systems, for example the ARGUS system by GOM Metrology [4], could serve as a source of inspiration to further develop high-end techniques applicable to composites forming. For metal forming, typically, a polka-dot pattern with a 1-5 mm resolution is applied to the blank using direct printing or chemical etching. The deformed pattern after forming is digitized using photogrammetry and used to calculate major strain, minor strain and thickness reduction. These quantities may be compared against simulations directly or related to forming defects through a forming limit diagram.

In composites forming the main deformation of interest is arguably the reorientation of the fiber direction(s), or the related shear angle [5]. Limited extensibility in fiber direction will have a pronounced effect on the overall deformation, resulting in dominant shear behavior and local thickening rather than thinning. The fiber directions may be tracked intuitively using drawn lines [6], a tracer in the fabric [7,8] or directly from the materials' inherent pattern [9,10]. However, full field strain measurements, using photogrammetry for example, provide a more complete picture of the local deformations. Haanappel et al. [11] have applied photogrammetry on a dot pattern to measure the deformation from stamp forming thermoplastic composites, allowing correlation of the measured shear strains on the top surface with simulation results. Sachs et al. [12] extended this technique by applying a pattern on both sides of the laminate to measure the relative movement of the outer plies through the thickness direction, used to validate ply-ply slip and friction in the simulations. Kunze et al. [13] showed that photogrammetry can even be applied on internal plies of a layup through CT measurements and a pattern applied with a special paint for good x-ray contrast.

This article presents a study where the versatile dome forming experiment is combined with a deformation measurement technique based on photogrammetry. The resulting measured deformation fields enable a quantified means to directly validate the in-plane material behavior in composite forming simulation models. By varying the blank dimensions and layup, the dome experiment allows for a wide range of deformations, highlighting the influence of the various underlying deformation mechanisms. However, in this study the layup will be limited to cross-ply, because of the pronounced role in-plane shear deformation has during forming and the direct link with wrinkling defects through the other dominant deformation mechanism, namely bending.

On a historical side note, there is a striking resemblance between the study described in this article and the work by Martin et al. [14] published 30 years ago. However, the capabilities of modern day computer simulations require a more detailed and quantified look into the local deformations, making this topic ever more relevant today.

Method

In preparation for the forming experiments, flat laminates were prepared from Toray TC1225 and Solvay APC materials, both are unidirectional carbon fiber reinforced thermoplastic composite tapes typically applied in the aerospace industry. Some datasheet characteristics on these materials are collected in Table 1.

Materials Research Proceedings 28 (2023) 293-304 https://doi.org/10.21741/9781644902479-32

Table 1. Material characteristics, from datasheet [15,16].

	Toray TC1225	Solvay APC
Fiber	T700	AS4D
Fiber areal weight [g/m2]	145	145
Fiber volume fraction [%]	59	59
Matrix	LM-PAEK	PEKK-FC
Resin content by weight [%]	34	34
Glass transition temperature [°C]	147	159
Melting temperature [°C]	305	337
Consolidated ply thickness [mm]	0.14	0.14

Laminates were press consolidated from loosely stacked plies inside a picture frame mold, with multiple laminates separated by caul sheets and release agents applied to all tooling surfaces. Solvay APC was consolidated at 375°C, 10 bar for 15 minutes and Toray TC1225 at 365°C, 10 bar for 20 minutes. Finally, blanks were cut to final dimension using a water cooled diamond saw. Blanks were dried at 120°C overnight and press formed the same day. The test matrix for the forming experiments is comprised of different layups and blank dimensions according to Table 2.

Table 2. Test matrix with number of formed blanks for combinations of width and layup. The same test matrix was used for both materials.

		$[0/90]_{2s}$	$[45/-45]_{2s}$	$[90/0]_{2s}$	$[0/90]_{4s}$
Width	40 mm	2			2
	80 mm	2			2
	110 mm	2			2
	140 mm	4	2	2	2

# Plies	8	16
Length	295 mm	380 mm
Thickness	≈ 1.1 mm	≈ 2.2 mm
Tool gap	3.1 mm	4.2 mm

Prior to forming, a dot pattern was applied in a rectangular grid to all blanks, see Fig. 2a. Dots are spaced 5 mm apart with a 1.7 mm diameter and the grid is aligned with both fiber directions in the layup. The pattern is painted onto the laminate using a heat resistant silver spray paint and a mask in the form of a sticker. This mask was cut using a CNC-plotter and applied to the laminate using transfer tape to prevent deformation.

Press forming was conducted on the 200 ton Pinette Emidecau Industries press at TPRC, in which the same procedure was applied as previous research [2]. Steel tooling was used having a square base and a hemisphere dome shaped cavity, with dimensions according to Fig. 1. The 8-ply laminates use a 1.1 mm nominal cavity, where it is 2.2 mm for all 16-ply laminates. The tool temperature was 220°C for all experiments.

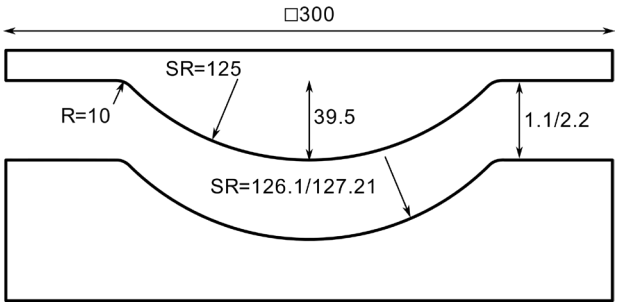

Fig. 1. Hemisphere tool set illustration with dimensions in millimeters. A single male punch is used in combination with two female dies for specific nominal cavity sizes.

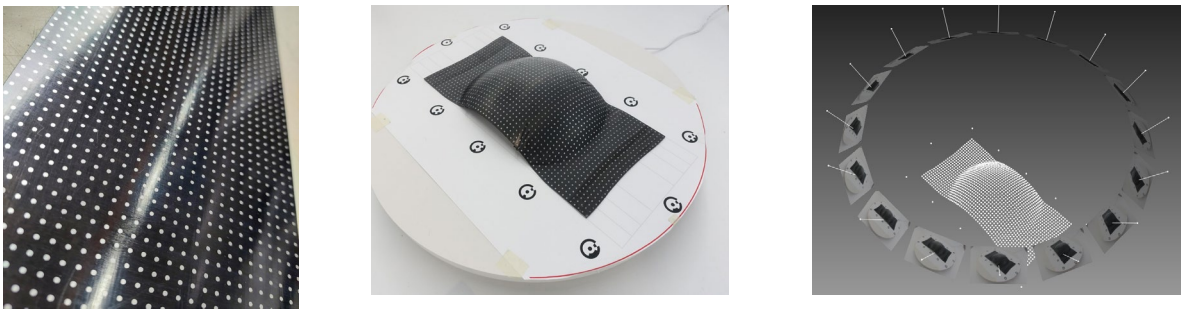
The forming process cycle consists of suspending the blank in a shuttle frame, equal to the previous study [2], with the dot pattern facing downwards towards the female die tooling. The blank was then heated to 365°C for Toray TC1225 or 375°C for Solvay APC inside an infrared oven, before a quick automatic transfer places it between the press tooling, which close to form the part. The velocity of the tool is approximately 100 mm/s initially and switches to 20 mm/s when the tools are spaced 10 mm apart. No consolidation pressure was applied, instead a fixed tool gap was used according to Table 2.

The deformation measurement method and calculation is similar to the study of Haanappel et al. [11], which utilizes photogrammetry to digitize the dot pattern on formed parts. First, the part is photographed in a dedicated photography set-up with adequate lighting, a remote control turntable, a surface with reference marks and polarizing light filters to cancel out unwanted specular reflections. A Sony DSC-RX100M3 digital camera was used with a small aperture (f/8) and a low iso-number (200) for a large depth of field and high picture quality. Each part was photographed from 16 equidistant angles around the part, at a fixed elevation. An example photo is shown in Fig. 2b.



(a) (b) (c)

Fig. 2. (a) Dot pattern on undeformed laminate (b) Formed Solvay APC $[0/90]_{2s}$ 140 mm wide part in photography setup (c) Digitized dot pattern in the PhotoModeler [17] software with camera positions for individual photos.

These photos were subsequently analyzed in the photogrammetry software PhotoModeler [17] First, all visible dots are marked for each photo. Then, the software optimizes for the camera orientation and parameters to determine the locations of each dot in 3D space, including a confidence region. A reference length is used to scale the point cloud to real world length units. An example of a final PhotoModeler project state is shown in Fig. 2c. The undeformed configuration was not analyzed with photogrammetry, but assumed to match the design of the paint mask pattern. Finally, points are sorted to have corresponding node locations and meshed with a triangular element topology that is the same for both configurations.

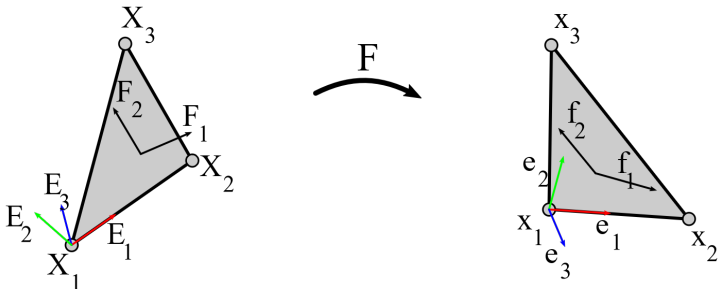


Fig. 3. Vector definitions in initial (left) and deformed (right) configurations.

The deformation can now be calculated for each triangular element by comparing the deformed configuration with the initial configuration, see Fig. 3. Elements in the initial configuration are defined by three nodes in 3D space (X_1, X_2, X_3), linear shape functions, two fiber directions (F_1, F_2) and a local coordinate system. The deformed configuration is similar, but has unknown fiber directions still. The deformation gradient tensor $\boldsymbol{F}$ is readily calculated from the shape functions [18] based on the 2D nodal coordinates in their respective local coordinate systems.

The deformation gradient tensor maps the fiber directions to the deformed configuration using

$$f_1 = \boldsymbol{F} \cdot F_1 \quad \text{and} \quad f_2 = \boldsymbol{F} \cdot F_2 \,. \tag{1}$$

And, based on the difference in fiber directions between configurations, the shear angle is calculated using

$$\gamma = \cos^{-1}(f_1 \cdot f_2) - \cos^{-1}(F_1 \cdot F_2), \tag{2}$$

based on unit fiber directions. Although only a single fiber direction is present on the outer ply, it is assumed that the second fiber direction on the ply below behaves according to the same deformation gradient. The latter term in equation 2, the initial fiber angle, is 90° for all laminates considered in this article. Next, the Green-Lagrange strain can be calculated from the deformation gradient according to

$$\boldsymbol{E} = {}^{1}/_{2}\,(\boldsymbol{F}^T \cdot \boldsymbol{F} - \boldsymbol{I})\,, \tag{3}$$

where $\boldsymbol{I}$ is the second order identity tensor. Standard tensor coordinate transformation rules are applied to align it with the first fiber direction. Finally, results calculated for each element are averaged component wise in the nodes for continuity arguments.

Results

Only six parts in Solvay APC material were analyzed for in-plane deformation due to an identified issue, which will be addressed in the discussion section. Pictures for each of the formed parts are nevertheless included in the digital dataset that is published alongside this article.

Fig. 4 shows the obtained results for a Solvay APC $[0/90]_{2s}$ dome with a width of 140 mm. Three components of the Green-Lagrange strain show that the majority of the deformation occurs in shear (xy-component). Most shear deformation is located in the four corners, near the base of the hemisphere, with a 10-13° shear angle at maximum. The shear deformation is not exactly symmetric over the vertical axis because the laminate was not centered over the dome geometry.

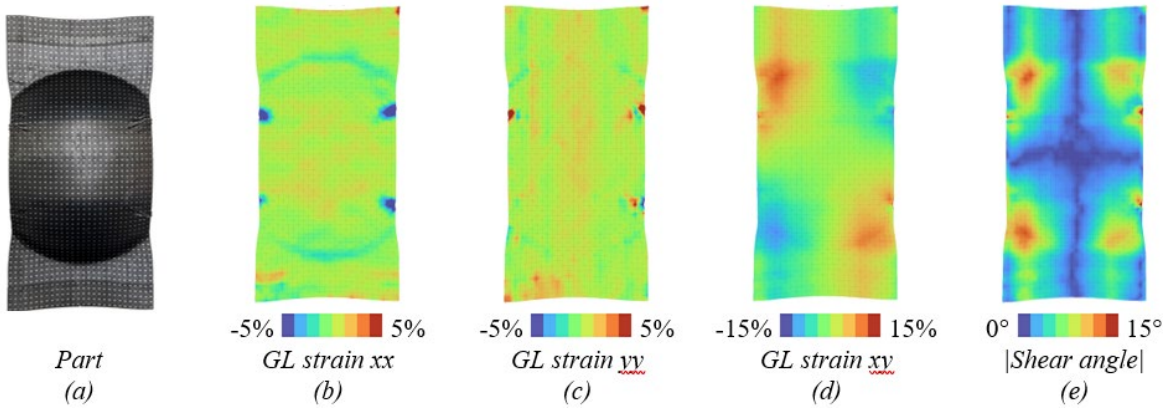

Fig. 4. Deformation results for a Solvay APC $[0/90]_{2s}$ dome 140 mm wide. The xx-direction is based on the local fiber direction, originally in length direction of the laminate.

Four distinct areas with significant compressive normal strain in xx-direction (fiber direction) are observed, which correspond with the locations of the wrinkles on the formed part. In the vicinity of a wrinkle the material is concentrated, bringing points closer together, therefore showing a compressive strain. The transverse strain (yy-component) has a band of positive strain values running in length direction over the dome, which could be related to transverse flow deformation. Near the wrinkles the distorted elements result in local high and low values for the transverse strain.

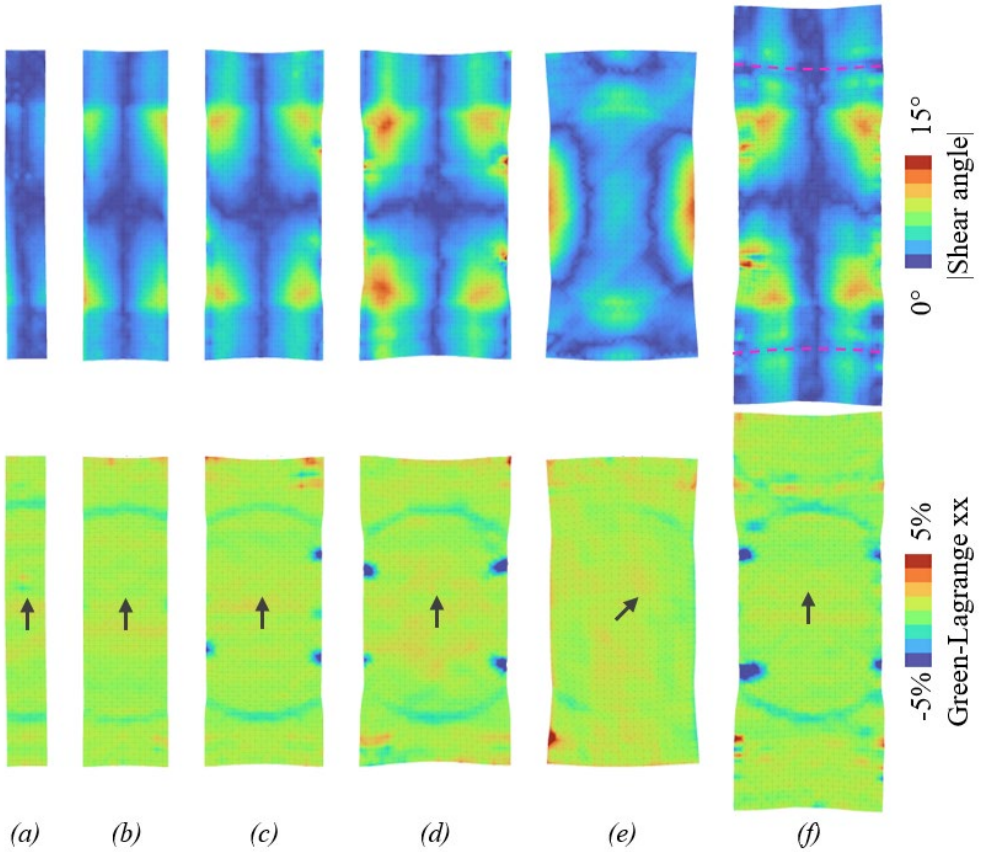

Fig. 5. Results for six domes from Solvay APC. Above: Absolute shear angle. Below: Strain in fiber direction (approximately indicated using an arrow). (a) $[0/90]_{2s}$ 40mm (b) $[0/90]_{2s}$ 80mm (c) $[0/90]_{2s}$ 110mm (d) $[0/90]_{2s}$ 140mm (e) $[45/-45]_{2s}$ 140mm (f) $[0/90]_{4s}$ 140mm.

Fig. 5 shows the most relevant results for each of the six parts analyzed. Subfigures (a)-(d) show parts with the same $[0/90]_{2s}$ layup and a varying width. It is observed that the shear deformation increases with width and the deformation is propagated more from the base of the dome towards the edge of the laminate. However, for the 110 mm and 140 mm wide parts the shear deformation is close to zero on the far left and right edge below the dome, indicating a sudden drop in in-plane deformation. This finding corresponds with the observations for the Green-Lagrange xx results in Fig. 5a-d, where wrinkling is indicated for widths of 110 and 140 mm by compressive strain. The results obtained for these parts thereby illustrate the interrelation between in-plane deformations, in particular the presence of local wrinkling, and the resulting decrease in shear deformation elsewhere in the part.

The part with a $[45/-45]_{2s}$ layup in Fig. 5e shows a completely different shear deformation pattern and no compressive strain in fiber direction. Indeed, no wrinkling was observed on this part. Therefore, this is possibly an interesting validation case for simulations due to the reduced influence of bending whilst still introducing large shear deformation.

The part with a $[0/90]_{4s}$ layup in Fig. 5f has the same typical shear deformation pattern in the four corners as the 8-ply variant, however, less shear deformation is propagated from the base of the hemisphere to the part edge, which may be related to the longer laminate length. Also, some deformation is concentrated around the two PI-tapes that were used to handle the molten laminate throughout the press forming process, indicated with magenta lines in Fig. 5f. This means that the influence of the tape cannot be neglected for this forming process, possibly due to adhesion and friction with the laminate, or an effect on the local laminate temperature.

Discussion

Because of the goal to use these deformation measurements for accurate validation of forming simulations, the discussion in this article focusses on the several aspects concerning the accuracy and precision of the methodology and its results.

Fig. 6 shows the element values for absolute shear angle. The element value is an intermediate result in the calculation, right before the nodal averaging is applied to obtain Fig. 5. For some parts, a pattern of lines is observed in these element value, possibly indicating an accuracy issue. Interestingly, this pattern cancels out during the nodal averaging step in the calculation, hence they are not observed in Fig. 5. Moreover, it seems that not all parts suffer equally from this artifact, meaning it is an inconsistent error in a fixed methodology.

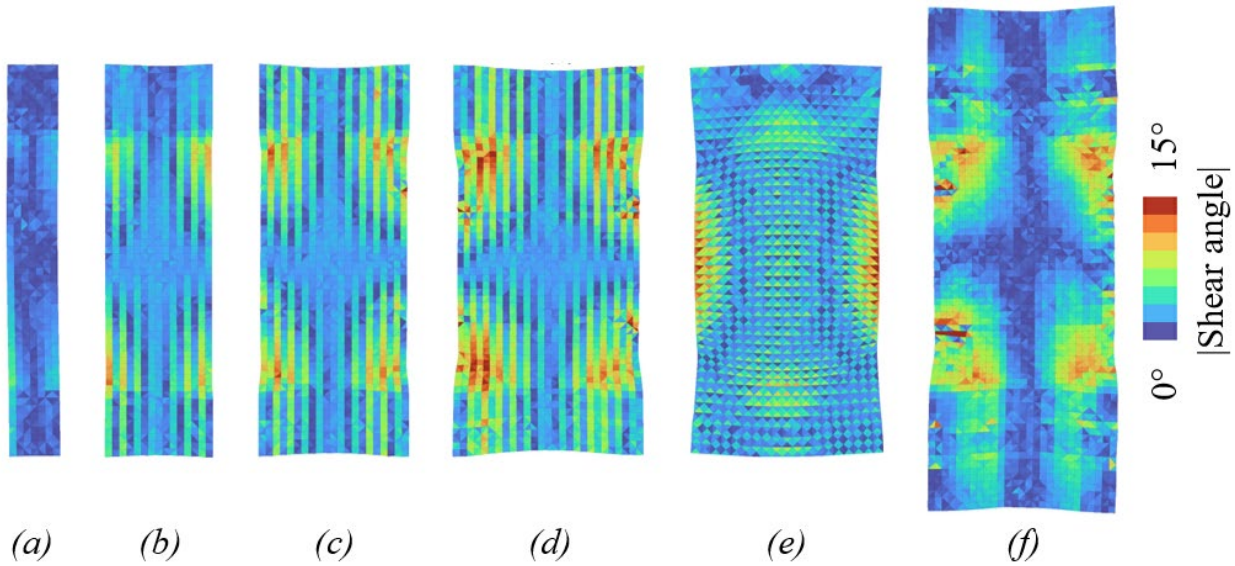

Fig. 6. Element values of the absolute shear angle. Subfigures a-f correspond with Fig. 5, in which the nodal values are plotted.

The cause for the observed element value artifacts was found in the application method of the dotted pattern onto the undeformed laminates. Fig. 7 shows a zoomed photo of an undeformed laminate, where alternating rows of dots are shifted horizontally. The same issue was found for the pattern in the paint mask sticker. Possibly, the scanning strategy of the plotter introduced this relatively repeatable error. The shift was quantified to be approximately 0.2 mm from a leftover sticker.

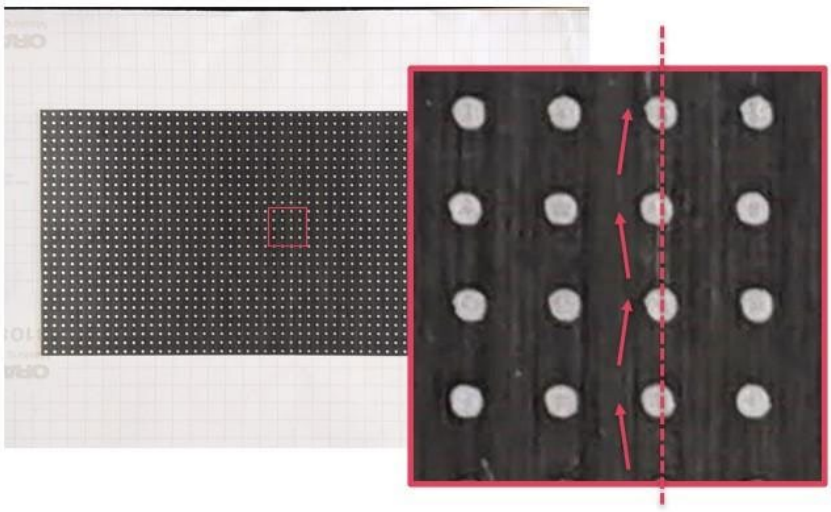

Fig. 7. Zoomed area of an undeformed laminate. A distortion is observed in the dot pattern where every other row has a horizontal shift.

Due to the repetitive nature of the error, a correction was attempted by manually assigning a 0.2 mm displacement to every other row of nodes in the undeformed configuration. This technique allows to resolve the striped patterns in the element values observed in Fig. 6c and 6d. The parts in Fig. 6a and 6f don't seem to have any issues, therefore not requiring any correction. Finally, parts in Fig. 6b and 6e have an inhomogeneous error and correction only works successfully for some areas. The effect on the nodal values is mostly zero, since alternating plus and minus contributions are averaged to zero in central node locations. However, non-zero contributions

remain in the nodal values on the edges of the part. The magnitude of which can be understood geometrically from the angle formed by the distortion and the grid size, through $\Delta\gamma = \left(\frac{0.2}{5}\right) \approx 2.3°$. Hence, it may be concluded that the inaccurate placement of the pattern resulted in a significant loss of accuracy for the nodal values on the edge of the part. Moreover, because the error can be inhomogeneous and inconsistent between parts, it is impossible to truly correct for.

The precision of the photogrammetry technique used to measure the locations of the dots in the deformed configuration will inevitably lead to a precision for the in-plane deformations measured. The PhotoModeler software [17] output includes precision values on the x-, y- and z-coordinates for each node, specified as one standard deviation for a normal distribution. This probability can be propagated using Monte Carlo simulation to assess its influence on the nodal values for each of the in-plane deformation results.

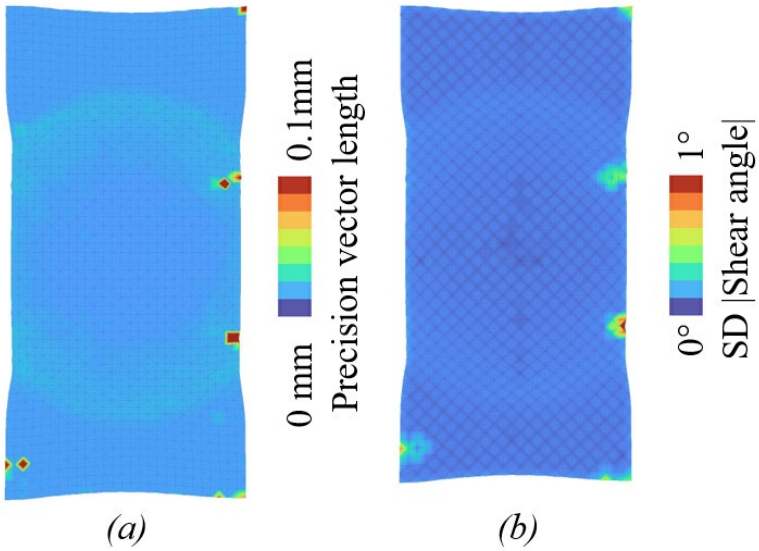

Fig. 8. Solvay APC $[0/90]_{2s}$ 140mm wide. (a) Euclidean length of the precision vector (standard deviations on x- y- and z-positions) (b) Standard deviation on the nodal absolute shear angle, obtained using Monte Carlo simulation from the precision on node positions.

An example is shown in Fig. 8 for the 140 mm wide $[0/90]_{2s}$ part in Solvay APC. The precision on the nodal positions, resulting from the photogrammetry analysis, is shown in Fig. 8a. It is observed that the majority of points was determined with a standard deviation of about 0.015mm on its 3D position, with a few outliers. Subsequently, a thousand meshes in the deformed configuration were sampled, with each node position based on individual normal distributions in x-, y- and z-direction. The resulting in-plane deformation values are approximately normally distributed with a standard deviation indicative of the precision, see Fig. 8b. Instinctively, a large precision vector results in higher standard deviation on the deformation in the surrounding area. Besides a few outliers, the majority of points has a standard deviation less than 0.15° on the absolute shear angle and 0.15% on each of the Green Lagrange strain components. Naturally, these values will be affected by the details of the photogrammetry implementation and are therefore specific to this study.

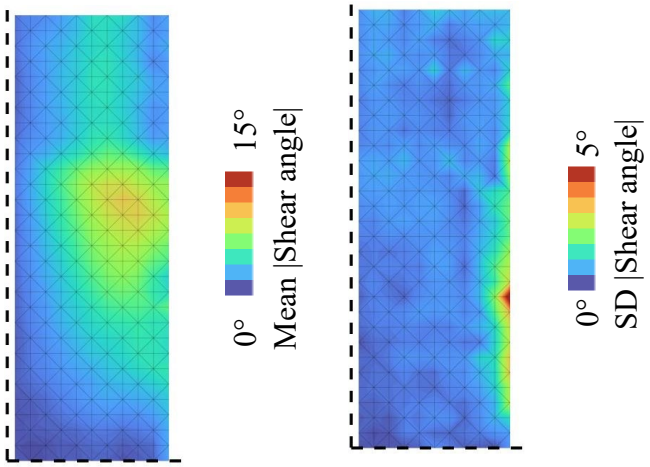

Fig. 9. Nodal results from quadrant averaging for Solvay APC [0/90]2s 110 mm wide. Dashed lines indicate symmetry planes. Results plotted on undeformed geometry. (a) Mean value (b) Standard deviation.

Process variability is another important aspect to consider in validation studies. Although not directly obtained from the analyzed parts in this study, the expected symmetry in the forming results may be used to estimate this variability. Fig. 9 shows an example were the symmetries were used to average the absolute shear angle over each of the four quadrants. In this way, a more reliable mean deformation was obtained to compare against simulations. The spread is indicated by the standard deviation, which is higher than the precision achieved with the photogrammetry method. Nevertheless, it is recommended for future studies to analyze repetitive experiments to account for inherent process variability.

Summary

This article presented results from a forming study on cross-ply laminates from unidirectional thermoplastic composite material combined with measurements of the in-plane deformations. This proposed combination of methodologies is able to provide high-resolution strain and shear angle data, allowing a quantitative validation of composite forming simulations. It is particularly suited to investigate the delicate balance between the in-plane shear and bending (wrinkling) mechanisms that dominate the forming of cross-ply layups, which can be influenced experimentally by changing the width and layup of the laminate formed over the dome geometry.

Validating and improving forming simulations requires the most accurate and precise knowledge of the real-world process as possible. To this extent, the accuracy and precision of the deformation measurement technique have been discussed. An accuracy concern was raised related to the undeformed dot pattern in the current study, which affected the nodal results on edges of a part. However, this mistake can easily be overcome in the future. Furthermore, propagation of the precision in photogrammetry towards the in-plane deformation results using Monte Carlo simulation showed that, in this study, a standard deviation of 0.15° on the shear angle and 0.15% on the Green Lagrange strain values were achieved. As such, the repeatability of experiments may be the bottleneck to obtain reliable data for validating composite forming simulations accurately.

Keywords: Polymer Matrix Composites, Cocuring, Resin Infusion, Metallization, Cold Spray

Abstract. Polymer and polymer matrix composites (PMCs) have found applications in aerospace sector. Thermosets (TS) possess higher corrosion resistance, shape retention and durability. Thermoplastics (TP) are easier for remolding in comparison to the former. Surface metallization is one of the recently applied trends for electrical and thermal properties improvement. In different metallization methods, primary restrain is the thermoset surface degradation, whereas thermoplastics have been found to be favorable for metallization. The presented article is part of continuous study aiming the cocuring of thermoset-thermoplastic resin with fibrous reinforcement. The composite manufacturing stage consisted of resin infusion (RI) process route for realizing the composite. Main objective of this stage was the through thickness and linear direction impregnation of thermoset to ensure the sound composite comprising contact between thermoplastic layer as well as fiber reinforcement. Fiber reinforcement combined with the resin infusion auxiliary materials were placed over the thermoplastic material prior to the vacuum bagging stage. Catalyzed thermoset resin impregnation in the vacuum bagged preform was conducted under the cocuring cycle. The composite panel was subsequently metallized via low-pressure cold spraying technique. The coating formation was analyzed with process parameters variation. Qualitatively, coating formation on such hybrid composite substrate was observed. However, the substrate manufacturing was found to have influence on the coating quality. Adhesion pull-off test displayed detachment zone directly in the coating substrate interphase. Presence of voids and less thermoset resin was noticed in the case of coating attempts varying process parameters such as traverse speed and standoff distance. Higher adhesion was noted with lowest selected 1 mm/s traverse speed and 10 mm standoff distance.

Introduction

Recent industrial sectors advances are aided by advanced materials and manufacturing technique development in order to ensure improved performance [1-7]. Specifically, in the aerospace sector, there has been an increase in the usage of polymer and PMCs to exploit the weight reduction as well as the high strength to weight ratio advantages. Reduced electrical and thermal conductivity are main limitations for the polymeric and PMC materials system, which have been addressed by using various techniques. Metallization is one amongst them, with primary focus on electroless plating, chemical vapor deposition (CVD), physical vapor deposition (PVD), which depicts their inherent process drawbacks [8]. Besides that, thermal spray processes suffers from substrate surface deterioration in high temperature conditions as well as high temperature induced flames [9]. On the other hand, since cold spray is the low processing temperature method, it is feasible to metallize polymer and PMCs [10,11]. Literature suggests adapting low pressure cold spraying

(LPCS) process for metallizing thermoplastic polymer substrate [12-14]. Major investigations comprised of deposition attempts of Al [8], Ti [15], Sn [16], Cu [13] and also formation of interlayers [13]. The focus of the cold spray (CS) study was in determining processing parameters influence on coating performance for the substrate materials such polymers and glass fiber reinforced polymer (GFRP), carbon fiber reinforced polymer (CFRP), and carbon fiber-polyetheretherketone (CF-PEEK) reinforced PMCs [17,18]. Conversely for the thermoset based composites, easier metallization is not feasible owing to the challenges including erosion of brittle matrix, fiber breakage, and exposure of fibers [19]. Che et al. attempted Al high pressure cold spraying (HPCS) study for CFRP substrate yielding substrate removal and fiber breakage [20]. In case of Cu deposition on thermoset epoxy substrate, presence of erosion and reduction in deposition efficiency (DE) was observed [12]. Several diverse strategies have been applied for mitigating the issues arising in thermoset metallization.

The "co-curing" strategy was described in literature in which placement of thermoplastic coupling layer over the thermoset substrate are subjected to the cure together to manufacture a hybrid composite [21]. During co-curing, diffusion of thermoset precursors in the thermoplastic species is intended to provide a reaction induced phase separation and interphase. The resultant heterogeneous morphology can exhibit the TP and TS mechanical interlocking [22]. Some investigations applied this approach for welding the TP and TS surfaces. The employed welding processes ranged from resistance welding, induction welding to ultrasonic welding [21,23,24].

Under the resin infusion process, the presented work contains a co-curing concept for manufacturing of thermoset-thermoplastic composite and LPCS process for metallization. The investigation is concentrated on realizing the co-cured hybrid composite and studying the effect of the CS process parameters variation on the coating quality. For manufacturing purposes, resin infusion process has been employed. A microstructural analysis was followed by the CS campaign. Adhesion between the coating and the substrate being important criteria, was assessed by the adhesion peel-off test. The article includes findings of this campaign and discussion based on it.

Materials and Methods

The material selection for the presented work was conducted focusing on advanced aerospace applications point of view. A high Tg (217°C) temperature amorphous thermoplastic PEI (ULTEM 1000) film was used with the resin infusion stack to form TS-TP composite. The high-density aerospace application grade RTM6 epoxy resin was selected for realizing a thermoset resin infused composites.

Vacuum assisted resin infusion (VARI) from the out of autoclave (OoA) manufacturing route was employed for the composite manufacturing. The RTM6 epoxy resin flow in the reinforcement was induced under VARI action (Fig. 1 a). Progressing flow front towards the spiral outlet is visible in the image. Placement of PEI layer bellow CF reinforcing layers and auxiliary materials is followed by vacuum bagging operation of the preform maintaining the vacuum inside the vacuum bag cavity. Two stage curing cycle was opted for facilitating the co-curing of the TS-TP inside the CF reinforcement. The designated curing temperature 180°C was considered for the Epoxy resin curing stage (also evidenced in literature for PEI-Epoxy interphase generation). As a primary stage, resin and mould preheating and beginning of resin infusion was initiated at 90°C temperature. Total two hours of dwell time was dedicated at the 180°C curing temperature with the intermediate hold at 160°C temperature.

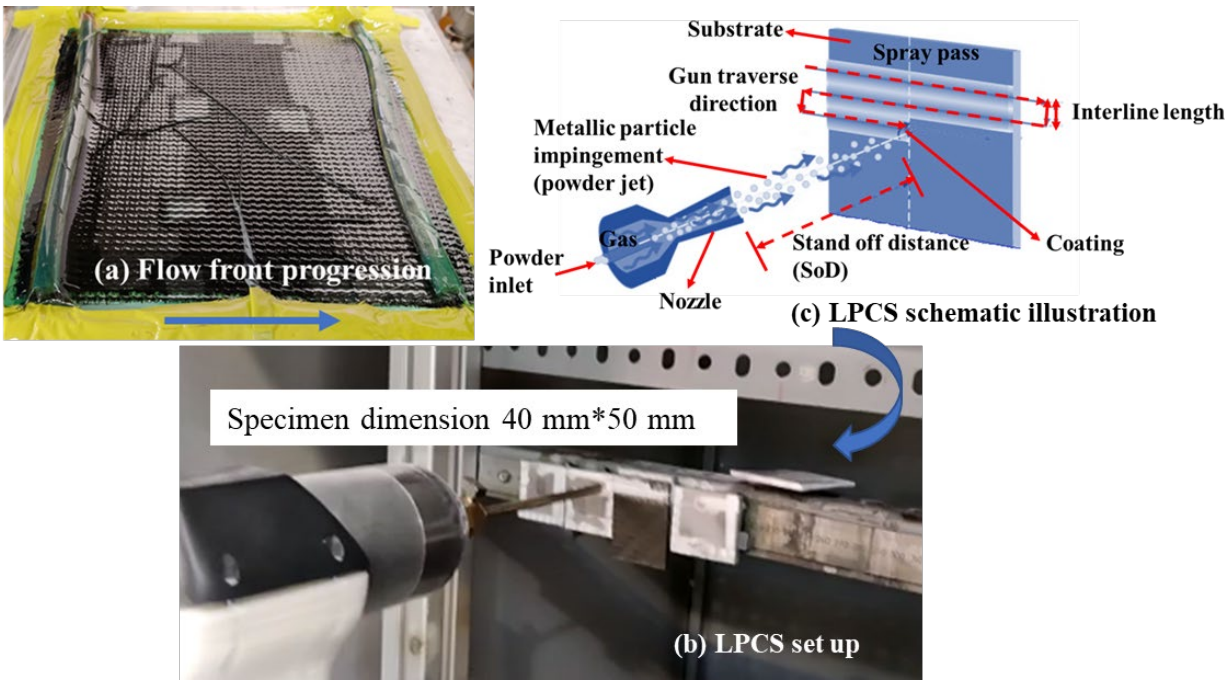

Fig. 1. (a) Resin infusion set-up for hybrid composite manufacturing consisting of 8 CF layers (b) LPCS metallization set-up (c) LPCS process schematic with general process parameters illustration.

The experimental scheme of process parameters for the LPCS of the manufactured composite panels is indicated in the Table 1. Fig. 1 (c) depicts illustrative view on the cold spraying process and highlights the relative process parameters while the actual set-up is included in Fig. 1(b). Processing parameters namely, traverse speed and stand-off distance (SoD) were varied while keeping constant interline length 3 mm and air flow 383 L/m. Al plus Al_2O_3 (min 1%) powder was utilized for the composite surface metallization. The cold spray gas temperature and chamber pressure were maintained constant at 360°C and 6 bar for each variation respectively. The total approximate spray duration to coat the composite sample (40*50*3) was 106 s. The manufactured reference case and metallized composite panels were subjected to the microstructural analysis by the optical microscopy (OM). Prior to the OM observation, the samples were subjected to the metallographic specimen preparation according to the standard prescribed procedure. The samples were cut by the abrasive disc cutter and polished with the abrasive rough paper grades and fine polished subsequently.

Table 1. Cold spraying processing parameters conditions.

Sample identification code	Gun Traverse Speed (mm/s)	SoD (mm)	Interline length (mm)
CS05	1	10	3
CS06	2	10	
CS07	1	30	
CS08	2	30	
CS12	2	20	

Adhesion peel-off test was conducted for determining the adhesion strength of the coated composite specimens. During the peel-off test, the Araldite (industrial grade) adhesive was applied over the sample surface and the test stub (dolly) with 10 mm diameter. Required force for the

complete debonding of the specimen and the stub was recorded for each combination. The failure surface observation of coated and uncoated surfaces was undertaken to understand the mode of failure and adhesion behavior of the coating-composite.

Results and Discussions

Analysis of manufactured hybrid composites.

In the primary stage of manufacturing a direct resin infusion step is conducted as opposed to the hybrid interlayer method [25] where hot pressing action is necessary. The presence of distribution media aided in the uniform distribution of the epoxy resin through the fiber bundles. The uniform pressure distribution due to the vacuum bagging operation resulted in the close contact between three interacting constituents beyond the preheating temperature of 90°C. The resin viscosity was decreased upon the preheating operation prior to the RI step. This step facilities reduction in the voids as well as smooth flow of the RTM6 through the spiral inlet and beginning with the linear flow front movement plus the transversal flow of the rein through reinforcing stack. A close contact between the PEI thermoplastic layer and the reinforcement stack being infused with the thermoset resin is established under vacuum. The flow front movement in all associated trials were found to be linear. The visual inspection of coated hybrid composite panel in the cross-sectional view indicated close contact of coating with the substrate. Fig. 2 (a) presents the coated hybrid panel which is further elaborated in Fig. 2 (b) and (c). The in-plane and through thickness percolation of the RTM6 Epoxy resin through the fiber tows during the RI process is highlighted in the Fig. 2 (b). A clear distinguishing presence of both the PEI and RTM6 resin was detected in the OM images acquired after the etching operation. In the micrograph Fig. 2, light-orange areas are highlighted as the PEI film and dark-orange areas corresponded to the RTM6 infused in the reinforcing fiber tows. Light areas are fibers and metallic particles. The empty spaces between the fiber tows, the inter-tow regions are filled with majorly RTM6 in the remaining substrate.

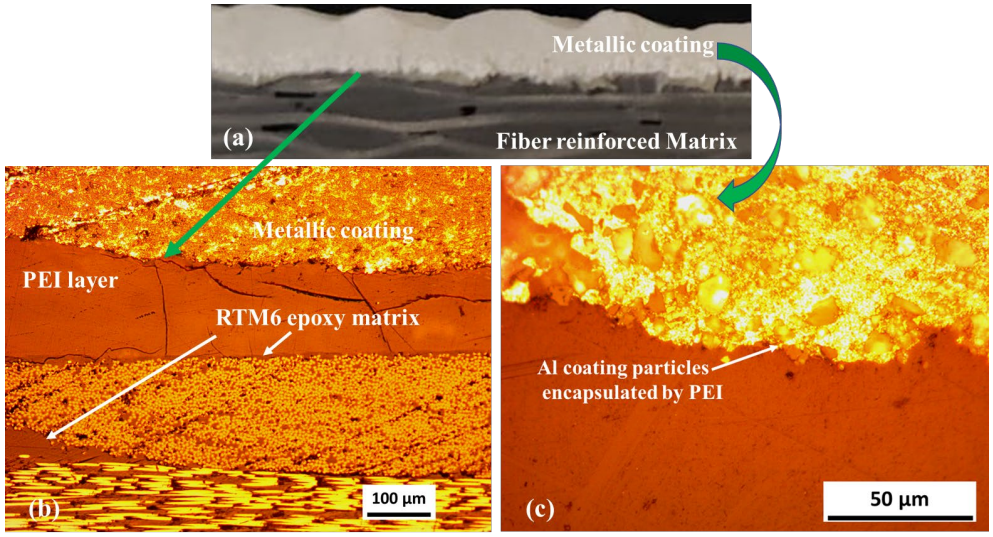

Fig. 2. The cross-sectional optical micrograph after the resin infusion depicting (a) hybrid composite panel cross sectional view (b) Presence of Epoxy resin in the inter-tow region and PEI-RTM6 close contact, magnification 10x. (c) PEI-coating region, magnification 50x.

The main area of interest is the interphase created at the top surface where PEI and Epoxy are said to have been experienced inter-diffusion in the curing stage. The dwell time of the 2 h was sufficient for cocuring of PEI-RTM6 constituents upon inter-diffusion.

Analysis of metallized hybrid composites.

The cold spray process parameters variation and its influence on the hybrid composite coating was assessed. The experiments were conducted at constant N_2 gas temperature and chamber pressure. The interline length after a preliminary campaign was determined to be 3 mm for each trial for covering the entire available surface area. The spray gun was facing the substrate side with PEI layer adhered to the composite substrate. Al (plus Al_2O_3) Coating was formed in each process parameters variation indicating the suitability of the gas temperature of 360°C for the PEI polymer softening. As indicated in Fig.2 (c), the softened PEI formed a close contact with imparting Al particles, also some amount of particle-particle bonding can be expected. The high velocity impact (also including the variation in the traverse speed and SoD) resulted in the adherent coating as confirmed in the visible inspection. The Fig. 3 left side images are representative sample top coating surface.

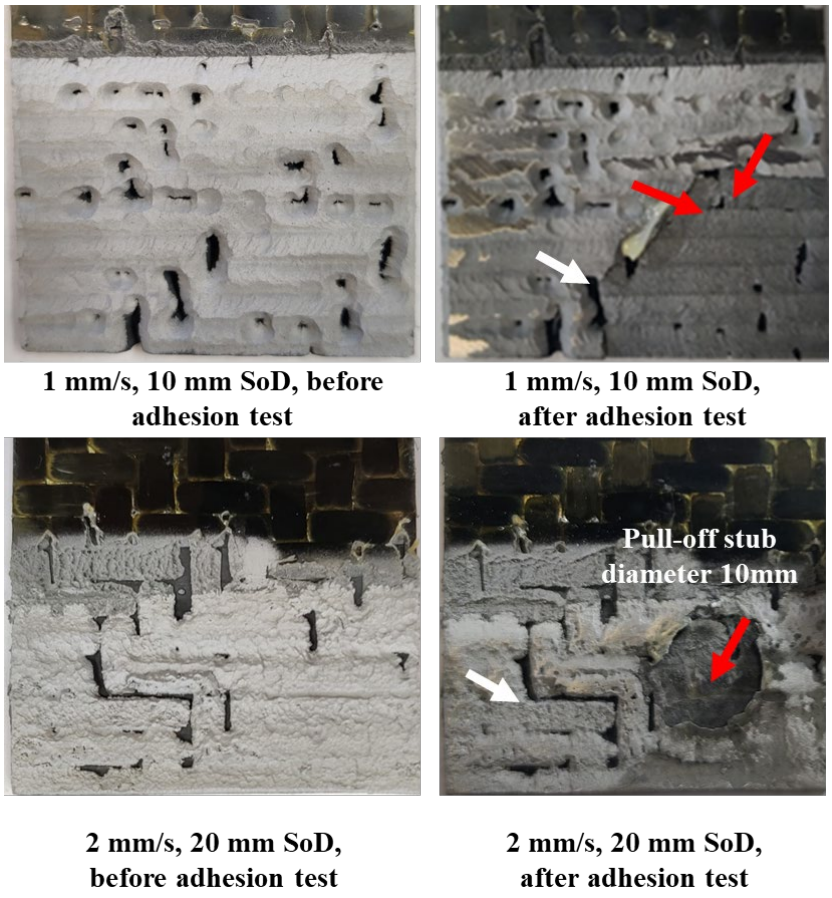

Fig. 3. LPCS panels with processing parameters variation and subsequent adhesion pull-off test coupons. The images contain top surface view to highlight the coating pattern and positioning of defects.

Visible voids extending from the coating through the TP layer and eventual up to the fiber reinforcing material was created in process of cold spraying. The formed coating top surface carried the impression of the fiber tows intertwined in the substrate reinforcing layers, where the voids appeared only in the inter-tow cites. Such occurrences are highlighted by means of the white arrows. The primary reason can be the substrate condition, which is favorable for the substrate excessive softening and cracking in the substrate while the particle impact impinges the coating particles into the substrate surface. Such abrupt occurrences are noted between the consecutive

passes and is the combined result of the manufacturing and coating processes. Overall, the coating thickness in the range of 0.3 mm to 1.5 mm was achieved. In comparison, lower traverse speed 1 mm/s in combination with SoD 10 and 30 mm achieved improvement in the coating thickness as compared to the cases with faster traverse speed of 2 mm/s. The possible reason for such attribute can be the greater exposure of the spray gun over the allocated surface locations of the substrate. Also, another process parameter SoD plays important role, where the intermediate 20 mm value with the higher traverse speed yielded thinner and less adherent coating on the substrate surface. Increase in the SoD generally promotes scattering of the impinging coating particles in the spray path and loss of coating material or loose bonding. Similarly, a faster nozzle speed can be insufficient for the bonding of the metallic particles with the available softened TP surface. Thirdly, as previously mentioned, the effect of the overall substrate manufacturing condition i.e., voids in the panel, voids between the TP layer and the fiber reinforcement, non-uniform contact between the TP and TS constituents, can affect the coating quality. In the opportune condition of optimum balance between the manufacturing and spraying condition, uniform and more adherent coating can be realized.

Adhesion test.

The adhesion pull-off tests were undertaken for the coated samples with different coating conditions. Referring to the Fig. 3 top left side image, the topography of the coating top surface was not flat. The pull off test necessitates a stronger attachment between the flat coating surface and the pull off stub (dolly) prior to the test. The coated samples were hence roughly grinded on the 320-mesh abrasive paper and were subjected to the application of the adhesive on the dolly and substrate surface. The circular impression of the stub was remained on the coated substrate post failure (highlighted with red arrows in Fig. 3). A complete detachment of the stub from the glued substrate surface and presence of any mode of failure i.e., adhesive or mixed mode was considered as the success of the test.

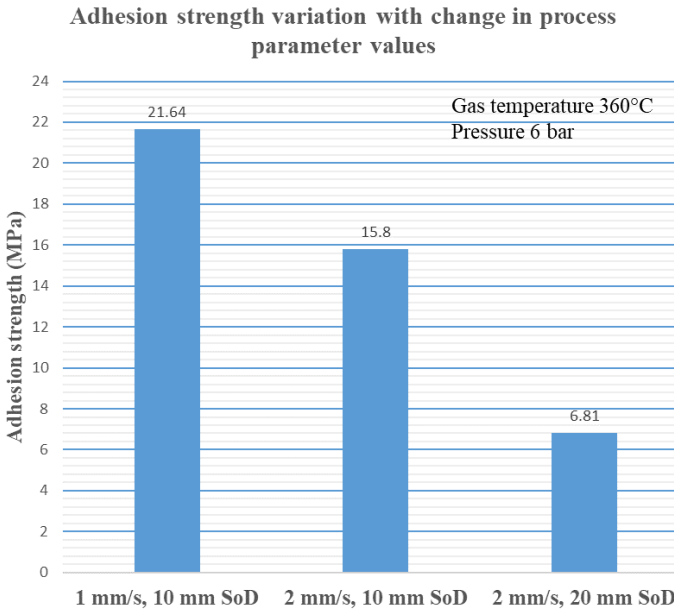

Fig. 4. obtained adhesion strength trend corresponding to the various cold spray conditions.

The obtained adhesion strength values for each condition of processing parameters are reported in the Fig. 4. Fracture surface observation (Fig. 3) indicated the presence of adhesive mode of failure, where certain portion of coating was detached from the substrate. Some loosely bonded Al particles are visible around this impression.

The inferior coating condition of 2 mm/s, 20 mm SoD also yielded a void and crack passing through the substrate in the circular impression. This again can be linked to the combination of manufacturing condition and spraying parameters influence. There is also a trend of reduction in adhesion strength with faster traverse speed, which in combination with SoD changes derives loosely bonded coatings with the substrate. The case of lowest SoD on the other hand provides a direct exposure of coating particle stream avoiding the particle scattering and less availability of the contact area surface in each time interval. These worked as the favorable working conditions for the interlocking of the impinging metallic particle in the softened PEI matrix. The designated

Tg for PEI is 220°C, and the provided gas temperature of 360°C can also in a way induce the substrate heating. This could be the primary condition for each of these coatings to be formed on the RI manufactured composite panels. The reinforcing fiber and encompassing RTM6 resin was well adhered to the PEI top layer, since the failure images show few cases of the substrate damage and fiber pluck out. Further research on the remaining CS condition is underway for determining the adhesion behavior of the coatings.

Summary

Hybrid thermoset-thermoplastic composite manufacturing was feasible by implementing resin infusion route. The manufacturing condition affected the coating deposition. In the cold spraying of PEI-CF- RTM6 epoxy composites, a clear influence of processing parameters traverser speed and SoD was found. Highest adhesion strength was obtained with lower values of traverse speed and SoD. Increase in SoD resulted in weaker bonding. Microstructural observations exhibited particle -particle bonding and coating particle encapsulation by means of PEI softened matrix during CS.

Abstract. The recyclability limitations of wind blades significantly reduce their environmental benefit as a green energy source. Therefore, the use of new and sustainable materials is crucial. The Zero wastE Blade ReseArch project (ZEBRA), led by the French technical research center IRT Jules Verne, is looking to accelerate the industry transition to circular economy by designing and manufacturing the first 100% recyclable wind blades using the thermoplastic resin Elium®, developed by Arkema, with a consortium regrouping: LM Wind Power, Arkema, CANOE, Owens Corning, ENGIE and Suez. In this work, the polymerization kinetics of the reactive thermoplastic resin Elium® was characterized through isothermal and dynamic Differential Scanning Calorimetry (DSC) tests. The experimental curves are fitted to two different models from the literature; then the model parameters are identified and used as input to simulations. One model is selected and evaluated using a PAM-RTM© simulation for pure resin and the infusion of Owens Corning glass/Elium® composites [1]. The numerical results are compared with experimental data collected from Vacuum-assisted resin infusion (VARI) tests with the help of a robust monitoring system [2]. Then the model is used to predict the flow and polymerization behavior for thick and more complex parts.

Introduction

The main objective of the ZEBRA project is to reduce the economic cost and environmental impact of wind turbine blades by studying the possibility to accelerate the wind market's transition to a circular economy. From a strategic consortium, an establishment made to bring together the entire value chain: from materials development to wind turbine blade recycling, manufacturing, operation, and dismantling was made. The roles in the project consortium are demonstrated in Fig. 1(b). The ZEBRA project, led by the IRT Jules Verne, brings together industrial players and research centers and aims to demonstrate the technical, economic and environmental feasibility of thermoplastic wind turbine blades with an eco-design approach to facilitate recycling. The project, launched for 42 months, has an overall budget of 18.5 million euros.

To make wind blades sustainable and recyclable, different stages are necessary, from eco-design to recycling passing by manufacturing. This paper mainly focuses on the reactive thermoplastic resin Elium® which replaces the conventional thermoset resin generally used. Vacuum-assisted resin infusion (VARI) processes [8] are generally used to make large or complex parts. Indeed, VARI is well known as a low-cost and straightforward composite manufacturing method, even if a large quantity of consumable material is used and wasted. Although the VARI process allows the manufacture of large and complex geometries, it is also sensitive to many factors.

First, the manufacturing conditions, particularly the atmosphere around the manufacturing set-up, which is not always controlled, especially for very large parts. The study presented here shows that the Elium® resin is very sensitive to the boundary and initial conditions of the process, notably in terms of temperature. Stacking defects, ply misalignments or geometrical difficulties will also cause high variability in the process control. Good management of the tooling and the consumables used (flow medium, vacuum bag, etc.) will also have an essential influence on good infusion. The operator efficiency can also lead to variations in the quality of the infusion. Mastering the infusion process depends on identifying the main risks associated with the different induced variabilities. Most of these variations can be identified in situ by a robust process control monitoring system. However, depending on the complexity and size of the part being manufactured, in situ monitoring can be complex and expensive. The numerical simulation tool is therefore valuable for anticipating possible challenges on the first hand, but also to propose appropriate infusion strategies leading to an optimal part quality. It is well known that the simulation of the composite transformation process requires a complete ecosystem, both numerical and physical. A complex multiphysics coupling is therefore necessary and needs to be fed by measured experimental data. Furthermore, the simulation will operate within a specific set of process conditions. Therefore, several results will be presented depending on different initial conditions, especially in temperature. As the simulation is complex, the work in this article will mainly focus on the polymerization kinetics of the Elium® resin used in this project. For a good description of the kinetics, both dynamic and isothermal tests are necessary to describe this very sensitive resin behavior correctly. The study is presented through three parts; first an experimental approach to validate the modeling of a thin

plate in the filling and polymerization phases. Second, the model is used to predict the process behavior for thick plates, the paper is concluded with some discussion and perspectives.

Experimental Set-Up and Observations

To study the whole infusion process, an experimental approach with increasing complexity is followed, along with using a robust monitoring system to observe the behavior of the resin, its temperature evolution, and its degree of polymerization over time. First on simple and thin plates, then on thicker and more complex parts. Focus on the thermal evolution and therefore, closely related to the polymerization will be explained here. To have access to the desired data, a complete monitoring bench was set up with several instruments such as thermocouples [13], heat flow sensors, dielectric sensors [11], optical fibers [12], profilometers, standard and infrared cameras for front-flow monitoring. The idea is to take benefits of each method and synchronize them to a unique monitoring system. All these data, in addition to revealing quantitative information about the infusion process, also allow a better understanding of the flow and resin transformation mechanisms.

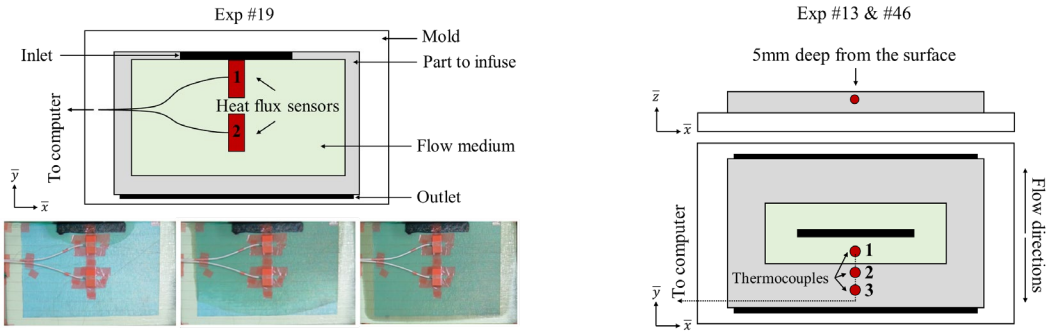

Fig. 2. Experimental set up: (a) infusion #19 using heat flux sensors, (b) infusion #13 and infusion #46 using thermocouples.

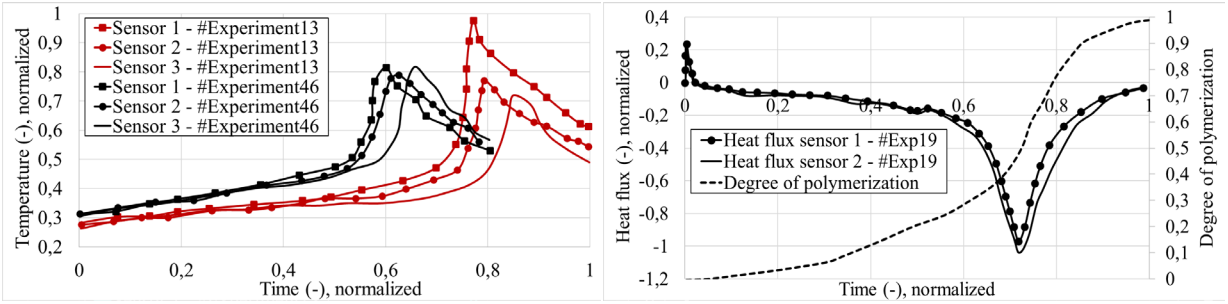
Many experiments led to a good understanding of the resin and of the process. In this work, only three of them are shown and are described in the Table 1 below.

Table 1. Experimental conditions of infusion 13, 46 and 19.

Parameter	#Exp13	#Exp46	#Exp19
Initial resin temperature [°C]	24.8	19.6	19.5
Peak temperature [°C]	≈ 65	60-78	≈ 40
Time to peak	2h56	3h52	4h10
Thickness of the plate [mm]	25	25	≈ 4.7

Experiments #13 and #46 are also described in Fig. 2(b). They are infused under the same setup, stacking, and boundary conditions. Only the initial resin temperature was different. The idea was to check its influence on the process. Indeed, an important data for mastering the resin Elium® is the thermal behavior for both filling and polymerization phases. To observe it, several experiments were done by using thermocouples (Fig. 2(b)). The acquired data, such as described in Fig.3(a), are then used to monitor the infusion but also to compare experimental data to numerical simulation. Also, using heat flux sensors as described in Fig. 2(a) gives information about the

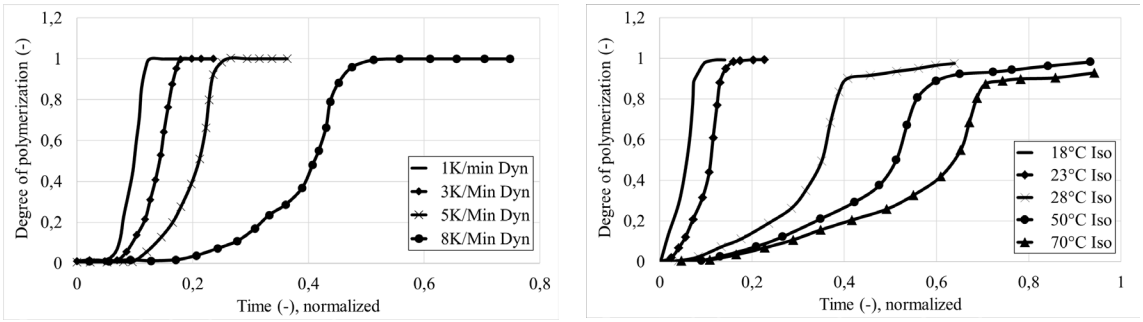
polymerization time and behavior. Fig. 3(b) shows the behavior of the heat flux in two different places. A post-treatment of these data leads to an estimation of the polymerization degree during the process.



(a) (b)

Fig. 3. Experimental observations: (a) temperature evolution during both filling and polymerization phases, (b) heat flow measured during filling and polymerization phases and the interpreted degree of polymerization.

In Fig. 3(a) it is possible to see that during the filling phase (0 to 0.4 units of time), the thermal behavior is mainly isotherm. On the contrary, after that step, the temperature rate quickly increases, and the behavior becomes mainly dynamic. It is also shown that the resin is very sensitive to its initial temperature but also very sensitive to its own reaction. It is therefore necessary to model both the isothermal and dynamic behavior (respectively Fig. 4(b) & Fig. 4(a)). Both DSC tests are then necessary, and the results are shown on Fig. 4.



(a) (b)

Fig. 4. Interpreted DSC scans of the resin: (a) dynamic kinetics, (b) isothermal kinetics.

The specific behavior of the resin and its sensitivity have a direct impact on the appearance of defects and geometrical distortions or internal stresses, which can occur even from the beginning of the process. To manage such difficulties, a multiphysics model and a numerical workflow, considering both isothermal and dynamic description of the polymerization kinetics during the whole process is necessary.

Modeling and Infusion Simulations

Several approaches exist in the literature [1, 3-7, 9, 14] to numerically model the behavior of the polymerization kinetics of the Elium® resin. Some of the previous studies follow a physico-chemical theory [3, 6, 7, 9] which leads to a subtil and detailed description of the mechanism during the polymerization. These models are often quite complex and require a lot of work to integrate and validate them into a simulation software. Moreover, for a manufacturing process simulation, staying at a larger scale without going into chemical details is enough. A macroscopical

approach is then enough to be able to reach the polymerization and thermal behavior of the resin during the filling and curing phases. From the literature two mathematical models seem to be adapted to model the resin kinetics [4, 5].
First, the polynomial form of Bailleul [5], coupled with an Arrhenius law (Eq. 1).

$$\frac{d\alpha}{dt} = A_0 e^{-\frac{E_0}{RT}} \sum_{i=0}^{7} a_i \alpha^i \quad (1)$$

This one is easy to identify but stay very sensitive since a polynomial form of degree 7 is used. Eq. 2 represents the second model which is a semi-empirical Arrhenius type autocatalytic model, adapted for the Elium® resin by the work of Han et al [1].

$$\frac{d\alpha}{dt} = A_1 e^{-\frac{E_1}{RT}}(1-\alpha)^{n_1} + A_2 e^{-\frac{E_2}{RT}}(\alpha_{max}-\alpha)^{n_2}\alpha^{m_2} \quad (2)$$

However, most of the works in those papers do not identify the kinetics for both the isothermal and the dynamic scans. Indeed, it is often difficult to satisfy a good fitting for both approaches. Nevertheless, as said earlier and considering the sensitivity of the Elium® resin, it is proposed here to assume some modeling error (while remaining within the experimental tolerance) which gives some flexibility in parameter fitting and identification to fit both isothermal and dynamic DSC curves. An inverse optimization method leads to the identification of the model parameters. Fig. 5 shows the results of the fitting for the two models. As can be seen, the Bailleul model does not fit properly for high temperature rate. It was then decided to only implement the identified Han model into PAM-RTM©. However, to ensure that PAM-RTM© solver compiles and computes the models correctly, a comparison of the numerical results from an in-house solver using the open-source library FreeFem++ [10] was made.

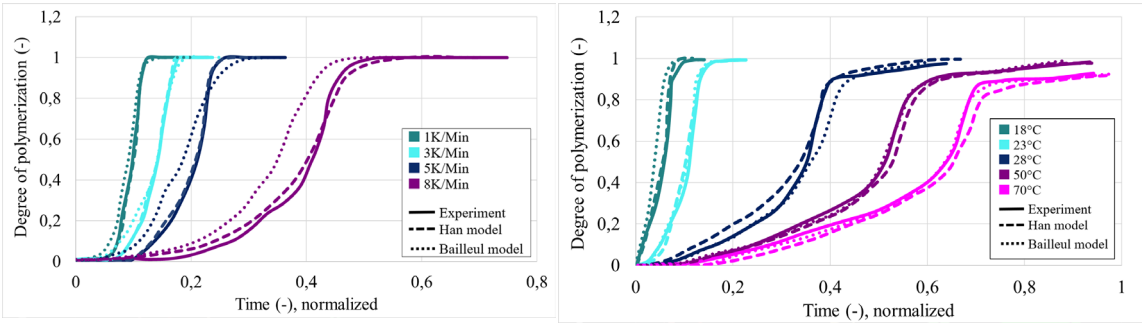


Fig. 5. Fitted model for the DSC approach: (a) dynamic behavior, (b) isothermal behavior.

Before comparing the thermal and chemical behavior of the resin, a correlation test simulation on the filling phase is also proposed in Fig. 6 for experiment #19. Indeed, many other parameters will influence the polymerization of the resin, such as the thickness of the part, the material defects like the preferential channels, gaps or overlaps, the influence of the flow medium, etc. Filling tests were carried out on thin plates first. Virtual sensors were also introduced into the PAM-RTM© infusion simulation software. It was experimentally found that the wetting effect at the flow front location could be neglected at first [8] for thin plates. A camera and infrared camera system were used to follow the flow front experimentally and the comparison with the simulation is shown in Fig. 6. It can be observed that the simulation gives a good flow result for this simple case. The value Δt on the figure represents the difference between the experimental and the numerical filling time for each step. At the beginning, there is a little delay between both approaches. It can be easily explained because of the fast track just under the inlet in the experimental set-up, which is not considered in the simulation.

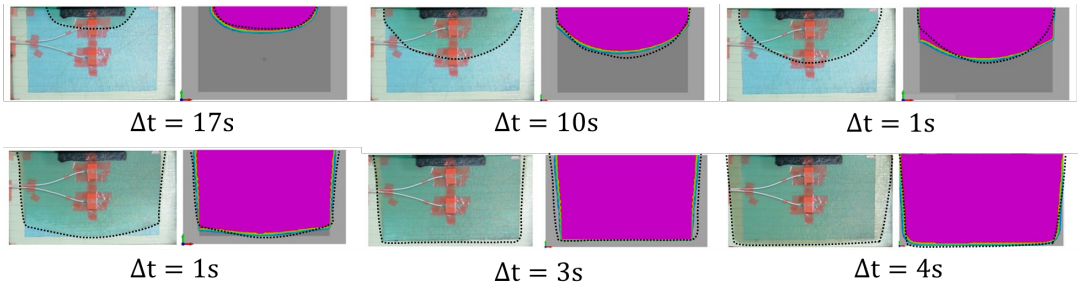

Fig. 6. Flow front comparison between experiment #19 and simulation on PAM-RTM©.

More local measurements were also made using the flow sensors to reach the thermal behavior of the resin and then deduce the degree of polymerization. It was useful to compare with the simulation and validate the model by confronting it with manufacturing cases.

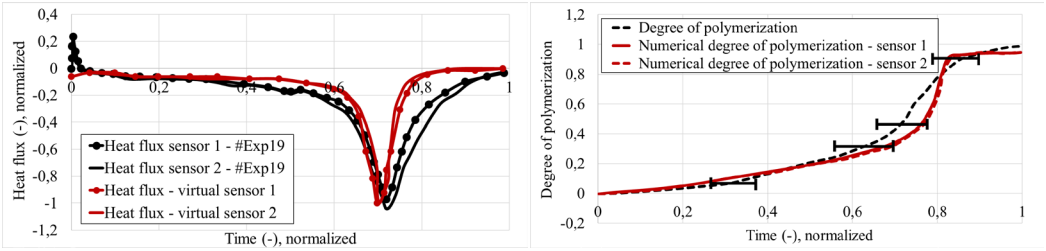

Fig. 7. Comparison between numerical and experimental data of experiment #19: (a) heat flow sensors, (b) extrapolated vs numerical degree of polymerization.

However, in Fig. 7(b) there is still a strong experimental variability in the polymerization phase. In the same way, the discrepancies between the experimental and simulated results shown in Fig. 7(a) also introduce some limitations either for the numerical model or experimental variabilities. The gaps between the flow measurements and the simulation approach (Fig. 7(a)) can be explained by different assumptions:

- Numerical initial conditions do not exactly match the initial measured temperature and thus affect the simulation results.
- Numerical boundary conditions do not represent the real forming process: considering the tooling thermal behavior, process artifacts (blanks, flow medium, ...), and convection around the part and mold.
- The use of a perfect numerical description of the material (perfect stacking, perfect permeability, no sensor intrusiveness, ...), which does not correspond to reality. Variations may therefore apply.

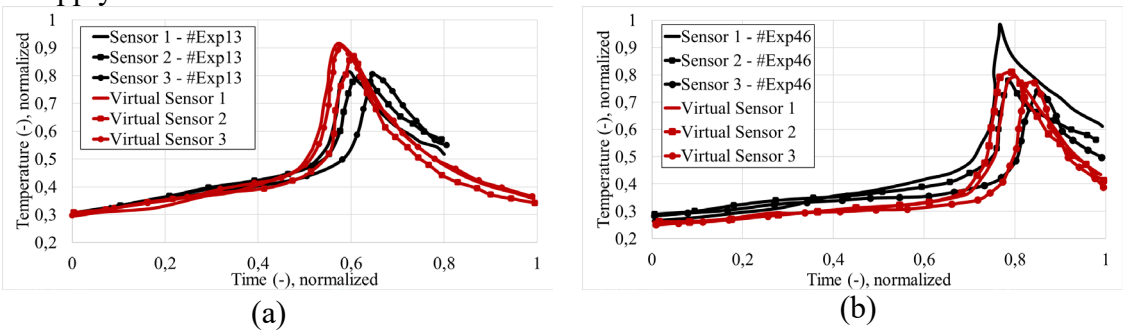

Fig. 8. Comparison of temperature between numerical and experimental approaches: (a) experiment #13, (b) experiment #46.

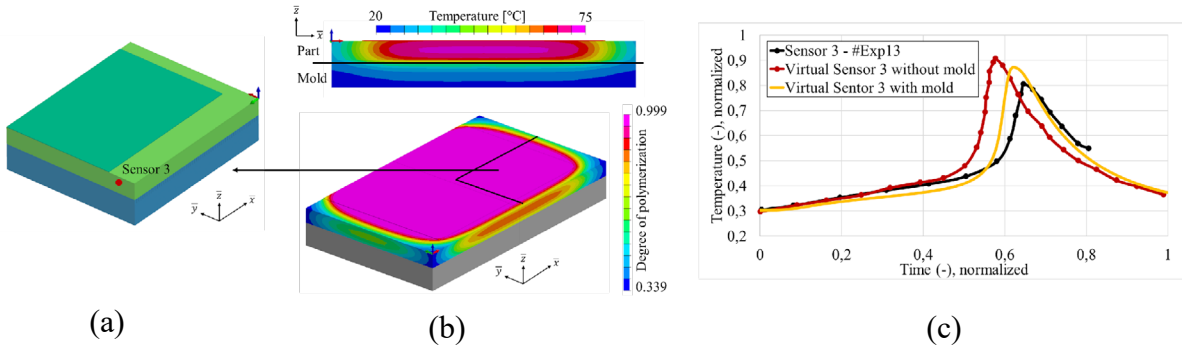
To check some of these assumptions, the simulation of experiment #13 and experiment #46 was made by applying different initial resin temperatures (Table. 1). Results can be seen in the Fig. 8. It can be seen that the model properly considers the variation of the initial resin temperature, which has a major impact on the peak time.

It is now shown that the infusion process using the Elium® resin is very sensitive to the initial condition, other simulations were made considering the boundary conditions. To do that, simulations on a 25 mm thick plate were carried out to predict the filling and polymerization behaviors for thick parts taking into account the influence of the tools on the thermal behavior.



(a) (b) (c)

Fig. 9. Influence of the set up on the thermal and kinetics behavior: (a) 25mm thick plate modeling using PAM-RTM© (Quarter of the part using symmetry of the problem), (b) temperature and polymerization field during the curing phase, (c) temperature behavior over time considering the mold.

To illustrate the influence of the boundary conditions on this process, Fig. 9 shows that the mold can have a considerable impact on the thermal behavior and then the polymerization of the resin if the part is thick (Fig. 9(b)). On Fig. 9(c), the management of the boundary condition (through the thermal conductance with the mold or the convection with the air) led to a better mastering of the simulation. Further investigations are under work to check the influence of these mechanisms on the final distortion of the part.

Summary

The work presented in this paper presents a simulation approach to the filling and polymerization phase of the Elium® resin using the commercial PAM-RTM© tool from ESI group. It is first shown that the polymerization model must take into account both the isothermal behavior and the dynamic behaviors of the chemical reaction. Consequently, a larger range of error in the modeling is made but by comparing with the experimental values, a good consistency on the simulated results is still possible. In fact, because of a robust and advanced monitoring system, it can be noticed that the behavior of the Elium® resin is very sensitive to its environment - boundary and initial conditions - and that the simulation allows having quite good predictions. It will also allow, in future works, to propose reliable predicted infusion strategies adapted to the studied case.

Keywords: Injection Molding, Fibers Reinforced Composite (FRC), Injection Gate Location, Fiber Orientation, Machine Learning

Abstract. This research presents an automatic algorithm, implemented in a Visual Basic Architecture (VBA), for the optimization of the gate location in thermoplastic injection molding of short fibers reinforced composite materials. The algorithm receives, as input, the geometry of the component and, according to the user's choice, defines the injection points grid, and relevant versors, on a pre-constructed mesh, automatically runs the finite volume method (FVM) simulation and exports the fiber orientation tensor (FOT) on each node of the mesh. The nodal coordinate of the part and the relevant FOT are then used as the training dataset for a Gradient Boosting (GB) algorithm for the full correlation between injection gate locations and the resulting fiber orientation distribution (FOD), allowing to define the injection gate configuration better suited to maximize the effectiveness of the reinforcement fibers. By coupling the trained GB algorithm with a finite element method (FEM) simulation it was confirmed that the developed algorithm can predict the influence of the gate location on the FOD and the resulting mechanical performances, improving the stiffness between 3.8% and 32.6%, on simple and complex geometries alike.

Introduction

In recent years, the injection molding process has been growing in both importance and utilization thanks to the development of innovative polymers and reinforcements [1, 2]. This is especially the case in the automotive industry, where lightweight design [3] and recyclability [4] are becoming ever-growing focus points for research and development. Although injection molding is considered a fairly well-established manufacturing process, several independent parameters must be properly set to achieve a high quality of the molded parts, especially in terms of minimizing warpage, shrinkage, and weld-lines on the critical region of the component [5-7]. Besides, the recent trend is to incorporate woven composite into an injection-molded thermoplastic matrix to achieve recyclability while enhancing the mechanical properties of the molded part [8].

For the case of short fibers-reinforced thermoplastic polymers (SFRTP) the fiber orientation is influenced by both the component geometry and the injection gates configuration. As it is well known from various recent contributions, fiber orientation is responsible for static, fatigue, and fracture properties of SFRTP [9, 10]. In addition, as demonstrated for both short glass fibers (SGF) and short carbon fibers (SCF), the interaction between polymer matrix and fibers reinforcement plays a pivotal role in controlling the notch sensitivity [11, 12]. Accordingly, controlling and optimizing the fiber orientation in injection molded components becomes of paramount importance to maximize the effectiveness of the reinforcement.

For SFRTP, the fiber orientation distribution (FOD) is influenced by both the injection gates and the geometry of the component, and in a lesser manner by the applied processing conditions. The component geometry varies from case to case and is not easy to generalize. For this reason, recent contributions dealing with the optimization of injection-molded components focused on controlling the global thickness distribution and inserting local rib networks to limit the warpage [13, 14]. On the other hand, injection gate (IG) design has also attracted the interest of researchers over the years, and various modeling technics have been applied to achieve greater optimization considering different criteria, as hereafter summarized.

Zhai et al. [15, 16] developed a recursive approach and a sequential linear programming algorithm to identify the IG locations, allowing for a balanced filling on injection-molded parts. The optimization criterion is based on a uniform distribution of the clamping force during the filling phase and was validated on a U-shape part. Li et al. [17] developed a black-box algorithm for the optimization of the IG considering the injection pressure, warpage, residual stress, and weld lines as optimization criteria. Similarly, Moayyedian and Mamedov [18] proposed a multi-objective optimization approach to defining the combination of process parameters and IG locations, allowing for a reduction of the molding defects, such as shrinkage, warpage, and short shot. More recently, Moayyedian and Mamedov [19] also proposed a methodology for the reduction of the same molding defects but based on an artificial neural network and Taguchi techniques, showing a relatively low margin error, quantified in 15%, and attributed to uncontrollable process variability. Besides, the only contribution dealing with fiber orientation optimization for the SFRTP focuses on the IM process parameters, thus the IG location was considered a constant in the analysis [20]. Other recent contributions proposed case studies investigating the effect of different IG configurations, and process parameters, on the filling time and quality of the molded component [21-23]. However, being these highly customized approaches, they can hardly be extended to different geometries and, most of all, they are all based on unfilled thermoplastic polymers. Accordingly, a general and customizable design approach for the gate location in the case of SFRTP seems to be missing in the literature,

To this aim, this research presents an algorithm able to automatically set up a user-defined number of injection molding FVM simulations, implemented in Autodesk Moldflow Insight 2023, run them, and export the fiber orientation tensor (FOT) on one or more control volumes defined by the user. The coordinates IG points, relevant versors, and the average fiber orientation tensor in the control volumes of interest are used to train and validate a machine learning (ML) model, based on the Gradient Boosting (GB) algorithm.

The proposed algorithm can suggest the best IG location allowing for the maximization of the FOD along one or more regions of interests and directions, with assigned priorities, resulting in customized stiffness enhancement. The maximization is carried out considering the load path, thus the directions along which the reaction forces are maximum, because of the applied displacements. The procedure has been developed and tested considering three geometries with an increasing level of feature complexity by mapping the FOD and relevant mechanical properties from the FVM simulation onto the FEM simulation, implemented in Abaqus 2020. The application of the IG optimization procedure allowed improving the component's stiffness between 3.8% and 32.6%, showing the effectiveness and the generality of the proposed algorithm.

Materials and Methods

This chapter is subdivided into three sections. The first deals with the proposed VBA algorithm for the automatic definition of the injection gate grid and the export of the FOD from each one of the FVM simulations. The first section also includes some details of the implemented machine learning model, based on the Gradient Boosting (GB) algorithm. The second section briefly describes the material properties of the employed polyamide-6 reinforced with 20% of short carbon fibers (PA6-20CF) and the relevant calibration into the FVM simulation. Finally, the third section

explains the mapping procedure for the transfer of the FOD, and relevant mechanical properties, from the FVM to the FEM simulation, for the evaluation of the stress distribution on the considered components as a consequence of the applied displacements.

Gate Location Optimization Algorithm

The IG location optimization algorithm is composed of four steps, as summarized in Fig. 1. All the steps are implemented in VBA programming, except for the ML-GB model of step#4, implemented in Python 3.11 and coupled with the scikit-learn 1.1.1 and SciPy 1.7.1 open-source libraries. In the algorithm, step#1 is devoted to the definition of the IG candidates on the selected model geometry that can be defined by the user on a predetermined grid or manually deployed. Step#2 receives the matrix with the IG candidates, and their relevant versors, to assure a perpendicularity onto the geometry and prepares the input files for the FVM simulation, comprehensive of all IG configurations to be tested.

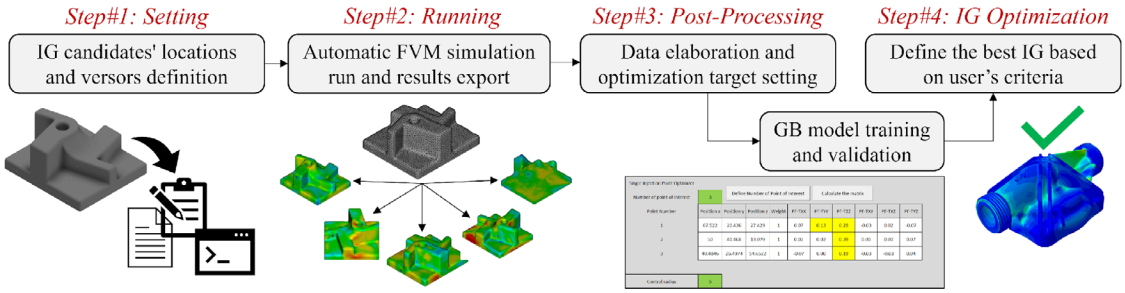

Fig. 1. Working flow for the injection gate (IG) optimization algorithm.

After the completion of all FVM simulations setup in step#2, step#3 creates a single result dataset file including i) coordinates of the IG point, ii) coordinates of all the nodes of the mesh (same for each simulation), and iii) results of the FOT (6 components) for each node. During step#3, the user is required to input the locations of interest and the relevant direction, or directions, along which the FOD should be oriented. To this aim, FEM simulations have been utilized to identify the regions of interest on the considered parts and, within those regions, the directions along which the stress components are maximum. Thus, by aligning the fibers along these directions, their effectiveness can be improved, allowing for an improvement in stiffness.

Before reaching step#4, the dataset constructed in step#3 is utilized to train and validate the prediction part of the architecture, based on the GB algorithm. 80% of the database is utilized for training purposes, whereas the remaining 20% is dedicated to validation. During the training, a k-fold validation, with k=5, is employed to assure accuracy and the absence of overfitting. If both conditions are satisfied, the user is presented with the location of the IG allowing for the maximization of the FOD in the locations of interest.

At this point, two important clarifications must be made. First, if the user is not satisfied with the accuracy of the prediction carried out by the GB model, the procedure can be upgraded by setting a finer grid for the IG location candidates in step#1, where only the new FVM simulations must be run and then integrated with those of the previous phase. Second, the proposed methodology considers only a single injection gate. Future studies are going to be focused on the direction of multiple IG optimization for better applicability in industrial applications.

Material Properties and FVM Simulation Setting

For the setting of the FVM simulations, the material properties relevant for the PA6-20CF material, as calibrated in previous works of one of the authors [9, 10, 12], have been employed. For their calibration into the FVM simulation, necessary for the subsequent mapping onto the FEM mesh,

the Ramberg-Osgood constitutive model, Eq. 1, has been employed and coupled with an anisotropic Hill'48 yield function, Eq. 2. The α and β parameters are calculated according to the FOT, for each element of the mesh as in Eq. 3, referring to the region of the model where it is maximum. In Eq. 3, λ_I represents the first eigenvalue of the fiber orientation tensor on each element of the mesh, whereas α_m, β_m and $\lambda_{m,I}$, are the reference values for the considered material, and are calculated during the material properties calibration. Fig. 2 shows the experimental engineering stress-strain curves for the considered PA6-20CF material (Fig. 2a), the comparison between experimental and constitutive modeling load-displacement curves (Fig. 2b), and model constants and reference values for the Ramberg-Osgood and anisotropic Hill'48 models (Fig. 2c).

$$\sigma = E^{1/n}\left(K\right)^{(n-1)/n}\left(\varepsilon_{p,eff}\right)^{1/n} \tag{1}$$

$$\sigma_{eff} = \sqrt{\frac{\left(\alpha\sigma_{11}-\beta\sigma_{22}\right)^2+\left(\beta\sigma_{22}-\beta\sigma_{33}\right)^2+\left(\beta\sigma_{33}-\alpha\sigma_{11}\right)^2+6\left[\left(\sigma_{12}\right)^2+\left(\sigma_{23}\right)^2+\left(\sigma_{31}\right)^2\right]}{2}} \tag{2}$$

$$\alpha\left(\lambda_I\right)=\theta+\left[\frac{\left(\alpha_m-\theta\right)}{\left(\lambda_{m,I}-1/2\right)}\right]\left(\lambda_I-1/2\right) \quad , \quad \beta\left(\lambda_I\right)=\theta+\left[\frac{\left(\beta_m-\theta\right)}{\left(\lambda_{m,I}-1/2\right)}\right]\left(\lambda_I-1/2\right) \tag{3}$$

Fig. 2. (a) Materials properties and (b) comparison between experimental and constitutive modeling results of load-displacement curves for 0°, 45°, and 90° directions. (c) Model constants for the Ramberg-Osgood model and anisotropic Hill'48 yield function.

As concerns the mesh for the FVM simulation, the same mesh strategy, 3mm side 3D tetrahedral elements, has been employed and verified through mesh sensitivity analysis. In terms of injection molding process parameters, to avoid any bias, the same mold temperature, molten material temperature (at the nozzle), and cooling temperature of 285°C, 85°C, and 25°C, have been employed in all simulations. Regarding the injection time, it has been kept automatically controlled during the simulation, to avoid short-shot, whereas the post-pressure has been set at 80% of the injection pressure, for a total of 20s.

FVM-FEM Mapping and Tested Components

To test the improvement of the FOD with respect to the applied displacements, a mapping procedure to account for the FOD-dependent material properties in the structural FEM simulation has been employed. The structural FEM simulation has been implemented in ABAQUS 2020. The procedure is summarized in Fig. 3 and is based on the Ramberg-Osgood and anisotropic Hill'48 formulations presented in the previous section whereas the mapping is carried out by Autodesk Helius 2023.

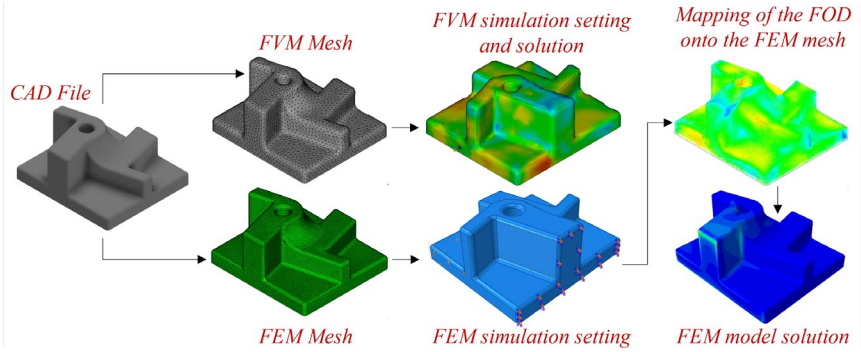

Fig. 3. Main steps in the mapping procedure for the consideration of the fiber orientation of the FVM simulation into a FEM structural simulation environment.

For each element of the FVM mesh, a corresponding set of elements in the FEM mesh is located based on their relevant position in the GCS, the same for both simulations. According to the FOT of each element of the FVM simulation, a specific set of mechanical properties is mapped onto the FEM simulation mesh. This procedure has been successfully applied and validated in other works of one of the corresponding author [9, 10, 12]. To test the IG design algorithm, three components have been considered, as shown in Fig. 4. The three parts have an increasing level of complexity and have all been subjected to a tensile displacement of 5 mm.

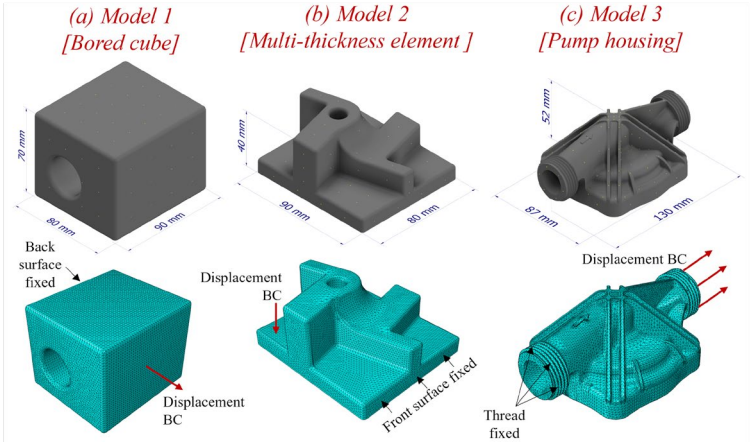

Fig. 4. Mechanical parts use for the validation of the IG location design algorithm. (a) Bored cube, (b) Multi-thickness element on a square base, and (c) Pump housing.

The three geometries of Fig. 4 have been all meshed with C3D10I tetrahedron elements, thanks to their good compatibility with those of the FVM simulation, whereas a quadratic integration scheme has been employed to allow for a better description of the deformation behavior between the edges and within the elements. The total number of elements for the three models is 306,165 (Fig. 4a), 243,183 (Fig. 4b), and 211,149 (Fig. 4c), respectively. The FEM simulations have been implemented in the ABAQUS/Standard environment, considering a static-implicit solution

technique. Finally, the simulation time has been divided into 100 steps for easier export and comparison of the results among the simulation cases of the same part.

Results and Discussion

To validate the IG location optimization algorithm, the procedure summarized in Fig. 1 has been applied to the three components of Fig. 4. The results, and relevant considerations, are reported in this chapter of the paper.

The initial step, prior to the application of the IG design algorithm, is the identification of the regions of the model subjected to high stress, or stress concentration, due to the displacement boundary conditions, or specific geometrical features. Accordingly, three FEM simulations considering only elastic material properties equal to E = 14GPa and ν = 0.37, representative of a sort of 0° direction for the PA6-20CF material, have been implemented. The results, reported in Fig. 5, allowed identifying two regions of interest for Model 1, four for Model 2, and three for Model 3, respectively. In Fig. 5, the normalized stress components (-1, +1 range) on the regions of interest are reported and are utilized as a reference for the directions along which to maximize the FOD. Rather than a quantitative estimation, the aim of this preliminary phase is the definition of the regions of the model where to focus on the optimization of the effectiveness of the FOD.

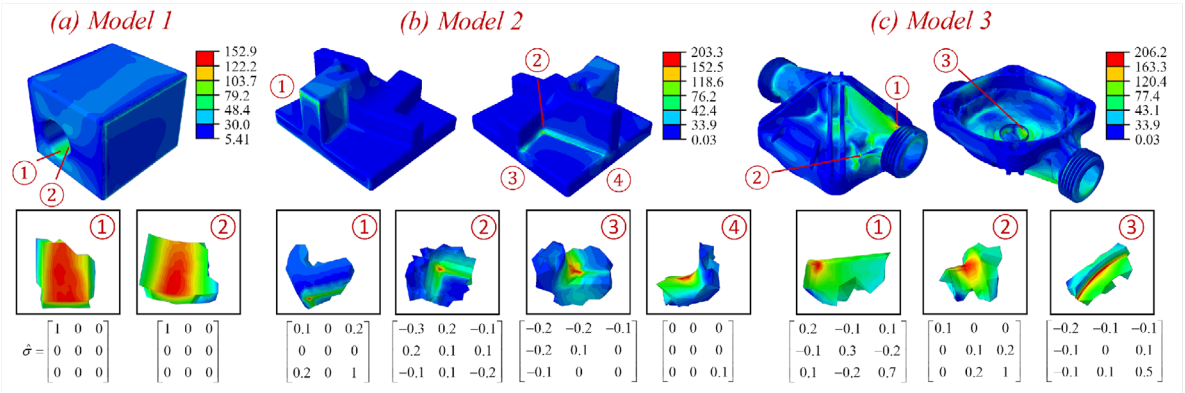

Fig. 5. Identification of the regions of interest from isotropic properties FEM for (a) Bored cube, (b) Multi-thickness element on square base, and (c) Pump housing models.

As defined in Fig. 1, the algorithm requires the definition of a mesh grid and the list of the IG candidates, with relevant versors, to assure perpendicularity with the geometry. For the three models of Fig. 4, 80, 70, and 140 IG candidate locations have been randomly assigned on an automatically generated 3 mm mesh grid in the relevant FVM simulations. The results, in terms of stress components ($\sigma_{x,y,z}$) for the best and worst IG locations, among the tested candidates, for the three tested components, are reported in Fig. 6a, 6b, and 6c, respectively.

The stress components of Fig. 6 are the average values relevant to a control volume of R = 5 mm around the element with the peak stress. As expected, a lower fibers alignment along the directions of loading (load path) results in a lower stress component along the same direction, a fact caused by a lower stiffness of the material. Since all simulations have been set up considering a displacement boundary condition, the reaction force is calculated according to the material properties, Fig. 2a. Thus, the higher the alignment of FOD with the reaction force direction, caused by the applied displacement boundary condition [9, 10], the higher the resulting stress.

This fact is clear when analyzing the difference between the best and worst IG configurations, for all three components reported in Fig. 6. For instance, in Model 1, due to the proximity of the two regions of interest, the average improvement is around +30%. For more complex parts, such as Model 2, the improvement is represented by a reduction of the compressive stresses, which has also a positive effect on the performances of the component due to the low compressive strength

of fibers reinforced materials. In general, the IG design algorithm gives priority to the regions identified by a high normalized value, as shown in Fig. 5. On the other hand, in some conditions, the optimization may result in a higher improvement of the effectiveness of the reinforcement in a region of the model which is not the main priority. This is clearly visible from the results of Fig. 6c, where region ③ shows a higher stiffness improvement than region ②, although the latter has the highest priority according to the normalized stress presented in Fig. 5c.

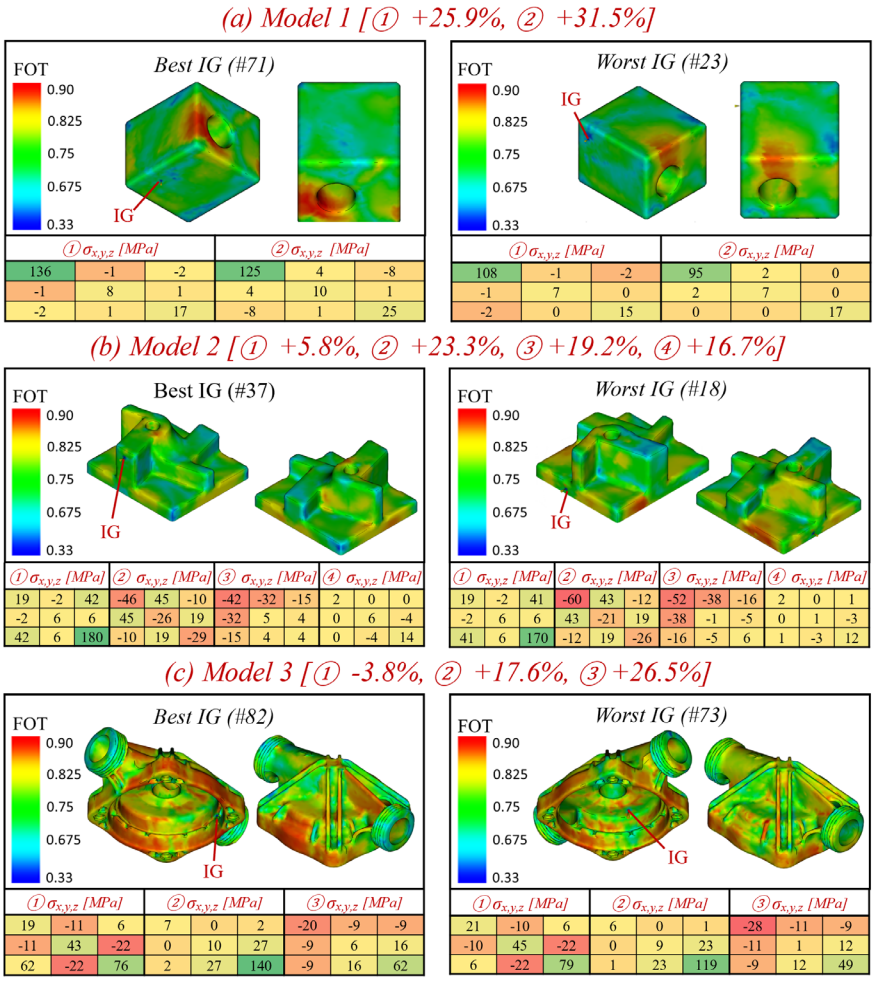

Fig. 6. FOT distribution (FVM simulation) and stress components (FEM simulation) for the best and worst IG locations for (a) Model 1, (b) Model 2, and (c) Model 3.

From a general perspective, it is interesting to highlight that, according to the results presented in Fig. 6, for all three models and even before the final optimization stage, implemented through the ML-GB algorithm, the average improvement in terms of FOD is clear and quantified in 28.7%, 16.3%, and 13.4% for the three investigated components. The almost two times higher stiffness improvement estimated for the bored cube part is related to the relative simplicity of the geometry, which makes it easier for the IG optimization algorithm to identify the best IG location.

In order to achieve full optimization for the IG location, the FOD resulting from the FVM simulations of each of the three components have been utilized for training and validation for the ML-GB algorithm. The average deviations between true and predicted values for the FOD for the components have been calculated at 5.6%, 4.8%, and 3.5% for the training datasets, and 5.2%,

4.8%, and 3.4%, for the validation datasets, respectively. These deviations are the average ones relevant for the 5-fold validations and show the quality of the prediction and the absence of bias.

By employing the trained GB model, further improvements on the FOD could be achieved, as reported in Fig. 7. For the case of Model 1, due to the low complexity of the geometry, the FVM simulation-based analysis was sufficient in identifying a fairly good IG location, thus the stiffness improvement provided by the application of the GB algorithm is minimal. However, for both Model 2 and Model 3, the application of the trained GB model allowed identifying a better IG location, not previously included in the FVM simulation database, which achieved a further improvement of the effectiveness of the fibers reinforcement. For Model 2 the average stiffness improvement, with respect to the results of Fig. 6, is quantified in 4.6%, whereas for Model 3 is it quantified in 3.3%.

Fig. 7. Stress components for the best IG locations before and after the GB-IG optimization for (a) Model 1, (b) Model 2, and (c) Model 3

Summary

The research presented in this paper detailed a highly customizable algorithm for the optimization of the injection gate location in the thermoplastic injection molding process for the maximization of the effectiveness of the fibers reinforcement in SFRC. The IG prediction algorithm proved to be able to achieve a concurrent optimization of the FOD in various regions of interest while prioritizing those with the highest stress distribution. Being implemented on freeware SW, the proposed algorithm can be implemented directly to various components, from low to high complexity, allowing for higher exploitation of the potentials of SFRC. On the other hand, as also previously mentioned, more research work should be oriented on extending the proposed methodology to multi-gate injection molding, to allow for the application to bigger geometries where a single IG is not sufficient. In addition to that, the influence of the injection molding process parameters on the FOD is going to be accounted for as well, to allow for a more comprehensive and realistic prediction and optimization of the IG locations.

Abstract. The through-thickness compaction behavior of engineering textiles significantly influences the resulting component properties during liquid composite molding processes (LCM). It determines the final fiber volume content and thus the necessary press force, the permeability as well as the final mechanical properties. In the present work, the behavior of a uni- and bidirectional carbon fiber non-crimp fabric (UD- & Biax-NCF) with the same fiber type and areal density of fibers in the respective main reinforcement directions is tested in a punch-to-plate setup. Thereby, the influence of the relative fiber orientation at the interfaces of a layup as well as the number of plies is investigated. A combined influence of roving nesting and superposition of stitching patterns is observed. This results in a common influence of decreasing resistance to compaction for higher numbers of layers, while the relative orientation of the interfaces in a layup is only significant for the Biax-NCF.

Introduction

Non-crimp fabrics (NCFs) have straight fibers compared to woven fabrics with undulated fibers and therefore provide a higher lightweight potential. The resulting component properties during liquid composite molding processes are significantly influenced by the through-thickness compaction behavior. It determines the final fiber volume content (fvc) and thus the necessary press force, the permeability as well as the resulting mechanical properties [1]. The compaction behavior of woven fabrics as well as biaxial NCFs (Biax-NCF) has been investigated more extensively [2-8], compared to unidirectional NCFs (UD-NCF) [9-11].

A typically measured thickness or fvc vs pressure diagram for engineering textiles has two distinct regions: the first region is dominated by a low compression resistance due to the low bending stiffness of crimped fibers and closing of initial gaps between the fibers; in the second region the fibers come into contact with each other and the resistance to compression is more dominated by an increasing number of high Hertzian contact forces [12]. The compaction behavior is largely determined by the architecture of the textile, the type of fiber and the areal density [4, 5, 10]. Textiles with a higher areal density tend to have a smaller resistance to compaction because they have more yarns in a roving and usually a more rounded shape of fiber bundles [4, 7, 13] Additional factors influencing the compaction of multi-ply stacks are the number of layers and layup sequence [7]. Increasing the number of plies in a layup reduces the resistance to compaction, due to rovings of different layers sliding into gaps at the inhomogeneous interfaces. This effect is called nesting and usually more pronounced for woven fabrics compared to NCFs [14]. For NCFs, the compaction behavior is also influenced by the superposition of the stitching patterns and tension in the stitching during production [7, 10, 14].

In a recent benchmark by Yong et al. [8] two glass-fiber fabrics (woven and Biax-NCF) were investigated at over 20 institutes in dry and wet conditions in order to investigate the conformity of compaction test results. Thereby, no distinct influence could be attributed to the size of the specimen, shape of the testing device or weight determination method. However, three main sources for variability were identified: thickness measurement method, machine compliance and specimen saturation in wet compression tests. However, a correction of the machine compliance as described by Sousa et al. [15] led to a good agreement between different institutions.

The compaction behavior of textiles is strongly dependent on the individual properties of the fabric and care must be taken when conducting the experiments to obtain compliant results. In this work, the behavior of a uni- and bidirectional carbon fiber NCF with the same fiber type and areal density of fibers in the respective main reinforcement directions is tested, based on the principles for the measuring method outlined in [15]. Thereby, the influence of the relative fiber orientation at the interfaces of a layup as well as the number of plies is investigated.

Experimental Procedure

Materials.

In this study, a unidirectional (UD300) and bidirectional (MD600) non-crimp fabric both without binder are used. The fabrics are manufactured by Zoltek and produced from the same PX35-50K continuous carbon (CF) fiber heavy tows. Both fabrics are stitched together with a 76 dtex PES yarn in a Tricot pattern. The UD-NCF consists of a single layer of aligned CF tows with thin glass fibers (GF) on the back for improved handleability and the MD-NCF of two layers in a 0°/90° orientation. Both fabrics have a similar number of CFs with about 300 g/m^2 in their respective main reinforcing directions. The most relevant characteristics of the NCFs used in this study are listed in Table 1.

Table 1. Characteristics of the investigated NCFs.

	Stitching length	*Tow width*		*Areal density*			
		0°	*90°*	*Total*	*0°*	*90°*	*stitching*
Unit	[mm]	[mm]	[mm]	[g/m^2]	[g/m^2]	[g/m^2]	[g/m^2]
UD300	3.6	5.0	-	328.86	309.86	9.7 (GF)	9.3
MD600	2.6	5.0	2.5	602.24	301.53	292.52	8.19

Punch-to-plate compaction tests.

The compaction behavior is investigated with a simple punch-to-plate setup mounted on a universal testing machine with a 50 kN load cell, cf. Fig. 1 a). Undeformed stacks of two, four, six or eight plies with a size of 200 x 200 mm^2 are compacted with a 150 x 160 mm^2 punch at a constant speed of 1 mm/min. Each measurement is repeated four times with a new stack of material for each test. Additionally, three different layups for each material are investigated with relative orientations of $\Delta\Theta = 0°, 45° \; or \; 90°$ between the CFs at the interfaces of each ply in a stack, cf. Fig. 1 b). In the UD-NCF layups, the front side (f) of the fabric with a zigzag pattern is facing up for each ply. This is the same for the Biax-NCF in layups with a relative interface orientation of $\Delta\Theta = 45°$ or 90°, while every second ply is flipped over with its back side (b) facing up for $\Delta\Theta = 0°$. The fabrics were stacked randomly to represent the typical case of an automated stacking process.

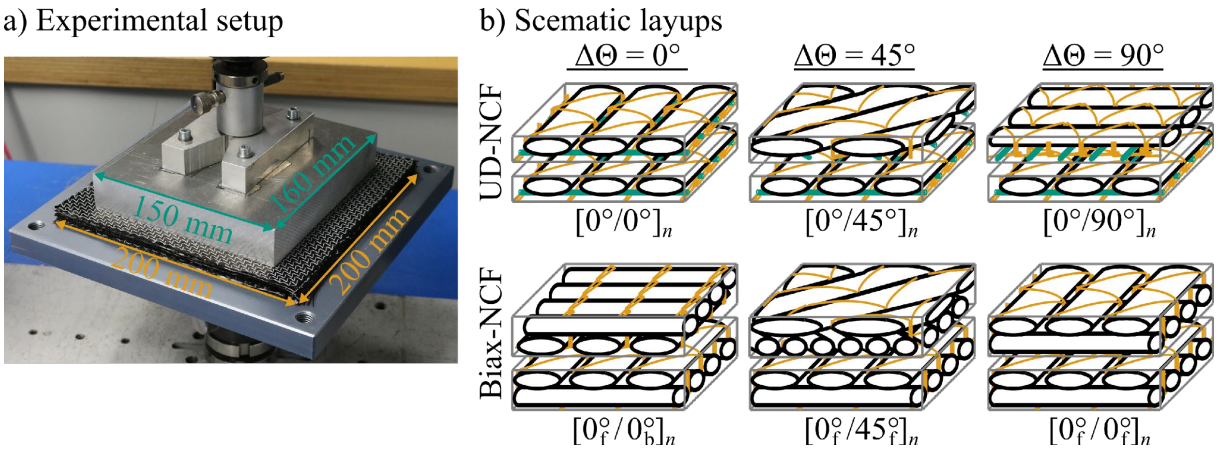

Fig. 1. a) Experimental punch-to-plate compaction test setup; b) Schematic lay-ups of the investigated combinations for different relative fibre orientations at the interfaces with the PES stitching of the NCFs in orange and the GF in green.

The fabric stacks of n_L-plies are compacted to a remaining thickness t_{rem} equivalent to a theoretical fiber volume content Φ of 65 %, cf. Fig. 2 a), according to

$$\Phi = \frac{m_A \cdot n_L}{\rho_{CF} \cdot t_{rem}} = \frac{(m_{total} - m_{stitching} - m_{GF}) \cdot n_L}{\rho_{CF} \cdot t_{rem}}, \quad (1)$$

where $\rho_{CF} = 0.00181\ g/mm^3$ is the density of the utilized CFs and m_A is the areal density of the CFs in the stack, which is approximated by subtracting the weight of the stitching $m_{stitching}$ and GFs m_{GF} from the total measured areal density m_{total}.

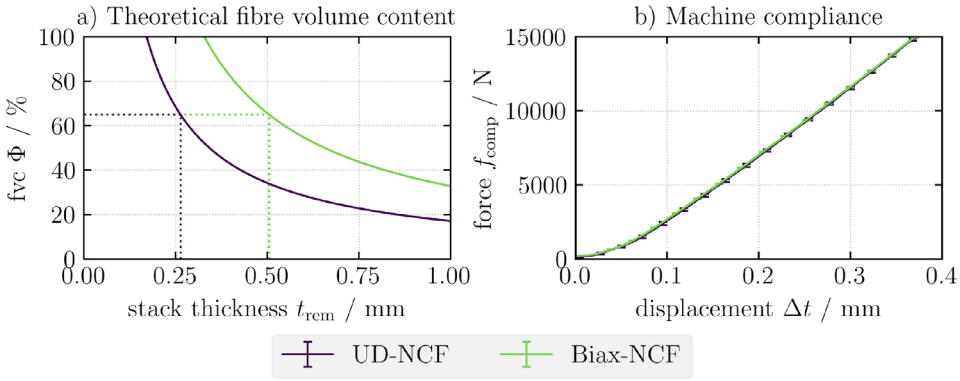

Fig. 2. a) Theoretical fibre volume content for a single layer ($\mathbf{n_L = 1}$) according to Eq. 1; b) Machine compliance curve during the loading stage.

Machine compliance adjustment.

Based on the results of the recent benchmark conducted by Yong et al. [8], machine compliance has a significant influence on the measured thickness during compaction tests. Therefore, the machine compliance was measured based on the method outlined by Sousa et al. [15]. Without a fabric, the top and bottom plates are brought into contact with each other ($\Delta t = 0$) and further pressed together with a prescribed speed of 1 mm/min. The machine force is measured as a

function of the cross-head displacement, cf. Fig. 2 b). The results were used to correct the true remaining stack thickness t_{rem} of each trial according to

$$t_{rem} = t_{meas} - \Delta t(f_{comp}), \tag{2}$$

where t_{meas} is the measured thickness according to the cross-head displacement reading and $\Delta t(f_{comp})$ is the thickness correction depending on the compaction force. The slight non-linearity of the curves indicates a small instability in the testing setup caused by non-controlled elements in the testing fixtures used (e.g. un-parallelism of the plates, internal friction, different materials). However, a good agreement is found between the compliance curve measured prior to testing of the UD- and Biax-NCF.

Results and Discussion

Influence of machine compliance.

In order to highlight the importance of adjusting the results for machine compliance, especially for varying numbers of layers n_{L}, Fig. 3 shows the results of the UD-NCF for the $[0°/0°]_n$-layups with ($[0°/0°]_n$) and without ($[0°/0°]_n^{\mathrm{raw}}$) machine compliance adjustment. Especially for high fiber volume contents, Φ is linear in n_{L} but very sensitive to small changes in the individual ply thickness, cf. Eq. 1. Since the compaction forces for all configurations are of the same order of magnitude, the thickness correction Δt results in larger deviations for the final fvc for fewer layers. This results in a deviation of $\Delta\Phi = 8 - 15\%$ from the targeted final fvc of $\Phi^{\mathrm{target}} = 65\%$. The maximum forces reduce due to the averaging over the smallest common resulting stack thickness t_{rem} among all trials after adjustment according to Eq. 2. Most importantly, however, the position of the curves changes in relation to each other. While an increase in the resistance to compaction is observed for the raw data, a decrease is observed after taking the machine compliance into account.

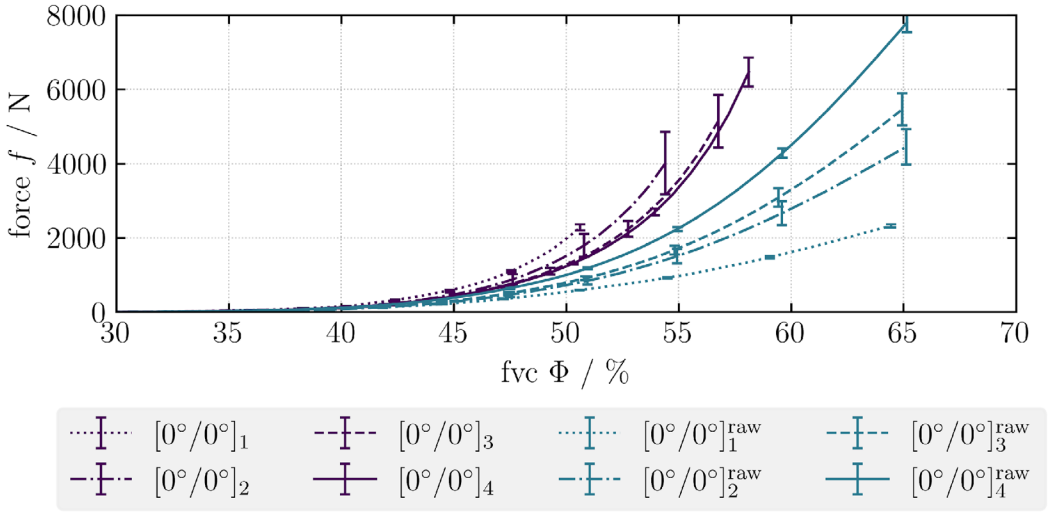

Fig. 3. Influence of the machine compliance adjustment on the results for UD-NCF with a $\boldsymbol{[0°/0°]_n}$*-layup.*

Influence of the number of layers n_L.

The resulting forces over fiber volume content for different $\Delta\Theta$ are presented in Fig. 4. All compaction curves show the well-known non-linear shape with progressively increasing forces [2]. For Biax-NCF the resistance to compaction decreases for an increasing number of layers independent of the layup sequence due to nesting of the layers. This observation is more

pronounced for a $\Delta\Theta$ of 0° or 90°. The offset of 45° decreases the area of superimposed stitching seams compared to continuously stacked layups [7]. This also results in a smaller scatter in the experimental results for $\Delta\theta = 45°$. Since the layers were stacked randomly, it is possible for stitching patterns for a $\Delta\Theta$ of 0° or 90° to coincide between the layers causing an increased resistance to compaction for some of the trials as shown by Korkiakoski et al. [10]. The decrease in resistance to compaction seems to diminish as the number of layers increase, indicating a threshold for even higher n_L. In literature, this threshold is reached at about 10-15 layers for many textiles [2, 3, 6].

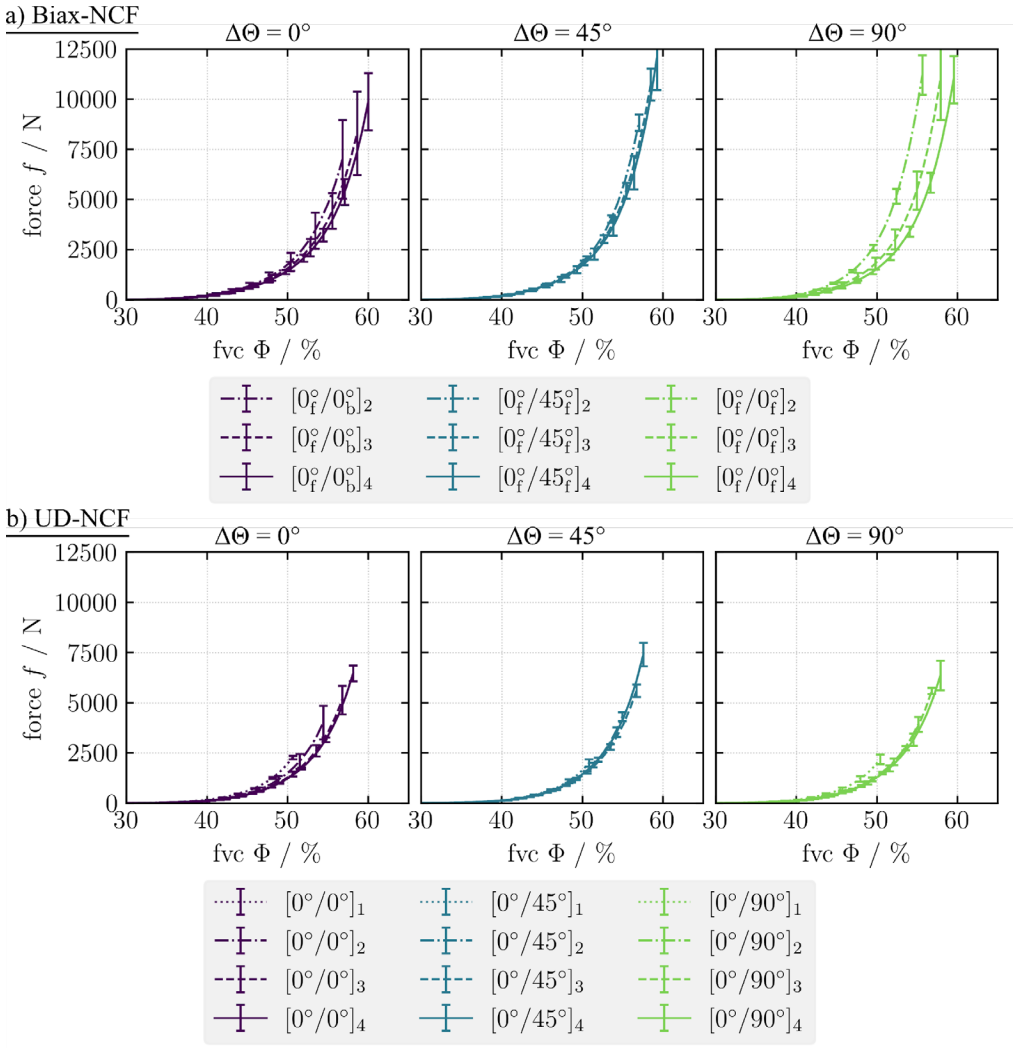

Fig. 4. Compaction test results for different relative interface orientations Θ | a) Biax-NCF; b) UD-NCF.

A similar trend is observed for the UD-NCF, but mainly for an increase of n_L from two to four, cf. Fig. 4 b). A further increase of the number of layers only slightly affects the compaction response with strongly overlapping experimental scatter. Presumably, the GF on the back of the UD-NCF prevent such a strong nesting effect as for Biax-NCF. For $\Delta\Theta = 45°$ the results for $n_L = 8$ is even lower compared to $n_L = 6$ and all curves in general are closer to each other just like for the Biax-NCF. This further indicates a noticeable influence of the superimposed stitching. The threshold for the influence of n_L for the UD-NCF seems to be nearly reached for 8 layers, indicated by a very small decrease in the compaction resistance for more than six layers.

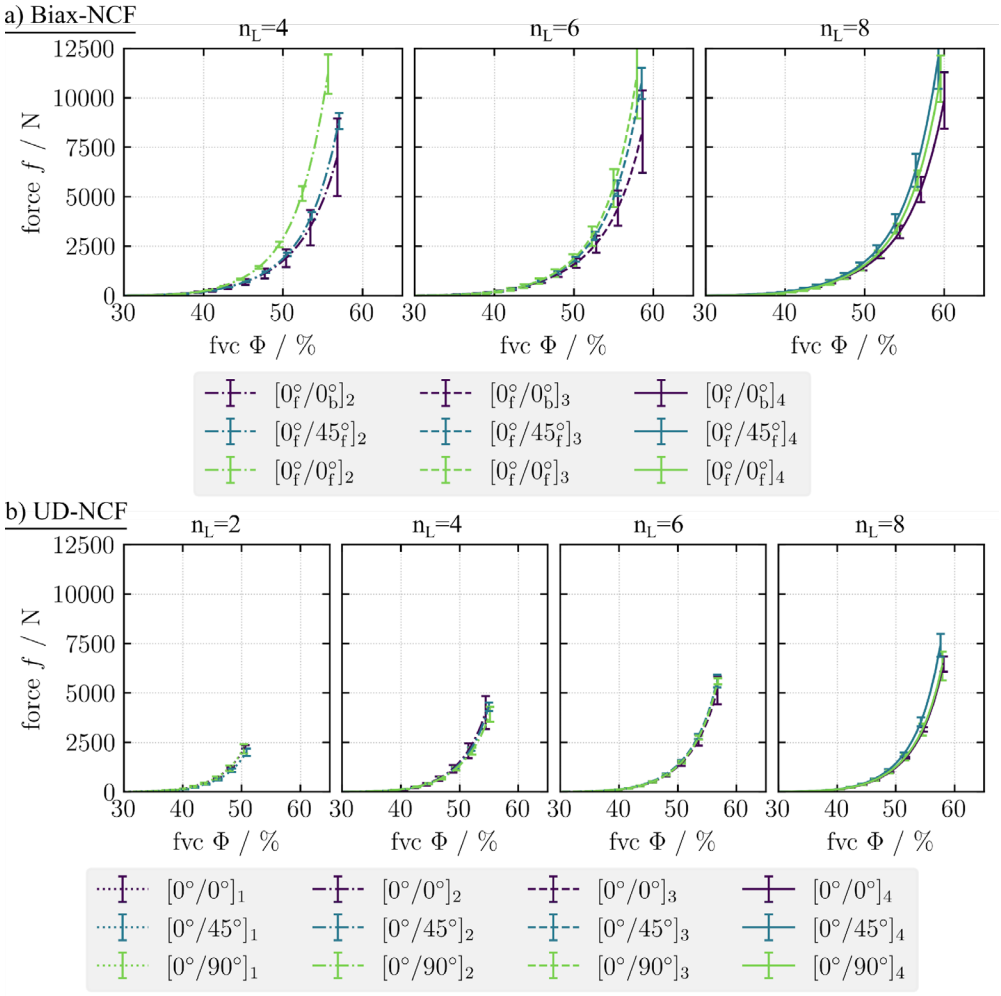

Fig. 5. Compaction test results for different number of layers $\mathbf{n_L}$ | a) Biax-NCF; b) UD-NCF.

Influence of the relative interface orientation $\Delta\Theta$.

To make it easier to assess the influence of the relative interface orientations, the results are shown again in Fig. 5 depending on the number of layers n_L. For Biax-NCF the $[0^\circ_\mathrm{f}/0^\circ_\mathrm{b}]_n$-layup requires the smallest compaction force to achieve a targeted fvc independent of n_L, cf. Fig. 5 a). This reinforces the assumption that the influence of the number of layers is caused by a combination of nesting of rovings as well as the influence of superimposed stitching patterns. For the $[0^\circ_\mathrm{f}/0^\circ_\mathrm{f}]_n$-layups, mainly superposition of stitching causes a decreasing resistance to compaction for larger stacks, while for the $[0^\circ_\mathrm{f}/0^\circ_\mathrm{b}]_n$-layups the effect is amplified by a stronger possibility for nesting of the rovings. In contrast, the compaction behavior of UD-NCF is barely influenced by the relative layer orientation and very similar for the respective number of layers, cf. Fig. 5 b).

Summary

In this work, a study on the compaction behavior of UD- and Biax-NCF for different layup-types and relative fiber orientations at the interfaces is presented. First, the relevance of considering the machine compliance was emphasized, especially in order to study the behavior for different numbers of layers. Comparing the UD- and Biax-NCF to each other, some similarities can be observed. With an increasing number of layers, the resistance to compaction for both materials decreases independent of relative interface orientation. This effect is weakest for $\Delta\Theta = 45°$,

indicating a combined influence of roving nesting and superposition of the stitching patterns. The stiffness decrease is smaller for the UD-NCF, which is presumably due to the glass fibers preventing pronounced nesting. For both fabrics, the influence of n_{L} is diminishing, indicating a threshold for these effects. However, more experiments with even more layers are necessary for both materials to identify the exact threshold. An influence of the relative interface orientation is only distinctly observed for Biax-NCF. Turning over every second layer in a $[0_{\mathrm{f}}^{\circ}/0_{\mathrm{b}}^{\circ}]_n$-layup reduces the required forces for a targeted fvc, which can be used to reduce required pressing forces [16].

The results of this study allow a better understanding of the two investigated non-crimp fabrics and could be used to parametrize an analytical or simulation model to design molding processes. Therefore, the compaction behavior for different velocities as well as very high and low numbers of layers should be addressed in further studies.

Acknowledgments
The authors would like to thank the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) and the French National Research Agency (ANR) for funding the collaborative project "Composite forming simulation for non-crimp fabrics based on generalized continuum approaches" (project number 431354059), which the presented work is carried out for. The work is also part of the Young Investigator Group (YIG) "Tailored Composite Materials for Lightweight Vehicles", generously funded by the Vector Stiftung.

Abstract. Stab protective clothing is used in a wide range of applications, including military and police applications, but is also becoming increasingly important for civilian users. A relatively new way of manufacturing personal protective equipment is additive manufacturing. This makes it possible to produce new types of stab protection geometries by applying polymer layers to textiles. Such composite structures represent a mechanical system of rigid bodies with constraints, especially with large continuous protective surfaces. As a result, the wearing comfort is limited. This paper presents two methods for numerically simulating the forming of reinforced textiles with solid polymer elements over the body as part of the development and optimization process of such garments.

Introduction

Stab protection clothing is getting more important for both military and civil users, as the statistics of the national polices of several countries shows. The fact that in countries such as the UK or Germany more than 40,000 attacks with a knife or other sharp object are reported each year [1, 2] is an argument that wearing stab protective clothing is essential for various professions. There are several investigation the possibilities of improvement of the stab resistance of textile structures, based on the using non-woven fabrics [3], or triaxial textiles [4]. The properties of the fabrics are important and normally fabrics with very high density and high seam slippage resistance are required [5]. Analytical methods for investigation of the stab resistance for woven fabrics is reported in [6]. Other researchers use combination of different fiber types and found that the use of wool fibers in combinations with aramid significantly increases the stab resistance of the woven structure [7]. In the latest decade the additive manufacturing provides new possibilities for integration of protective elements in the textiles, as both laser sintering [8] and fused filament disposition of polymers [9] are applied for such applications and demonstrate that can satisfy the norms. The placement of additional solid elements increases the stab protection especially against needles and other small elements, but with the increasing of the size of these elements, can again gets negative effect in the reduction of the wear comfort of the protective clothing. This work presents a method for numerical simulation of the forming of reinforced textiles with solid polymer elements over the body as part of the development and optimization process of such clothing.

Problem Description

Safety textile products for stab protection have often additional elements, who have to stop the sharp elements and avoid the interpenetration on the human body [10]. In order to ensure some freedom of the motion, it is essential to have smaller protective plates on the areas of the body, where more motion happens or where the radius of the curvature is lower (Fig.1), and larger plates on the more statical areas and such those with lower curvature, in order to keep the protection rate higher.

Fig. 1. Curvature areas on the human body, hier viusalised as Gaus curvature.

The protective elements can be produced with different form and integrated on the textile structure using additive manufacturing. Fig. 2 demonstrates one possible form of such protecting elements, which can be printed over knitted structure.

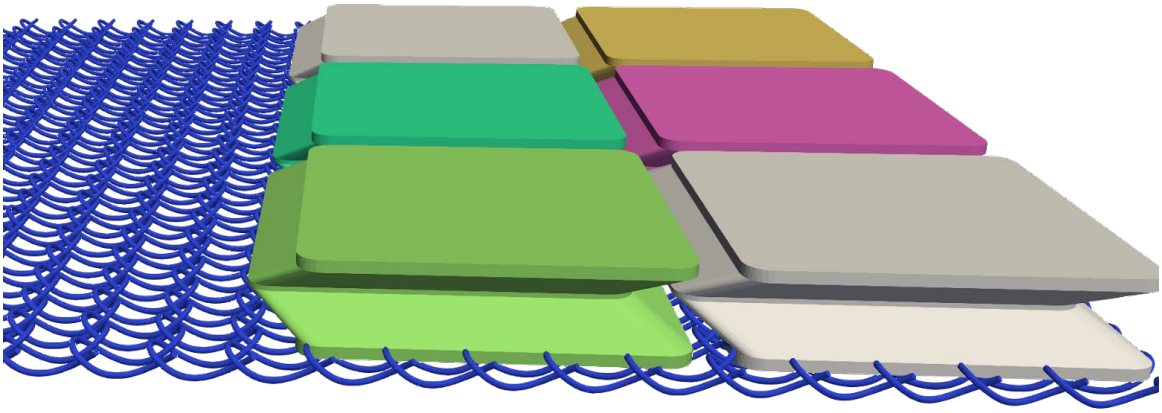

Fig. 2. Schematic illustration of a possible protective elements applied to a knitted fabric.

After determining and testing the required thickness and suitable material for the panels [9], the main task for the developer of protective clothing with such elements is the placement of the protective elements in a way, which provides the best function – in this case stab protection and the best wear comfort. In order to provide best function, elements the plates are prepared with a form which allow that they incline in each other (Fig. 3).

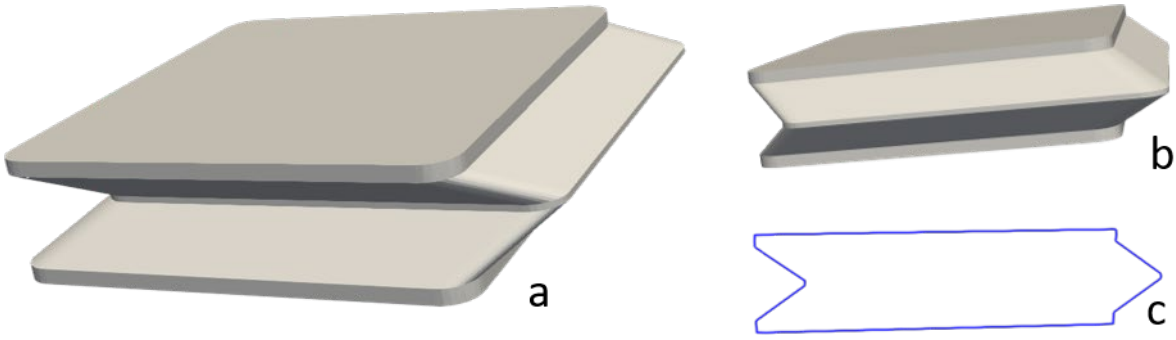

Fig. 3. Element of the protective structure a) and b) side view c) cross-section.

The convex triangle element on the two sides can incline in the concave negative elements on the other sides of the next plates and in this way to provide dense structure (Fig. 4a). Such structure retain small flexibility and allow some limited bending over curvatures which depends on the distance between the plates (Fig. 4b and 4c).

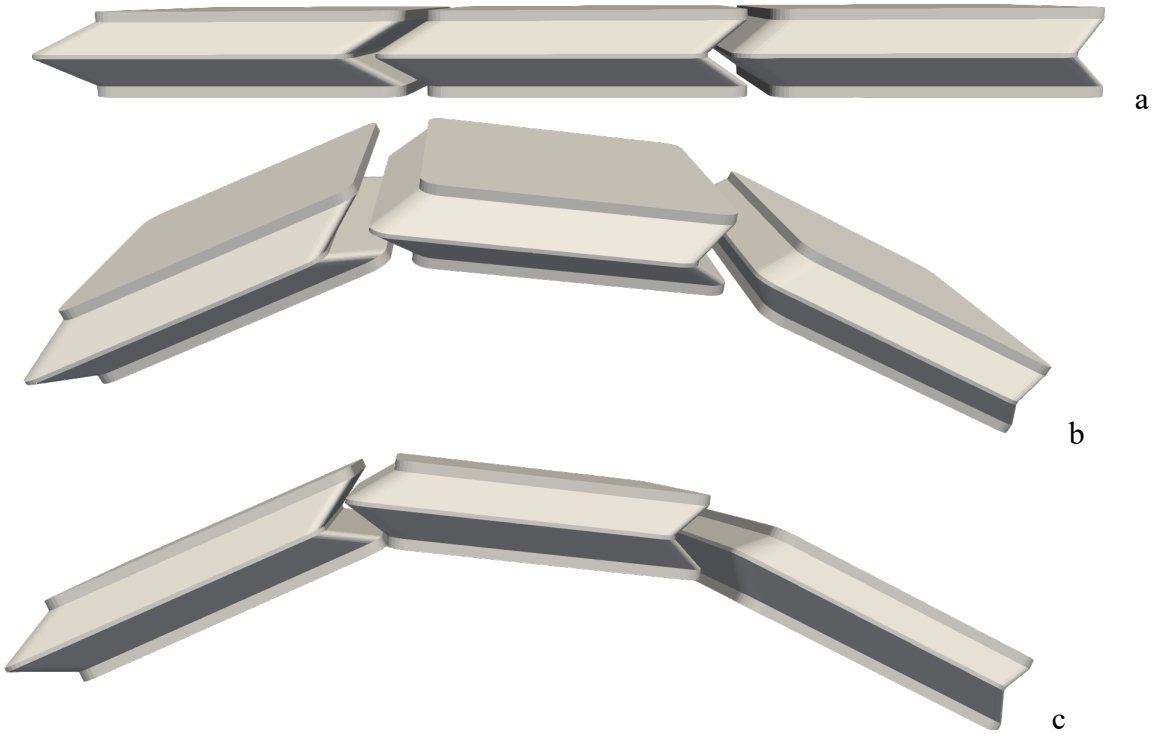

Fig. 4. Set of additive manifactured elements a) in horizontal direction b) bent with larger distance between the plates c) bent with smaller distance beween the plates.

The principal question is with which algorithms, software or method the forming over the body of such composite structure (basis textile and plates) can be simulated in order the optimal parameters for the geometry of the plates, the distance between these, the elasticity of the textile and the final pattern construction can be optimized. The common clothing CAD software can perform well draping simulation on the body, but consider all accessories as buttons in the best case as connected to the textile, but ignore their contact detection. The classical FEM software would require complex mezzo-scale level simulation of the structure, connected with the plates, but such one requires large simulation times and is not really suitable for engineering development process at the current time.

Proposed Procedure

The classical methods from the last 25 years in the area of composites forming are reported very detailed in [21]. The commonly used and reported there shell and solid shell methods could be extended for simulation of the current case of soft materials with integrated plates, but as in the current case the properties of the structure are dominated by rigid bodies, the authors decided to use another technique. The basis textile structures can be generated as 3D geometry using different software packages. Wisetex is very powerful for creation of woven fabrics [11], TexMind Weft [12] and Warp Knitting Editors [13] provide 3D geometry for the corresponding structures [14, 15]. In the current case the weft knitted structure is generated parametrically with the TexMind Weft Knitting Software and exported as STL file. 3D protective elements can be created with

Autodesk Fusion 360 and also saved as an STL file. The human body can be obtained by 3D or 4D scanning, but for the testing of the procedure is generated with MakeHuman [16].

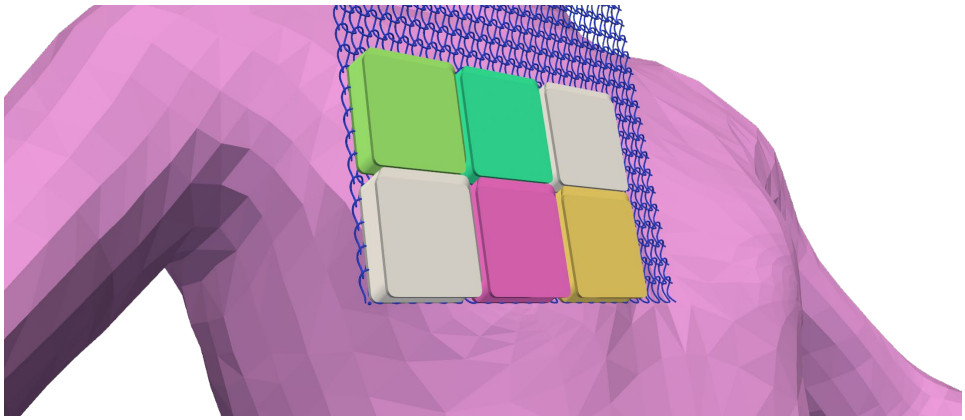

Fig. 5. Task describtion – protective elements, placed over elastic textile have to be formed to suit the human body.

For the simulation with large number of contacts and complex geometries with rigid bodies with constraints the impulse based methods are reported to provide very good performance and simplicity of the code [17, 18]. In the current case the implementation of BulletPhysics [19], especially its Python port is applied [20]. The Library allow import of the geometries as contact shapes from STL files, setting friction coefficients and all required dynamic effect. For the simulation the physical system is simplified and the complete textile layer, which provides the connection between the plates is replaced by a constrains between the plates. As suitable replacement of the complete knitted structure (Fig. 6a) two point-to-point constrains between the plates are applied (Fig. 6b).

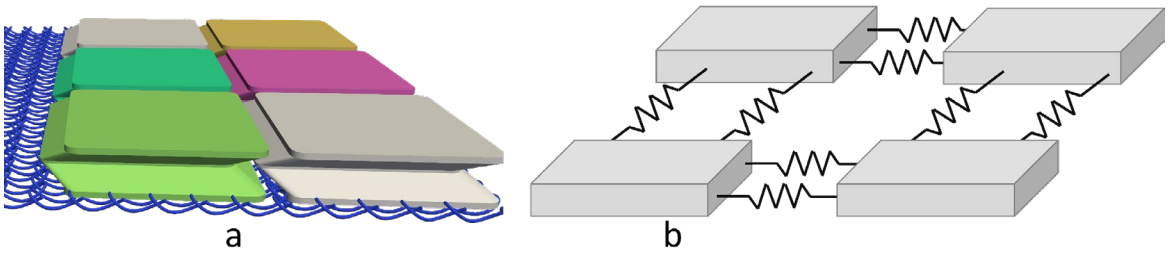

Fig. 6. Modelling of the elasticity of the knitted structure as paired springs (connecting links).

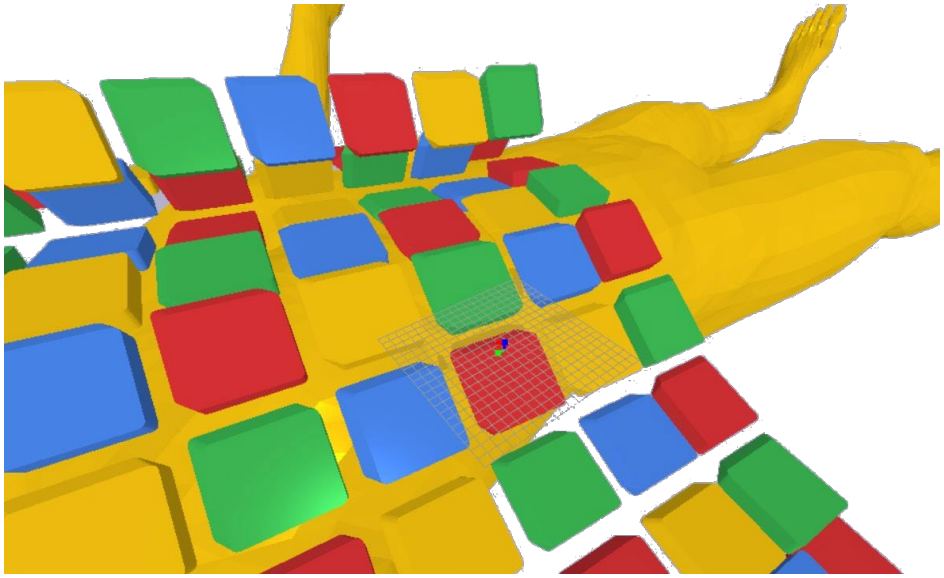

Fig. 7. Modelling of the elasticity of the knitted structure as paired springs (connecting links).

The paired two connection between each plate actually leaded to very stiff structure (Fig. 7), where the rows moves completely as a rigid type and does not allow single plates to move over the human body as it is the case if the distance between the plates is larger.

In a second trial the two pairs are replaced by only one per connection between the plates (Fig. 8a). In this way the single elements have more freedom to more around the body, as it is the case if they are produced with additive manufacturing over flexible textile structure. The starting simulation step is visualization in Figure 8b, where the plates are starting to move down to the body based on the applied acceleration.

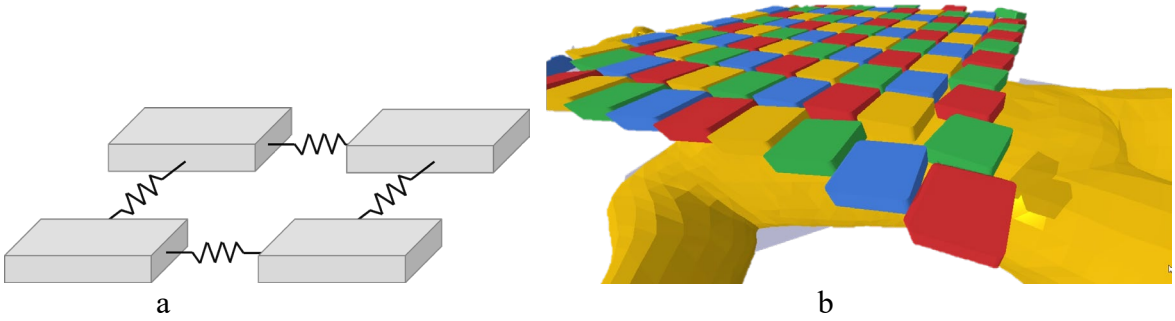

Fig. 8. a) Mechanical model of the plates, where each one is connected to the next with only one constrain b) view from the beginning of the simulation process.

After adjustment of the limits of the constraints (limitation of the maximal force) the model was able to run and simulate the process, where the initially printed elements over the flat textile will deform over the human body (Fig. 9). The principle was proven and seems that can be a basis for refinement for complex simulations, but it has shown as well several open problems, which becomes not solved until the finalization of this text. One of these is that for the proper contact simulation of the elements with concave geometry does not work properly with the simplified using of boundary box of the element and requires special treatment, forcing using the algorithms for concave triangular meshes. Applying this algorithms for the form (Fig. 3) at lower distance between the plates leads to sticking of the elements and completely limiting their flexibility. Another parameter is the limit of the maximal force in the constraints between the plates. It has

the physical meaning similar to the stiffness of the connection. For low values the solver needs very long time to converge the structure and satisfy the constraints. Using high level of the maximal force the plates leads to unnatural configurations in case the plates contacts together.

Fig. 9. Example of simulation state of the structure over the body.

Summary

Novel structures for stab protection can be produced using additive manufacturing, depositing polymer layers over textiles. Such composite structure represent mechanical system of rigid body with constraints. For the analysis and optimization of such structures, and especially the forming process when the clothing is wearied, in the current case impulse based solver is applied and two models are tested. The more natural replacement of the textile background trough two constrains parallel between each two plates leads to rigid structure and was not able to be formed over the human body with the current simulation trials. Probably more careful adjustment of the simulation parameters could give the better results. A model with only one constrain as connection between each two plates demonstrated ability to be used for forming simulation, but remains sensible regarding all model parameters. Although all difficulties and sensibilities, the models were computed on a normal home use computer with Intel 7 processor with 2,6 GHz and 16 GB RAM for few seconds, which is promising for integration in engineering software after refinement of the model and parameters.

Keywords: Filament Winding, CFRP, Pressure Vessel, FEM Simulation

Abstract. Recently, Università Politecnica delle Marche and COMEC Innovative srl are involved in the research project "Smart Tow Winding" funded by MIUR (Ministry of Education, University and Research), concerning the development of an innovative process for the realization of a pressure vessel through Filament Winding (FW) technology. In this context, a design procedure for type IV composite pressure vessel is proposed. To design the component, the dedicated simulation software CADWIND was used to virtually generate the pressure vessel through the definition of the desired geometry, the type of prepreg, the number of layers and the bandwidth. The generated file was imported in the FEM simulation software Siemens NX with the aim of evaluating the structural resistance under an internal pressure of 70 MPa. Different external configurations of mandrels and stratification were tested in order to optimize the geometry of the vessel and the resistance to weight ratio. A high performance and low weight vessel configuration was finally identified.

Introduction

In recent years, the market for lightweight structural components has constantly increased and it has triggered the use of high performance composite materials such as Carbon Fiber Reinforced Polymers (CFRPs). These components find applications in several sectors such as sport equipment, energy production, and biomedical. Moreover, they are particularly suitable for road and aerospace transport applications. In fact, the weight saving achieved by means of high specific mechanical properties composites can result in a reduction in fuel use and, consequently, lower service life costs and environmental impacts [1-3]. Despite significant effort in automation [4], at present, carbon fiber parts production strongly relies on manual operations and it is therefore time consuming and expensive. For this reason, to achieve a sustainable development of composite materials and innovative transport systems, it is crucial to improve manufacturing systems automation and production speed [5].

In this context, MIUR (Ministry of Education, University and Research) is funding the research project titled "Smart Tow Winding" concerning the development of an innovative process for the fabrication of a pressure vessel through Filament Winding (FW) technology involving the Marche Polytechnic University and COMEC Innovative srl.

In this regard, the development of the technology of Smart Tow Winding constitutes an innovation in the corporate sector as it allows to combine an innovative material, such as composite, with an automated production process. This technology is an automated version of the conventional filament winding (FW) process, which is a widely practiced technique for high performance composite structures, such as pressure vessels, fuel tanks, pipes, and rocket motor

cases. FW allows the production of composite parts by winding composite filaments over a rotating mandrel. The winding angle of the filament can be modified depending of the expected loads on the components, maximizing the mechanical resistance along the most stressed directions. In this way it is possible to satisfy the stringent structural requirements of the aerospace and transport industries.

Smart tow winding can be used for the construction of fuel storage tanks, containing from combustible gases to natural gases, which nowadays are an excellent solution to reduce CO_2 emissions. The traditional structure of tanks, used for on-board storage of gaseous fuel under pressure, present a central cylindrical body and two dome-shaped external caps; this is due to the fact that spheres incur the lowest membrane stress on their walls compared to any other shape [6,7]. These pressure tanks can be realized in metals, composite materials or obtained as a combination of these materials. In particular, five different types of vessels are defined [8]: Type I, II, III, IV, V. Type I is fully made by metal material, while Type II consist in an inner metal liner supporting 55% of the internal pressure load, reinforced with composite hoop wraps. Type III, is similar to Type II with an inner metal liner, externally covered by a composite reinforcement supporting up to 80% of the pressure load. For what concern Type IV, it is made externally of composite material and presents an inner liner made of plastic material, which does not support the load, but contains the gas and works as a mandrel for the Filament Winding process. The last typology, Type V, it is fully made by composite material, without internal liner.

Generally, gas used in industrial applications is stored inside cylindrical Type I tanks, since they are the least expensive, but the heaviest. Type II tanks, on the other hand, are commonly used at high pressures for stationary applications: they are lighter than Type I tanks, but at the same time more expensive. For uses where high lightness must be guaranteed, Type III, IV, and V tanks are used, in which the composite material is generally reinforced by means of glass, aramid, or carbon fibers [9].

Specifically, Type IV and V ones are the lightest ones at all, as they do not have metal liners; however, they are the most expensive due to the use of composite material.

With regard to the winding patterns with which these tanks can be made, they vary, depending on the geometry of the tank, the manufacturing process, the fiber arrangement, the precision of the machine, and the cost. Since filament-wound composite pressure vessels are more inclined to failure in domed sections, the shape of the dome and the winding of the fibers are important for the structural integrity of the vessel [10].

The high number of parameters related to pressure vessel production (e.g. number, percentage coverage and orientation of layers, filament path, raw materials, internal liner..) makes the design process complicated and time consuming. For this reason, a rapid and easy to apply design procedure for filament wound parts is required.

Hence, in the context of advanced composite manufacturing processes and simulations [11], this work focuses on the design and optimization of a type IV pressure vessel since it is a promising alternative in various applications (i.e. energy and transport) were low weight and high performances are required. After preliminary considerations with structural theories (netting theory, isotensoid vessel), virtual models were created by means of a FW dedicated software that allowed to define all the parameters of several possible composite layers. An iterative procedure with a FEA software was then used to optimize the structure parameters considering typical working loads (70 MPa internal pressure) and constraints.

Materials and Methods

In the present work, a preliminary design of a Type IV pressure vessel was investigated. The tank under pressure is characterized by a 380 mm diameter in the central cylindrical zone and a total length of about 540 mm. An internal thermoplastic liner, in high-density polyethylene (HDPE), is used as mandrel during the filament winding process. For the composite material used for the external winding, a towpreg composed by a thermosetting polymer matrix reinforced with carbon fibers, was chosen. The internal service pressure and burst pressure values were defined equal to 70 and 105 MPa, respectively, with a safety factor of 1.5, according to the suitable values in several transport applications [12]. Details about the material parameters according to their datasheet are reported in Table 1. The mechanical properties of the composite material were calculated considering the general "rule of mixture" and a fiber weight fraction equal to 68%.

Table 1. Mechanical properties of matrix, carbon fibers and composite material.

Material parameters	Unit	Values
Carbon fibers (Toray T700)		
Tensile strength	MPa	4900
Young modulus	GPa	230
Elongation at break	%	2.1
Density	g/cm³	1.8
Volume fraction	%	56.3
Epoxy resin		
Tensile strength	MPa	73
Young modulus	GPa	3.7
Elongation at break	%	9
Density	g/cm³	1.1
Volume fraction	%	43.7
Composite		
Tensile strength (longitudinal)	MPa	2790
Tensile strength (transversal)	MPa	~73
Young modulus (longitudinal)	GPa	131.1
Young modulus (transversal)	GPa	8.3
Density	g/cm³	1.6

To design the pressure vessel, an iterative procedure was followed (Fig. 1). Input geometric parameters were used to define the dome profile through a spreadsheet, while the design parameters, such as carbon fiber mechanical properties, service pressure and safety factor, were used to lead the netting analysis. The obtained results were implemented in CADWIND simulation software to virtually generate the pressure vessel through the definition of the desired geometry, the type of prepreg, the number of layers and the bandwidth. Then, the generated file was imported in the FEM simulation software Siemens NX with the aim of evaluating the structural resistance under the internal service and burst pressure values of 70 and 105 MPa. If the results obtained satisfy the safety structural requirements, the stratification analyzed can be considered as an acceptable design from the mechanical requirements perspective; otherwise, the study should continue identifying a new stratification that improves criticalities arising from the previous one. Moreover, other than the structural requirements, the weight of the structure was evaluated during

each design iteration in order to identify the alternative that fulfils safety conditions and presents the lightest weight possible among the considered laminations.

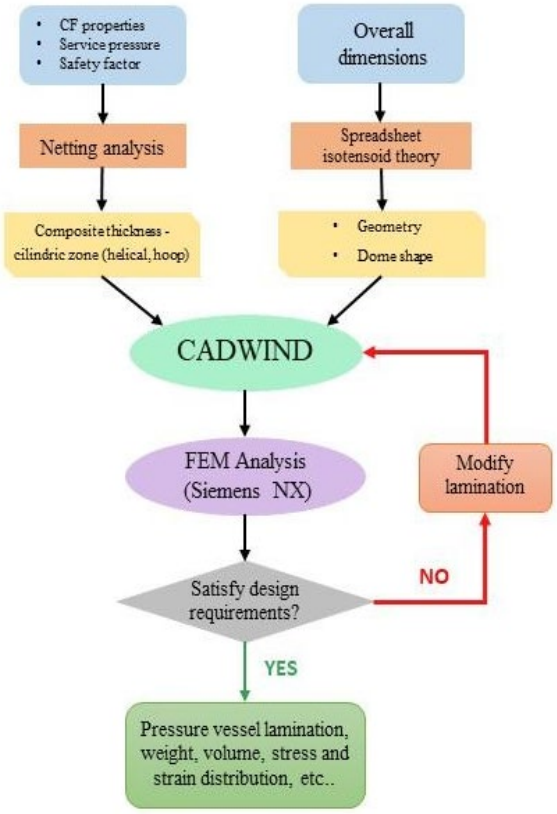

Fig. 1. Iterative design procedures applied for the definition of the optimal pressure vessel.

Netting analysis.

The netting analysis is a method that can be used to preliminarily estimate the thickness of helical and hoop layers of a composite tank that allow it to withstand the working loading conditions. The analysis considers that the pressure load is only supported by carbon fibers and the epoxy resin does not give any structural contribution. According to Mariotte theory, the internal pressure yields to two main stress components along the circumferential and axial directions. The first one is supported by helicoidal windings, while the second by hoop windings. For this reason, many tubular structures or tanks are produced using both low values of winding angles (helicoidal windings) and values near to 90° (hoop windings). Therefore, this theory allows to calculate the thickness of the fiber layers considering any combination of two different values of winding angles to obtain the tank laminate structure [13].

Spreadsheet isotensoid theory.

In order to guarantee high structural strength of the pressure vessel, the definition of the external geometry of the domes is fundamental since it is the most complex zone of the component. To generate the tridimensional geometry, a meridian curve was realized and then was rotated around a central axis. Referring to the European patent of isotensoid tanks obtained by filament winding process [14], this curve was defined by points through a spreadsheet in which input data of cylindrical zone diameter and length and opening end's diameter were inserted. The output

information of this step was the meridian curve, which was than exported to a file compatible with the filament winding dedicated software CADWIND.

Filament Winding process simulation.

The simulation of filament winding process was performed using CADWIND software, which can simulate the winding process, based on a physical model, and calculate the fiber path and winding pattern (Fig. 2) [15]. After importing the geometry of the mandrel, composite laminates were created using different process parameters, which are listed in Table 2.

This allows to create a file to be imported in FEA software that reports information about the model mesh, and laminate stratification, orientation and thickness. With this model, the wound filament is considered perfectly straight and possible undulation and degradation of the composite mechanical properties are not considered [16].

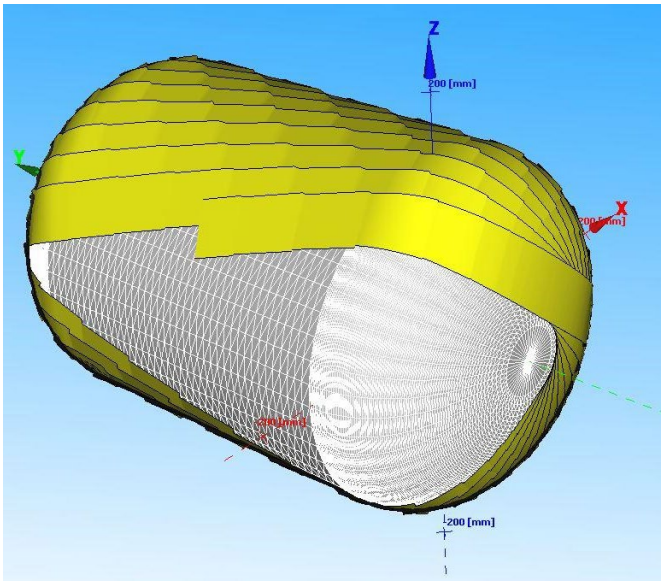

Fig. 2. Simulation of filament winding process performed using CADWIND software.

A friction factor equal to 0.3 was considered for the composite prepreg in the process simulation. The “Turning zone” represent the zone in which the filament orientation starts to change the winding angle in order to come back and wind the opposite mandrel side and the “Coverage” represents percentage of filament coverage on the mandrel. The associated values are defined to obtain a symmetric component avoiding a high overlap of the wound material that implicates a thickness increase. The material parameters are listed in Table 3.

Different external configurations of mandrels and stratification were tested in order to optimize the geometry of the vessel and the resistance to weight ratio.

An accurate choice of layering requires many considerations such as identifying the number of composite layers to deposit and defining the winding angle of each layer. The latter is fundamental, as the more the angle is reduced, the greater is tank’s area covered. The choice of the winding angle also influences the mechanical resistance of the component: if it is about 90°, the resistance to tangential stresses increases, while material layers with low values of winding angle better withstand axial stresses.

Table 2. Laminate parameters.

Laminaton	**Winding angle [°]**	**Turning zone front to**	**Turning zone back from**	**Coverage [%]**
1	10	20	105	102.1
2	15	14	111	133.3
3	20	8	117	107.0
4	25	5	120	102.1
5	30	7	118	130.1
6	35	5	120	122.8
7	40	6	119	147.1
8	45	9	116	153.6
9	50	12	113	150.2
10	55	15	110	140.3

12	65	27	98	123.8
13	70	30	95	188.2
14	75	35	90	155.5
15	80	41	84	162.2
16	85	40	85	184.7

Table 3. Material parameters.

TEX value (single roving) [g/km]	Bandwidth (single roving) [mm]	Fiber density [g/cm3]	Fiber volume fraction [%]	Fiber mass fraction [%]	Matrix density [g/cm3]	Resulting ply thickness [mm]
1000	6	1.8	56.5	68	1.1	0.16

Moreover, it is necessary to deposit some hoop layers after a defined number of helicoidal layers both to compact the underlying layers and to remove any resin's excess.

Once identified the layering to analyze, the FEM file created is imported on the software used to conduct FEM analysis.

Structural simulation of the pressure vessel.

In order to simulate the performances of the composite pressure vessel, the software Siemens NX was used, with the FEA NX Nastran solver. To this purpose, the file created in CADWIND was imported in NX to analyze the selected laminate. The model was imported as constituted by 2D shell elements with a defined laminate structure. The linear-elastic material mechanical properties were defined, and a structural linear simulation was carried out. The preliminary structural simulations of the pressure vessel conducted considering two fixed constraints on the most external frames, at the end of the domes.

Results and Discussions

Thickness distribution on pressure vessel.

The netting theory was used to evaluate the thickness distribution on layers with both hoop (~90°) and helical (variable θ) winding angles. The angle θ was continuously varied from 0° to 90°, and the resulting laminate thickness was registered. It was observed that by increasing the value of θ, the required thickness of helical layers increases while the number of hoop layers decreases.

For θ values between 54° and 55°, if constant internal pressure is considered, the total thickness value of the pressure vessel is minimized.

The resulting minimum total thickness of carbon fibers is about 10.18 mm, which is divided in 3.84 mm for helicoidal layers and 6.34 mm for hoop layers. Considering that netting theory evaluates only the fibers contribution and that fiber volume fraction is about 56.3%, the minimum thickness of total composite laminate is about 18.08 mm.

Pressure vessel model definition.

Based on pressure vessel dimensions, as described in section *Spreadsheet isotensoid theory*, a meridian curve that represents the external domes profile was obtained. The medium thickness of each layer depends on both the towpreg characteristics and the coverage percentage. In fact, in order to guarantee a good covering of the mandrel, the towpreg tends to overlap itself involving a greater coverage percentage than 100% on each layer. So, this confirm that the medium thickness of each layer which approximately various from 0.2 mm to 0.3 mm depends on the coverage percentage.

Considering these values and the results obtained by netting theory, to ensure that the tank operates safely at least 70 - 80 layers of towpreg are required. According to this information, the first layering tested was $[85_6/10_4/15_4/20_4/85_6/30_4/35_4/45_4/85_6]$.

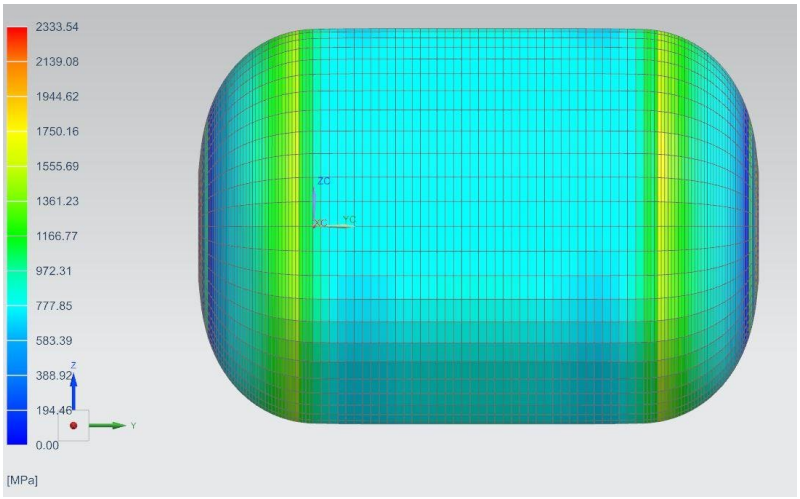
Table 4. Maximum stress and strain values of each reference layer.

Winding angle	**Maximum stress**		**Maximum strain**	
	Internal pressure 70 MPa	*Internal pressure 105 MPa*	*Internal pressure 70 MPa*	*Internal pressure 105 MPa*
85°	993 MPa	1500 MPa	0.004	0.006
10°	1290 MPa	2333 MPa	0.004	0.026
15°	899 MPa	1350 MPa	0.022	0.022
20°	788 MPa	1200 MPa	0.006	0.014
85°	990 MPa	1482 MPa	0.007	0.009
30°	720 MPa	1116 MPa	0.006	0.009
35°	800 MPa	1170 MPa	0.006	0.008
45°	820 MPa	1265 MPa	0.005	0.006
85°	992 MPa	1485 MPa	0.005	0.006

FEM simulations.

The mentioned layering was tested using both a service pressure of 70 MPa and a burst pressure of 105 MPa to analyze the pressure vessel structural response under bursting conditions. This laminate was characterized by 84 plies, a weight of 21 kg and a thickness of the cylindric zone of about 20 mm. To observe the resulting stress and strain values of the pressure vessel, the results obtained were analyzed considering a reference ply for each winding angle used in the laminate. Table 4 shows the maximum values of stress and strain along the fibers direction evaluated in each reference layers, imposing the different pressure values of 70 MPa and 105 MPa.

(a)



(b)

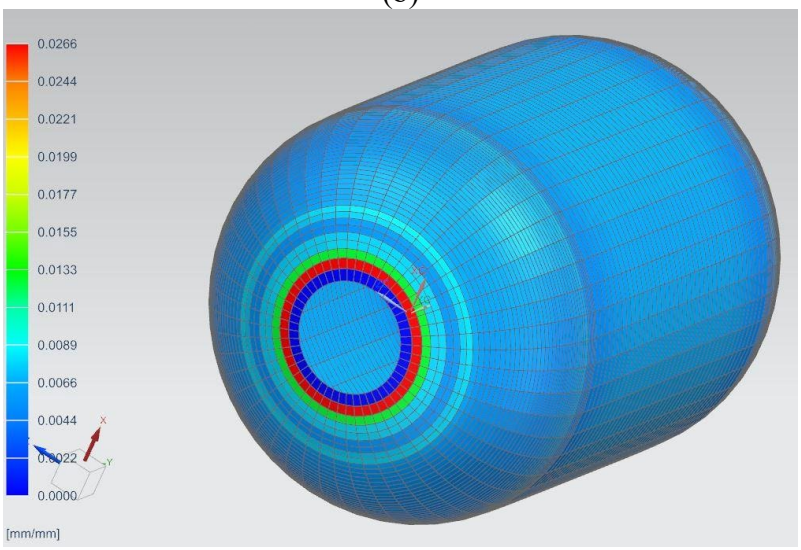


Fig. 3. (a) Strain and (b) stress distributions on the ply with 10° winding angle for the 105 MPa test.

Fig. 3 shows the strain and stress distributions on the ply with 10° winding angle obtained by CADWIND software simulations. As far as the stress values is concerned, Fig. 3b shows that the pressure vessel is in safe conditions also when internal burst pressure is applied; although there are some areas that are more stressed than others, they fall within the set limit values of 2500 MPa. For what concerns the strain values resulting from the service pressure analysis (Fig. 3a), the tank is generally in safe condition with the exception of the ends of external domes where the reached strain values are greater than the limit value of 0.007. As expected, it is noticed that stress and strain values resulting from the test performed using burst pressure (105 MPa) are greater than those obtained using the internal service pressure (70 MPa).

Summary

This study addressed the procedure used for the preliminary design and the structural analysis of a Type IV pressure vessel. The focus was both on the definition of external domes geometry and on the composite material used for the winding which confers the structural strength to the tank. The identified laminate sequence is chosen using CADWIND, a software which is dedicated to

filament winding processes. Then it was analysed to verify its structural behaviour through Siemens NX FEA software. The main results are summarized below:

- According to netting analysis, the minimum value of total composite laminate thickness is about 18.08 mm. Considering the thickness of the cylindric zone, the netting theory provides results that are similar to those of the FEM simulations. However, more complex approaches are needed for the domes of the vessels.
- Using a spreadsheet and knowing pressure vessel's dimensions, the external domes isotensoid geometry was defined.
- Netting analysis combined with CADWIND allowed to determine the minimum number of layers to introduce on the layering, which is about 70 - 80 layers.
- The used laminate sequence is characterized by 84 plyes, a weight of 21 kg and a thickness of the cylindric zone of about 20 mm.
- The FEM analysis shows that the tank tested using an internal pressure of 70 MPa is in safe conditions in terms of stress and strain except for some criticalities on the ends of the external domes.
- Instead, the tank tested using an internal pressure of 105 MPa is in safe conditions in terms of stress only: strain values are higher than the limit on almost all layers analyzed.

This study can be considered as a starting point to optimize the layering through an iterative process. In this way it is possible to obtain a pressure vessel which is in safe conditions also considering strain values. Moreover, the procedure here presented can be used as a reference point for the design of filament wound components with different mandrel geometry. Future works could focus on a further optimization of the composite lamination by means of localized reinforcement (i.e. composite patches) that provides increased strength in the highest stress regions while reducing the number of laminate layers and the overall part weight. The FEM results will be validated by means of pressure test to determine the quality of the lamination and the proposed design procedure.

Keywords: Hyperelastic, Invariant-Based, Constitutive Modeling, Multiaxial Coupling

Abstract. During the forming of woven fabrics, different multiaxial stress states can occur, depending on the given process conditions and the complex deformation mechanisms of the interwoven structure of the textile. Particularly under constrained forming conditions, induced e.g. by blank holders or by adjacent metal layers in fiber-metal-laminate (FML) forming, the multiaxial stress states may include in-plane compression. A hyperelastic, invariant-based constitutive model has been proposed in previous work to consider such biaxial and normal-shear coupling for both positive and also negative strains. In the present work, this constitutive model is applied to forming simulation at component scale to investigate the significance of individual coupling aspects for the prediction of the forming behavior under different multiaxial stress states. For that purpose, FMLs and pure fabric laminates are formed to a tetrahedron geometry. In a comparative simulation study, the individual strain couplings of the invariant-based material model are differently activated or suppressed. The simulation results reveal that biaxial coupling has a significant effect on the draping behavior, if the draping is partially constrained. In contrast, the coupling effects are much smaller for free draping conditions.

Introduction

In the past two decades, a large number of material models have been developed to describe the forming behavior of textile materials at meso and macro scale [1,2]. However, only macroscale models are suitable for forming simulation at component level [3] and enable virtual validation and optimization of forming processes [4,5]. Since textiles are prone to large shear, non-orthogonal material models are required [6-8]. This can be realized by hypoelastic or hyperelastic material modeling. Hypoelastic approaches [9-11] describe stress rates as direct functions of strain rates, depending on the stiffness. At each timestep, stress increments can be calculated directly from strain increments, which makes hypoelastic approaches convenient for implementation in nonlinear finite element approaches. For sufficient accuracy, however, they require sufficiently small timesteps. The advantage of hyperelastic approaches [12-14] is the integral representation of the stress-strain relationship, which enables timestep-independent solutions. The stress-strain relation is based on the strain energy density and their differentiation with respect to strain measures.

For woven fabrics that exhibit pronounced orthotropy with two preferred directions, the strain energy potential can be easily decomposed into distinct strain energy components, depending on different invariants of the deformation state [15-17]. The invariant-based energy formulation has the additional advantage of being independent of the choice of the basis reference system. Since experimental studies have shown interdependencies between distinct strain components, hyperelastic models with invariant-coupling, e.g., biaxial-tension [18] and tension-shear coupling

[19], have been proposed. A recent review on modelling coupling mechanisms in woven fabrics, with particular focus on invariant-based constitutive modeling is given in [20].

In the context of fiber-metal-laminate (FML) forming, Schäfer et al. [21] have introduced an invariant-based model, which considers both biaxial and normal-shear coupling, but not just for positive strains (i.e. tension), but also for negative strains. The additional consideration of compressive strains in biaxial and normal-shear coupling becomes necessary, if wrinkling is suppressed during forming, e.g. due to adjacent metal layers as in FML forming, but also due to blank holders or grippers [21]. Under such constrained condition in thickness direction, the bending and wrinkling behavior becomes insignificant compared to the complexly interacting components of the membrane behavior, namely shear, tension and compression [22,23].

In the present work, the invariant-based constitutive model presented by Schäfer et al. [21] is used to evaluate the significance of different strain couplings in forming simulation at component scale. For that purpose, the invariants that control the couplings in the different components of the strain energy densities are activated or suppressed in different combinations. Additionally, the effects are compared for strongly constrained forming of FML and less constrained forming of a pure fabric laminate. First, the material [21] is summarized with the most essential equations to indicate the interactions that are considered in the strain energy density components. Subsequently, the numerical test case, a tetrahedron geometry, and the applied materials are introduced. Finally, the forming simulation results are presented and discussed in terms of the coupling aspects and their significance on the forming results for varying forming conditions.

Hyperelastic Multiaxially Coupled Invariant-Based Constitutive Model

The hyperelastic invariant-based model, examined in this work for multiaxial coupling effects, was originally proposed and verified in our previous work [21]. For the sake of brevity, only the most important equations of the model are presented in the following. For more details, the reader is kindly referred to [21]. The invariant-based model was implemented in a user subroutine VUMAT for forming simulation in ABAQUS/EXPLICIT. Membrane and bending behavior are modeled in a decoupled way by superimposed finite membrane elements M3D3 and finite shell elements S3R. The membrane elements use the new VUMAT, while the shell elements use a bending idealization with section integration and deactivated membrane properties.

The basic assumption of the membrane model is the additive decomposition of the total strain energy density

$$W_{tot} = W_{TC}(I_4, I_8) + W_{S,TC}(I_{10}, I_4, I_8) \tag{1}$$

into a tension-compression component $W_{TC}(I_4, I_8)$ and a tension-compression-dependent shear component $W_{S,TC}(I_{10}, I_4, I_8)$. The components are based on invariants I_i of the right Cauchy-Green (RCG) tensor to be independent of the choice of the coordinate system.

Tension-compression coupling.

The tension-compression-dependent strain energy density component W_{TC} is composed of two components $W_{M,a}$ and $W_{N,b}$ according to the two fiber directions a and b, where the indices M and N represent tension (T) or compression (C). The composition depends on the current strain state:

$$W_{TC}(I_4, I_8) = W_{M,a}(I_4, I_8) + W_{N,b}(I_4, I_8) \tag{2}$$

with $M = T$ for $I_4 > 1$; $M = C$ for $I_4 \leq 1$; $N = T$ for $I_8 > 1$; and $N = C$ for $I_8 \leq 1$ [21]. The invariants I_4 and I_8 are the quadratic stretches in fiber directions a and b, respectively.

For tension, the strain energy densities are

$$W_{T,a}(I_4, I_8) = \widehat{W}_{T,a}(I_4) \cdot k_{TC,a}(I_8) \quad and \quad W_{T,b}(I_4, I_8) = \widehat{W}_{T,b}(I_8) \cdot k_{TC,b}(I_4) \tag{3}$$

with the uniaxial strain energy densities

$$\widehat{W}_{T,a} = a_a\left(\sqrt{I_4} - 1\right)^3 + b_a\left(\sqrt{I_4} - 1\right)^2; \quad \widehat{W}_{T,b} = a_b\left(\sqrt{I_8} - 1\right)^3 + b_b\left(\sqrt{I_8} - 1\right)^2 \tag{4}$$

where a_i and b_i are material parameters to be determined by unidirectional tensile tests. In Eq. (3), the influence of transverse strains is considered by the fiber-fiber-interaction factors

$$k_{TC,a}(I_8) = exp\ exp\ \left(c_a\left(\sqrt{I_8}-1\right)\right) + p_{min,a}\ \left(1 - exp\ exp\ \left(c_a\left(\sqrt{I_8}-1\right)\right)\right) \quad (5)$$

$$k_{TC,b}(I_4) = exp\ exp\ \left(c_b\left(\sqrt{I_4}-1\right)\right) + p_{min,b}\ \left(1 - exp\ exp\ \left(c_b\left(\sqrt{I_8}-1\right)\right)\right) \quad (6)$$

taking values greater than 1 for transverse tension and values between 0 and 1 for transverse compression. The tension-compression parameter $p_{min,i}$ is introduced to limit the influence of the transverse strains on the tensile strain energy density, which is particular important in the case of negative transverse strains [21]. $p_{min,i}$ can take values between 0 (complete strain energy reduction due to compression is possible) and 1 (no influence). In this work, $p_{min,i}$ is set to 0.75 for negative and positive transverse strains. Primarily, the biaxial coupling coefficient c_i provides a strictly monotonous increase or decrease of the strain energy density for positive or negative transverse strains, respectively. It can be determined by biaxial tension tests.

Compression is typically not considered in composite forming simulation, since the textile material can easily buckle and wrinkling can occur. However, under constrained conditions, e.g. by blank holders or adjacent metal layers, wrinkling is suppressed and the resulting multiaxial stress states may include in-plane compression. In this case, a linear stress-strain relation and no strain components coupling is assumed, leading to the compressive strain energy densities

$$W_{C,a}(I_4) = d_a\left(\sqrt{I_4}-1\right)^2 \qquad and \qquad W_{C,b}(I_8) = d_b\left(\sqrt{I_8}-1\right)^2 \quad (7)$$

where d_i are material parameters that are proportional to the compressive [21]. To date, there is no test setup available for a reliable characterization of the compressive stiffness, since the fabrics are prone to buckling. Therefore, the compression stiffness is assumed according to numerical parameter studies performed by Werner et al. [23].

Normal-shear coupling.

Shear is a prevalent deformation mechanism in woven fabrics, and thus, crucial for material modeling. According to the mesoscopic nature of the interwoven fiber bundles, pure shear can be divided in three zones with very low, medium and high shear stiffness. To capture this steadily increasing shear stiffness, a polynomial of third order is assumed for the stress-strain relation, which leads to the shear strain energy density

$$W_S(I_{10}) = \frac{1}{2}s_1 I_{10}^2 + \frac{1}{3}s_2 I_{10}^3 + \frac{1}{4}s_3 I_{10}^4 \quad (8)$$

where the shear invariant I_{10} represents the shear angle, and material parameters s_i can be determined by pure shear tests [21]. The shear strain energy density is increased for superimposed fiber tension and decreased for superimposed fiber compression. In the case of positive fiber strains, additional strain energy densities

$$W_{ST,a}(I_{10}, I_4) = \frac{1}{3}\ I_{10}^3\ s_{T,a}\ (I_4 - 1)^2\ ; \quad W_{ST,b}(I_{10}, I_8) = \frac{1}{3}\ I_{10}^3\ s_{T,b}\ (I_8 - 1)^2 \quad (9)$$

are added, where $s_{T,i}$ are material parameters that can be determined by combined tension-shear tests [21]. In the case of negative fiber strains, the shear strain energy densities (8) and possibly (9) are multiplied by exponential reduction factors

$$k_{SC,a}(I_4) = exp\ exp\left(s_{C,a}(I_4 - 1)^3\right); \qquad k_{SC,b}(I_8) = exp\ exp\left(s_{C,b}(I_8 - 1)^3\right) \quad (10)$$

with the compression-shear parameter $s_{C,a}$ to achieve a smooth asymptotic reduction of the shear strain energy density [21]. Thus, $k_{SC,i}$ can take values less or equal to 1, but always greater than zero.

Total strain energy density.

Combining the tension strain energy density (3) and the compression strain energy (7) with the shear strain energy density (8), influenced by fiber tension (9) or fiber compression (10), yields:

$$W_{\mathrm{tot}} = \begin{cases} W_{\mathrm{T,a}} + W_{\mathrm{T,b}} + W_{\mathrm{S}} + W_{\mathrm{ST,a}} + W_{\mathrm{ST,a}} & \text{for} \quad I_4 > 1 \text{ and } I_8 > 1 \\ W_{\mathrm{T,a}} + W_{\mathrm{C,b}} + \left(W_{\mathrm{S}} + W_{\mathrm{ST,a}}\right) \cdot \ k_{\mathrm{SC,b}} & \text{for} \quad I_4 > 1 \text{ and } I_8 \leq 1 \\ W_{\mathrm{C,a}} + W_{\mathrm{T,b}} + \left(W_{\mathrm{S}} + W_{\mathrm{ST,b}}\right) \cdot \ k_{\mathrm{SC,a}} & \text{for} \quad I_4 \leq 1 \text{ and } I_8 > 1 \\ W_{\mathrm{C,a}} + W_{\mathrm{C,b}} + W_{\mathrm{S}} \cdot \ k_{\mathrm{SC,a}} \cdot \ k_{\mathrm{SC,b}} & \text{for} \quad I_4 \leq 1 \text{ and } I_8 \leq 1 \end{cases} \tag{11}$$

Fig. 1 depicts total strain energy surfaces for selected shear angles I_{10}.

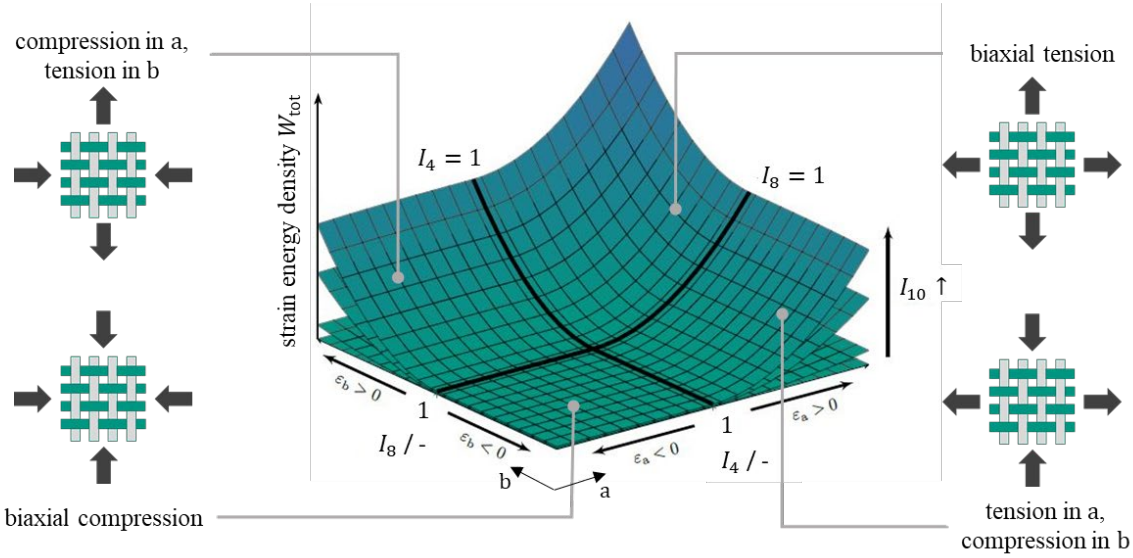

Fig. 1. Qualitative representation of the total strain energy density W_{tot} for selected shear angles I_{10} and with dependence on the invariants I_4 and I_8. The bold lines $I_4 = 1$ and $I_8 = 1$ represent superposition of uniaxial load in fiber directions b and a, respectively, with shear I_{10} [21].

Model verification.

The prediction capability of the new multiaxially-coupled invariant-based constitutive model was verified by means of tensile and bias-extension tests [21], partly with comparison to experimental results. The simulation results of these verification tests at coupon level revealed that the new model is capable to capture transverse coupling effects, i.e. transverse stresses in the case of constrained loading and, vice versa, transverse strains in the case of free loading [21]. This is in contrast to the ABAQUS built-in FABRIC model, which is not able to predict transverse effects. In Fig. 2, the effect of differently activated coupling mechanisms is illustrated at the example of a simple uniaxial tensile test, where the resulting transverse strain component ε_{22} is compared to experimental results from Cherouat and Bourouchaki [24]. The results in Fig. 2 and particularly in Fig. 2 (b) confirm that the biaxial normal strain coupling is responsible for correctly predicting the deformed fabric shape [21], which is clearly concave in transverse direction, as observed in experiments [24].

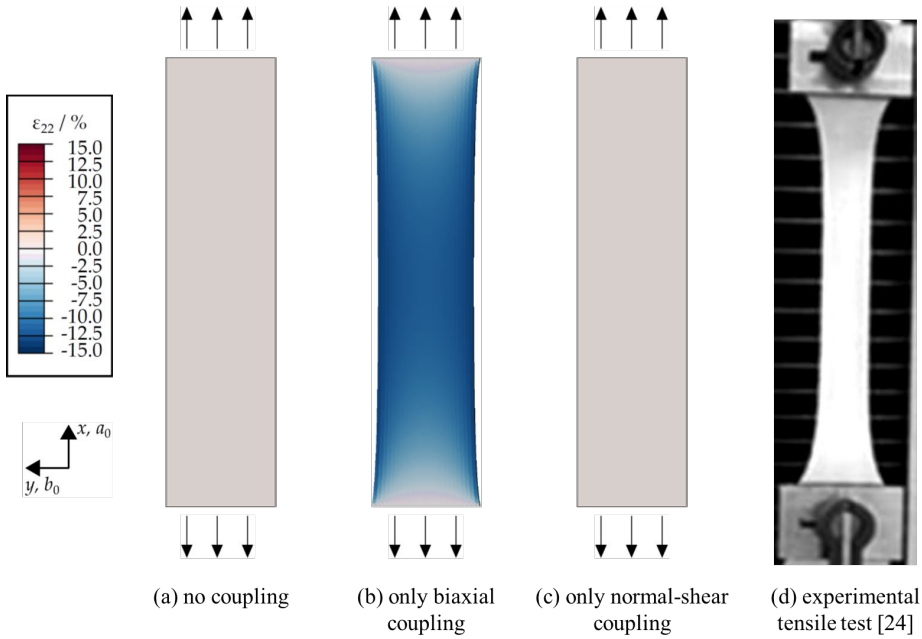

Fig. 2. Transverse strain component ε_{22} in a uniaxial tensile test for differently activated couplings [21].

Parametric Study on Individual Multiaxial Couplings and their Effects on Forming Results

To investigate the significance of the different tension-compression and normal-shear interactions, the proposed constitutive model is applied to forming simulation at component scale. Furthermore, forming simulation of a fiber-metal laminate (FML) is compared to forming simulation of a pure fabric to analyze the effect of different forming constraints on the multiaxial interactions.

Numerical test case and materials.

A 280 x 280 mm FML with three woven fabric layers and two metallic cover layers is formed into a tetrahedron shape, following the work of Yao et al. [19]. For comparison, three fabric layers without metal blanks are formed into the same geometry. In both cases, a blank holder pressure of 2 MPa is applied to prevent wrinkling. The inter-ply behavior between the rigid-body tools, the metal sheets and the fabric plies is modelled as COULOMB friction with the same friction parameters as used in [21]. The model setup including dimensions and boundary conditions is given in Fig. 3.

The metal material is steel DC04 and is assumed to behave elastic-plastic, as characterized experimentally and modelled by Werner et al [22,23].The fabric material is a plain weave fabric according to the industrial TWINTEX® TPP60N22P-060 with comingled glass/PP fibers, used and characterized by Komeili et al. [25]. The material behavior of the woven fabric is assumed nonlinear elastic according to the equations given in Section 2. The material parameters of the nonlinear models for steel and woven fabric are all the same as in our previous work [21], partly taken from the mentioned literature [22,23,25] and partly assumed. Failure and damage are not considered, neither in the metal sheets nor in the woven fabric.

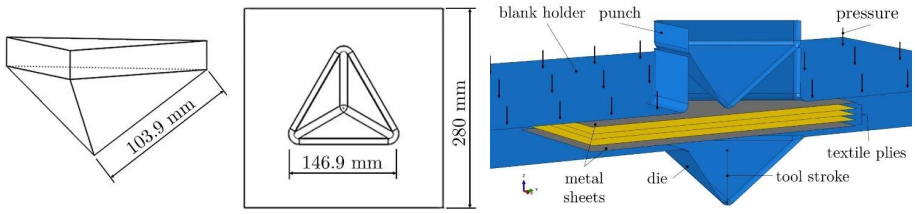

Fig. 3. Tetrahedron geometry: Dimensions and half FE-model of tool and FML.

Materials Research Proceedings 28 (2023) 357-366 https://doi.org/10.21741/9781644902479-39

It needs to be noted that the forming simulation example is a purely numerical test case to expose the effect of different interactions. Some of the material parameters are assumed, the blank holder pressure is comparatively high to avoid wrinkling and the forming simulation is conducted up to a rather large tool stroke with strains reaching values beyond failure or yielding. Nevertheless, the test case is chosen and suited to illustrate the importance of the distinct multiaxial coupling aspects for stronger and weaker forming constraints.

Results for FML forming.

Fig. 4 shows the distribution of the resulting shear angle γ_{12} for the deformed FML, where the Fabric material model available in Abaqus (Fig. 4a) is compared to four different configurations of the new hyperelastic material model with differently activated strain couplings.

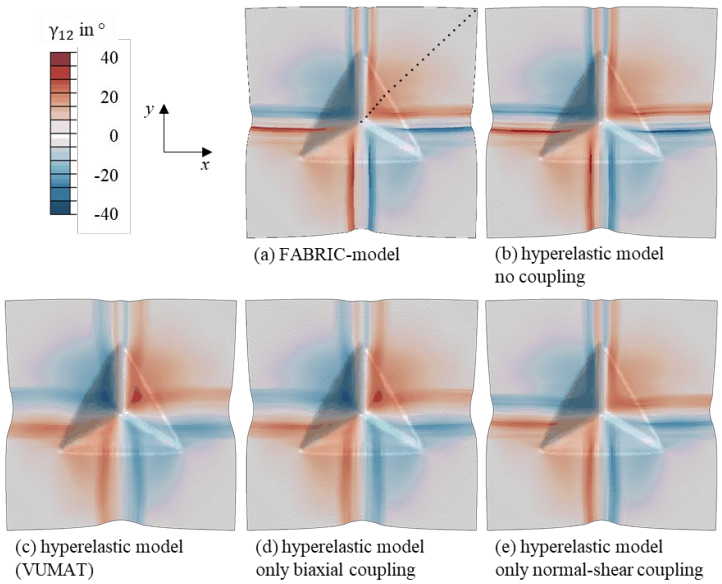

Fig. 4. Shear angles γ_{12} within the inner fabric layers of an FML with two metal blanks, formed into a tetrahedron geometry: Comparison of (a) the FABRIC material model and (b to e) four different configurations of the new hyperelastic material model with differently activated strain couplings.

The results reveal that the *normal-shear coupling* (Fig. 4e) has only marginal effect on the forming results, since the shear angle distribution is comparable to the *FABRIC model* (Fig. 4a) and the *hyperelastic model without coupling* (Fig. 4b). In contrast, the *fully coupled hyperelastic model* (Fig. 4c) and the model with *biaxial normal coupling* (Fig. 4d) lead to considerably higher shear angles. The same conclusion can be drawn from Fig. 5, where the shear angle is plotted along the dotted line in Fig. 4a and is compared for all five configurations. An explanation for the strong influence of *biaxial normal coupling* is the presence of high normal stresses due to the encasing metal layers that hinder formation of wrinkles and promote deformation in shear. Interestingly, just a minor effect of normal-shear coupling can be observed by the green *only normal-shear coupling* curve in Fig. 5. It is located just slightly below the gray *no-coupling* curve, because the higher tensile strains partly impede shear deformation. The same is observed for the *fully coupled VUMAT* model, which is slightly below the *only biaxial coupling* curve that neglects normal-shear coupling.

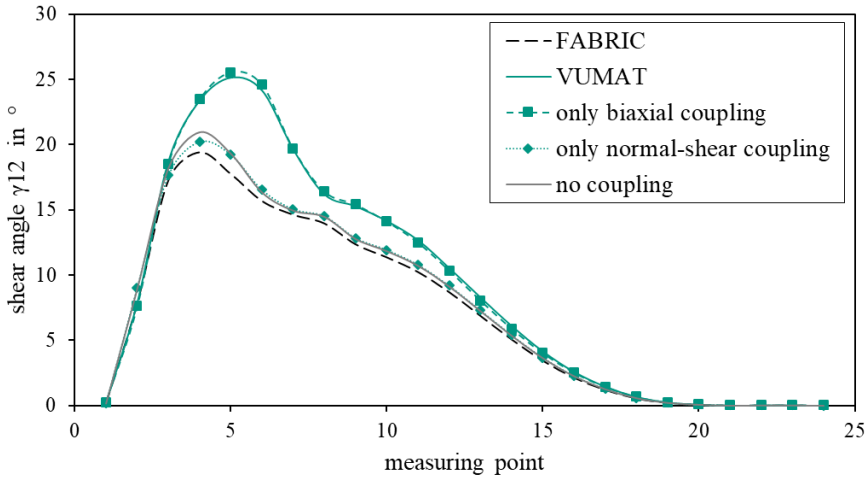

Fig. 5: Shear angle γ_{12} within the formed inner fabric layers of an FML along the dotted line in Fig. 4a: Comparison of the FABRIC material model and four different configurations of the new hyperelastic material model.

Results for pure fabric forming.

To investigate the relevance of biaxial and normal-shear coupling for weakened forming constraints, forming simulations are performed for three fabric layers without metal blanks. Furthermore, the friction coefficient between fabric and tool is smaller than the friction coefficient between fabric and metal sheet, which further reduces the resistance against deformation in the fabric. These modifications are implemented to facilitate shear deformation and material draw-in, and thus, to reduce normal stresses in fiber direction.

The resulting shear angles γ_{12} of the deformed three fabric layers are depicted in Fig. 6. Again, the ABAQUS/EXPLICIT built-in FABRIC model (Fig. 6a) is compared to four configurations of the new hyperelastic material model with differently activated strain couplings. As Fig. 6 reveals, the influence of interacting strain components on the resulting shear deformation is much smaller than in the more strongly constrained FML forming case. This conclusion is again confirmed by Fig. 7, where the shear angle is plotted along the dotted line in Fig. 6a. Again, the results of the fully coupled hyperelastic model (Fig. 6c) and the biaxial normal coupling (Fig. 6d) are close together and are above the results of the other configurations, but the difference between the curves is much smaller than for the constrained forming results shown in Fig. 5. Overall, the shear deformation is, as expected, larger than in the case of FML forming with metal blanks, which results from reduced friction, smaller normal strains and less coupling effects.

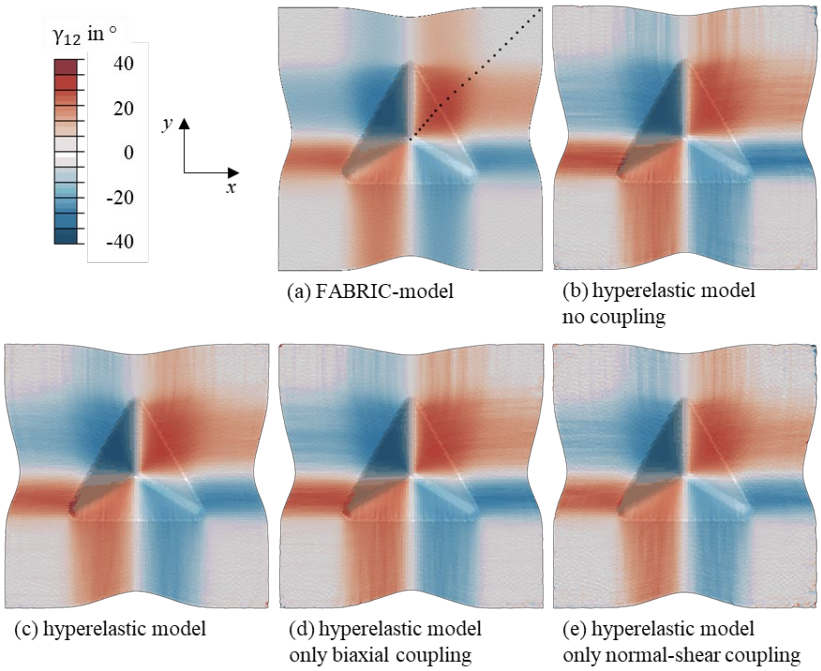

Fig. 6. Shear angle γ_{12} within a pure woven fabric with three fabric layers, formed into a tetrahedron geometry without metal blanks: Comparison of (a) the FABRIC material model and (b to e) four different configurations of the new hyperelastic material model with differently activated strain couplings.

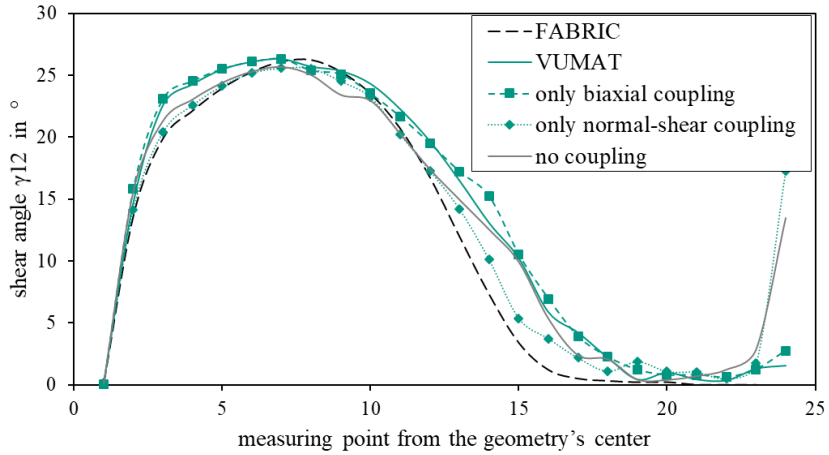

Fig. 7. Shear angle γ_{12} along the dotted line in Fig. 6a within the formed pure woven fabric: Comparison of the FABRIC material model and four different configurations of the new hyperelastic material model.

Summary

Forming simulation at component scale was performed to evaluate the significance of individual coupling effects in constitutive modeling of the fabric plies. For this purpose, a previously proposed invariant-based constitutive model, which includes biaxial and normal-shear coupling for positive and negative strains, was examined at the example of forming simulation to a tetrahedron. To compare the influence of strong and weak forming constraints on the multiaxial coupling effects, a fiber-metal laminate (FML) and a pure fabric laminate were formed to the tetrahedron geometry. Based on the simulation results, it could be shown that biaxial coupling has a significant effect on the forming results, if forming is constrained by adjacent metal layers. In the case of free or almost free draping conditions, this coupling effect is much smaller.

Nevertheless, blank holder forces also cause forming constraints that can partially prevent wrinkling and promote the importance of biaxial strain coupling. The results also revealed that biaxial coupling has a larger influence on the forming results than normal-shear coupling.

Abstract. Hand layup is still appreciated in modern industry for processing composite materials. Since is a manual process, reaching a standardization is impossible and this limits the applicability of this process. AFP and ATP offer a good level of automation and standardization, but both these processes are effective on simple-shaped surfaces. The conventional manufacturing processes have been increasing their level in automation thanks to the implementation of tooling machines and software that are able to automatically generate routes and tasks for manufacturing of a desired component. The goal of this research project is to take a step forward in the evolution of CAE software for tasks and routes management of the robotic layup process. In this paper a script implemented with MATLAB is described. The implemented script can automatically generate movements for robotic layup given a desired mold: starting from a user-given surface, the surface can be divided into sub-surfaces, and the software can automatically generate paths for each part of the surface according to the manual techniques studied by professional laminators.

Introduction

Advantages properties of fiber reinforced polymers (FRPs) have promoted their wide usage in several applicative sectors, ranging from aerospace, automotive, through to naval and construction industries [1] to improve the performance and reduce the weight of their components [1–14]. Advanced FRPs are multi-phase materials made of continuous reinforcing fibers, oriented in one or more specific direction, embedded within a polymeric matrix.

Nevertheless, despite of high specific strength and stiffness, corrosion resistance, and design flexibility, FRPs are affected by some drawbacks limiting their further application. As a multi-phase material, FRPs have an anisotropic behavior dependent on reinforcements' orientation [6]. This leads to excellent performance under longitudinal loading, but scarce (matrix dependent) behavior in case of transverse loading. In most lightweight composites, matrix is constituted by polymeric materials, both thermosetting or thermoplastic resins, whose main roles are to keep together the fibers, transfer and distribute loads, and protect them from the atmospheric agents. To improve the material properties and reduce anisotropic behavior, the most used strategy is to lay the fibers plies in different directions [15].

Hand layup has been the earliest manufacturing technique used for shaping composite products [16]. Also classified as a no-industrial process, this technique offers the advantage of low-cost suitability for the production of small batches. But as a manual process, the hand layup carries all the problems lead by the operator actions. From a quality point of view, this means that it is impossible to reach a standardization of all the pieces produced [4]. To improve the repeatability and reduce the human intervention, other manufacturing processes have been developed such as, among others, liquid composite molding, pultrusion, filament winding. Through the years, most of the manufacturing processes to fabricate fiber-reinforced composite products are based on conventional techniques such as the autoclave. But the demand for automation is rapidly increasing in the industry in order to achieve lower costs, repeatability, and reduction in material scraps [5].

Recently, the application of automated manufacturing to composite layup led to the development of an innovative process, namely robotic composite layup [5], based on the replacement of human operations by one or more opportunely programmed and eventually collaborative robots [17].

During past few decades, advancements in automated composites manufacturing processes such as, automated fiber placement (AFP) and automated tape placement (ATP) (or other commonly known name of automated tape layup, ATL) technologies have revolutionized the fabrication of aerospace components. Major aircraft manufacturers have been utilizing automated techniques for many years now in their production lines to rapidly manufacture their flagship aircrafts such as Boeing 787 and Airbus A350 XBW, containing more than 50% composite parts by weight [7], [8]. Compared to other aerospace manufacturing techniques e.g., resin transfer molding (RTM), AFP and ATP systems are the most advanced and commercially used automated machines for large-scale aerostructures manufacturing. In terms of functionality, both AFP and ATP systems are very similar even though both methods use different approaches to fabricate specific components using resin pre-impregnated fabrics (commonly known as prepregs) [9]. One of the major differences between the two processes is that the AFP machine places multiple narrow pre-impregnated fiber tows whereas the ATP machine lays up larger and wider unidirectional tapes [9], [10]. Instead of conventional robots, both AFP and ATP use machine tool-based processes that can significantly reduce the cost of composite parts, especially large components, main wing structure, ribs, fixed trailing edge, nacelle structure, spoilers, flaps, ailerons, and tail cones [5]. Despite the benefits in terms of automation and reduced human involvement, these two processes are expensive: they are effective only for large parts with low to medium geometric complexity and have been implemented in those industrial fields capable of justifying high capital and operating costs. AFP/ATL are therefore technically and economically incompatible with the production of small to medium-sized components or complex-shaped parts, or with production volumes that cannot justify the usage of such expensive systems. In such situations, manual processes are needed leading to variability in part quality depending on the experience of each operator [18]. In this context, the robotic layup process has been developed to offer a high level of automation and standardization, reducing human involvement while at the same time offering the ability to process even complex shapes. Many efforts have been made in recent years to improve robotic processes and make them free from the actions of operators. Most of the knowledge about prepreg layup has been developed from the personal experience of professional laminators, who have implemented and collected strategies and techniques over the years to improve the layup process and reduce time and defects. Transferring this knowledge to a robotic process requires the constant attention of a professional laminator when coding robotic movements. The goal of this research project has been to implement a code capable of automatically handling the laying of a complex shaped surface. Another constraint that was considered during this study is to plan the entire layup of the mold surface using only one properly equipped robotic arm and clamp system. As demonstrated in previous work, processing the layup with two or three collaborative robots can certainly provide more accurate robotic handling as well as can promote the success of the process, but all this make the process complex and economically disadvantageous.

The implemented algorithm is able to handle a set of strategies and techniques on different mold geometries. The experience of professional laminators was translated to be used with a robotic arm equipped with a specific end-effector.

Materials and methods

In order to collect and organize the techniques implemented by professional laminators, CAE software has been used to implement an algorithm to manage the surfaces of each mold analyzed and manage layup strategies. The software used has been MATLAB. "Gmsh," an open-source CAE software widely used for FEM analysis, has been used for mesh generation.

Complex-shaped molds have been used during testing to make the experimental campaign as generalizable as possible. The three molds used for the test campaign have been designed to be a workbench for the implemented algorithm. They have different shapes and require different layering strategies. They include planes with different inclinations, curved parts, fillets, and spherical parts. Moreover, they also include concave and convex parts that require specific steps to be processed.

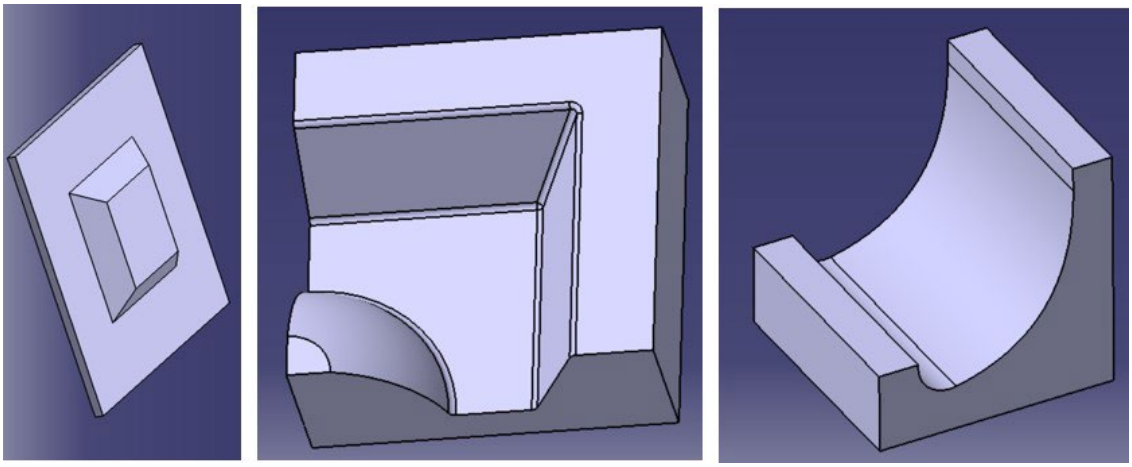

Fig. 1. The molds used as workbench

As a collaborative robotic, a Comau Smart SiX 6 has been used, which is a robotic arm with 6 degrees of freedom (DOF). All the simulations are performed in MATLAB environment and the robotic process is simulated thank to Robotics System Toolbox add-on. The information regards the robot is included in the URDF model which uses the XML standard to describe a robot which includes kinematic and dynamic behavior, visual representation, and collision model.

For this test, the end-effector used is composed of three terminals: cylindrical roller for flat surfaces, a profiled roller for fittings and small radius curvatures, and a punch for consolidating prepreg in corners and tight parts. The cad models of the end-effector and the mold have been made with CATIA V5 CAD software, loaded into MATLAB environment, and then the end-effector linked to the robotic arm model and mold placed in desired position inside the virtual working area of the robot.

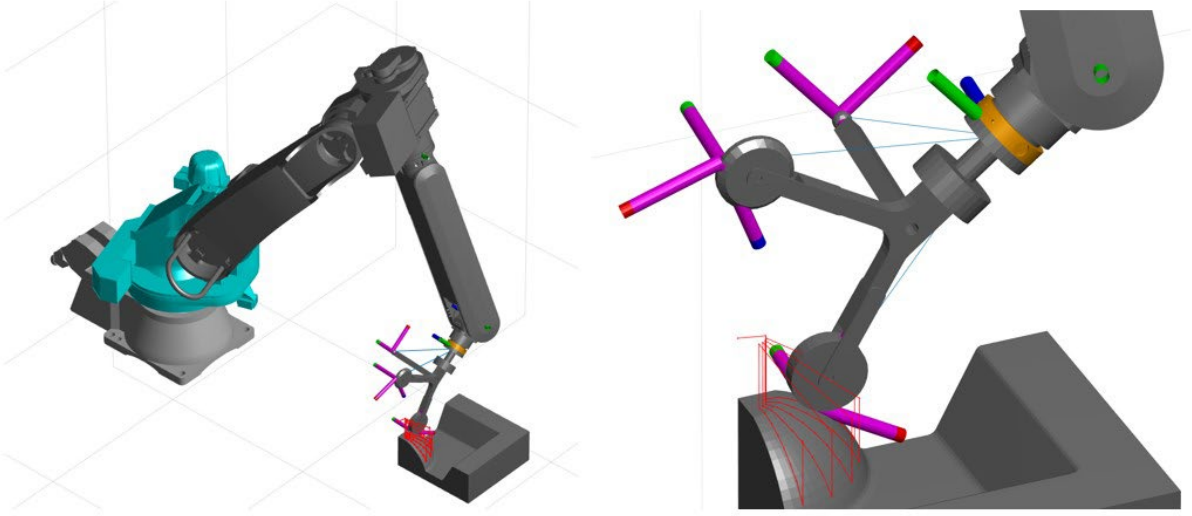

Fig. 2.The robot, the end effector, and a mold imported in MATLAB environment

The implemented algorithm is able to recognize the different parts of the surfaces of a mold and apply the correct strategies for the layup phase.

The process begins with loading the mesh of the mold surface. Triangles have been chosen for the elementary entities of the mesh. The mesh includes information about the coordinates of the points and how they are connected together to form the triangles. Cleaning the surface from unnecessary points is the first step: the mold mesh also includes sides that are not required for layup. The sides of triangles were used to identify the normal vector of each elementary surface: the vector product of two sides gives a vector directed to the normal of the plane identified by the triangle. By placing this vector in the center of the triangle and considering only its modulus, the normal vector of the triangle has been obtained. The normal vectors are then used to identify the sub-surfaces that compose the mold surface. An algorithm has been implemented that can analyze the orientation of the normals and group triangles with the same orientation in space and collect them into an array. At this point, the mesh, mesh nodes, and triangles are ready to be used in the next step, where paths are defined according to the strategies of experienced laminators.

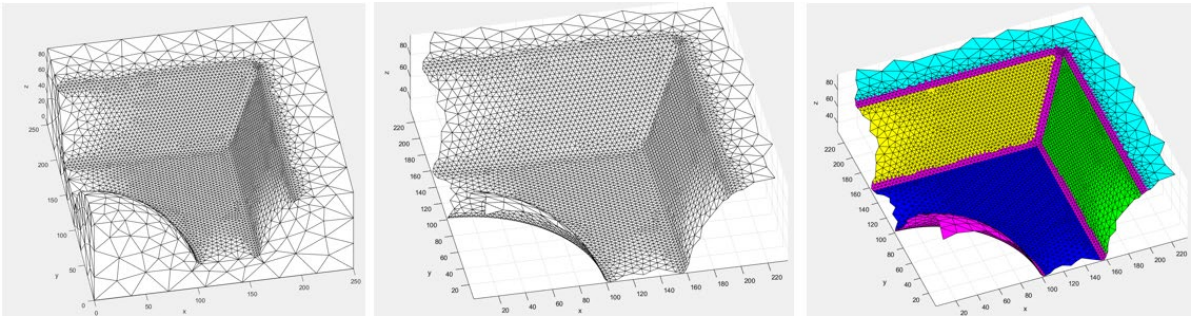

Fig. 3. The mesh of a used mold (left); the same mesh cleared of elements not to be processed (center); the mesh divided into sub-surfaces (right)

The strategies have been translated into routes and tasks to be performed in a specific situation. Starting from a literature review, the approaches used during the experimental trials have been collected. Following the most common scenarios are listed with the approaches used in previous works.

The main human techniques have been listed in the work of M. Elkington et al. “Hand layup: understanding the manual process” [19]. Eight different techniques used in different scenarios are described in this paper: one handed guiding; two handed guiding; manual folding; hoop shearing; double-tension shearing; tension-secured shearing; tension and sticking; mold interaction shearing. Some of these techniques involve both of the operator's hands. But in most cases, careful selection of a prepreg clamp system or choice of starting point can enable the robot to replicate the same pressure applied by the operator.

An important aspect is the definition of the boundaries of each sub-surface. These boundaries are defined by the user with a manual selection of points. In this way, it is possible to define how the parts of the surface are connected to each other and their relative inclination.

Another challenge is the choosing the areas of the sub-surfaces to process first. The friction between mold and prepreg is very high (and even higher between two consecutive layers). For this reason, starting layup from the correct part of the surface is crucial to the good result of the process. For example, if the surface to be treated has a concave shape, starting with the upper parts of the mold with the idea of then moving to the lower areas may lead to insufficient prepreg to cover the lower part, resulting in bridging defects (Fig. 4A).

The same could happen with an edge that joins two or three sub-surfaces with different inclinations. In these areas, depending on the order of the processed surfaces, two different

Materials Research Proceedings 28 (2023) 367-374 https://doi.org/10.21741/9781644902479-40

scenarios could occur: an excess of material, which could lead to wrinkling; or a deficiency of material, which could lead to bridging [20].

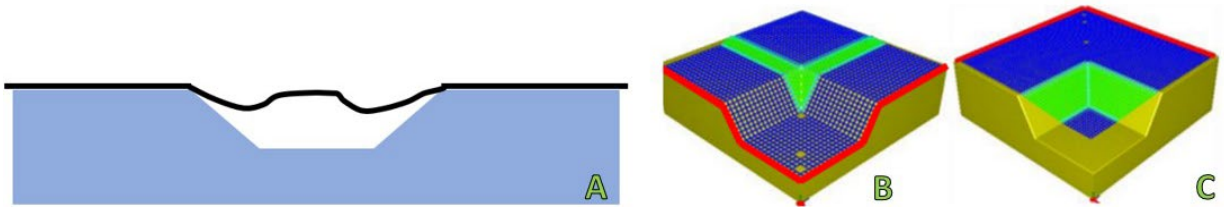

Fig. 4. On the left (A), an incorrect choice of starting point that led to the bridging defect; on the right, a mold processed in two ways: in the first (B), the process began by consolidating the lower part (red lines); the second (C) began by consolidating the upper part. The green areas represent the portions of prepreg where the defect occurs.

The Fig. 4B and Fig. 4C show that different starting positions lead to the two situations mentioned. In case shown in Fig. 4B, the layup has started consolidating the lower part and then moving to the upper part: the green part represents the area where there is excess material, which led to wrinkles. In case shown in Fig. 4C, the layup has started from the upper part: the green part is not enough to cover the remaining area, which led to a bridging defect.

To avoid the problems mentioned above, the algorithm is able to study the shape of the surfaces and whether there are any concave or convex parts. If so, the software implements routes starting from the bottom of the concavity or the top of the convexity: the layup will then begin by laying the material starting from the proper sub-surface. In this way, the amount of prepreg will be sufficient to cover that part of the surface avoiding defects such as bridging.

Several cases are included in the algorithm that are based on the experience gained during previous work and the experience of professional laminators. The algorithm is able to understand the inclination or curvature of sub-surfaces. For each subsurface, the shape of the surrounding parts is detected. Through the analysis of the normal vectors of the triangles and the coordinates of their centers and nodes, it is possible to understand whether a subsurface is located, for example, at the bottom of a concave mold. In this way, it is possible to determine the most appropriate sub-surface to start layup.

After sticking the first subsurface, the algorithm is programmed to start consolidating the nearest fittings, and routes are designed starting from these edges. Moreover, processing a subsurface requires gradual movement. For this reason, each part of the surface is processed in steps: movement along the entire length of the subsurface is avoided and steps are chosen according to the extension of the surface and the size of the tool used.

Results and discussion

The implemented algorithm can process the given mesh elements and generate specific routes based on the experience of professional laminators. From the experiences gained in the works mentioned, starting on the proper side of the mold surface is critical to achieving a good layup. For the given molds, the algorithm proposed the following sub-surface sequence (Fig. 5).

In mold "a," the algorithm chose to start from the top and then move down toward the base of the mold. The reason for this choice is that the elements of the other sub-surfaces gradually go down without a subsequent ascent. In mold "b," which is probably the most complex, the algorithm chose to start at the bottom of the mold, then consolidate the neighboring fillets, and then work its way up. In this case, the chosen part represents the bottom of a cavity. Therefore, in order to have enough material to cover the other parts, the streaking action of the end effector on the prepreg must start from that surface. In the "c" mold, on the other hand, there are two planes at different heights joined by a concave surface. In this case, the best solution would be to start from one of

the two planes by gradually moving upward. The algorithm chose to start from the higher plane because this choice is shared with other cases contained within it. In all these cases, pre-shearing prepregs can reduce the occurrence of defects. After consolidating each subsurface, the algorithm generates instructions to consolidate neighboring fittings before moving further. The solutions shown are just a proposal derived from a series of cases included in the implemented algorithm. Of course, the end user can control these sequences by clicking on the mesh elements: after rejecting the proposed solution, the software asks the user to select the sub-surface where they want the layup to begin.

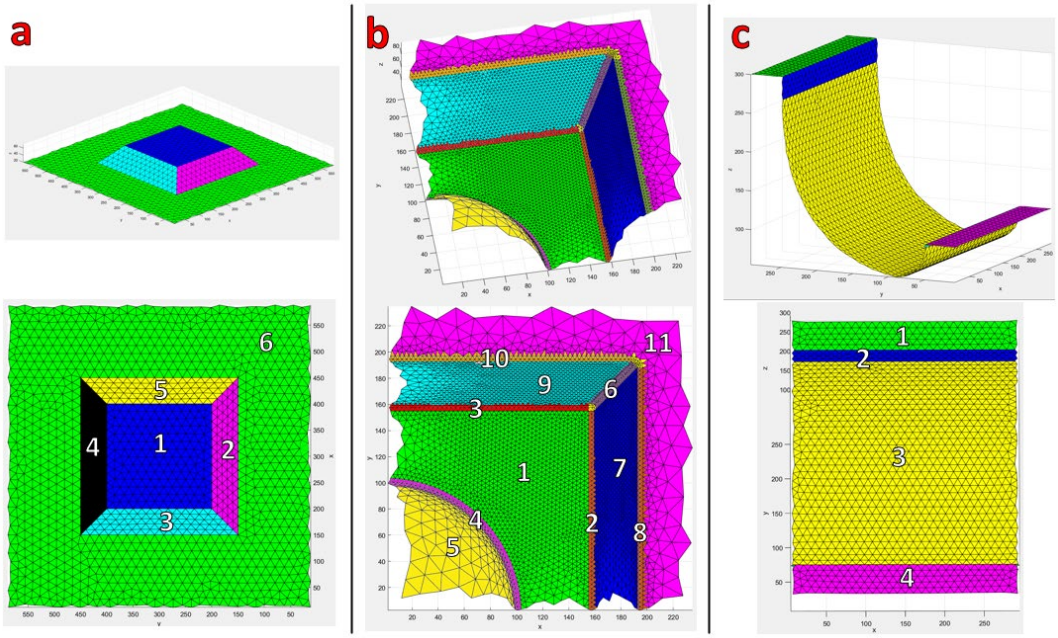

Fig. 5.The meshes of the molds in which the order of layups for each mold is indicated.

It is also possible to introduce new cases to increase the range of different recognized scenarios.

Summary

The implemented algorithm makes possible the automatic handling of mold meshes in order to design their layup. Since automatic actions have been implemented, the design time for an assigned mold to be processed is reduced: trajectory calculations are automatically performed by the software, which also generates the correct positioning of tangent, normal, and binormal vectors. The proper management of these angles prevents the occurrence of unwanted collisions during layup. The operator who now sees a routing solution offered for the end effector is still required to perform a check, thus a simulation of the process. But the time to calculate the positions of the mentioned vectors has still been reduced.

This results in faster reconfiguration and adaptability of the used resources, i.e., the robotic cell, and also reduces its actual utilization time.

Clearly, the end user is free to reprogram the layup to his liking.

Keywords: Mesoscopic Defects, Buckles, Gapping, In-Plane Pull-Out, Woven Fabric

Abstract. The manufacturing of composite materials can be ensured by several industrial processes, like Liquid Composite Molding (LCM). This technology is used to produce composite parts with complex geometries because it provides a very good compromise in terms of repeatability, production rates and cost. During the forming phase of an LCM process, a fabric can be formed by highly double curved punch geometries where it could be submitted to several deformations and mechanical stresses that lead to the appearance of different types of defects: buckles, gapping, in-plane pull-out, etc. In order to understand their phenomenology, different types of defects were generated inside samples of glass and carbon fabrics so as to understand their mechanisms of appearance. This work focuses on the phenomenology of appearance of forming defects and the definition of experimental parameters allowing the generation of calibrated defects, such as buckles and gapping, inside samples of glass and carbon woven fabrics. The definition of these parameters allows the manufacturing of composite parts with calibrated defects, which in turn helps to define the influence of these defects on the mechanical behavior of composites materials.

Introduction

Composite materials are broadly used in several industrial fields, thanks to their excellent mechanical properties. They are usually used to substitute metallic alloys due to their higher strength, lower weight and improved service life. Numerous manufacturing processes of composite materials are known in the industry [1] where the choice of a specific process depends on various criteria. The Liquid Composite Molding (LCM) process is among the most interesting processes to produce composite parts with complex geometries. In addition, this process is appropriated for the forming of fiber-reinforced polymeric composites due to its economic advantages and the capacity to produce high performance parts [2]. An LCM process has two main phases: the forming of a fabric and the injection of a liquid resin inside the formed fabric. Many research have focalized on the forming phase overall the past years [3,4] because during this phase, the fabric is subjected to several stresses that induce various deformation mechanisms such as stretching and compression, in-plane and out-of-plane bending, and shearing [5,6]. These mechanisms often lead to the appearance of several forming defects at the macroscopic scale (wrinkles) [7] and the mesoscopic scale (buckles, in-plane pull-out, and gapping) [8,9].

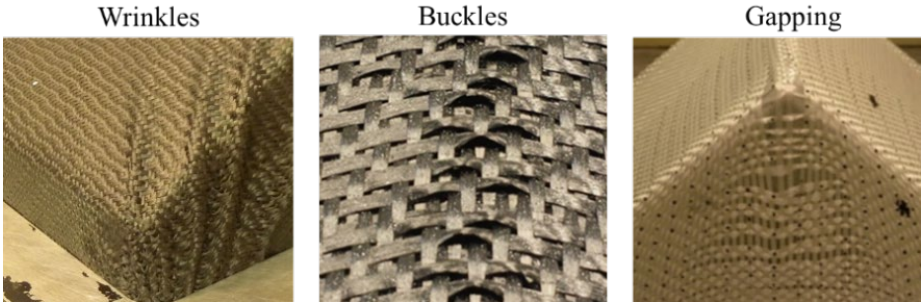

Fig. 1. Forming defects of different types [9].

The appearance of forming defects leads to a local heterogeneity of the preformed fabric and might impact the mechanical properties of the final composite parts. Hence, the understanding of the mechanisms of appearance of the defects seems to be crucial to avoid them or at least to reduce their magnitude. Wrinkles defects were widely studied in various studies [7,10,11]. Shanwan et al. [12] have proposed several experimental strategies to reduce their appearance or sometimes even completely avoid them. As for the mesoscopic defects, they are still not completely understood. In an interesting field of investigation, C. Tephany et al. [13] developed an experimental bench to study the buckle defects during a complex forming of a flax woven fabric. They used Digital Images Correlation (DIC) technique to accurately measure the buckle's height. Allaoui et al. [14] studied the effect of the inter-ply sliding on the buckle's appearance during the forming of woven fabrics on a prismatic tool. Capelle et al. [15] designed a specific blank holder system in order to optimize the preforming process parameters during complex geometry forming. To continue these investigations, Cruanes et al. [16] have focused on the impact of buckle defects on the mechanical properties of composite materials, specifically on the fatigue behavior. Their results showed that the orientation of buckles with respect to the tow's paths can highly reduce the mechanical performance of the composite parts. M.M. Salem et al. [17] investigated the influence of the cohesion of different woven fabrics on the reduction or prevention of the appearance of sliding defects of some vegetal and synthetic fabrics. On the other hand, Labanieh et al. [18] held an experimental and analytical research to study the mechanisms of appearance of gapping defects during the preforming of a woven carbon fabric by a hemispheric shape. Their results have demonstrated the strong effect of shear stresses and yarn tension on the appearance of gapping.
Further investigations of buckles and gapping defects were carried out by Shanwan et al. [9,19] to understand and analyze these defects in depth. In order to acheive this goal, they developed a new experimental and polyvalent machine which makes it possible to produce different types of calibrated defects within samples of woven fabrics. Due to this machine, it is possible to ensure two main goals: the first one is to understand the mechanisms and criteria of appearance of forming defects while the second goal aims to produce composite parts from fabric samples containing calibrated defects, generated by the machine, of different types and amplitudes. The produced composite samples could be tested and compared with composite samples without defects. Due to this machine, the defects are generated under the same experimental parameters and the same boundary conditions that could be found during the forming phase of an LCM process. In this work, we present a new analysis of buckles, in-plane pull-out, and gapping defects, which is more developed than the one described in [9,19] where the experimental analysis was only focalized on gaping and buckles defects without referring to the in-plane pull-out. In addition, this study has experimentally approved the assumption of the previous studies [9,19] (i.e. the concomitance between the gaping and the buckles defects).

Material and Experimental Procedure

Two types of fabrics were used for this study: the first one is a balanced plain weave glass fabric (taffetas), produced by Chomarat Company and denoted G-WEAVE 600P. This fabric has an areal weight of 600 g/m^2 ± 5% and a thickness of 0.55 mm. The yarn width is 3 mm and the average spacing between two yarns is 1 mm. The yarn count is 600 Tex for both the warp and the weft directions. The second fabric is a 2.5D interlock carbon fabric, denoted G1151®, produced by Hexcel company. It has a surface weight of 630 g/m² and a unit cell of 6 warp yarns and 15 weft yarns, distributed on three levels. The tested samples are cut as a plus (+) form of 300x300 mm^2 with a usable central area of 100x100 mm^2, as shown in Fig. 3 and Fig. 4.

The machine used in this work is equipped with four brushless AC servo motors. Each motor commands one machine axis individually, either by a force command, or by a displacement command with different speeds. Each axis is also equipped with a displacement sensor, a force sensor and two position sensors to define the beginning and the end of its stroke. In order to record the experimental parameters during the experiments, a special LabVIEW program was developed to command the machine and to ensure the acquisition of different parameters, such as the tensile forces, the speed and the position of each axis. The bench is also equipped with a digital camera and an interferometer (Gocator 3100) placed above the sample during the test. The interferometer is a three-dimensional Digital Image Correlation (DIC) system that progressively measures the height of buckles during the experiments. The acquisitions of the camera and the interferometer are adjustable to be asynchronized in order to have two information sources about the sample evolution. Fig. 2 shows an example of such acquisitions whereas Fig. 3 illustrates a sample on the bench, where the lower longitudinal and the two transverse sides of the sample are clamped by a defined and adjustable compression. However, few tows from the upper longitudinal side are completely clamped by a tight fixation and pulled at a constant speed up to a defined displacement (in-plane pull-out in the direction of the yellow arrow in Fig. 3). This displacement simulates the same movement of the tows in contact with the punch during the forming phase of an LCM process. During the experiments, the forces and the displacements of each axis are continuously recorded by a LabVIEW program and synchronized with a simultaneous acquisition of images of the interferometer and the camera.

Results and Discussion

The results of this section confirm a previous expectation that we assumed during the studies [9] and [19] about the concomitance between buckles and gapping defects. In addition, this study presents a detailed investigation to better understand the interactions between the displacement of the longitudinal yarns and the deformation of the transverse yarns and its influence on the possible appearance of buckles and gaping defects. These investigations are explained by means of Fig. 4 and Fig. 5. As shown by Fig. 5, the displacement of the pulled longitudinal yarns leads to a displacement of the transverse yarns due to the friction between the two networks of the fabric yarns. Subsequently, an in-plane bending of the transverse yarns takes place in the useful area of the sample, whereas the parts of the same yarns, which are clamped between the transverse jaws, do not rotate because of the static friction between the metal and the yarns. When the traction force, transmitted to the transverse yarns, overcomes the static friction between the metallic jaws and the fabric, the transverse yarns between the jaws rotate and continue their an in-plane bending.

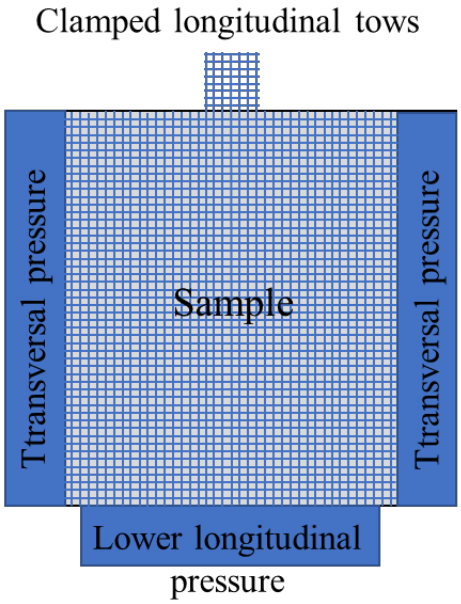

Fig. 4. Form of the prepared samples before the experiments.

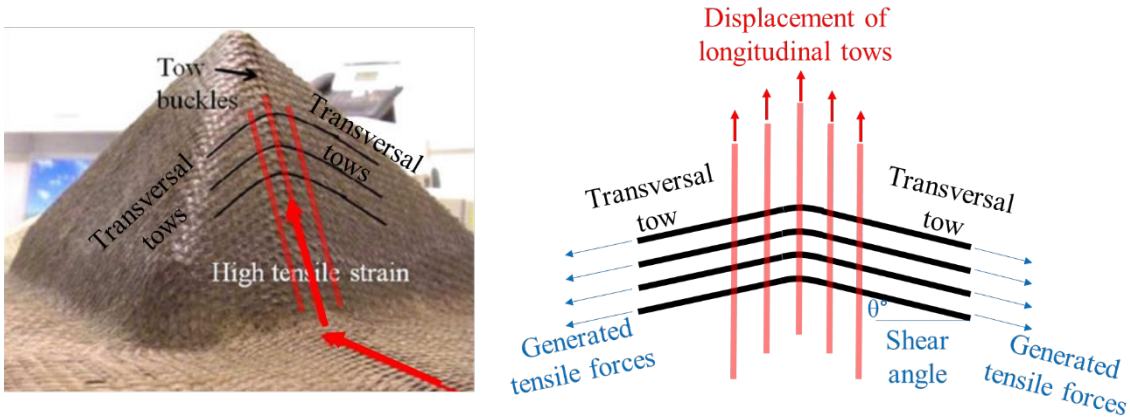

Fig. 5. Phenomenology of appearance of the forming defects [9].

Depending on the bending stiffness of the yarns, the in-plane bending continues until a defined shear angle where it stops and becomes an out-of-plane bending of the transverse yarns. It is at this moment that the buckle defects appear. Then, the amplitude of buckles increases until the end of the first phase which ends at the peak of the curve force/displacement, as shown in Fig. 6. At this moment, the traction force applied on the yarns overcomes the static friction between the fabrics yarns (cohesion) where a relative sliding of the longitudinal yarns takes place with respect to the transverse ones. This moment announces the beginning of the second phase (in-plane pull-out). Depending on the homogeneity of the transverse pressure, applied on the transverse yarns, and/or the regularity of the sample thickness, the displacement of the longitudinal yarns provokes either a simple pull-out of these yarns from the fabric or a displacement of some transverse yarns with the pulled longitudinal ones with respect to the other transverse yarns. In this last case, we observe the formation of some gaps inside the sample which lead to the appearance of weave pattern heterogeneity defects, sometimes called decohesion or even gapping defects. The second phase is also characterized by many oscillations due to a stick-slip phenomenon. Finally, the third phase of the curve starts at the beginning of the loss of contact between the lower part of the sample and the metallic jaws that clamp it. This phase continues until the sample is no longer held between the jaws.

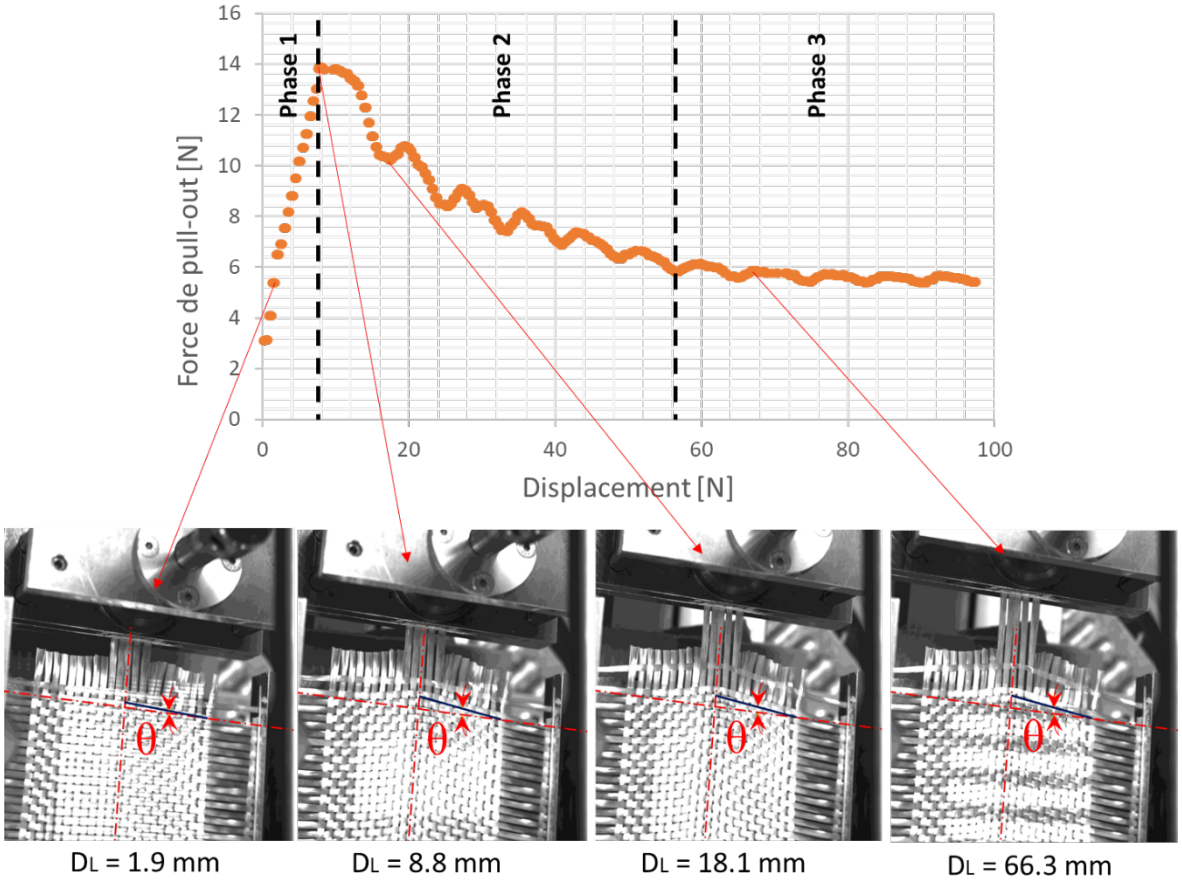

Fig. 6. Different phases of preforming defects appearance.

The above-mentioned phenomenology was verified by a measurement of displacements of the transverse yarns, directly executed on the recorded images (Fig. 6), by means of the ImageJ software. The measurements showed that the shear angle θ° increases during the phase 1, up to 13°, then it remains constant during the other two phases. The measured values are presented in

Table 1, where D_L and D_T respectively refer to the displacement of the longitudinal and the transverse yarns.

Table 1. Relationship between the yarn's displacements and the shear angle.

Phase 1			Phase 2	Phase 3
$D_L = 0$	$D_L = 1.9\ mm$	$D_L = 8.8\ mm$	$D_L = 18.8\ mm$	$D_L = 66.3\ mm$
$D_T = 0$	$D_T = 2.1mm$	$D_T = 5.2mm$	$D_T = 5.2mm$	$D_T = 5.2mm$
$\theta° = 0°$	$\theta° = 8.6°$	$\theta° = 13°$	$\theta° = 13°$	$\theta_s = 13°$

Next, the appearance of defects was investigated on two types of fabrics, as a function of four experimental parameters: the number of the pulled tows, the transverse compression, the longitudinal compression, and the speed of displacement of the pulled longitudinal yarns. Each parameter was tested at three different values with a repeatability of three experiments per value while the other parameters were fixed for each tested parameter. In total, 36 experiences were carried-out for each type of fabric (4 parameters * 3 values * 3 repeatability). Fig. 7 shows an example of one set of such experiments, carried-out on a cross glass fabric sample, where the transverse pressure was set at 0.05, 0.10, and 0.15 bars whereas the other experimental parameters were fixed as follows: The lower longitudinal pressure = 0.05 bar, The speed of displacement = 1 mm/sec, and the number of pulled tows = 7. The choice of these parameters was selected as those of a forming process.

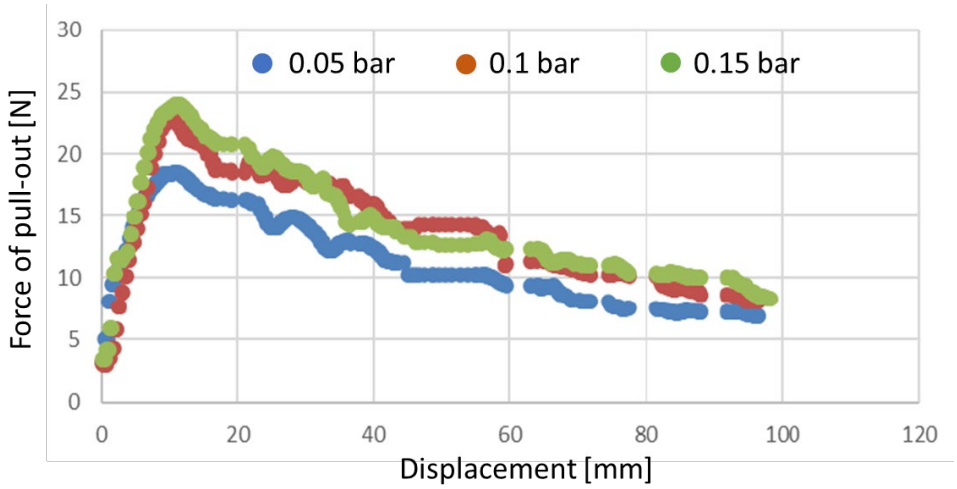

Fig. 7. Evolution of the pull-out force of the upper longitudinal yarns with the displacement.

As shown by these curves, an increase of the transverse pressure leads to an increase in the pull-out force of the longitudinal yarns. This increase is very logical as the traction force should overcome the friction between the fabric and the blank holder which increases with the normal pressure according to the Coulomb's law of friction. The tests presented by these curves corresponded to the appearance of buckles and gapping defects, with respect to the above-mentioned parameters. Fig. 8 shows an example of buckles and gapping appearance.

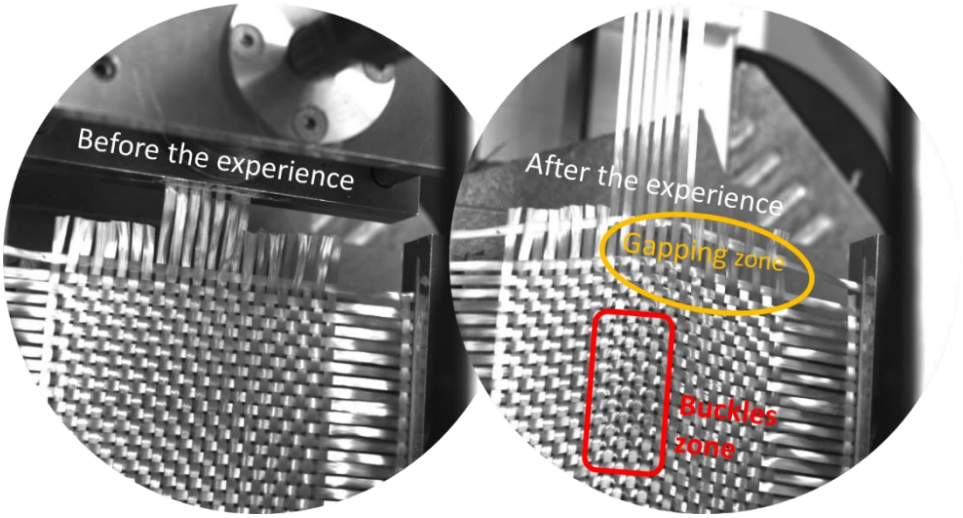

Fig. 8. Appearance of buckles and gapping defects on samples of glass fabric.

The Table 2 presents the group of experiments that studies the influence of the transverse pressure evolution on the defect's appearance. The experiments were repeated for three numbers of the pulled tows (3, 5, and 7) whereas the other experimental parameters were kept constant as follows: the longitudinal pressure = 0.05 bar, and the speed of displacement = 1 mm/sec. Thus, the Table 2 contain 9 series of experiences. In this table the symbol (✓) refers to the appearance of the defects whereas the symbol (x) indicates to a non-appearance of defects. Many deep analyses could be done but at this stage of the study we focalized on the definition of the experimental parameters allowing the appearance of forming defects and the comparison between the influence of these parameters on the defect's appearance for two types of fabrics.

Table 2. Experiments parameters allowing the appearance of buckles and gapping in glass fabric samples.

Number of tows	Transverse Pressure (P_T)	Buckles	Gapping
3	0.05 bar	x	x
	0.1 bar	✓	x
	0.15 bar	✓	x
5	0.05 bar	✓	x
	0.1 bar	✓	x
	0.15 bar	✓	x
7	0.05 bar	✓	✓
	0.1 bar	✓	✓
	0.15 bar	✓	✓

For the other experimental parameters, the influence of their evolution on the forming process was also tested. The Fig. 9 shows, for example, whether the velocity of pull-out has an influence on the pull-out force. The curves show a decrease in the pull-out force if the velocity increases and

the ratio of the force reduction is almost proportional to the ratio of increase in the velocity. This result needs a deeper analysis with other effects that should be considered, like the dynamic effect, the variability related to the heterogeneous behavior the fibrous structures.

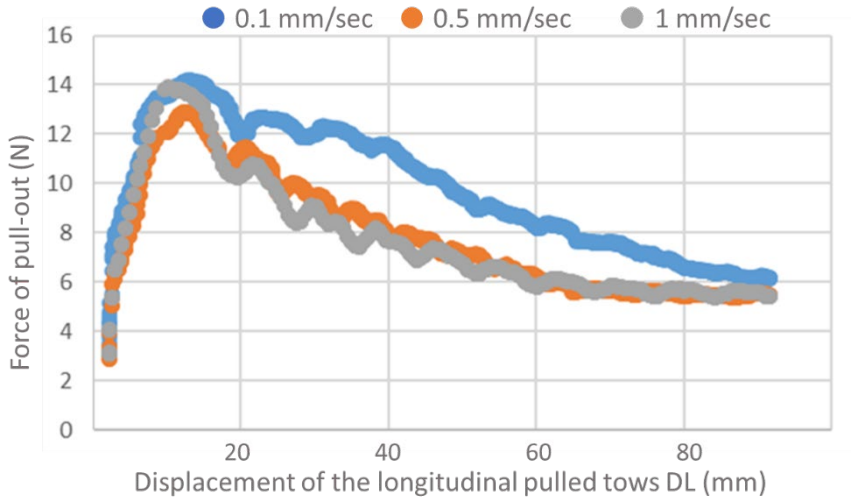

Fig. 9. Influence of the pull-out velocity on the pull-out force evolution.

Finally, when applying the same experimental parameters, that allowed the appearance of buckles and gapping defects in the case of glass fabric samples, on samples of the interlock carbon fabric G1151, it was possible to generate buckles defects only, without any appearance of gapping. Consequently, it can be concluded that the appearance of preforming defects is not only related to the experimental parameters, but also to the cohesion of the fabric as well as the boundary conditions during the process. This conclusion was indeed confirmed by the experiences presented in Fig. 10 that shows two examples of forming experiments on carbon and glass fabrics where both tests were executed under the same following conditions which are as follows: width of the pulled tows = 25±2 mm, displacement speed = 1 mm/sec, transverse pressure = 0.15 bar, and the longitudinal pressure = 0.05 bar.

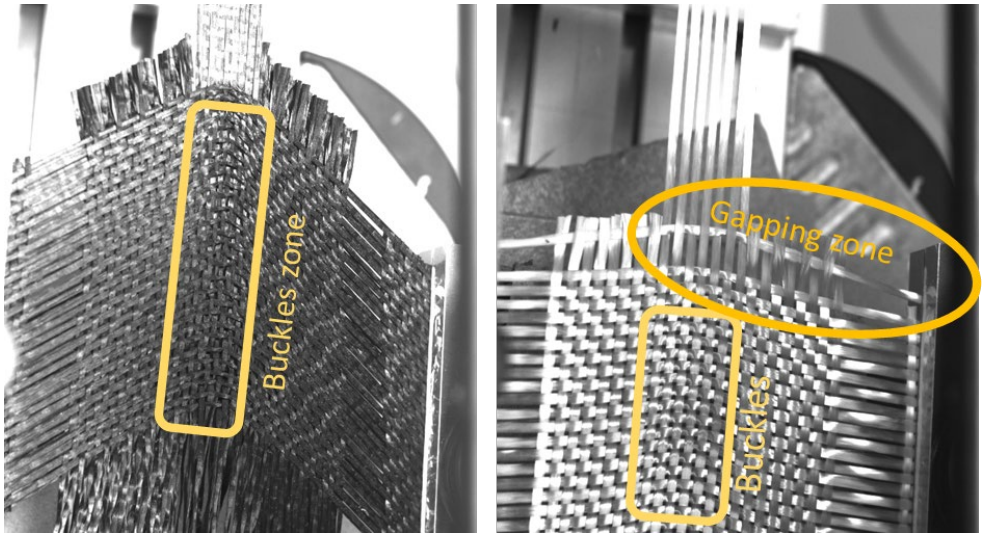

Fig. 10. Generated defects on glass and carbon fabrics.

Summary

This research contributed to the understanding of preforming defects and their mechanisms of appearance. It has been demonstrated that buckles, gapping and/or pull-out defects could not be separated even if it is sometimes possible to generate this or that defect. These defects are always concomitant and the appearance of one or both of them depends on the experimental parameters, the boundary conditions and the cohesion of the tested fabric.

Abstract. In the thermoforming process shearing of fiber reinforced thermoplastics (FRTP) leads to wrinkle formation and is therefore one of the most critical deformation mechanism. The target value to predict wrinkle formation is the shear angle which is considered in this paper. To predict the shear angle distribution during the thermoforming of FRTPs a Convolutional Neural Network (CNN) is used. The approach is based on the consideration of the principal curvature characteristics, resulting in the reduction of any complex geometry to planar, parabolic, elliptical, semi-spherical and hyperbolic areas. In similar research, CNNs are trained for each specific geometry. In this work, the CNN refers to a database of the mentioned curvature characteristics. In theory, all forming geometries can be created from these, which is why the CNN is enabled to predict the forming result of any complex geometry. In this paper, the benchmark geometry of a double dome is selected as the validation geometry and the error in the prediction of the shear angle is compared with the results of numerical forming simulations performed.

Introduction

Due to their high mechanical properties combined with low densities, FRTPs offer a high potential for lightweight design applications. The production of flat components made of FRTP is often realised by the thermoforming process, which represents a high potential for large-scale production [1]. Thermoforming usually involves heating fiber reinforced thermoplastic sheets (organo sheets) above the melting temperature of the matrix to enable draping of the fibers in the melt-viscous matrix during the forming process.

The draping behaviour is mainly determined by the in-plane shear property of the organo sheet. Furthermore, the different deformation modes transverse compression, out-of-plane bending and in-plane tension are important variables which influence the formability of the material and thus the forming result [2]. Accordingly, multiple defects such as wrinkling or fiber fracture can occur due to excessive shear stresses or tensile stresses [2]. The defects are mainly reduced by the selection of suitable process parameters, which increases the component quality. In addition to adjusted process parameters, additional technical supporting structures such as clamping systems or blank holders can be used to reduce the formation of wrinkles through the application of in-plane tensile stresses [3]. Due to the different influences of process parameters and additional supporting structures on the occurrence of defects, large cavity depths, sharp geometric transitions and three-dimensional space corners are difficult to produce and object complexity is limited [4]. A possible process adjustment for an increase in part quality for complex cavities is the implementation of stepwise forming with segmented stamps [5]. Due to this innovative tool concept, the parameter space of the process is increased. However, in order to avoid inefficient and expensive experiments, numerical investigations were implemented in order to examine

optimal segmentation and sequencing strategies for selected cavities. The numerical modelling of FRTPs even on the most common used macro-scale is timesensitive due to the complex material behaviour, thus surrogate models are useful for further time savings in the prediction of suitable segmentation and sequencing strategies. These types of Machine Learning (ML) architectures are already able to model the forming behaviour of different geometries as well as different process conditions [6]. These approaches will be addressed in this paper and extended with the approach explained in the following chapter. The presented investigations are the basis for further work on the implementation of the ML-based prediction of segmentation and sequencing strategies for increasing the prediction quality of shear stresses.

Curvature Analysis Approach

The goal of this research is to link a shear angle as the target variable with curvature values derived from the geometry of the cavity. The implementation of different basic geometries as a database enables a deep learning architecture the prediction of shear angles for all possible geometries.

The target value is the shear angle, which represents an important parameter for the prediction of local wrinkling, while the input value is given by the curvature of an examined complex cavity. This approach was derived from Coutadin et al. and developed further [7]. In this previous research, an existing tool geometry is imported as an STL file and the curvatures of the cavity are calculated. In the areas that exceed a previously defined critical curvature value, a segmentation cut is applied. Sequencing is further performed through a genetic optimisation algorithm. In the work of Zimmerling et al. [8], the topology of the test geometry is imported into the convolutional neural network as greyscale images as well as the output of the shear angle. The approach presented in this paper differs from [7] by reducing the data set for the CNN to the 5 most frequently occurring curvature characteristics. This avoids the necessity of a continuous implementation of new test geometries, since the description of all forms of complex geometries is possible using the five main forms of curvature. The methodology behind the approach is illustrated in Fig. 1.

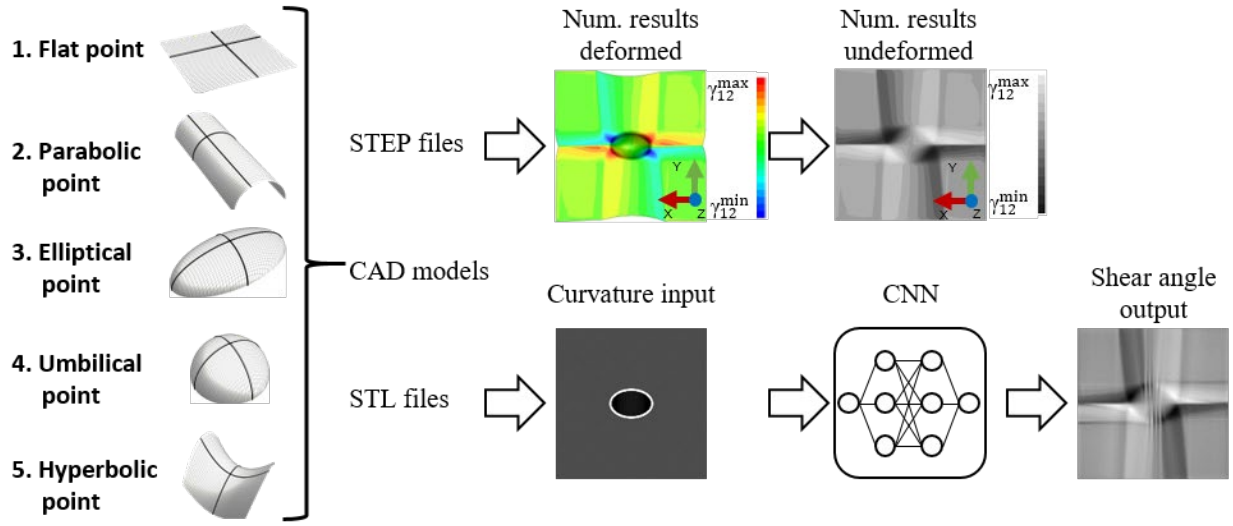

Fig. 1. Workflow of the curvature analysis approach.

The five relevant curvature characteristics are shown on the left. Out of these, the first four curvatures shown in Fig. 1 are considered in this paper. All curvatures are dependent on the two principal curvature components κ_1 and κ_2. If $\kappa_1 = \kappa_2 = 0$, a flat point results. Accordingly, a planar surface is defined by this point. A parabolic point exists if the product of the two curvatures is $\kappa_1 \cdot \kappa_2 = 0$, with $\kappa_1 + \kappa_2 \neq 0$. An elliptical point is defined by $\kappa_1 \cdot \kappa_2 > 0$. A special type of the elliptic point exists for $\kappa_1 = \kappa_2$. This is referred to as the umbilical point, which results in a hemispherical geometry. The case of a hyperbolic point, considered in further work, occurs if $\kappa_1 \cdot \kappa_2 < 0$. [9]

Parameterized CAD models were developed from the curvature components illustrated and a large number of geometry variants were created. From these, STL files were derived, which are used for the curvature calculation. In this work, the mean curvature H (see Eq. 1) is applied, which represents the arithmetic mean of the two principal curvatures.

$$H := \frac{1}{2}(\kappa_1 + \kappa_2) \tag{1}$$

Numerical models are built for the individual surface curvatures in order to create an FEM database for the surrogate model. The models represent the pure curvature types, therefore no boundary effects occur in the output of the shear angle. Therefore, the resulting shearing effects exclusively result from the curvature types.

The calculated curvature values are then combined with results on the shear angle of the simulations. As a result, the curvature values are assigned with the shear angle distribution for the material used and provides the surrogate model with a training data set. The coupling enables the surrogate model to predict complex geometries not previously trained, since the local geometric characteristics of the cavity can be reduced to the previously trained curvature characteristics.

Parametrization

For the creation of the CAD models, the parameterization of the ellipse and the paraboloid visualized in Fig. 2 is chosen. The outer dimensions of the die, which also equal the main dimensions of the organosheet, were left constant. For the ellipse, variants were created in the intervals shown for the radii R_{ye} and R_{xe} with a step size of 1 mm for the database. With the same step size, variants with variable radius R_{xp} and variable depth were created for the models of the paraboloid. For the visualisation of the occurring curvature characteristics of the geometries as well as for the representation of the simulation results in the undeformed sheet, greyscale images are used based on Zimmerling et al. [8]. The geometry variants created are further transferred as a step file to the automated numerical model generation in the software LS-Dyna.

Ellipse	Symbol	Parameter	Interval
	L_e	Length die ellipse	235 mm
	B_e	Width die ellipse	235 mm
	R_{ye}	Radius y-direction ellipse	20...50 mm
	R_{xe}	Radius x-direction ellipse	30…60 mm
	R_a	Outer Radius	4 mm
Paraboloid	**Symbol**	**Parameter**	**Interval**
	L_p	Length die paraboloid	235 mm
	B_p	Width die paraboloid	235 mm
	R_{xp}	Radius x-direction paraboloid	10…50 mm
	R_a	Outer Radius	4 mm
	depth	Depth paraboloid	10…60 mm

Fig. 2. Parametrisation of elliptical and parabolic models with the parameter-range for generation of the training dataset.

Numerical Model

In the FEM software tool LS-Dyna, an isothermal forming simulation is set up consisting of punch, die and sheet. The blank is a glass fiber reinforced organo sheet with polyamide 6 matrix (Tepex dynalite 102RG600(4)/47%). The fabric is an E-Glass roved in twill 2/2 style with 47% fiber content and a total thickness of 2 mm. In the forming simulation, the temperature is chosen marginally above the matrix melting temperature, which is around 220°C for polyamide 6. Punch and die are modelled as rigid bodies, while the organo sheet is described by the material card MAT_249_REINFORCED_THERMOPLASTIC [10]. Within this material card, the fibers are described as an anisotropic-hyperelastic material and the matrix as elasto-plastic. The material card has been calibrated and validated in previous work using tensile and bias extension tests. A disadvantage of the material card is the lack of options for implementing bending stiffnesses. For numerical models using shell elements, the stiffness is unrealistically high, due to the fact that in classical approaches such as the Kirchhoff theory, the bending stiffness is given by the tensile stiffness and thickness while slippage between fibers leading to lower bending stiffness is not considered [11]. Therefore, the bending behaviour is adjusted through the position and number of integration points to the neutral axis of the sheet [12]. The friction between the individual contact pairs was investigated using a friction test setup. From these investigations, values for the friction coefficients above the matrix melting temperature at 230°C are obtained and used.

As a result of the simulation, the shear angle is given, which is projected onto the mesh of the initial sheet. Therefore the element-size was set to 2 mm, resulting in a mesh with 117x117 elements. This is exported together with the element IDs and the coordinates of the nodal points in order to couple the shear angles with the curvatures of the cavity in the subsequent step.

Design of the Artificial Neural Network

In this research, CNNs, which are a kind of feed-forward network, are used because they are specially designed for spatially structured data such as the grey-scale mesh resulting from the previous chapter [8]. The basic structure of a CNN consists of an input, several convolutional and pooling layers and the output. The activity of each neuron is determined by stepwise comparison with smaller convolutional matrices (kernels) moved over the input. In the process, each kernel extracts different features from the input data, allowing the individual activated neurons of deeper layers to abstract only local sections of the entire input data and creating what is called a "feature map". In deeper layers, the data is further compressed, which enables the detection of more complex features. Subsequently, compressed data is decoded in the decoder by transposed convolutional layers. [13]

The CNN presented in this paper is built using the deep learning framework PyTorch and the library fastai. A total of 87 variants of ellipses, 31 paraboloids and 10 planar surfaces were taken as the dataset, which was split randomly into 90% training data and 10% validation data. The training data set was divided into 16 batches and a total of 300 epochs were trained. First, the elliptical variants were trained for 200 epochs, followed by the parabolic and planar surface variants. The batch normalisation implemented in PyTorch counteracts an internal covariate shift and ensures a high learning rate in the network [14]. In a subsequent step, we tested variants of each geometry with out-of test range parameters and two previously unseen double-dome geometries with the CNN in order to investigate the prediction quality of this curvature approach.

Results and Discussion

Fig. 3 shows the results of the training geometries of a flat surface (plate), the parabolic and the elliptical geometries. In addition to the listed geometries, the curvatures serving as input for the CNN and the results of the FEM simulations are presented as comparative images. The simulation results are visualised on the undeformed blank and display the shear angle distribution as a greyscale image. The representation of the curvatures and the FEM simulations each represent normalised values within fixed limits to ensure comparability. Furthermore, three result values of the prediction are shown. The root mean square error (RMSE) along with the minimum and maximum shear angle differences $\left|\Delta\gamma_{12}^{min}\right|$ and $|\Delta\gamma_{12}^{max}|$ of the prediction compared to the FEM results. The shear angle differences are calculated by subtracting the shear angle obtained from the numerical model from the predicted shear angle.

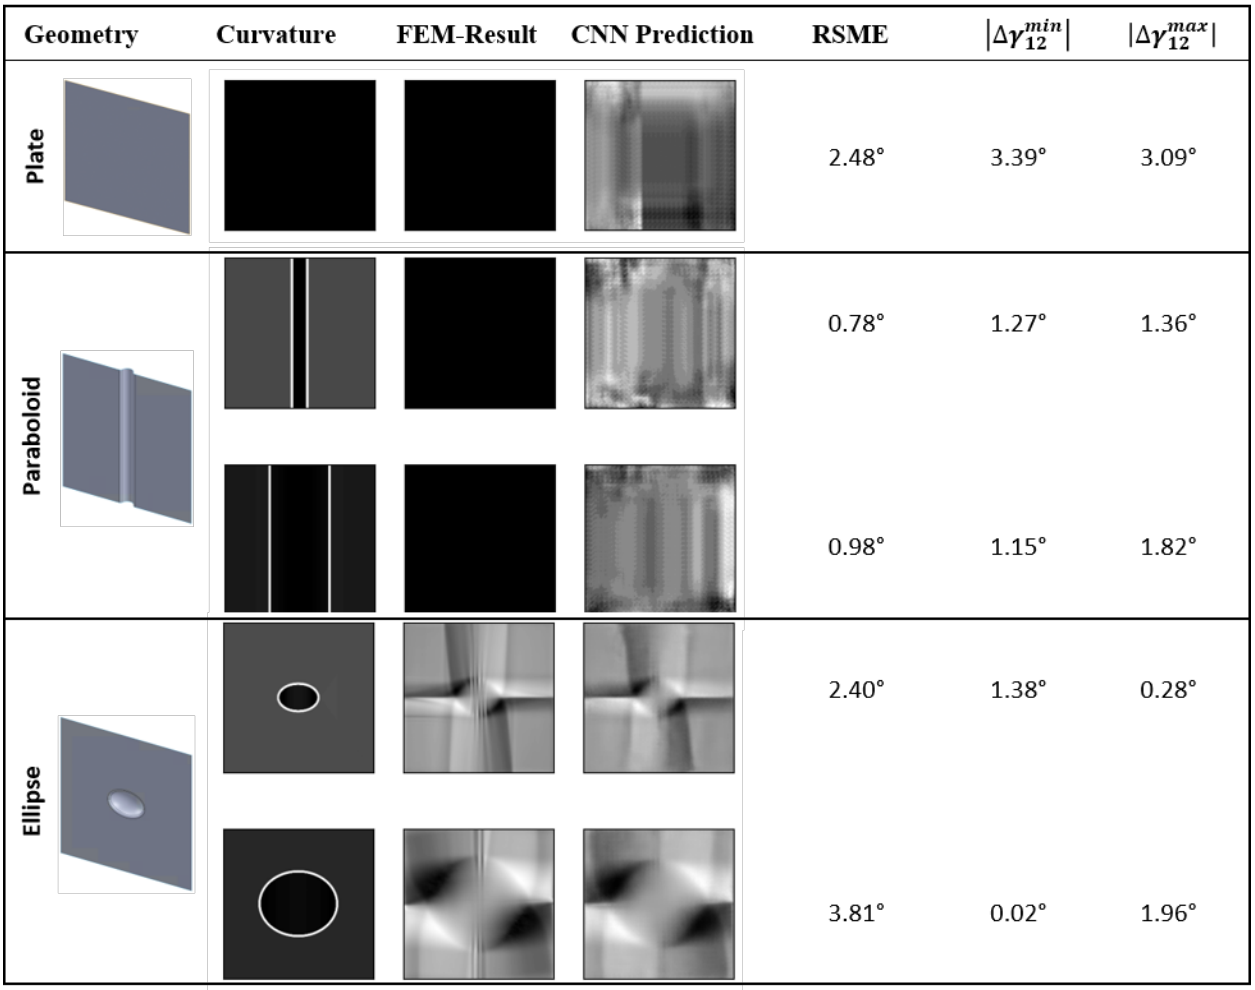

Fig. 3. Visualisation of the test geometries, their curvatures and the results for the shear angle from the FEM-Model and from the CNN Prediction.

For ellipse and paraboloid, the smallest (top) and the largest (bottom) parameter combination are shown, which were examined during testing, but not part of the training data. The comparison of the result images and values shows a high agreement between simulation and prediction of the CNN. Here, the percentage error values for the plate are 4.33 %, while the error for the parabolic validation geometries is below 2 %. The error of the ellipse can also be described as low with 4.19 % for the smallest parameter combination (top image ellipse in Fig. 3) and 6.65 % for the largest combination, so that a reliable prediction of the shear angle can be achieved through the curvature images with a very small data set.

As a final validation, a complex geometry of a double dome, which was not part of any previously used dataset, was examined with the CNN. Two configurations were chosen as examples, which are visualised in Fig. 4. The double dome is composed of the two trained curvature variants of the ellipse and the paraboloid. The network was presented with both a double dome with identical ellipses (bottom) and a double dome with elliptical areas of different sizes (top).

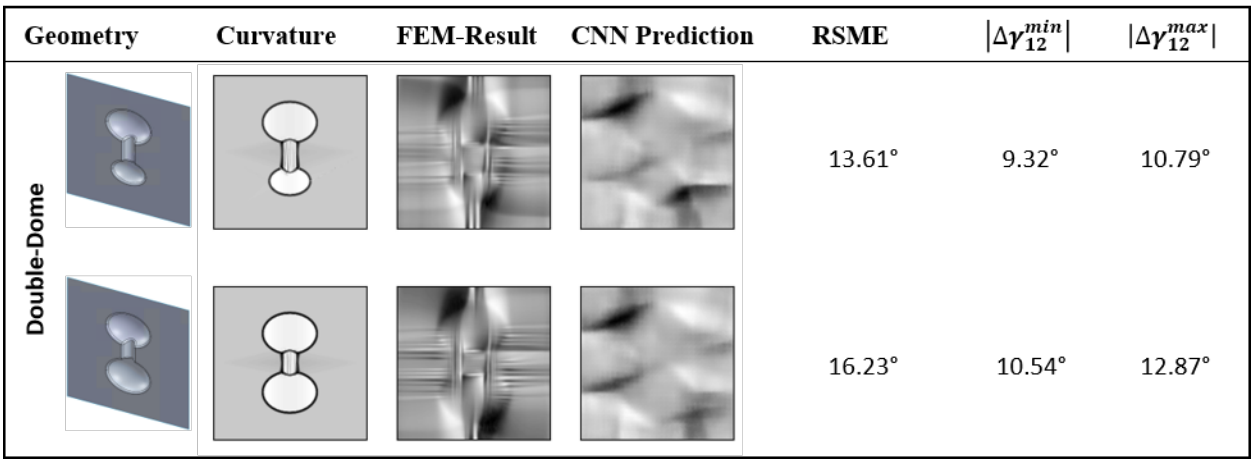

Fig. 4. Visualisation of Double-Dome Geometry, its curvatures and the results for the shear angle from the FEM-Model and from the CNN Prediction.

As shown in the result values, the RSME of the double-dome geometry with elliptical areas of different sizes is lower than the RSME of the double-dome geometry with two ellipses of the same size. Nevertheless, both errors are larger than the test errors of the elliptical, parabolic and planar geometries, with a percentage deviation of over 20 %. This is particularly visible in the transition between the elliptical and parabolic sub-area, which is not reliably predicted by the CNN. One reason for this may be the hyperbolic course in the transition, so that in further work the fifth curvature variant of hyperbolic geometries should be implemented for a more accurate result.

Summary

In the thermoforming process for manufacturing flat components from thermoplastic fiber composites, one of the main deformation mechanisms is shear deformation. As a result of high shear angles in the composite, wrinkles occur during the forming process. Predicting the shear angle as a parameter for localisation of upcoming wrinkles is therefore of central importance, hence the reliable prediction of this parameter was carried out in this paper by means of a Convolutional Neural Network. The results of numerical forming simulations provided the basis for the data. The training of the network was done by using only the occurring curvatures to predict the forming result of unseen, complex geometries (double dome) on the basis of the shear angle with a currently increased error in the range of 23 % to 28 %. In further work, the remaining curvature of a hyperbolic structure will be added to the database and further adjustments to the CNN will be applied. This should ensure in future that the neural network can reduce all complex geometries to the 5 curvature characteristics and thus provide a reliable prediction with a lower error for the selected target variable.

Abstract. Pultrusion processes have been widely used and developed to produce composite profiles in fiber-reinforced thermoset. Recently industry and research community are investigating the adoption of thermoplastic polymers in the production of pultruded components exhibiting structural stability at higher temperatures and improved sustainability. Aiming to study the thermoplastic pultrusion process and how the process parameters settings affect the composite profiles produced, a laboratory-scale pultrusion line has been designed and produced. The pultrusion die is fed by polypropylene pre-impregnated tapes reinforced by unidirectional continuous glass fibers. It consists of a tapered converging cavity heated by electrical plates governed by PID controllers and a straight cooling die. This work aims to study the feasibility of the process, the consolidation of the tapes, and the interactions between the processed materials and the cavity walls by using embedded traveling thermocouples and load cells. The experimental test presented in this paper highlights that the preimpregnated tapes processed have been well-consolidated with the parameters adopted and the pultruded profile presents good quality at a visual inspection of the external surfaces and cross-section, indicating a good melting and hardening of the polypropylene matrix. The interactions between the processed materials and the die walls are evaluated by means of a cross-analysis of thermal and load data.

Introduction

Pultrusion is a widely consolidated process for the manufacturing of constant cross-section profiles in continuous fibers reinforced thermoset [1]. The success of this process is related to several factors: i) the high tensile properties due to the orientation and the volume fraction of the reinforcement; ii) the continuous nature of the process, which in turn guarantee high productivity, repeatability, and automation; iii) the low energy and human intervention required; iv) low or null waste of raw materials [2,3]. Due to their properties, pultruded profiles are widely employed in many industrial or civil sectors [4,5]. Traditionally, thermoset systems have been preferred for their low viscosity and their easy manufacturability. Nevertheless, generally, thermosets presents several drawbacks if compared to thermoplastics, namely lower in-service temperature, lower mechanical properties, production of dangerous volatile compounds due to the polymerization during the manufacturing or process related defects and distortions [6,7]. Moreover, the thermoplastic polymers can be remelted and re-used, promoting a more sustainable production [8].

Of course, the adoption of a different matrix system requires a different pultrusion line, equipped with features designed to process thermoplastics. The major difference stands in the

presence of a heating die and a successive cooling die. The former is responsible for the matrix melting and flowing; the latter give place to the matrix cooling and hardening [9]. In the thermoplastic pultrusion the reinforcement impregnation can be done either online or offline. In the first case, the polymeric system is heated up, in order to minimize the viscosity and injected through the advancing fibers within the heating die. The offline impregnation is based on the usage of preimpregnated tissues or tapes [10]. The pultrusion of preimpregnated tapes guarantees a better distribution of the matrix and the absence of dry zones, but it requires longer crossing time to ensure the tapes consolidation in a unique composite profile, and therefore, a lower processing speed. In the case of pultrusion of preimpregnated tapes, the heating die presents a highly sloped tapered chamber, converging to the final cross-section shape. Such slope constrains the advancing tapes and determines an increase in the pressure, which in turn confers the shape of the profile, promotes the transversal flow of the melted matrix and consolidates the tapes. The cooling die presents a straight cavity with the shape of the final cross-section which holds the materials in their positions while the matrix is hardening [11,12].

Therefore, the main factors affecting the thermoplastic pultrusion are the heating ramp, determining the thermoplastic softening and melting, the transversal compression, determining the transversal flow of the polymer and the compaction of the tapes, and the cooling ramp, hardening the thermoplastic. The main challenges in the monitoring of the process and the measurement of the variables of interest in pultrusion are related to the fact that all the transitions and shaping phases are included into a closed non-transparent die. The method of the traveling thermocouple is the most commonly adopted to collect the internal temperature data [7]. It is carried out by connecting a thermocouple to the advancing materials at the die entrance and measure the temperature during the time necessary to cross the pultrusion die. The data collected in the time domain can be transferred to the position domain since the velocity of the process is constant and known and it corresponds to the pulling speed. The evaluation of the pressure can be achieved by means of pressure sensors [13], nevertheless these sensors cannot be fixed easily in a pultrusion die without altering its geometry. Moreover, the measurement achieved is representative of the localized pressure at the sensor location, while the pressure in a tapered cavity exhibits a marked variability along with the die [14]. More pieces of information on the advancing materials transitions and on their interaction with the die cavity, can be indirectly inferred from the measurement of the pulling force, since it strictly depends on the nature of the interaction between processed materials and the die cavity walls [15].

This study aims to analyze the pultrusion of tapes in glass fiber reinforced polypropylene pultruded in a laboratory scale line. The internal temperature and the pulling force data have been analyzed to detect, describe, and quantify the main behaviors occurring along with the pultrusion die.

Materials and Methods

The pultrusion line adopted in the present experimental activity consists of a 300 mm heating die followed by a 300 mm cooling die. The line adopted is illustrated in Fig. 1a.

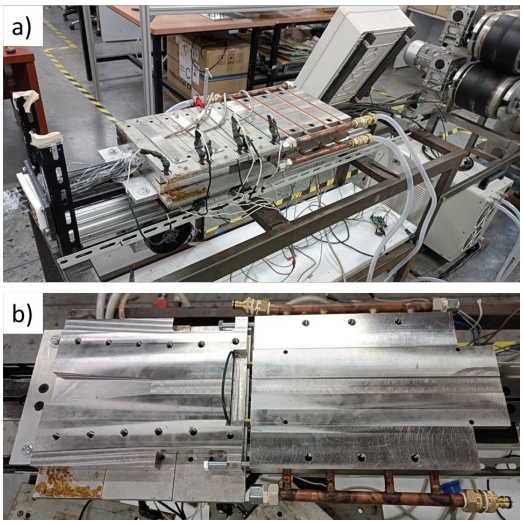

Fig. 1. a) Thermoplastic pultrusion setup; b) view of the disassembled lower sides of the heating die and cooling die.

In the thermoplastic pultrusion setup shown in Fig. 1a, the advancing direction is oriented from the left towards the right. The preimpregnated tapes approach the pultrusion line presents from the heating die side, where three couple of electric platens are provide heating energy to the system. The platens' powers are governed by three PID controllers, receiving the feedback signals from three sensors fixed on each of the upper side platens. The cooling die is mechanically fixed downstream the heating die. The cooling system is based on water circulation through a copper pipes grid embedded within milled cavities. The water cooling and circulation is governed by an industrial chiller, with temperature setpoint of 13°C. Fig. 1b shows the internal cavities of the disassembled lower sides. The heating die presents a tapered converging zone to favor the tapes entrance and to compact them, followed by a straight cavity with constant cross-section. The tapered zone has a length of 160 mm. The cavity of the cooling die is straight with constant rectangular cross-section 25 mm wide and 4 mm thick.

This setup has been used to pultrude preimpregnated tapes provided by CompTape BV (Delft, Netherlands) in glass roving reinforced polypropylene. Each tape has dimensions of 6.35 mm in width and 0.6 mm in thickness and contains the 60% in volume of reinforcement. The tapes have been arranged in 6 layers of 4 tapes per layer. With this arrangement, 24 preimpregnated tapes have been pultruded, to achieve a profile with a fiber volume fraction of 55%. Considering the polypropylene matrix, a temperature of 200°C has been set for the platens. The dies have been mounted on supports free to slide on a longitudinal guide. At the limit of the guide a compressive button load cell is fixed to measure the pulling force (Fig. 2b). The pulling system, consisting of counter-rotating caterpillars, moves the tapes at a velocity of 170 mm/min.

The internal temperature of the advancing tapes within the pultrusion dies has been measured using the traveling thermocouple method: Once the process is stationary (the pulling force are stable), the bulb of a wire thermocouple is connected to one of the tapes, in such a way to have the bulb between the third and the fourth layer and at the middle of the pultruded width. The aim is to measure the temperature of a point as close as possible to the barycenter of the cross-section. The wire must be as thin as possible to have a low invasive measure. In this case, the two wires for the two conductor alloys of the k-type thermocouple (chromel-alumel) have diameter of 0.2 mm. Once the bulb crosses the entire length of the two dies, the wires have been cut.

During pultrusion, the load cell measures the overall force resisting to the pulling. Such force is related to the interactions arising at the contact between dies' walls and pultruded materials. The

local interaction between die and advancing materials has been evaluated cutting the tapes at the heating die inlet and analyzing the unloading curve, as described in [16].

The collection of the data acquired by the load cell and the thermocouple has been managed using an Arduino board equipped with signals' amplifiers (Fig 2a) and connected to a computer.

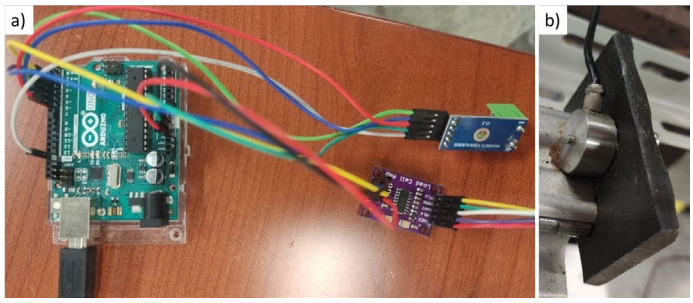

Fig. 2. a) Data collection management board equipped with signals' amplifiers; b) compressive button load cell fixed at the guide limit.

Results and Discussion

The described setup for thermoplastic tapes pultrusion has produced well compacted and continuous pultruded composites.

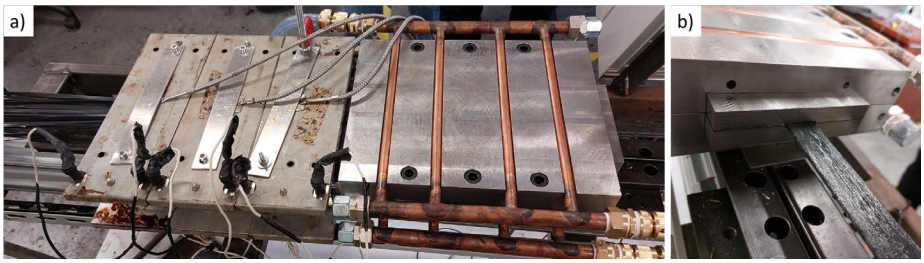

Fig. 3. a) Pultrusion setup while processing glass-polypropylene tapes; b) obtained pultruded profile.

Fig. 3a shows the pultrusion dies during the process. It is worth noting the tapes approaching to the heating die inlet. Each tape is separated with each other, and all of them are converging driven by the shape of the heating die cavity. At the cooling die outlet, the pultruded profile appears continuous and compacted, as demonstrated in the close up in Fig. 3b.

The internal temperature of the pultruded materials acquired by the traveling thermocouple and the load discharge curve measured by the load cell is reported in Fig. 4.

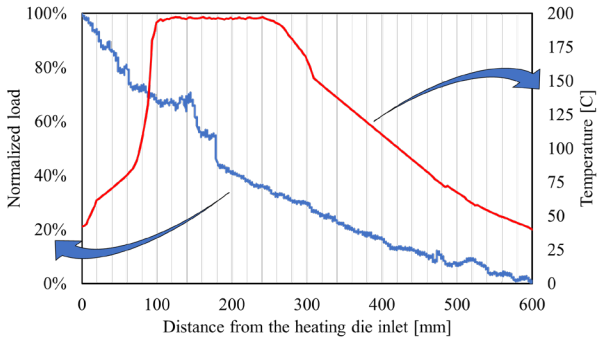

Fig. 4. Total load discharge curve and internal temperature of the advancing materials along with the heating and the cooling dies.

The tapes reach the heating die entrance with a temperature slightly superior to the environmental conditions, due to the diffusion in the air of the heat from the heating die. The temperature increase is slight along with the initial 80 mm. Indeed, at the heating die entrance, the cavity is wider, and the tapes are not in direct contact with each other and with the die. After this point the compaction and compression of the tapes driven by the converging walls determines a sharp increase in the temperature, which reaches approximately 195°C. This temperature is kept constant until 250 mm of distance from the heating die inlet. Even if the cooling die starts from 300 mm from the inlet, the heat dissipation of the cooling fluid affects also the temperature of the final portion of the heating die. The transition effects are visible in a continuous decrease in the slope of the temperature curve until the end of the heating die. Along with the last 300 mm, the heat dissipation gives place to a linear decrease in the temperature.

The polypropylene transitions are driven by the temperature and affect the interaction with the dies' walls. The earliest 150 mm are characterized by an irregular decrease of the total load with large fluctuations. Indeed, in this zone, the tapes are not compressed against the die walls. The contact is furthermore irregular if compared to the stationary process because of the absence of the pretension due to the cut of the tapes. The tape compaction can be recognized by the drop in load between 140 mm and 160 mm of distance from the die inlet. The melting temperature is reached and overcome starting from 100 mm from the heating die inlet. The effects of melting and rheological evolution of polypropylene can be observed clearly between 160 mm and 180 mm by a marked drop in the resisting load. Drops in the cumulated load indicate peaks in the local force. Indeed the thermoplastic passes from a solid state to a gel state, characterized by an adhesive local interaction typical of the high viscosity fluids, and finally reaches the melt state. The low viscosity reached by the polypropylene after 180 mm from the die inlet gives place to a lubricant effect promoting the sliding of the materials. The main resistance between 180 mm and 350 mm from the heating die inlet is related to the viscous drag. The linear decrease in the total load curve indicates a constant resistant force along with this zone. The polypropylene solidifies again in the last 250 mm from the inlet. The transition to a solid compact composite determines a solid friction interaction between the die walls and the pultruded profile surface. This interaction can be recognized by the fluctuations visible from 350 mm from the heating die inlet and becoming larger in the last 150 mm of the die.

Summary

This work presents an experimental setup for the pultrusion of glass/polypropylene preimpregnated tapes. The measurement of the internal temperature evidenced that the polypropylene melts in the heating die, where it is compacted and shaped. The heat dissipation in the cooling die gives place to a fast solidification of the matrix. The compaction of the tapes gives place to the most prominent local loads peaks, while the melted polypropylene acts as a lubricant, promoting a regular and smooth sliding of the advancing taps.

Keywords: Crush Core Forming, Sandwich Structures, Variable Thickness, Composite Materials

Abstract. Sandwich structures, constituted in honeycomb core and skin in composite material, are usually employed to produce parts having a constant thickness or simple shape. Indeed, sandwich components with complex shapes, curvature or varying thickness are costly to manufacture due to the preliminary machining operations required on the core prior the molding process. A novel approach to manufacture complex sandwich structures, knows as Crush Core Forming (CCF) process, consisting in press-forming simultaneously the core material and the skins into the shape is under study. Such a method is potentially able to increase the production rate and lowering the overall costs. The present work aims to develop an experimental route to produce sandwich panels by means of CCF process and build a FE model of the forming process and validate it against the experimental studies. Experimental study was conducted to derive the fundamental parameters and properties for core and skins to be added in the FEM model of the CCF process. After, the numerical model was implemented to simulate the forming of the core and skins. Finally, a laboratory scale sandwich part was produced to validate the model outputs and assessing the reliability of the proposed approach.

Introduction

Composite sandwich structures offer opportunities of lightweight design and sustainable mobility thanks to their high strength-to-weight ratio, especially bending and torsional stiffness. Sandwich panels are currently employed in several fields, from aeronautics, to automotive and marine transportation [1]. Examples of application include aircraft interior, car body panel, boat hulls [2]. Sandwich panels usually are produced by means of autoclave processes bonding the composite skins with the core under the action of pressure and heat, however in the last years new pre-pregs, which can be processed by out-of-autoclave (OoA) techniques and can be cured under vacuum condition and with conventional ovens, have been commercialized [2,3]. Moving from the autoclave manufacturing toward OoA processes allows to significant cost saving and faster production routes without sacrificing the performances of the components [4–7]. Despite these progresses, composite sandwiches are commonly produced only in simple shape and have constant thickness.

For the manufacturing of more complex shape structural panels, the core is generally obtained through machining operations, while the bonding and curing of the skins are made as subsequent steps [8]. Recently, the use of additive processes allows to realize core with high strength-to-weight ratio and with more complex shapes known as lattice structures [9,10]. However, the low production rate does not allow the development of such technology for series products.

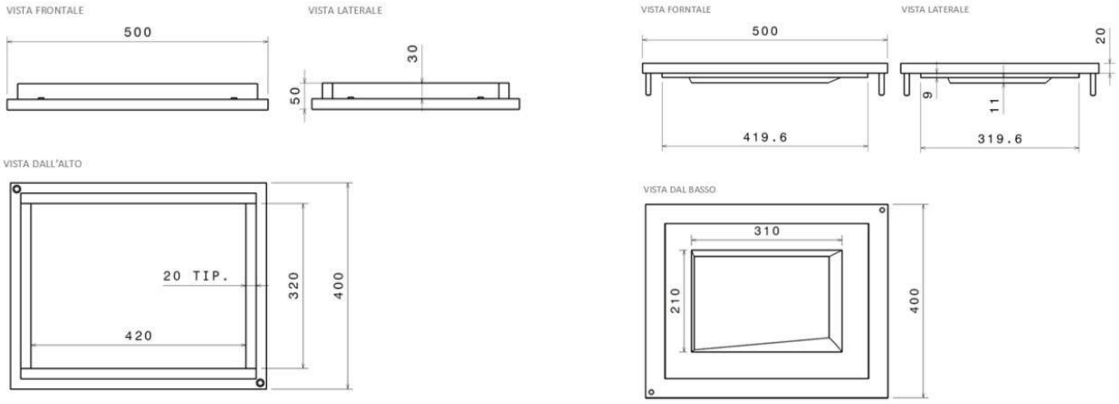
Recently, in high-volume production application, such as lightweight automotive interiors, a reduction in production time is required to manufacture sandwich structures compatible with market demands. For this purpose, first studies on core crushing are present in scientific literature [11,12]. Forming behavior of curved sandwich plates differ from that observed in monolithic sheet material and in composite panels due to the presence of the core material, which affects the overall deformation of the sandwich plate and the occurrence of surface defects [12]. During the manufacturing core and skins are subject to complex load and multi-axial deformations, including in-plane tension/compression and shear and out-of-plane bending [12].

Typical issues observed during the forming process are surface waviness, local buckling, fracture of the skins as well as crushing of the core structure, and they were ascribed as the main factors limiting the formability of thin sandwich panels [11–15]. Optimization of the core design, so that it can provide sufficient resistance against skin buckling and core cell collapsing, demonstrated to be able to mitigate these defects and, therefore, plastic forming method could be used to produce complex shaped panels from flat sandwich plates [12]. In this context, development of numerical simulation techniques for the sandwich forming process able to predict the forming behaviors of core and skins and the forming-induced defects would be helpful. In very recent works, Cai et al. [12] and Chen et al. [11] proposed finite element models and analytical models to determine the main failure factors in plastic forming of curved sandwich panels. The first authors investigated the multi-point forming of sandwich structures having polyurethane egg-box-like core and aluminum face sheets. They observed that the limits in formability are mainly related to occurrence of wrinkling or dimpling on the face sheets, while the core cell fracture has lower influence [12]. The other authors developed a multiscale model of the sandwich structure having composite skins and honeycomb cellular core. The results indicate that the formability of sandwiches with complex curvature is due to the local crushing of the core. In the authors' best knowledge, besides these few contributions no other works dealing with numerical simulation or experimental approach are available for the published literature, especially in the case of composite skinned sandwiches for structural applications. Moreover, there are no studies that investigate not only the plastic forming process of the core but also the efficacy of the bonding between skins/core and the resin cure of the skins in a one-shot forming process of structural parts. In the present manuscript a novel approach to manufacture complex sandwich structures, knows as Crush Core Forming (CCF) process, consisting in press-forming of both core and skins in a one-shot operation, is under study. Such a method is potentially able to increase the production rate and lowering the overall costs. The present work aims to develop an experimental route to produce sandwich panels by means of CCF process and build a FE model of the forming process and validate it against the experimental studies. In fact, compression tests were performed on the honeycomb core to estimate the deformability and the densification of the core material under the action of the forming load, while the composite skins were subjected to bias extension and cantilever test to assess their formability. These properties were used as input data for the FEM model developed to simulate the forming of the core and skins and estimate the occurrence of forming-induced defects. A laboratory scale sandwich part was produced to validate the model outputs and assessing the reliability of the proposed approach.

Materials and Methods

Fig. 1 shows the case study designed for the investigation of the CCF process. For the forming process, a press system was used with heated plates up to 250°C with dimensions 400x400 mm^2. EP121-68-40 fiberglass prepreg impregnated with 40% epoxy resin from Gurit Ltd was used as face sheets for the sandwich panels. It is a prepreg with 8H satin texture and a resin cure temperature of 120°C. The skins were produced with 2 plies layered with rolling direction in the direction of the long side of the panel.



a) b)

Fig. 1. Scheme of the upper half mold (a) and lower half-mold (b) for the case study considered (dimensions in mm).

The hexagonal cell honeycomb HRH10-3.2-48 from Hexcel HexWeb was adopted as core. It is a core in Nomex that has cell dimensions of 3.2 mm, height of 19 mm and a density of 48 kg / m^3. The characterization of the core was conducted according to ASTM C365 along the thickness of the core, both at room temperature and at the prepreg cure temperature of 120°C. The compression tests were conducted with three replicas for each test temperature (see Fig. 2).

a) b)

Fig. 2. Compression test of the core: a) During test; b) at the end of the test.

The formability of prepreg skin was assessed by bias extension test (Fig. 3) and by cantilever testing, respectively for the in-plane shear behavior and the out-of-plane bending behavior. The specimens for the bias extension test are 50 mm x 200 mm in dimension and were tested at testing speed of 50 mm/min. Three replications were considered for the test. ASTM D1388 standard was adopted for the cantilever test, which recommends specimens with size of 10x100 mm^2 and an overhang length of 50 mm. Five replications were considered.

Materials Research Proceedings 28 (2023) 399-406 https://doi.org/10.21741/9781644902479-44

Fig. 3. Bias extension test per EP121-68-40.

Once the single parts of the sandwich have been characterized, the CCF process was conducted. The optimal process parameters were determined by the trial-and-error method, evaluating the goodness of the adhesion between skin and core through ultrasonic non-destructive testing. The process parameters, which resulted in free-defects sandwich panels, are: 100 kN closing force, molds temperature of 120°C, holding time of 90 min. The temperature trend on the mold was measured by using J-type thermocouples placed inside the mold as shown in Fig. 4. Once the cure of the skins was completed, the mold was opened, and the component extracted.

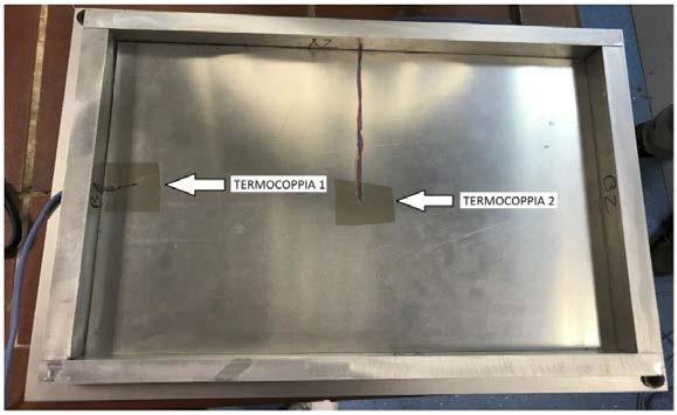


Fig. 4. Locations of the thermocouples on the surface of upper half-mold.

The numerical analysis was conducted by adding the properties of the materials, derived from the experimental characterization in the PAM-FORM software developed by Esi Group. For the present case study, brick-type and shell elements were considered for the core and skins, respectively (see Fig. 5 and 6). Specifically, for the skins and tools Belitschko-Tsai type 4-node square elements were used, while Flanagan-Belytschko type 8-node elements were used for the core. The tools were modeled as rigid bodies, while the mechanical behavior of the core and skins was implemented in the software as a point list.

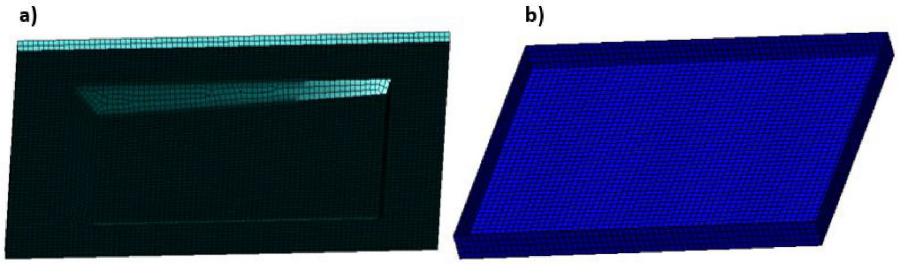

Fig. 5. CAD tools in PAM-FORM environment: a) upper mold; b) lower mold.

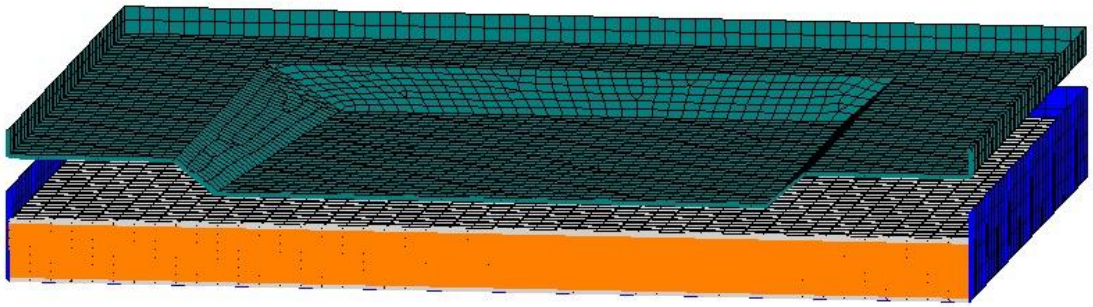

Fig. 6. Section view of CCF process developed for the case study in PAM-FORM environment.

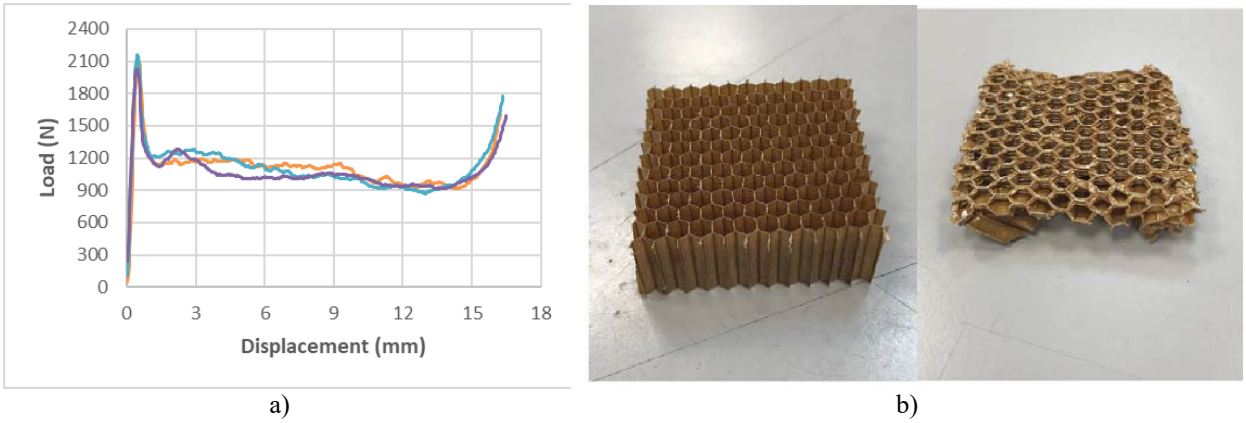
Results and Discussion

In this section the results from the experimental characterization and numerical analysis of CCF process are reported and discussed

Compression test.

Fig. 7 report the force/displacement curves acquired during the compression tests on the three specimens and the photos of core before and after the test. By analyzing the curves, it is possible to observe a first peak of mechanical resistance of about 2100 N, after which there is a collapse of the load and a plateau up to an overall displacement of 14 mm of the upper plate. In this stage of the test, the failure of the core cells occurred, which, once completed, led to a new increase in measured load. Therefore, the investigated core is compressible up to a thickness of about 5 mm, lower than that necessary for the realization of the case study of the present work. Tests conducted at 120°C showed the same results, but with about 30% lower initial stiffness and strength.



a) b)

Fig. 7. Compression test results on the core material: a) Load-displacement curves; b) specimen image before and after the compression tests.

Cantilever test.

The results from the cantilever tests on prepreg laminates are shown in Fig. 8. From these it is possible to observe that the flexural stiffness of the prepreg EP121-68-40 at room temperature varies between 22 and 28 kPa. In the case of tests conducted at the forming temperature, the flexural stiffness has lower values between 17 and 18 kPa. In the latter case, the tests showed a greater repeatability of the measurement with a limited scattering.

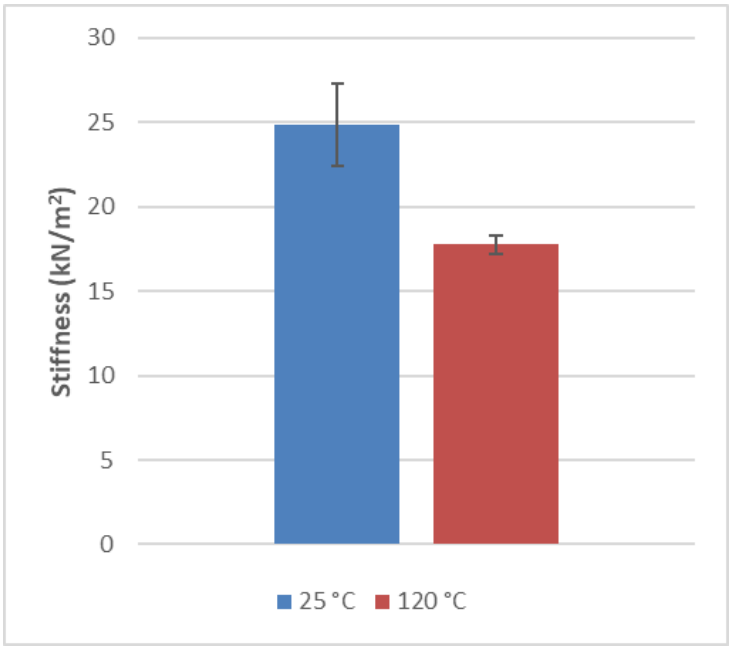


Fig. 8. Prepreg stiffness derived from cantilever test.

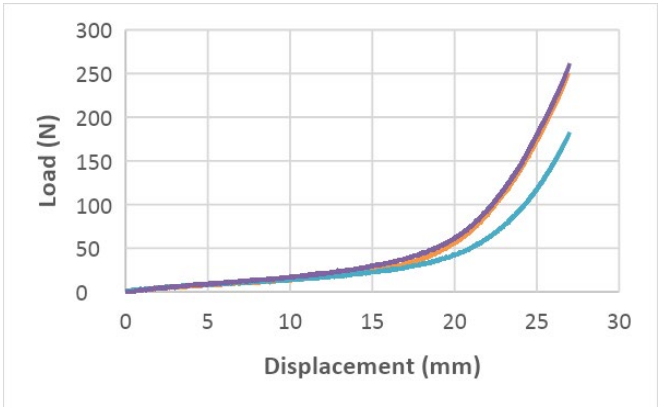
Bias extension test.

The results from the bias extension test are shown in Fig. 9. The load-displacement curves showed an exponential trend, with a significant increase in load after a displacement of approximately 15 mm. These curves were normalized with respect to the size of the specimen, then the average curve was extrapolated and used as input into the PAM-FORM calculation code.



a)

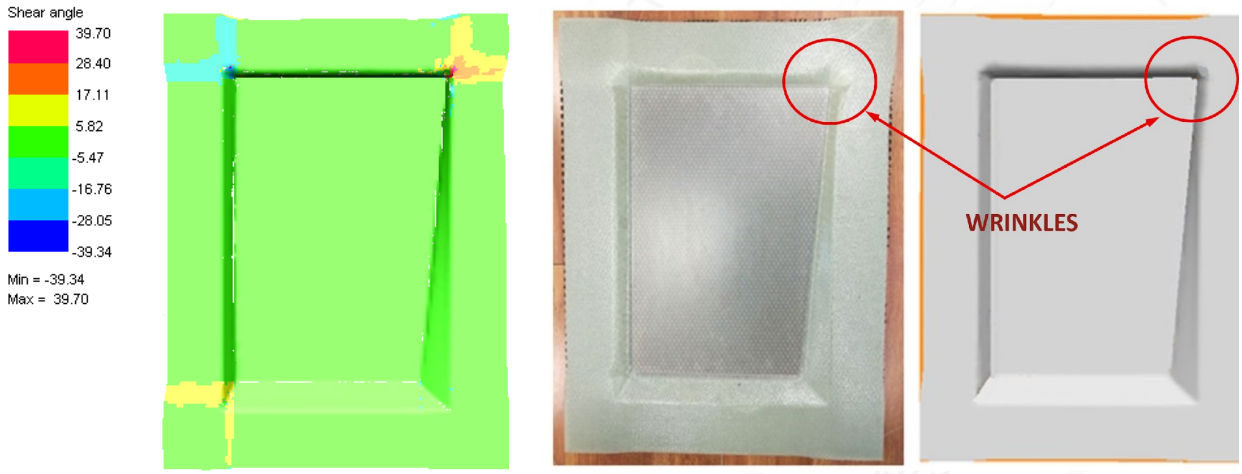
b)

Fig. 9. Results from bias extension test on the EP121-68-40 prepreg: a) load vs displacement curves; b) images of the prepreg specimens during the test.

CCF process: comparison between experimental and numerical outcomes.

Measurement of temperature by using thermocouples during the forming process and the ultrasonic control on the formed part confirmed soundness of the manufactured sandwiches, confirmed by the good adhesion between core and skins after the forming.

From visual analysis it can be observed that the variation of orientation of the fabric is located near the vertices of the cavity, or where there is a greater variation of the normal of the piece surface (Fig. 10). By analyzing the simulated panel, it is possible to assess that the software was able to predict with good accuracy the formability and directional variation of the reinforcement of the skin with the presence of wrinkles near the vertices of the pocket.



a) b)

Fig. 10. Sandwich panel manufactured by CCF process: a) numerical shear angle; b) comparison between experimental and numerical results.

Summary

In the present work, an innovative approach to produce structural sandwich structures, known Crush Core Forming (CCF), has been investigated. This process allowed to form simultaneously the core and the skin in a single forming step to produce structural sandwich panels with complex shapes, reducing time and manufacturing costs. First, the mechanical behavior of the core and the skins has been obtained through compression tests, bias extension tests and cantilever tests. Subsequently, the results of the tests conducted on the prepreg cure temperature of 120°C were added as input in the PAM-FORM simulation environment. A case study has been realized through CCF process, showing the reliability of the proposed approach, while the outcomes proved the model's capability to predict the plastic deformation of the core and relative angular variation of the skin sheets with the formation of wrinkles near the vertices of the cavity.

Keywords: Composite Materials, Resin Infusion, Permeability, Genetic Algorithms

Abstract. Vacuum Assisted Resin Infusion (VARI) method employs a mould on top of which a number of fabric pieces are laid up and impregnated by resin drawn through vacuum. Simulation of VARI depends on the determination of fabric permeability. In this work, permeability value is selected from a set of discrete values by a genetic algorithm. An impregnation simulation model is run on Comsol^{TM} to compute the flow front propagation inside the fabric. The genetic algorithm compares the evolution (propagation) of the impregnation front, in a space and time dimension, with the corresponding result of one single actual impregnation experiment, obtained by machine vision. A simple part suffices for this experiment assuming homogenous fabric porosity. The computational cost of the method is low, making it superior to experimental determination of permeability on expensive custom-made devices.

Introduction

Industrial production of large batches of laminate, e.g. carbon or glass fibre, composite parts, of small to medium size and complex geometry is mostly conducted exploiting Resin Transfer Molding (RTM) using a heated mold pair arrangement. The resin along with the catalyst (hardener) is then injected into the mold through the inlet ports. After hardening, the part is separated from the mold. RTM imparts good dimensional accuracy and good surface quality to both sides of the part. Vacuum Assisted Resin Infusion (VARI) is a comparatively low-cost method that is able to produce small to large parts, its main characteristics being similar to those of RTM. However, instead of the metal top surface of the RTM mold, an elastic membrane is used. Moreover, VARI uses vacuum to draw the resin into the mold displacing the air it encounters and flowing towards the vacuum port(s). The mold is in contact with only one surface of the fabric, the other surface being of inferior surface finish.

Permeability of the fabric is an extremely important factor in VARI as it is directly related to the completion of the impregnation. Experimental and computational / numerical simulation methods or a combination have been used to determine it.

Experimental determination of permeability is based on monitoring the propagation of resin front by exploiting different sensors, such as pressure sensors [2], images of the evolution of the front through the fabric [3], custom designed dielectric sensors [4], optical fibers woven into the preformed material [5]. Both saturated and unsaturated flow tracking was reported in some of these works. Based on experimental data, neural networks have also been trained to predict permeability from input parameters (fabric type, porosity, input pressure) [6,7].

To calculate permeability numerical models based on the Stokes / Darcy equations are experimentally validated. The models express macro-scale phenomena using standard software

such as Comsol™ [8] or 2D schemes based on voxels or boundary elements [9,10]. Models at micro-scale [11] are inevitably of limited size. In macro-scale modeling the way in which the fabric is modeled is pivotal, e.g. using permeable and non-permeable yarns [12], incorporating stochastic fabric diversity [13].

Since the permeability of a fabric is not known a priori to use the corresponding value in the numerical model, several simulations are performed until the results match the experimental ones either following brute force [8,13] or within an optimization loop [14]. Another approach reported computes bulk permeability and saturation rate at mesoscale and introduces them to the macroscale simulation validated against experimental measurement in a 1D infusion test [15].

In a very comprehensive review on composite forming, benchmarking work on 1D and 2D permeability measurement is reviewed being expected to lead to a pertinent ISO standard [16]. However, it is also recognized that shear and compaction of preforms does alter permeability locally, which undermines to some extent the generality of the benchmarking concept.

In the present work, determination of the fabric permeability value is based on the comparison of experimental results and the numerical prediction of the propagation of the flow front, iteratively through a genetic algorithm. The difference of the two fronts at consecutive moments yields the evaluation of the corresponding permeability value tested. Due to its stochastic nature the approach is efficient requiring only one experiment on a simple shape recorded on camera.

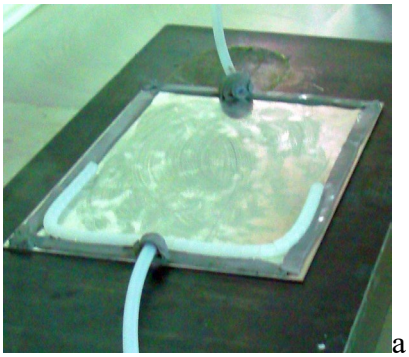
The next section describes the numerical modeling of the VARI process. Next is the description of the experiment providing the reference of the front evolution and in the next section the genetic algorithm that determines the optimal permeability for the specific fabric. Then, conclusions and suggestion of future work are drawn up.

Experimental Recording of Flow Front Evolution

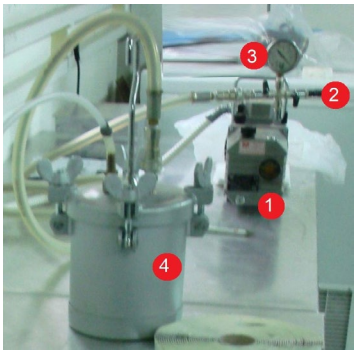
A single VARI experiment suffices to provide a reference for the evolution of the flow front for comparison with the predicted evolution by the numerical simulation subsequently.

The specimen consists of two-ply glass fiber fabric measuring 200 X 75 mm with a nominal thickness of 0.02 mm per ply, plain weaving and weighing 25 gr / m^2. An appropriate peel ply was used with 0.15 mm thickness, a flow medium (mesh) with 1.2 mm thickness, a bottom bag (perforated) with 65 MPa strength and a vacuum bag (SBF 130B) with strength 45 MPa and thickness 0.075 mm. Entry and exit tubing had a diameter of 10 mm.

The resin was a 2-part Alphapoxy™ HX-3 by Vivacity Engineering. Its viscosity at 25ºC is 325-375 mPa.s. Usage time at 25ºC is 45-60 min, full hardness being achieved after 24 hr. The mold was an aluminium plate of 1 mm thickness stiffened by ribs, see Fig. 1(a).



a



b

Fig. 1. Experimental layout (a) mold with fabric, vacuum bag and in/out pipes (b) vacuum pump (1), regulating valves (2), manometer (3), resin trap (4).

Special sealing tape is employed to secure the vacuum bag on the mold. A two stage vacuum pump (DVP™ RC.8D) is used with nominal pressure is 0.01 mbar and flow rate: 10.2 – 9.5 m^3/hr. A manometer of range – to -1 bar was used to measure the actual vacuum pressure achieved and a

system of hand-regulated valves is used for controlling the vacuum circuit, which also comprises a downstream resin trapping vessel. The equipment is shown in Fig. 1(b).

The resin-saturated fabric is visibly darker than the unsaturated part, therefore the flow front is clearly delineated, see Fig. 2(a). In order to record the evolution of the front a 12 Mpixel CCD camera was used and 22 snapshots were taken at 1 sec intervals until the resin front reached the end of the fabric. Six tracks were defined about the axis of symmetry of the fabric parallel to it and the intersection points of the flow front with these tracks were recorded at each snapshot, see points A – F in Fig. 2(b). Their distance along flow direction (x axis) from the starting edge of the fabric was measured in pixels and scaled to mm. Thus, the mean distance of the six points defining each flow front was calculated representing a 'linearized' flow front,

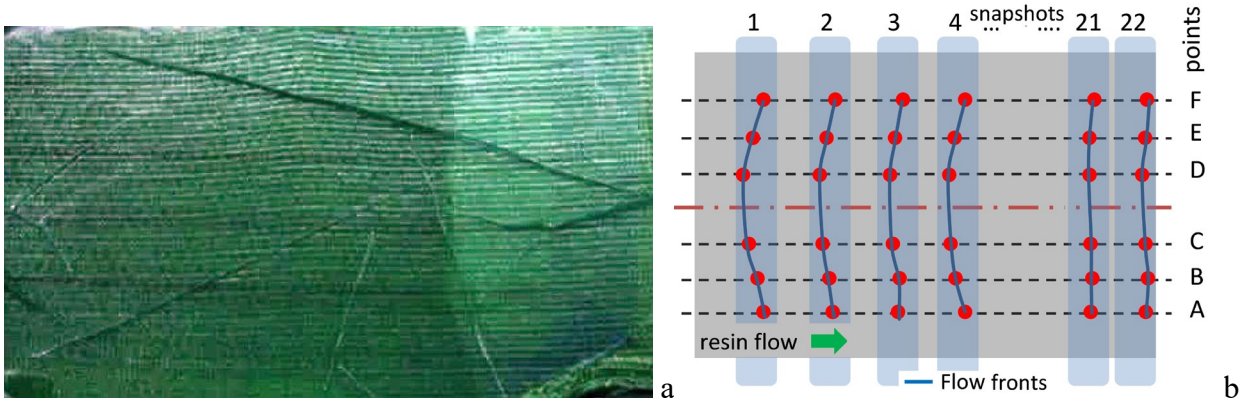


Fig. 2. Resin flow front (a) snapshot during the experiment (b) designated snapshots and points.

Numerical Simulation of VARI

Darcy's law governing one dimensional flow through porous media is expressed as:

$$v = \frac{k}{\mu}\frac{\partial^2 p}{\partial x^2} \tag{1}$$

v: resin velocity (m/s), k: fabric permeability (m^2), μ: resin viscosity (Pa·s), p: pressure (Pa).

Fabric filaments are bundled into tows which leave gaps between them as they are intertwined. These are visible as they are of the order of magnitude of mm (inter-tow gaps). Within a bundle gaps exist of 2-3 orders of magnitude smaller than those (intra-tow gaps). Resin flow between filaments of a bundle is modelled by a sink term describing resin flow around the gap. A corresponding expression for mass continuity is:

$$\nabla v = -S \tag{2}$$

where S is the sink term, its negative sign denoting that resin flow is reduced in the regions of non-saturated intra-tow gaps because it is absorbed by them.

Combining Darcy's law and continuity equation [28]:

$$v = -\frac{k}{\mu}\nabla(p) \tag{3}$$

$$\frac{\partial(\rho\varphi)}{\partial t} + \nabla(v\rho) = 0 \tag{4}$$

where φ is fabric porosity. Finally, using the sink term and assuming incompressible resin:

$$\varphi \frac{\partial S}{\partial t} - \nabla\left(\frac{k}{\mu}\nabla(p)\right) = 0 \quad (5)$$

As the viscosity ratio of resin to air is quite high (10^4-10^6) zero pressure drop is assumed in the unsaturated section of the part and thus equal pressure on the flow front and the exit. Function S is defined to ensure smooth transition from a saturated to an unsaturated region [8]:

$$S(p) = \frac{2}{\pi}(ap) \rightarrow \frac{\partial S}{\partial t} = \frac{\partial S}{\partial p}\frac{\partial p}{\partial t} = \left(\frac{2}{\pi}\frac{\alpha}{1+(\alpha p)^2}\right)\frac{\partial p}{\partial t} \quad (6)$$

where $\partial S/\partial p$: moisture capacity and α: form factor [1/Pa] determining the length corresponding to phase change. [8].

The point at which the resin changes phase is determined by comparing the pressure resulting from Eq. 6 to the characteristic pressure at the flow front: $p > p_c a$. Normally, p_c = 1000 Pa [8].

The model was set up on Comsol™ concerning a fabric shaped as a parallelogram with resin flowing from one narrow end to the opposite along x direction, see Fig. 3(a).

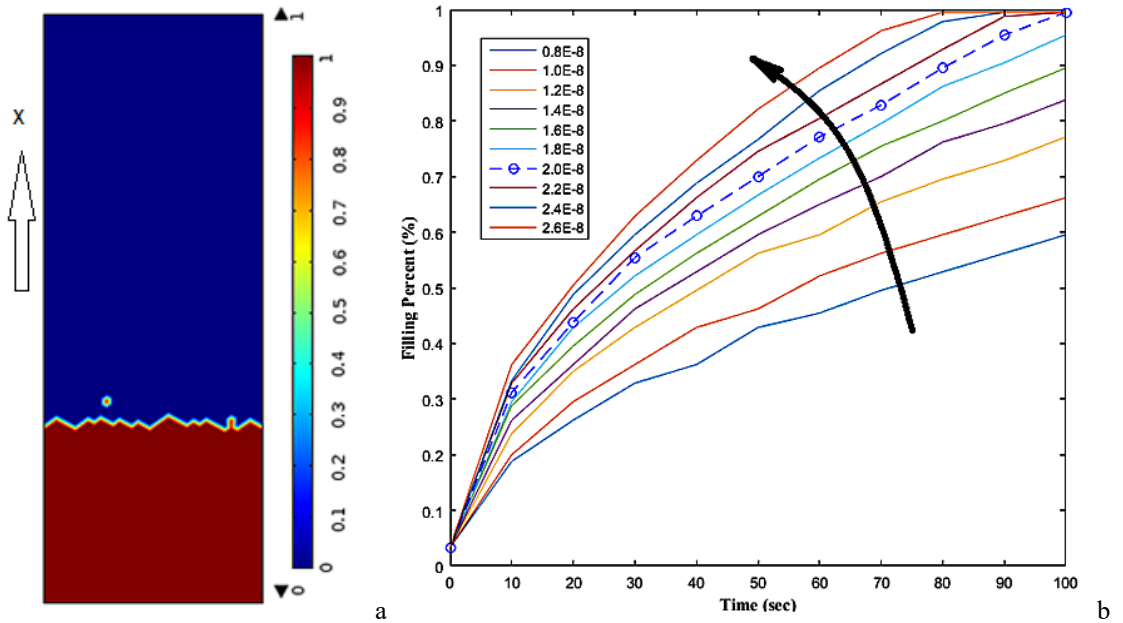

Fig. 3. Simulation of resin infusion (a) flow front snapshot for t=30 sec, permeability 3.2e^{-12} m^2 and quadric fine mesh (b) evolution of filling percentage for different fabric permeability values.

The resin's change of viscosity with time was not modelled since it was considered fairly small (for AIRSTONE 710EL Epoxy Resin and 713H Hardener which is equivalent to the system used in the experiment, viscosity is reported by the manufacturer to be 150-200 mPa.s within the first 30 min, whereas impregnation time was a small fraction of 30 min in this case. Note that the fabric was modelled at single scale, i.e. ignoring the intra-tow gaps, which is knowingly a simplification at the same time allowing faster computation compared to dual scale modelling.

It is possible to record the flow front along a few lines parallel to the flow direction, interpolating between these points to draw up the complete flow front line, see Fig. 3(a). In addition, the filling percentage is used as a termination criterion for the simulation as calculated using the Derived Values>Average>line_Average method in COMSOL™. Fig. 3(b) shows the variation of filling percentage with time for various permeability values. It is clear that the higher the permeability, the earlier the filling ends, even before the front touches the fabric's right edge.

The density of the mesh can be set by the user as Extra Fine, Fine and Normal. In addition the discretization type of elements can be selected from the set: linear, quadratic, cubic, quatric, quintic, sextic and septic. Selection of different combinations impacts not only the accuracy of the flow front solution but also the actual position of the mesh nodes in the domain studies and hence the distance of the predicted flow front from the experimentally determined one. In particular, different combinations were tried for a simulation run for two layered GFRP fabrics at 0.8 bar vacuum and permeability 8.94 X 10^{-10} m^2. Concentrating on the experimental flow front position corresponding to the first snapshot recorded, which is located 10.52 mm downstream the entry baseline, Table 1 clearly shows superiority of combination Linear – Fine.

Table 1. Difference in predicted distance of the flow front from the baseline.

Density	**Extra Fine**		**Fine**		**Normal**	
Discretisation	Distance (mm)	Rel.error (%)	Distance (mm)	Rel,error (%)	Distance (mm)	Rel.error (%)
Linear	3,97	-62%	**10,53**	**0%**	12,96	23%
Quadratic	1,69	-84%	4,8	-54%	5,9	4,6
Cubic	2,74	-74%	6,85	-35%	8,43	2,07

Repeated execution of the simulation with different input values for permeability is implemented by corresponding calls from within a Matlab™ program by exploiting the Livelink™ application. Results are also transferred in the same way, in this case the flow front vector depicting its position at a predefined number of time points. Such repeated calls and passing back of the results are needed by the Genetic Algorithm described next.

Permeability Determination by Genetic Algorithm

The optimum value of permeability is the one that yields minimum deviation between the experimentally determined evolution of the flow front and the evolution predicted by the simulation model. This is determined by a Genetic Algorithm (GA) that uses the simulation model in order to evaluate the potential permeability solutions, see Fig. 4. The GA is based on the one reported on in [17].

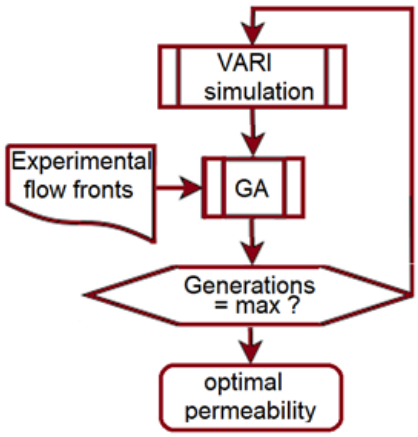

Fig. 4. Evolutionary determination of permeability overview.

The chromosome consists of an integer index to a set of 1000 permeability values spanning a user-defined range, in this case 3 X 10^{-9} to 9 X 10^{-10} (m^2). Thus the integer representation is decoded into a real representation.

The evaluation functions used is the Root Mean Square (RMS) of the difference of the x coordinate of the experimental (x_{e_i}) and the corresponding simulated (x_{s_i}) flow front considering all snapshots (T):

$$f_{eval} = \sqrt{\frac{\sum_{i=0}^{i=T}(x_{e_i} - x_{s_i})^2}{T}} \quad (7)$$

Note that the simulated flow front is by model construction a vertical line, whereas the experimental flow front can be considered as a circular arc with large radius that passes from the six 6 recorded points per snapshot, see Fig. 1(b). Thus, the experimental flow front is replaced by a vertical line passing from the mean x coordinate of these six points. The value of f_{eval} can be considered as a metric for the mean distance between the two flow fronts, measured and simulated one, over all snapshots considered. Normally all 22 snapshots taken should be taken into account, but it is up to the user to exclude any 'outlier' snapshots.

Since the chromosome is just one integer variable crossover operator would not keep any genes of the parent but the offspring would be an entirely new chromosome, which is exactly what mutation operator does in this case. Thus, crossover operator was abolished and only mutation was applied, indeed with a high probability of 40%. Elitism was constrained to 10%. Population consisted of 10 individuals and the initial population resulted from a random selection of 10 out of the 1000 permeability indices.

In order to validate the approach, the genetic algorithm was run first using instead of experimental flow front data the ones obtained by running the simulation model with a known permeability value, namely 3.7 X 10^{-9} m^2. In order to save computational cost only 10 snapshots were considered and the results are shown in Table 2. The cost was 0.554473 mm, which is deemed small enough to be accepted and the permeability determined was 3.71 X 10^{-9} m^2. The non-zero cost and associate small difference in predicted permeability is due to the discretization, i.e. the element nodes being inevitably some small distance apart from the actual flow front which is determined in the continuous domain rather than the discretized one.

Table 2. Difference between target and predicted flow fronts for the validation run.

snapshot number	1	2	3	4	5	6	7	8	9	10
time (sec)	0	2	4	6	8	10	12	14	16	18
target (mm)	9,55166	60,62378	85,18519	104,2885	119,29825	134,308	144,83431	158,8694	169,3957	178,9474
predicted (mm)	9,55165	60,62378	85,18518	104,2885	120,2729	134,308	146,39376	158,8694	169,3957	178,9474
relative error (%)	0,000001	0	0	0	-0,008170	0	-0,010767	0	0	0

The GA was then run with the actual experimental flow front evolution values for 500 generations. The evolution of the cost with the number of generations is shown in Fig. 5. The optimum permeability determined is 8.71 X 10^{-10} corresponding to a cost of 8435 μm.

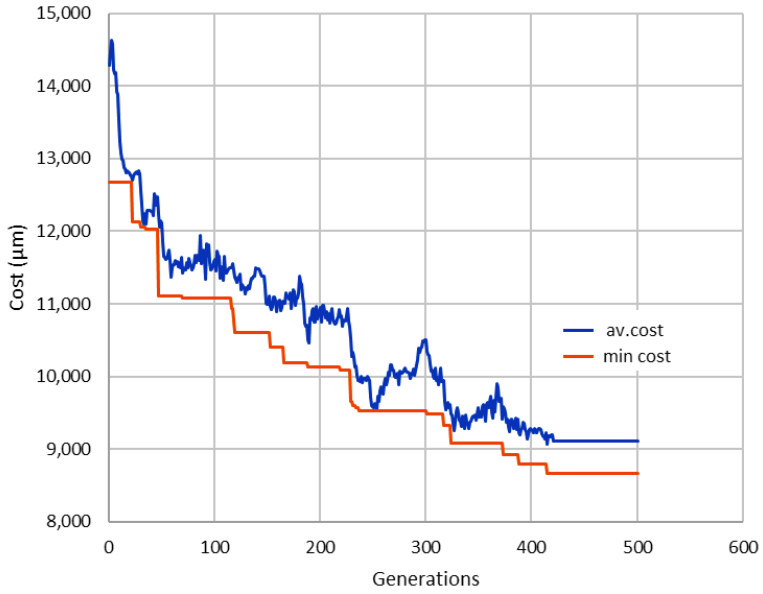

Fig. 5. Evolution of average and best (minimum cost) solution for the experiment conducted.

Characteristic snapshots of the experimental and the simulated flow front are shown in Fig. 6.

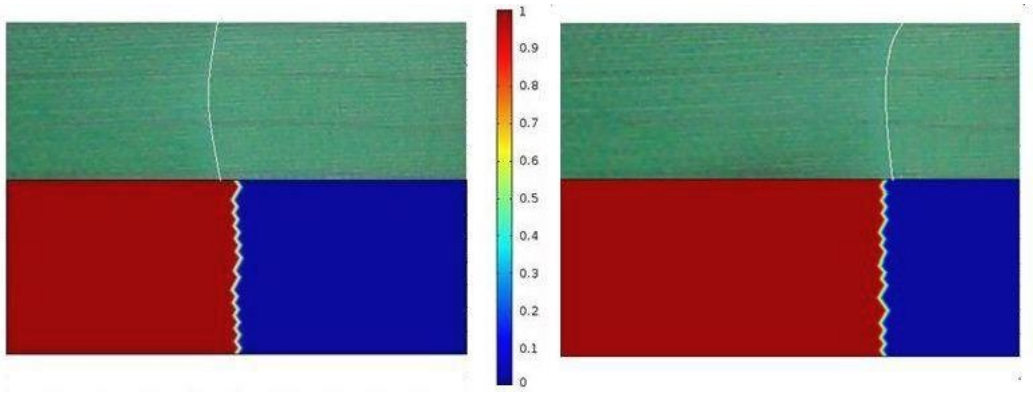

Fig. 6. Experimental (up) / simulated (down) flow front at 6 sec (left) and 12 sec (right).

A comparison between experimental and optimally predicted by the simulation flow front evolution in terms of their mean distance from the baseline is shown in Table 3 for a set of 11 snapshots for the 2-ply fabric. Furthermore, analogous experiments increasing the number of fabric plies to 3 and 4 was performed and the flow front evolution was measured as in the 2-ply experiment. The GA was run for these cases, too, resulting in lower overall permeability as well as higher impregnation time, namely 3,59 x 10^{-10} m^2 and 51 sec respectively for 3 plies and 1,07 x 10^{-10} m^2 and 117 sec respectively for 4 plies. This decrease in permeability with the increase of number of plies is reasonable and has also been reported in literature, e.g. [19]. The comparison between experimental and optimally predicted flow front evolution for the 3 ply fabric is also provided in Table 3.

Table 3. Difference between measured and predicted flow fronts for 2 and 3 ply cases.

plies	snapshot number	1	2	3	4	5	6	7	8	9	10	11
2	time (sec)	0	2	4	6	8	10	12	14	16	18	20
	target (mm)	10,5	42,5	72,5	97	114	134	146,5	159	172,5	185	192,5
	predicted (mm)	10,53	60,62	83,24	102,73	120,27	133,33	144,83	156,92	167,45	177,97	186,94
	relative error (%)	-0,29	-42,64	-14,81	-5,91	-5,50	0,50	1,14	1,31	2,93	3,80	2,89
3	time (sec)	0	5	10	15	20	25	30	35	40	45	50
	target (mm)	2,5	34	61,5	85,5	108,5	130	146,7	165	176	187,5	197
	predicted (mm)	2,74	59,99	82,97	102,18	117,83	132,81	144,81	156,59	168,6	180,02	189,62
	relative error (%)	-9,60	-76,44	-34,91	-19,51	-8,60	-2,16	1,29	5,10	4,20	3,99	3,75

Given that the simulation model is at single scale, i.e. approximate compared to a dual scale approach, the results are promising, namely the deviation of the experimentally determined and simulated flow fronts is mostly acceptable except for the snapshots corresponding to the first 20% of the experiment duration. The latter may, in addition to this simplification, be attributed to the effect of the vacuum bag compressing the fabric non-homogeneously, as also noted in [18].

On an Intel® Core™ i7-5500U computer 800 generations were run in about 80 min. The simulation run takes about 20 sec. Thus, an exhaustive search of 1000 permeability values would take by comparison 330 min.

Summary

The method advocated for determining permeability of fibre reinforced fabrics relies on simulation with a flow front evolution reference determined by a simple experiment on a simple fabric shape. By comparison, dedicated devices for determining permeability purely experimentally make use of special sensors and are expensive to make or acquire. Nevertheless, benchmarking has led to an ISO standard (ISO/DIS 4410). As far as this is still under development, visual tracking of the flow front coupled with numerical simulation in an optimisation loop may be a worthwhile addition to the sensor-based methods. In fact, there is plenty of scope in this direction since research on permeability evaluation in Liquid Composite Moulding (LCM) processes is an ongoing topic of research and of particular significance in process simulation [16].

The genetic algorithm as a tool for optimization coupled with a set of discrete values of permeability proved efficient, although it was, by definition, impossible to validate the result against experimentally measured permeability. Yet, the trend of permeability decreasing with increasing number of fabric pieces was clear and in accordance with results reported in literature.

The number and position of points to be considered on the flow front in the experimental setting and their simulation counterparts does influence the predicted permeability. This is connected to the fact that, for reasons of lowering computational cost, the fabric is modelled as single scale, i.e. ignoring the intra-tow gaps, that would otherwise have provided more accurate flow front shape. This is clearly an issue for further improvement.

The formulation of the genetic algorithm would most probably benefit from a binary representation of the integer indices to permeability. It is suggested that in the same range of values

a finer step could be applied in this way and also that crossover operator could be meaningfully introduced in which case the number of generations to reach the optimum permeability would be slashed by at least one order of magnitude. This is the next step in further work, which will also allow inclusion of the type and density of finite element discretisation in the chromosome as two extra variables to be optimized. The chromosome could also be augmented by the critical pressure for phase change of the resin as a variable to be optimized, which has been taken as constant from literature (1000 Pa).

Keywords: Hot Extrusion, 7075 Aluminum Alloy, Tribology in Manufacturing

Abstract. 7000 series aluminum alloys are high-strength alloys used in various lightweight products in the transportation equipment and aerospace industries. AA7075 extrusions are expected to find further applications in multiple fields, including aircraft parts, automotive parts, and sporting goods. However, the high deformation resistance and surface cracking defects caused by tool galling and adhesion have resulted in extremely low productivity. In this study, the V-groove compression test was proposed as a method to determine the coefficient of friction in hot metal forming. Using AA7075 as the experimental material, what did the V-groove compression test at various temperatures to compare the results with calibration curves created from the numerical analysis and observe the growth of adhesion.

Introduction

The advantages of 7000 series aluminum alloys are high strength, excellent corrosion resistance, and good electrical and thermal conductivity. Thus, these are used in various products to reduce weight in transportation equipment and aerospace applications [1]. In producing aluminum alloys by hot extrusion, the billet is passed through an opening die and pressed to shape. A cross-sectional shape with a surface finish can be obtained in a single deformation. Hot extrusion is widely used in the production of aluminum alloys because of its high productivity and extrusion yield [2]. However, AA7075 has the lowest extrusion productivity due to cracks that develop on the extrudate surface during hot extrusion, especially under high speed and high-temperature conditions, and due to adhesion to the tool. This cracking defect is known as tearing. In addition, AA7075 is one of the least deformable aluminum alloys and has high flow stress, which significantly limits the extrusion speed from 0.8 to 2.0 m/min. In our previous research, we reported that tearing was caused by low-melting intermetallic compounds containing magnesium (Mg) and zinc (Zn) [3]. It reported that the intermetallic compound with a low melting point locally melted due to the heat generated by the forming process.

The crack propagates due to the strong tensile stress applied to the product at the forming part during extrusion. As a method to suppress tearing defects that occur during the hot extrusion of 7000-series aluminum alloys, a coating on the die bearing section is proposed to reduce friction between the billet and tool interface [4]. Three coatings, AlCrN, TiAlN, and Diamond-like Carbon (DLC), were applied. The hot forward-backward extrusion friction test measured their friction coefficients, a friction test simulating plastic working at high temperatures. The friction coefficients from the friction tests and the occurrence of tearing when various die coatings were used showed that tearing was reduced for the low-friction AlCrN at high temperatures. It reported

that this was due to the improvement of material flowability, and homogenization of tensile stress imparted to the product by low friction in the forming section. Therefore, it is necessary to investigate the extrusion tribology that contributes to tool adhesion and material fluidity to suppress tearing.

Friction tests for plastic forming can be classified into three types: basic friction tests such as pin-on-disk tests, friction tests simulating plastic forming, and friction tests using actual workpieces. The basic friction test is a simple way to obtain the coefficient of friction. Still, it does not apply to plastic forming because it does not involve a deformation process involving an increase in surface area. In particular, the surface area expansion ratio becomes extremely large when extrusion or forging is assumed. Friction tests using actual machines are only possible on those machines, making it challenging to obtain general-purpose results. Therefore, conducting friction tests that simulate extrusion and forging is necessary. The most common friction test that simulates extrusion and forging is the ring compression test. However, the compression ratio of this test is only about 50 percent and a friction test that allows a larger surface area expansion ratio is needed. In addition, reports of friction tests simulating hot extrusion and hot forging include the two-cylinder crossed friction test by Kalin et al. [5-7] and the Warm and Hot Upsetting Sliding Test (WHUST) by Dubar et al. [8-10] as examples of hot friction tests. Although these have been reported, there are few examples of friction tests simulating hot extrusion and hot forging. The hot forward-backward extrusion friction test conducted by the authors is also a friction test that simulates plastic forming. Still, it can only identify the friction coefficient for the entire process and is not suitable for measuring friction phenomena that change in complex ways during forming [4].

Zhang et al. proposed the T-shape compression test (TSCT), which can evaluate friction in complex extrusion and compression deformations and achieve a high surface area enlargement of more than 50% [11]. From the stimulation of the TSCT, Fereshteh-Saniee et al. conducted friction tests on AZ31 and AZ80 alloys in this test for hot plastic working of magnesium alloys. They reported that the experimental and simulation results agreed [12]. In addition, TSCT and ring compression tests were conducted to evaluate the friction of Dry, MoS2, and CASP during hot working. And it was reported that the experimental and simulation results agreed and that MoS2 was highly influential in lubricating the alloy during hot working based on the calibration curve created from the simulation. In addition, the friction coefficient of TSCT is higher than that of the ring compression test due to the difference in surface area expansion. These reports indicate that TSCT is effective as a basic friction test for micro- to macro-scale, cold- and hot-forging.

In this study, a hot V-groove friction test is proposed as a friction test that simulates hot extrusion and forging regarding the TSCT. In the hot V-groove friction test, a cylindrical test piece is compressed using a V-groove tool. The friction coefficient is identified from the aspect ratio of the compressed product since either longitudinal extrusion or transverse compression is the preferred deformation because of friction. The characteristics of this test are that it combines both extrusion and compression deformation, has a high surface area expansion ratio of more than 50 percent, and is a two-dimensional deformation in which the circle is collapsed. The dimensions and compression ratio can be easily changed. In this research, tool dimensions and the mechanism of adhesion under different temperatures and compaction amounts are investigated as part of the development of the V-groove friction test. By using AA7075 as the test material and varying the temperature and stroke amount, this study aims to examine the effect of working temperature on the process of adhesion growth during hot forming.

Experimental Method

The AA7075 shown in Table 1 was used in this study. The test pieces were turned to a diameter of 7.0 mm and a length of 70 mm. These dimensions were chosen because the size should be at least 10 times larger than the diameter so that deformation in the depth direction can be ignored.

Fig. 1 shows the 100-ton vertical hydraulic press used in this experiment. The press has a furnace in the forming section to provide a hot test environment. A data logger from the hydraulic system and a displacement transducer read the test force and stroke rate.

Table 1. Chemical composition of AA7075 (mass%).

Alloy	Si	Fe	Cu	Mn	Mg	Cr	Zn	Zr	Ti	Al
AA7075	0.08	0.21	1.78	0.05	2.46	0.19	5.61	-	0.01	Bal.

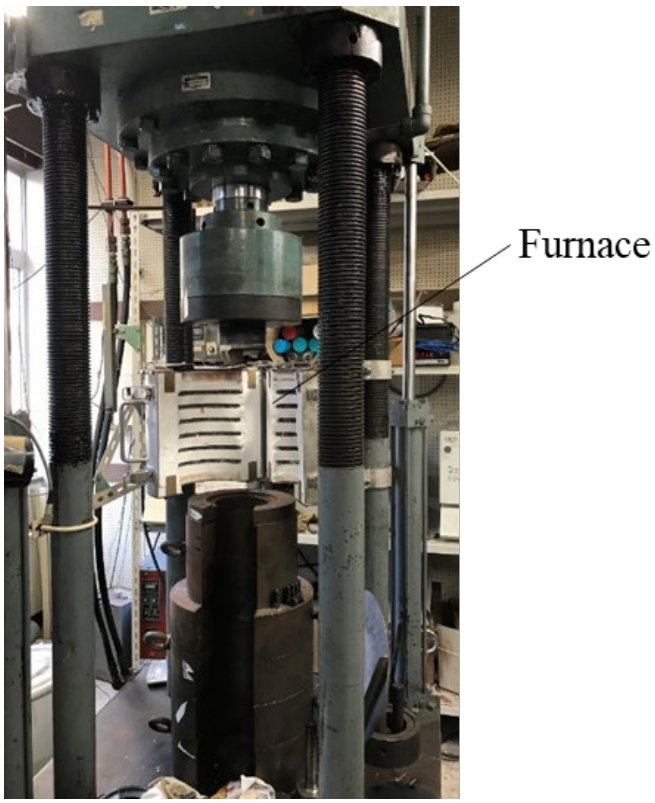

Fig. 1. 100-ton vertical hydraulic press machine.

Table 2 shows the conditions of the hot V-groove friction test and the numerical analysis conditions. Fig. 2 shows a schematic diagram of the V-groove friction test AISI H13 (HRC48) nitrided tool used as the tool material. The numerical analysis software used was DEFORM-3D by Yamanaka Eng Co., Ltd. The groove angles were 15° and 30°, and the groove corner radius R was 1.0 mm and 3.0 mm, referring to the study by Zhang et al. to examine the tool geometry for the hot V-groove friction test [11]. The groove depth was set to 10 mm. The punch stroke is set to 0.1 mm/s with a stroke volume of 4.5 mm. The temperatures of the billet and testing machine were 400°C and 500°C.

The Hot V-groove friction test numerical analysis was performed for shear friction coefficients $m = 0.1, 0.2, ...,1.0$. The shear friction model was used as the friction model. The material data was used from previous authors' AA7075 research [4]. Friction changes the height (H) and width (W)

of the test piece after the V-groove friction test. When friction is low, extrusion becomes dominant, and the height of the test piece increases.

On the other hand, when friction is high, compression becomes dominant, and the width of the test piece grows. Calibration curves were created from the sample's aspect ratio (H/W) after forming at each friction coefficient. The friction coefficients were identified by comparison with the aspect ratio of the model after the experiment. Experiments were conducted three times each for reproducibility.

The amount of elemental deposition on the V-groove tool surface was measured by Electron Probe Micro Analyzer (EPMA, JEOL) to confirm the deposition growth process. Fig. 3 shows the schematic diagram of the measurement points.

Table 2. V-groove friction test and numerical analysis conditions.

Testing conditions

Experimental Results

Fig. 4 shows the calibration curves for each tool condition generated from the numerical analysis. The friction coefficient cannot be determined for the R1, 15° condition because the shear friction coefficient does not determine the magnitude of the aspect ratio. Under the R3, 15° condition, a right ascending calibration curve was observed, but the aspect ratio increased and decreased under low friction, indicating that an accurate friction coefficient may not be obtained. In the R3, 30° condition, the shear friction coefficients of m = 0.9 and 1.0 could not analyze, and a calibration curve could not be generated. Based on these results, the basic V-groove shape of the die for the V-groove compression test was determined to have an R radius of 1 mm and a V-groove angle of 30°.

Fig. 5 shows the V-groove compression test conducted at a test temperature of 400°C. As a result, H/W was 0.526, and the coefficient of friction was m = 0.9.

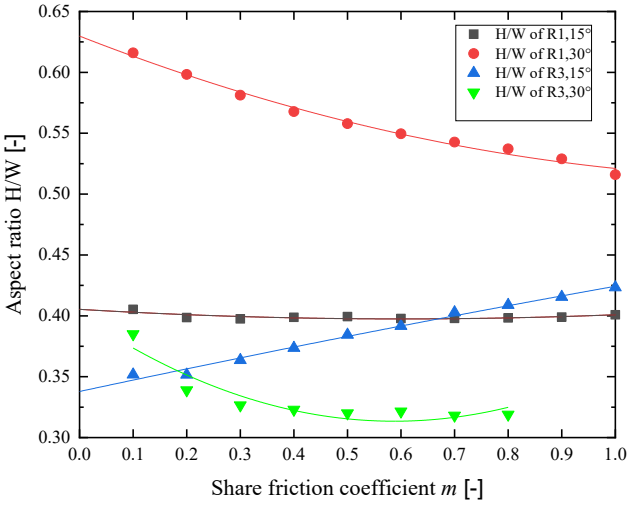

Fig. 4. V-groove compression test calibration curves for each tool condition (Simulation soft: DEFORM-3D, Temperature: 400°C, punch speed: 0.1 mm/s).

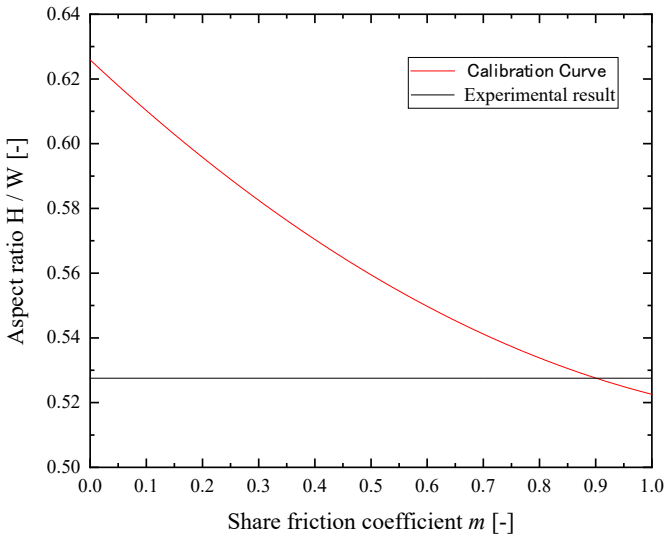

Fig. 5. Calibration curves and experimental aspect ratios (test temperature: 400°C, punch speed: 0.1 mm/s).

Fig. 6 shows an numerical analysis (m=0.9) and experimental force-punch stroke diagram for the V-groove friction test at a test temperature of 400°C. The experimental and numerical force curves were similar. The maximum force was 176.0 kN in the numerical analysis and 176.9 kN in the experiment. Fig. 7 compares the material flow between the experimental and numerical results. At the corner radius R, the material flow is divided into extrusion in the direction of punch travel and compression in the vertical movement of the extrusion. From the sample dimensions after the test shown in Fig. 7 and the calibration curve shown in Fig. 4, it can assume that material flow in

the direction of extrusion is dominant when friction is low, and material flow in the direction of compression is dominant when friction is high.

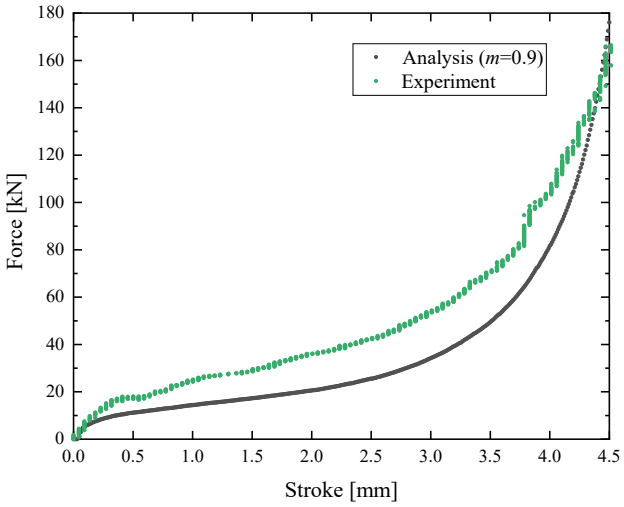

Fig. 6. Force-stroke curves for V-groove compression test and numerical analysis (test temperature: 400°C, punch speed: 0.1 mm/s).

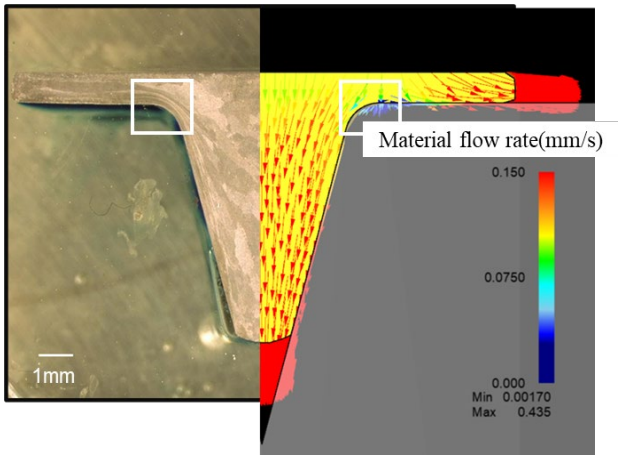

Fig. 7. Comparison of experimental and numerical material flow (test temperature: 400°C, punch speed: 0.1 mm/s).

Based on the experimental and numerical results of the V-groove compression test at 400°C, this test was validated as a friction test simulating hot extrusion and forging. Friction and adhesion between the die and aluminum on the tool surface are assumed to be significant causes of tearing defects on the product surface and burning on the tool at high temperatures and high forging speeds, which is a friction problem in extrusion and forging. Therefore, we conducted a V-groove compression test at 500°C and compared the results with those at 400°C to evaluate friction and adhesion to the tool as a function of temperature.

Fig. 8 shows the experimental results of the V-groove compression test at 500°C and the calibration curve. H/W from the experiment was 0.538, and the coefficient of friction was m = 1.0. The results of a previous hot forward-backward extrusion friction test at 500°C between a nitrided tool and AA7075 conducted by the authors also showed m=1.0, which is the same result as in the present study [4].

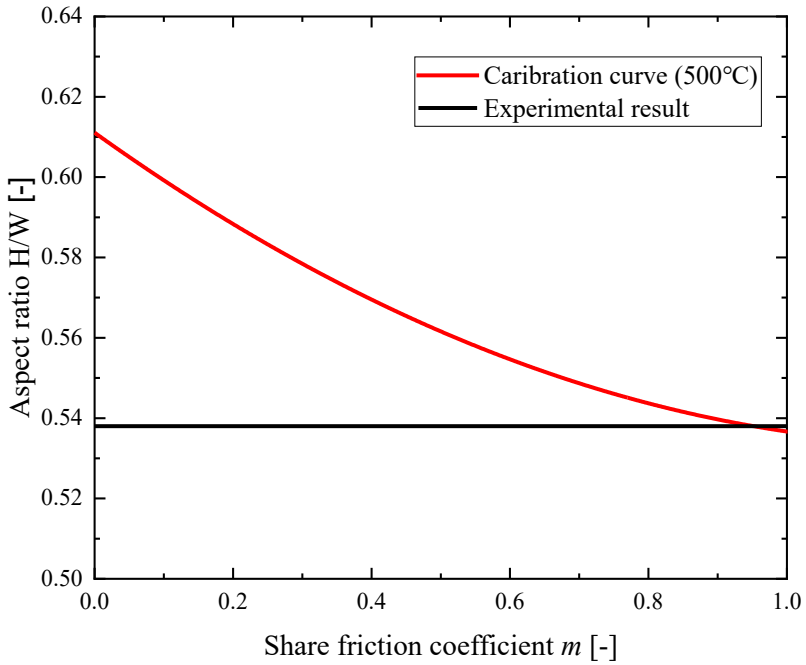

Fig. 8. Calibration curves and experimental aspect ratios (test temperature: 500°C, punch speed: 0.1 mm/s).

Fig. 9 shows the adsorption of alloying elements and oxygen (O) on the tool in the V-groove compression test at 400°C and 500°C. Before the test, aluminum (Al) was removed with sodium hydroxide solution and then analyzed by EPMA. The results of the EPMA analysis show that the adsorption of the alloying elements increased with increasing temperature in the Mg case. The strong O reaction on the entire tool surface at 500°C indicates that the tool surface is strongly oxidized, while the responses of Cu and Zn are small at 400°C and strong at 500°C, respectively. Previous studies by the authors have confirmed that magnesium oxide (MgO) is deposited by O on the tool surface and oxidized at high temperatures during the hot extrusion of AA6063 and Mg contained in the alloying elements [13]. At 400°C, the reaction of O is also vital in the Mg range, suggesting that MgO is formed.

On the other hand, at 500°C, the entire tool is uniformly oxidized, and the extent of Mg deposition is considered to have increased. The V-groove friction test also showed the same tendency, with Mg firmly adhering at the R part where the high surface pressure is applied, and from the quaternary state diagram of the Al-Zn-Mg-Cu alloy, Al+ $Al_2Mg_3Zn_3$+ $Al_5Cu_2Mg_2$ at 400°C or higher [14]. Since the composition of AA7075 in this study contains 1.6% Cu, $Al_2Mg_3Zn_3$ melts at temperatures above 480°C, and $Al_5Cu_2Mg_2$ melts at temperatures above 500°C. The Cu and Zn have not adhered at 400°C on the tool.

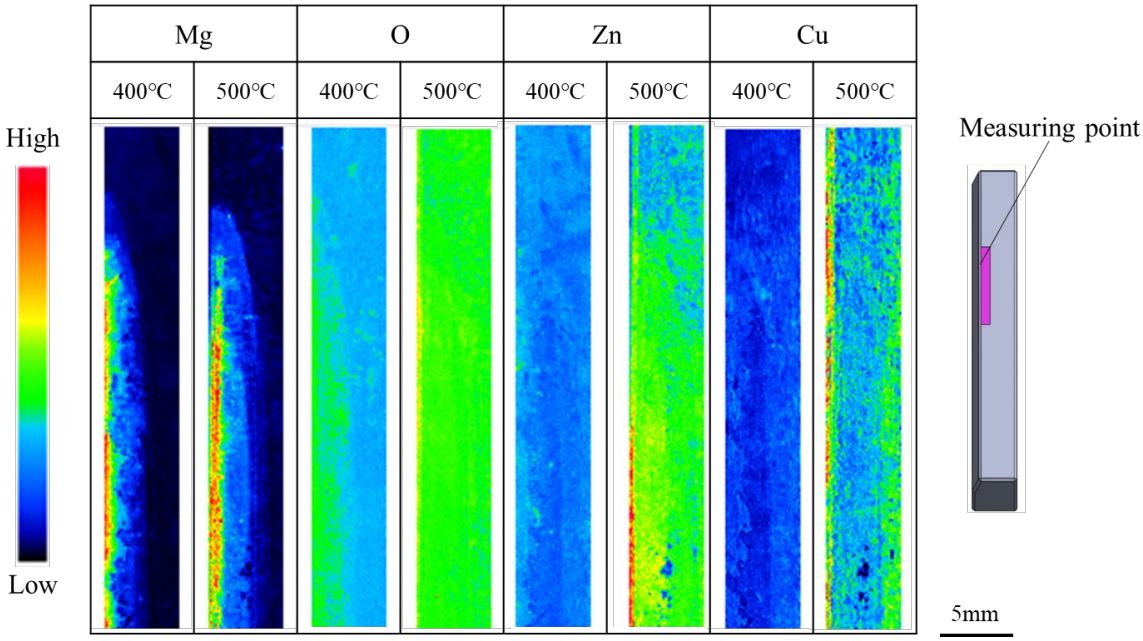

Fig. 9. Elemental analysis of tool surface after V-groove compression test (test temperature: 400, 500°C, punch speed: 0.1 mm/s).

Summary

In this study, the hot V-groove friction test is proposed as a friction test simulating extrusion and forging, measuring the coefficient of friction at various temperatures, and evaluating the adhesion to the tool surface. The hot V-groove friction test is practical as a friction test that simulates plastic forming at high temperatures because it achieves a high surface area expansion ratio. In addition, it was possible to reproduce the adhesion process of the tool surface during extrusion. The results obtained are listed below.

- The tool geometry was optimally affected by friction when the corner radius of the groove R was 1.0 mm, and the groove angle was 30°.
- From the calibration curve obtained from the numerical analysis, the shear friction coefficient *m* of AA7075 at 400°C was 0.9, and at 500°C, the shear friction coefficient *m* was 1.0.
- The EPMA evaluation of tool surface adhesion at 400°C and 500°C showed that the extent of Mg adhesion increased with increasing temperature, and the oxidation of the tool surface became stronger; Cu and Zn adhesion became more active at 500°C due to melting of intermetallic compounds.

Future research will include investigating the effects of surface pressure, heat generation, and tool surface adhesion using analysis and investigating the impact of tool surface treatment on tribological properties by applying die coating, tool surface texturing, and V-groove compression testing.

Keywords: NiTi Alloys, Cold-Drawing, Low-Temperature Annealing, Sensing Properties

Abstract. As an intelligent material, NiTi alloy exhibits shape memory effect and superelasticity. Its electrical resistance varies with deformation, thus making NiTi alloy a potential sensing material. Linearity and sensitivity are the two principal characteristics of sensors. Linearity reveals the deviation of the actual resistance-strain response from an ideal straight line and sensitivity is the change in input required to generate a unit change in output. Though conventional polycrystalline NiTi alloys possess high sensitivity and large strain range, the non-linear resistance-strain responses were not negligible thus hindering their sensing application. It was found that cold-drawing combing with low-temperature annealing had affected the linearity, while the influence rules were not clear. The electrical resistance of the fabricated NiTi alloy wires with various areal reductions were measured during stretching, and the results shown that the cold-drawn and annealed NiTi alloys exhibited better linearity though with decreased sensitivity. This investigation provides foundation for subsequent research on improving or tailoring the sensing properties of NiTi alloys.

Introduction

Shape memory alloys (SMAs), particularly NiTi alloys are special class of smart or intelligent materials gaining remarkable attention[1]. NiTi alloys possess the outstanding properties of shape-memory effect, superelasticity, high damping capacity as well as excellent wear resistance[2]. And they have been extensively applied in automotive, aerospace, mini actuators and micro-eletromechanical systems (MEMS).

Electric resistance is an important physical property of SMAs and it have been used to investigate the martensitic transformation, orientation, aging and plastic deformations[3]. Several researchers have noticed that changes in deformation are coupled to changes in electrical resistance of superelastic NiTi wires[4–6]. This relationship is of great importance because it makes NiTi a potential perception material, thus could further enrich its intelligent performance. Linearity and sensitivity are the two principal characteristics of sensors. The linearity is characterized by the non-linearity error, which is the maximum deviation of the change in the resistance from a specified straight line applied to the measured data points. The sensitivity is the ratio of change in the resistance to the strain. However, conventional polycrystalline shows a severer non-linear resistance-strain response, which hinders its sensing application.

The functional properties of NiTi are structure-sensitive, so they are possible to be improved by some process through creating well-developed structures. Lin et al. [7] fabricated three polycrystalline NiTi samples with different grain sizes from 35 nm to 110 nm and one crystalline-amorphous NiTi nanocomposite sample. They found that grain refinement and partial

amorphization can significantly improve the linearity of stress-strain response. Hua et al.[8] produced NiTi crystalline-amorphous nanocomposite by cold rolling with low-temperature annealing, which demonstrates near-linear superelasticity under stress of 2.3 GPa. Inspired by these strategies for improving its mechanical properties, we consider it practicable to change the electrical behaviors of NiTi by introducing amorphous structure. According to the preliminary results, it was found that cold-drawing combing with low-temperature annealing had affected the electrical behavior of NiTi alloy wires, while the influence rules were not clear.

The present work aims to investigate the effects of cold-drawing and low-temperature annealing on the sensing properties of NiTi alloy wires.

Materials and Experiments

Commercial superelastic NiTi wires with an initial diameter of 0.3 mm were purchased from PEIERTECH Incorporation (Jiangsu, China). The as-received nanocrystalline NiTi alloy wire was solution treated at 800 ℃ for 60 min in a muffle furnace and subsequently quenched by water.

Then the solution-treated samples were cold-drawn to thinner wires by continuous multi-pass processes using diamond dies without intermediate annealing. The die was lubricated with MoS_2 and the drawing speed was 300 mm/min. Due to the significant work hardening and cracking, it is difficult to lead the wires to pass through the die. And mechanical grinding is not applicable to make the wire end to a thinner diameter. Instead, a corrosion solution of HF: HNO_3: H_2O=1:5:20 by volume ratio was used to reduce the diameter of the wire end. According to the initial wire diameter of each drawing pass, the corrosion time varied from 5 min to 30 min. The summarized cold-drawing parameters including corrosion time, die diameter, pass or total areal reduction were listed in Table 1.

Table 1. Cold-drawing parameters of the NiTi wires.

Drawing Pass	Wire Diameter	Corrosion Time	Die Diameter	Pass Areal Reduction	Total Areal Reduction
1	0.3 mm	30 min	0.25 mm	30.6 %	30.6 %
2	0.25 mm	20 min	0.2 mm	36.0 %	55.6 %
3	0.2 mm	15 min	0.17 mm	27.8 %	67.9 %
4	0.17 mm	12 min	0.15 mm	22.1 %	75.0 %
5	0.15 mm	10 min	0.13 mm	24.9 %	81.2 %
6	0.13 mm	8 min	0.11 mm	28.4 %	86.6 %
7	0.11 mm	5 min	0.1 mm	17.4 %	88.9 %

The cold-drawn wires with final diameters of 0.2 mm, 0.15 mm, 0.1 mm (area reduction were 55.6 %, 75.0 %, 88.9 %, respectively) were then annealed at 300 ℃ for 60 min. As shown in Fig. 1, the tensile tests were executed on an MTS E44 testing machine with a loading and unloading rate of 5 mm/min at room temperature. The specimen elongation was measured via the crosshead travel monitor with resolution of 0.04 μm. The gauge length of the specimen was about 50 mm and the maximum elongation was 3 % with a strain rate of about $1.7 \times 10^{-3}\ /s$. The variations of electrical resistance were synchronously measured by a high precision multi-meter (GDM-8342, Good Will Instrument) with an accuracy of 0.1 %. The end of thin wire was clamped by three-jaw metal collet, and the electric cables of the multimeter were fixed on the collet by screws. For ensuring the NiTi wires insulate from the tensile machine, the collets were connected to the grip

holders with insulated handles. Both the crosshead travel distance and the measured electrical resistance were transferred to PC for further processing.

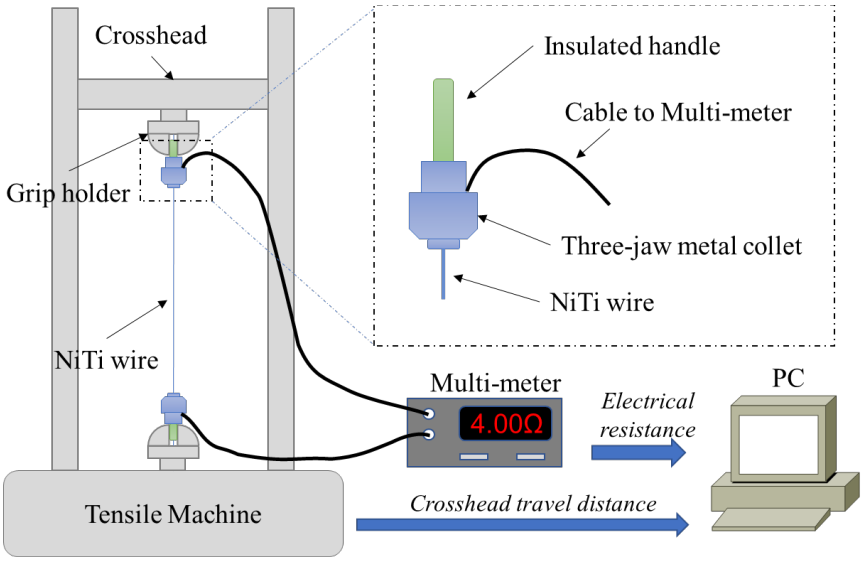

Fig. 1. Schematic diagram of the electrical resistance measurement.

Based on the measured data of electrical resistance and crosshead travel distance, the change ratio of resistance-strain curve is achieved. Through the least-squares method, the fitting line is achieved based on the experimental data. The calculation schematic of linearity and sensitivity is shown in Fig. 2. The sensitivity is defined as the slope of the fitting line, which is a unitless value. The linearity is characterized by the non-linearity error (NLE), which is calculated by Eq. 1.

$$NLE = \frac{\Delta_{max}}{Y_{max}} \times 100\% \, . \tag{1}$$

where Δ_{max} is the largest difference between the experimental data and the fitting line and Y_{max} is the largest change ratio of resistance.

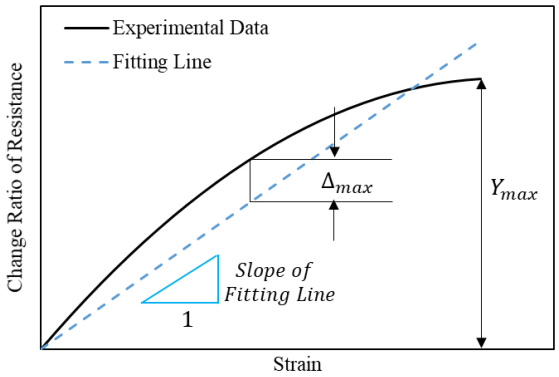

Fig. 2. Schematic diagram of the calculation of linearity and sensitivity.

According to the resistance formula (Eq. 2a and Eq. 2b), the electrical resistance is determined by two factors: the electrical resistivity (ρ) and size factor (L/S).

$$R_0 = \rho_0 * L_0/S_0 \, . \tag{2a}$$

$$R_\varepsilon = \rho_\varepsilon * L_\varepsilon / S_\varepsilon \,. \tag{2b}$$

where R is the measured resistance, ρ is the electrical resistivity, L is the length of the wire and S denotes the cross-sectional area of the specimen. The subscript 0 and ε stands for initial undeformed state and deformed state with a strain of ε, respectively.

From the constant volume assumption (Eq. 3a) [9] and the strain formula (Eq. 3b), the relative change ratio of electrical resistivity is inferred as Eq. 4.

$$L_\varepsilon * S_\varepsilon = L_0 * S_0 \,. \tag{3a}$$

$$L_\varepsilon = L_0 * (1 + \varepsilon) \,. \tag{3b}$$

$$\frac{detdet\,(\rho_\varepsilon)}{\rho_0} = \frac{\rho_\varepsilon - \rho_0}{\rho_0} = \frac{R_\varepsilon * {L_0}^2}{R_0 * {L_\varepsilon}^2} - 1 = \frac{R_\varepsilon - R_0 * (1+\varepsilon)^2}{R_0 * (1+\varepsilon)^2} \,. \tag{4}$$

Then assuming that the resistivity is constant, the relative change ratio of size factor is inferred as Eq. 5.

$$\frac{detdet\,(L_\varepsilon / S_\varepsilon)}{\frac{L_0}{S_0}} = \frac{L_\varepsilon/S_\varepsilon - \frac{L_0}{S_0}}{\frac{L_0}{S_0}} = (1+\varepsilon)^2 - 1 \approx 2\varepsilon \,. \tag{5}$$

To clarify the crystal structural change by cold-drawing and low-temperature annealing, Micro X-ray diffractometry (Micro-XRD) was carried out on Bruker D8 Advance using Cu-Kα radiation operated at 30 kV, 150 mA and a scanning speed of 4 °/min. A 2θ angle range from 5 ° to 85 ° was selected.

Results and Discussions

As shown in Fig. 3, the initial electrical resistivity exhibits a large variability in different NiTi alloy wires. The as-received NiTi alloy material possesses an initial electrical resistivity of 0.9 $\mu\Omega \cdot m$, which is higher by two orders of magnitude than common metal such as copper, aluminum. The resistivity of the cold-drawn NiTi (CD) increases significantly with the areal reduction. For the low-temperature annealed NiTi wires (CD+LTA), their resistivities maintain the same variation trend with the areal reduction but they decrease comparing with their cold-drawn counterparts. Notably, the electrical resistivities of the annealed NiTi wires with different areal reduction remain above that of the as-received.

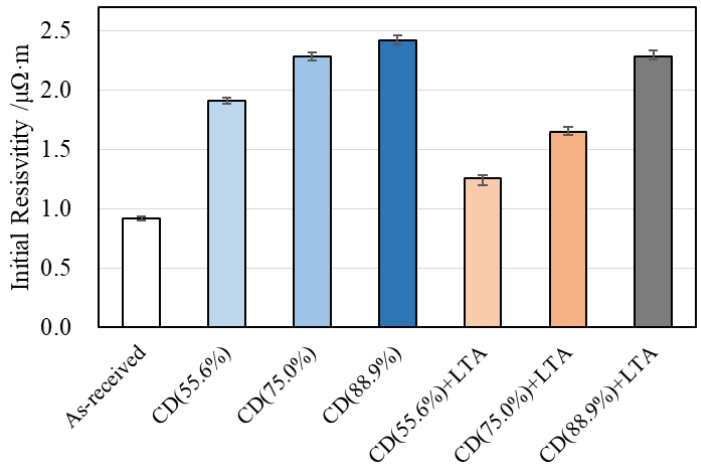

Fig. 3. The initial electrical resistivity of the NiTi alloy wires.

Materials Research Proceedings 28 (2023) 429-436 https://doi.org/10.21741/9781644902479-47

Fig. 4(a) displays resistance change ratio as a function of strain obtained during stretching of the as-received NiTi alloy wire and six tailored materials. The sensitivity and the non-linearity errors are summarized in Table 2. By comparing with the as-received sample, the cold-drawn and annealed NiTi wires demonstrates nearly linear resistance vs. strain relationship though with decreased sensitivity. With similar properties of linearity, the low-temperature annealed NiTi wires exhibited higher sensitivity than the cold-drawn ones.

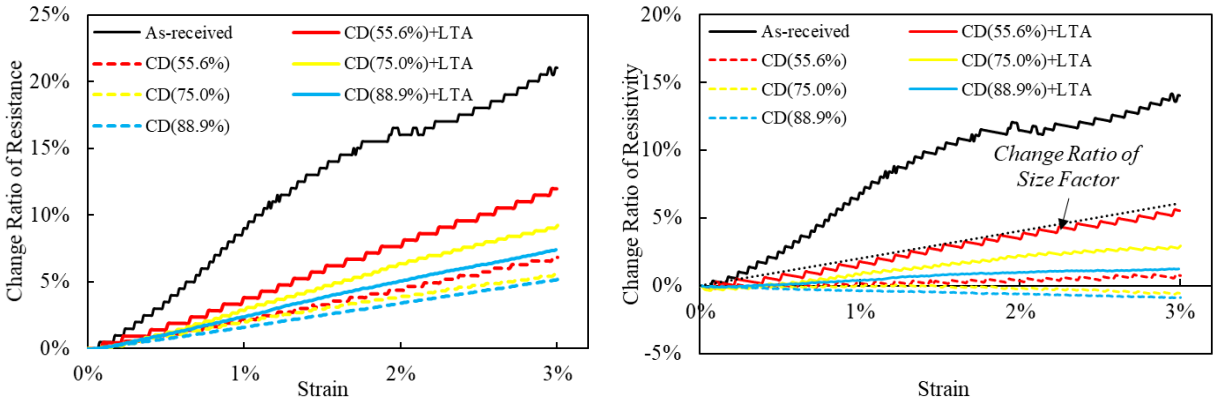

Fig. 4. (a) The resistance change ratio vs. strain curves and (b) the resistivity change ratio vs. strain curves of different NiTi alloy wires.

Table 2. Sensing sensitivities and non-linearity errors of different NiTi alloy wires.

Sample	Sensitivity	Non-Linearity Error
As-received	7.00	10.68 %
CD(55.6 %)	2.29	3.77 %
CD(75.0 %)	1.84	4.84 %
CD(88.9 %)	1.72	2.17 %
CD(55.6 %)+LTA	3.99	5.07 %
CD(75.0 %)+LTA	3.15	3.35 %
CD(88.9 %)+LTA	2.48	2.64 %

The factors of resistance variation were decoupled to the resistivity and the size factor. According to Eq. 5, the change ratio of size factor is only determined by strain and the slope is about 2. The resistivity change ratio vs. strain curves of different NiTi wires are shown in Fig. 4(b), in which the curve of size factor change ratio also added. For the as-received sample, the resistivity change ratio displays severe nonlinearity as well as a bigger slope than the size factor. The linearities of the tailored material are much better than the as-received one though the slopes are smaller. The slopes decrease with the areal reduction both for the cold-drawn and the annealed NiTi wires, while the latter ones are better than the former ones. Worth noting is that the resistivity change ratio becomes negative for the cold-drawn NiTi with 75.0 % or 88.9 % areal reduction and this issue will be discussed later.

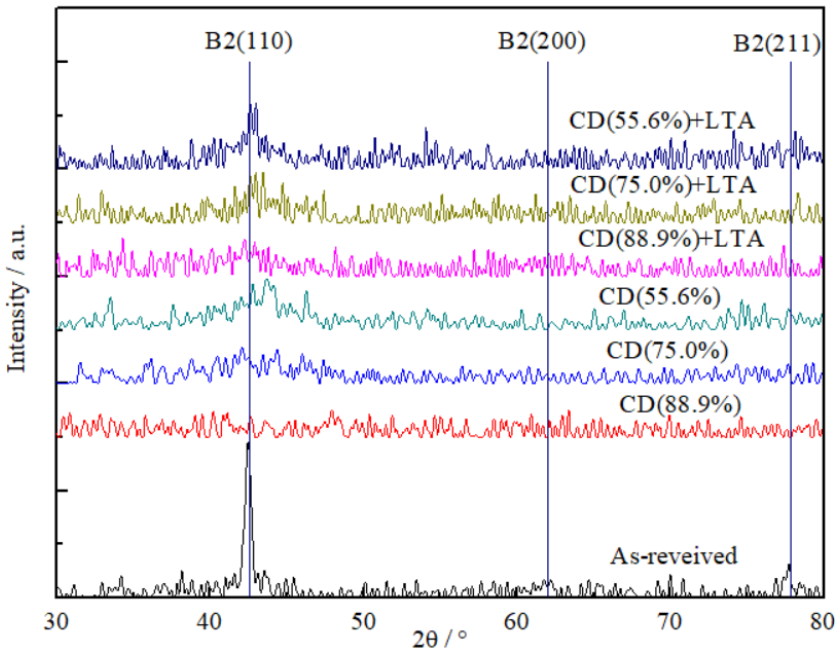

Fig. 5. Micro-XRD patterns of the as-received NiTi wire and six tailored ones.

Fig. 5 gives the Micro-XRD patterns of the different NiTi alloy wires. The Micro-XRD patterns of as-received wire shows that it is comprised of austenite phase (B2). There are marked drops in the intensity of the austenite peak for all of the cold-drawn wires and the low-temperature annealed wires. With the increasing of areal reduction, the intensities of the austenite peaks of both two kind of materials decrease, which illustrates that amorphization is intensified. The peak intensity of the annealed NiTi is higher than the cold-drawn one with the same areal reduction, which indicates that recrystallization of the austenite occurs to a certain extent in the low-temperature annealing processes.

According to the initial electrical resistivities and the Micro-XRD patterns, it suggests that cold-drawing leaded to amorphization of NiTi alloy and the amorphous phase rise with the increasing of areal reduction. In the subsequent low-temperature annealing, amorphous phase is subjected to recrystallization. For the as-received nanocrystalline NiTi material, elastic deformation appeared first in the stretching process and the stress-induced austenite-to-martensite transformation occurred when the strain exceeded about 1.5 %. The non-linear resistance-strain response is directly relevant to the stress-induced phase transformation. Ahadi and Sun [10] carried out in-situ tensile X-ray diffraction experiments for investigating the structure evolution during stress-induced transformation. NiTi alloy with a low B2 peak exhibited a continuous and smooth peak shift from B2 peak to B19'(Martensite) peak, while NiTi alloy with a higher peak displayer a sudden appearance of B19' peak. For the cold-drawn and the annealed NiTi wires, the containing amorphous phase suppresses the austenite-to-martensite transformation resulting in a continuous and smooth transformation, thus leading a more linear resistance-strain response.

Considering the negative slope of resistivity-strain response of the cold-drawn with great areal reduction (75.0 %, 88.9 %), it is assumed that the resistivity of pure amorphous phase is negative correlation with deformation. The amorphous phase is unstable and it can be subjected to crystallization under the stress [11]. The resistivity decreases in the crystallization process as the resistivity of crystal is lower than that of amorphous. Thus, there is a competitive relationship between crystalline and amorphous, which haves opposite effect on electrical resistivity of the deformed NiTi material. For CD 75.0 % and CD 88.9 %, the amount of amorphous is higher than other samples, so the amorphous phase plays a major role in resistivity variation resulting in a

negative slope. The changing sensitivity, i.e., the slopes of the resistance vs. strain curves, is attributed to the differences of amorphous phase content.

Summary

In this study, the effects of cold-drawing and subsequent low-temperature annealing on the sensing properties of NiTi alloy wires were investigated. The cold-drawn and annealed NiTi alloys exhibited better linearity though with smaller sensitivity. The greater areal reduction caused a better linearity. Combing with the initial electrical resistivities and the XRD patterns, it is inferred that amorphous phase is generated in NiTi alloy due to cold-drawing and low-temperature annealing. The amorphous phase suppresses martensitic transformation of the crystalline phase and consequently contributed to the improvement of linearity in the resistance-strain response.

Cold-drawing combining with low-temperature annealing is a practicable approach to regulate the sensing properties of NiTi alloys. For further investigations, the quantitative relationships between microstructures and sensing properties should be appealed.

Keywords: EBSD Technique, Porthole Dies, Aluminum Extrusion

Abstract. Electron backscatter diffraction was used to analyze the crystallographic texture within extruded AA6005 hollow profiles, allowing for the analysis of metal flow through various extrusion porthole die designs of different metal deformation conditions. Control of metal flow through a die design is necessary to meet industry demands for faster-running dies, tighter tolerances, thinner walls, and reduced extrusion loads. A standard die was compared with an innovative die design that doubled the extrusion exit speed. Analysis of metal flow was performed to provide additional insight into the uniformity of the metal flow, especially near the extrusion welds. Finite element method simulations were performed to predict the die exit temperature and plastic strain distributions. Local texture varied across the core and surface regions of the tube wall but remained consistent between both extrudates. A peripheral coarse grain structure was found within both extrudates, due to their elevated exit die temperatures.

Introduction

The purpose of this work is to develop a quality control tool, which can analyze the homogeneity of an extrudate's microstructure and local crystallographic texture for an innovative porthole die design that allows for the minimization of the resistance to deformation. This translates into increasing the efficiency of the extrusion production process in the area of forming limit diagrams. A die design that ensures optimal metal flow translates into an increase in the flow rate in the connection with the load capacity of the press. An optimal die design also provides a reduction in the extrusion force, which is beneficial from the point of view of energy balance and die strength [1]. For these reasons, testing is required to determine the dies' effectiveness. Finite element method (FEM) numerical simulations as well as metallurgical characterization techniques may be utilized to predict and determine part properties. In this study, a standard porthole die design was compared to a new innovative porthole die design with increased extrusion exit speed in an attempt to increase production during the extrusion process. FEM numerical calculations were performed using QForm UK Extrusion software. The extrusion model is based on the Lagrange-Eulerian approach, which included coupled simulations of the material flow and die deflection during the process [2]. The approach uses a proprietary material model of a deformed aluminum alloy developed based on a high-temperature compression test on a Gleeble 3800 metallurgical process simulator. Simulations of different variants of dies were carried out under identical process parameters, including heating the billet to 480°C. FEM numerical calculations were performed to predict both the exit temperature and plastic strain distribution throughout the extrudate cross sections but still requires validation through experimental data.

Electron Backscatter Diffraction (EBSD) was utilized as the experimental method of choice to characterize the localized microstructural texture and average grain size within the resultant extrudates, as a result of their deformation conditions. Election backscatter diffraction, or backscatter Kikuchi diffraction, is a scanning electron microscope (SEM) based technique that can be used to determine local microstructural texture, generally associated with the crystallographic orientation of individual grains within a material. This allows for microstructure reconstruction and detailed characterization of the microstructural properties of a material [3]. EBSD utilizes automated Kikuchi pattern indexing software to determine the orientation of multiple grains at once, making it a fast and accurate method for generating large quantities of data. Indexing of patterns involves the identification of individual (Kikuchi) bands based on the presence or absence of specific crystallographic poles (zone axes) as well as bandwidth [4, 5]. It is important to define the notation of the extrudate axes to better describe the areas of interest for the EBSD analysis, which is shown in Fig. 1, below.

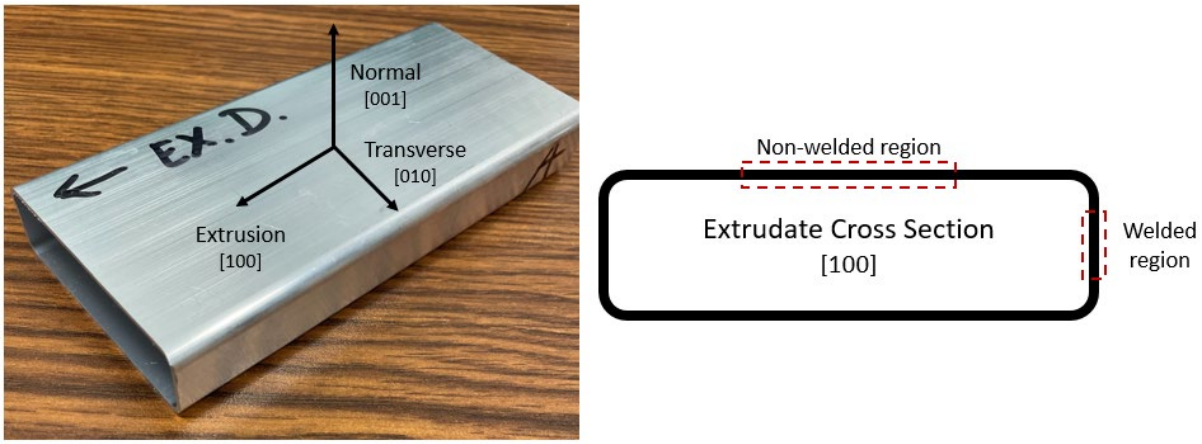

Fig. 1. Example of extrudate direction notation and regions of interest.

It is expected to obtain a homogenous microstructure within the extrudate as a result of die design, and therefore, altering deformation conditions. EBSD, as a proposed modern tool for metal flow analysis, will help to indirectly verify these results and the FEM predictions of exit temperature and plastic strain distribution.

Experimental Procedure

The samples analyzed in this study were thin-walled extrudates from 7-inch AA6005 billets extruded on 17 MN hydraulic press. Two profiles, A and D, were developed and extruded at the same temperature within different two-cavity dies consisting of similar web designs. Thus, the localization of transverse welds was the same. Profile A consisted of a conventional die with a maximum extrusion exit speed of 24 m/min and a specified maximum ram load of 15.36 MN. Profile D consisted of a new die with an innovative design ensuring an almost doubled increase in the extrusion exit speed of 42 m/min. The construction ensured a reduced plastic flow resistance, which was indicated by a lower maximum extrusion load of 14.88 MN. Both extrudates were cooled on the press run-out table under forced air. The maximum extrusion speed was determined for each of the dies in industrial trials while maintaining the required product surface quality. The measurement of the extrudate extrusion exit speed corresponded to the puller speed on the runout table. This was measured by sensors and using press software. The maximum speed was determined by the force capabilities of the press with simultaneous control of the temperature and the quality of the extrudates surface.

Improved process parameters were the result of using an extrusion die with larger ports, increasing the volume of metal flow by 45%. Thin webs were also used to ensure an even metal flow to the welding chambers. Equal filling of the bearing took place using a special port with a dedicated geometry. The new die design was developed based on FEM numerical simulations of the extrusion process. In the extrusion process design for the hollow sections of aluminum alloys, the exact conditions required to occur on the bearing surface must be determined. This can be obtained by numerical analysis, which includes parameters such as plastic strain and temperature distributions [6]. The developed extrusion process ensured a slight die deflection but yielded a high dimensional accuracy of extrudates. Both numerical simulations and physical measurements confirmed this. The deflection in the core and bearings was the result of numerical simulations, which is an elastic deformation that translates into the geometric accuracy of extrudates. Physical measurements were carried out after the experiment, which confirmed no evidence of plastic deformation of the tooling.

To prepare for experimental characterization, the extrudates were sectioned using a Struers Accutom-50 high-speed abrasive cutoff blade and mounted in epoxy resin, set in a vacuum to remove air bubbles, and left to cure overnight. Samples were metallographically prepared to a 0.25 μm finish with diamond media on a Buehler AutoMet250 automatic polishing unit before a 0.05 μm finish with colloidal silica on a vibratory polisher. Samples were cleaned in an ultrasound bath with ethanol and airdried using high heat. Silver paint was applied to the surface of the sample and left to dry for a minimum of 12 hours to prevent the buildup of current on the sample surface within the electron microscope.

Electron backscatter diffraction (EBSD) was performed in an FEI SCIOS Focused Ion-Beam (FIB) unit. Data was generated using EDAX TEAM software and analyzed with TSL OIM v8 software. EBSD maps were rebuilt using NPAR and further cleaned to achieve higher accurate confidence indexing (CI > 0.2) throughout the area of interest. An accelerating voltage of 10 kV was used in combination with a current of 6.4 nA during image collection. Maps were taken with a maximum sampling grid of 1024 x 800 pixels, individually modified to reduce both the scan area and total collection time. Maps were generated using a step size between 3-4 μm, consisting of hexagonal pixels. The EBSD camera was optimized using an *Ultra-Fast* setting to acquire a maximum of 170 frames per second (fps) under the listed conditions.

Numerical Investigation

FEM numerical simulations of the exit temperature and plastic strain distributions were performed for both extrudates A & D. The areas of interest highlighted within a black box, shown in both Fig. 2 and 3, for both the *non-welded* and *welded* regions correspond to the fields of view discussed later in the *Results & Discussion* section, shown as EBSD maps in Fig. 4. The exit temperature simulations, shown in Fig. 2, exhibited a variation of 10 °C throughout the entire cross-section, but was consistent across the full wall thickness at any given point, within a single degree. Comparing both profiles, A & D, a maximum exit temperature of 550°C was recorded near the center of the *non-welded* regions, steadily decreasing to a minimum temperature of 540°C as the cross-sectional corners were approached. In respect to the *welded* regions, profiles A & D were again consistent amongst each other, but with opposing results at either side of the extrudate. For the purpose of this study, the area of interest was focused on the right side of the extrudate cross-section, with a recorded exit temperature of 550°C.

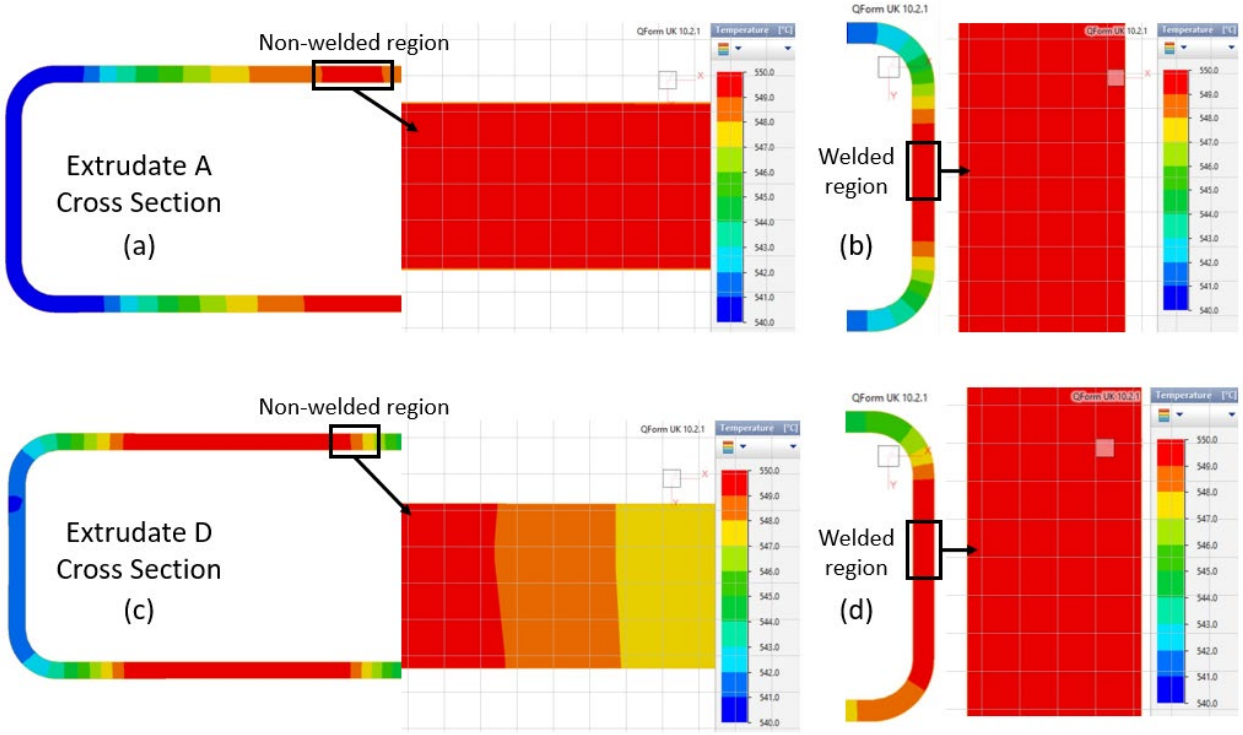

Fig. 2. FEM simulation of Exit Temperature for both Extrudate A (a, b) and Extrudate D (c, d).

The plastic strain simulations, shown in Fig. 3, exhibited a consistent strain gradient throughout the entire die other than at the center of both *welded* regions, including both sides of each extrudate. A minimum plastic strain, corresponding to the light blue color, was recorded at the center of the wall thickness where the least deformation is expected to occur. A gradient was recorded on either side of the wall thickness as the surface was approached, where the extrudate and die are in contact and the most deformation is expected to occur. The only discrepancy in the strain gradient occurred within the *welded* regions, where the localization of the longitudinal weld is believed to exist. Overall, the outer surface of the extrudate experienced a larger plastic strain compared to that of the inner surface, which was more apparent within the *welded* regions than within the *non-welded* regions. Upon closer inspection, a more balanced strain distribution across the wall thickness was revealed for profile A in the *non-welded* region, whereas a more balanced distribution was revealed for profile D in the *welded* region.

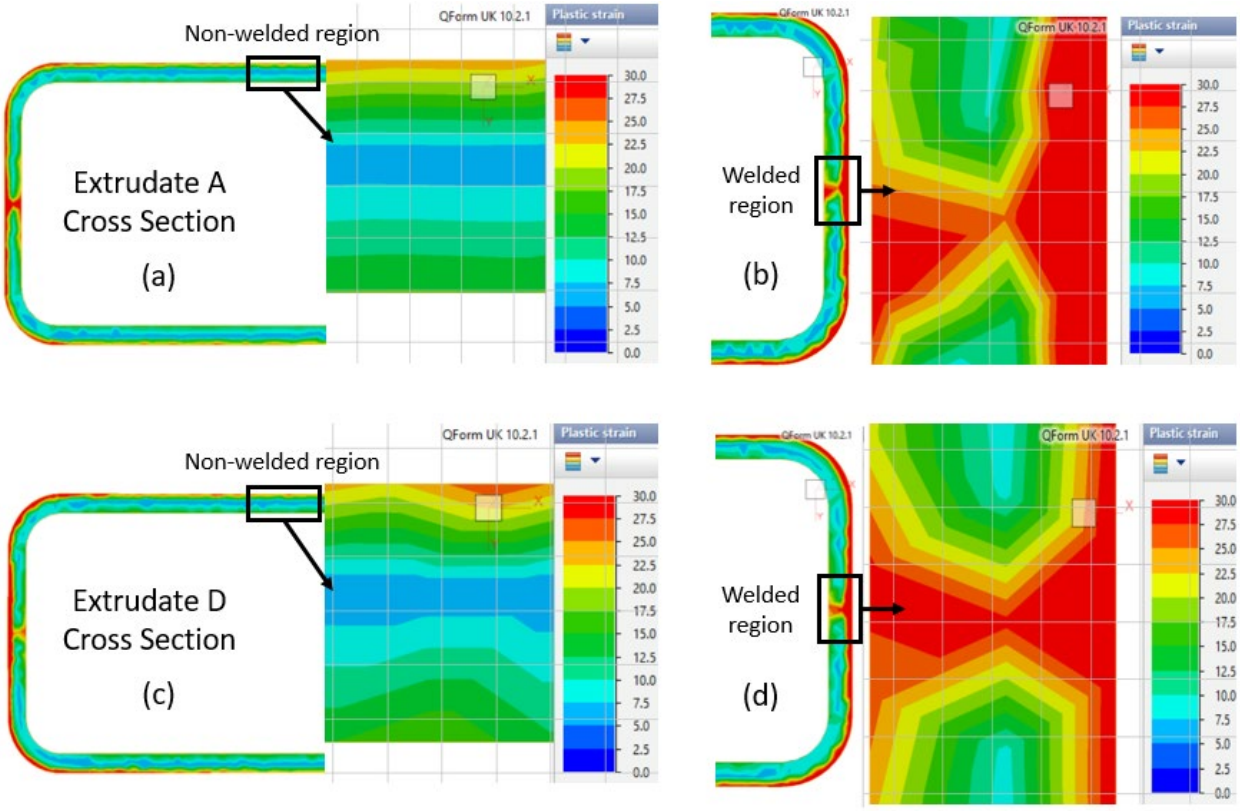

Fig. 3. FEM simulation of Plastic Strain for both Extrudate A (a, b) and Extrudate D (c, d).

Results and Discussion

Election backscatter diffraction was utilized to measure the microstructural texture and grain size of hot extruded AA6005 billets. A few considerations were made to generate accurate indexed patterns. As aluminum is a beam-sensitive material, a low accelerating voltage/beam current was necessary to reduce beam damage during mapping, which led to a loss in collection time and pattern quality. In addition, low magnification (80-100x) imaging was necessary to generate large enough fields of view for the regions of interest within the extruded samples. Below a magnification of ~250x, distortion of the image can occur due to a large focal plane when tilted at 70° for the EBSD technique. Using a low magnification can also make smaller grains difficult for the software to distinguish. A step (pixel) size of 3-4 µm was used to balance between pattern quality and collection time. The EDAX TEAM software incorporates Neighbor Pattern Averaging and Re-indexing (NPAR), which was used for post-process map rebuilding, greatly improving the accuracy of results and quality of the images presented in this study [7, 8].

Samples A and D were analyzed. EBSD maps of their areas of interest were generated, shown in Fig. 4. Throughout each field of view for both samples, the center of the extrudate exhibited a strong [001] texture corresponding to the color red/orange, whereas the surfaces in contact with the die transitioned into a [101] texture corresponding to the color green. In addition, a weak [111] texture corresponding to the color blue was recorded throughout the extrudate, but in larger amounts near the extrudate surface. The localized microstructure can be seen to vary from extrudate core to its surfaces due to different strain and friction conditions of the die. This result was to be expected and validated the plastic strain gradients recorded in the FEM simulations in Fig. 3.

Comparing the *non-welded* regions (Fig. 4a & 4c) the overall texture profile remained the same, but a decrease in average grain size from 95.6 µm to 83.7 µm occurred as the extrusion exit speed doubled. Within the *welded* regions (Fig. 4b & 4d) there was a drastic increase in average grain size from 66.5 µm to 82.8 µm. This increase in average size was likely a result of abnormal grain

growth, occurring near the outer surface within extrudate D. It is necessary to state that microstructural imperfections are known to occur during hot extrusion of aluminum alloys, such as in this case, a peripheral coarse grain (PCG) structure. This was more evident within the *non-welded* regions, but existed for both profiles A & D. Eivani et. al. concluded that elevated temperatures above 500°C during extrusion could cause PCG to form [9]. The presence of a PCG structure within both profiles may validate the FEM simulations in Fig. 2, which recorded exit temperatures entirely above 540°C. Van Geertruyden et. al. concluded that PCG is likely the result of delayed recrystallization, forming within a few seconds after exiting the die at elevated temperatures. He also found that a lack of recrystallization-inhibiting elements, such as Cr, increased the depth of PCG within the AA6xxx extrudate [10]. The low alloying content of these AA6005 extrudates while also undergoing air-cooling suggested the presence of PCG was likely to occur.

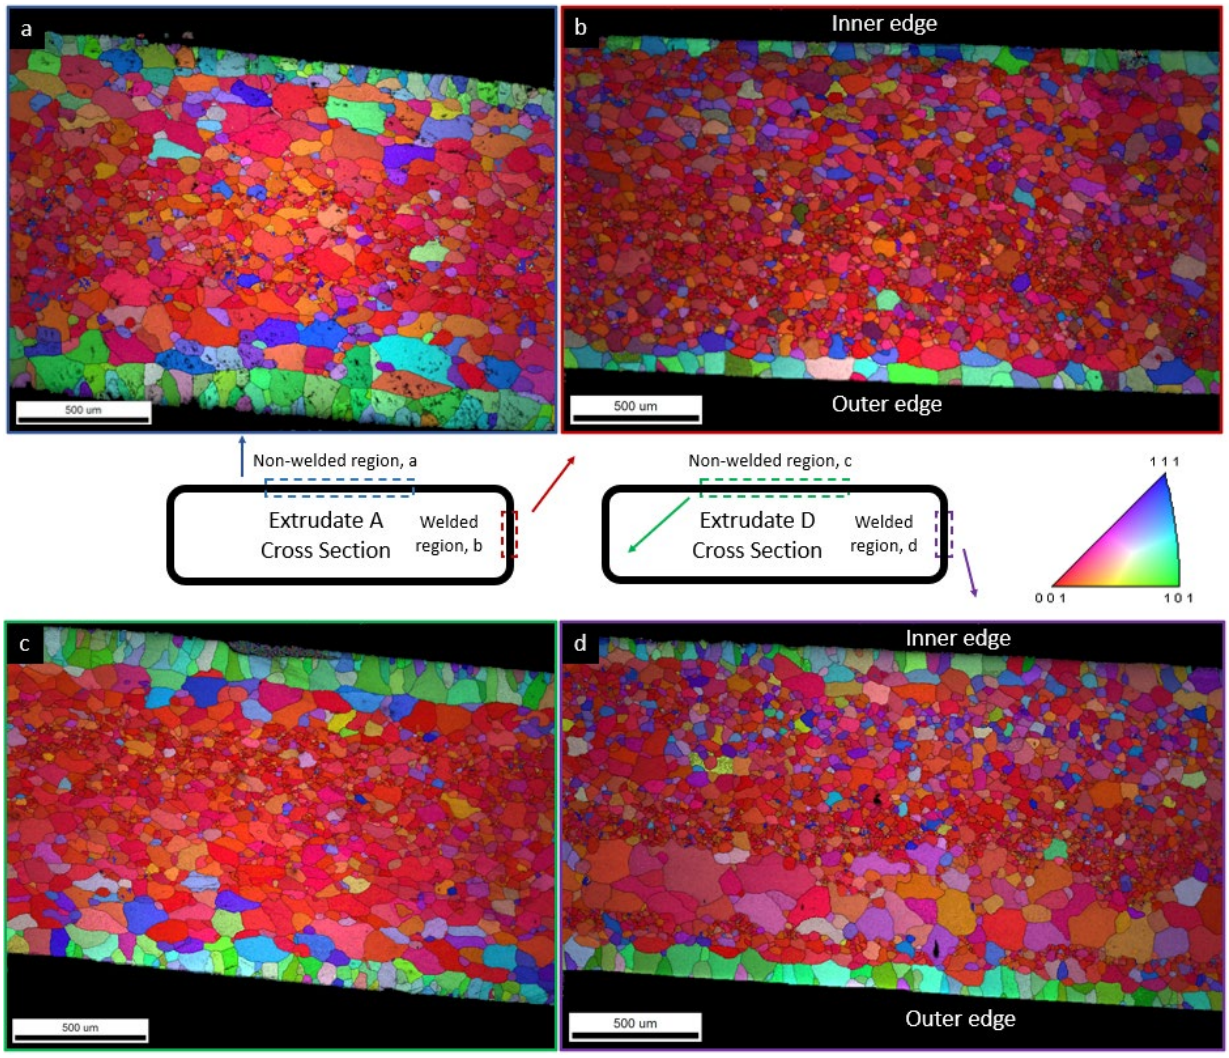

Fig. 4. EBSD crystallographic orientation maps of Extrudate A (a, b) and Extrudate D (c, d).

Inverse pole figures (IPFs) were generated for each region of interest corresponding to the extrusion [100], transverse [010], and normal [001] directions. These figures represent binary black-and-white intensity maps that relate to the area of points (in this case, grains) bound to a specific crystallographic direction. A higher intensity of dark area correlates to a stronger texture for any given plane. Fig. 5, shows the majority of grains were orientated towards both the <100>

and <110> family of planes along the extrusion [100] direction for both *non-welded and welded* regions between both extrudates. While along the transverse [010] direction, there was a weak or randomized texture as the intensity of points was spread homogeneously between the IPFs. Comparing each family of planes between all four areas of interest exhibited a consistent texture profile, implying that increasing the extrusion exit speed had little to no effect on the result of microstructural orientation.

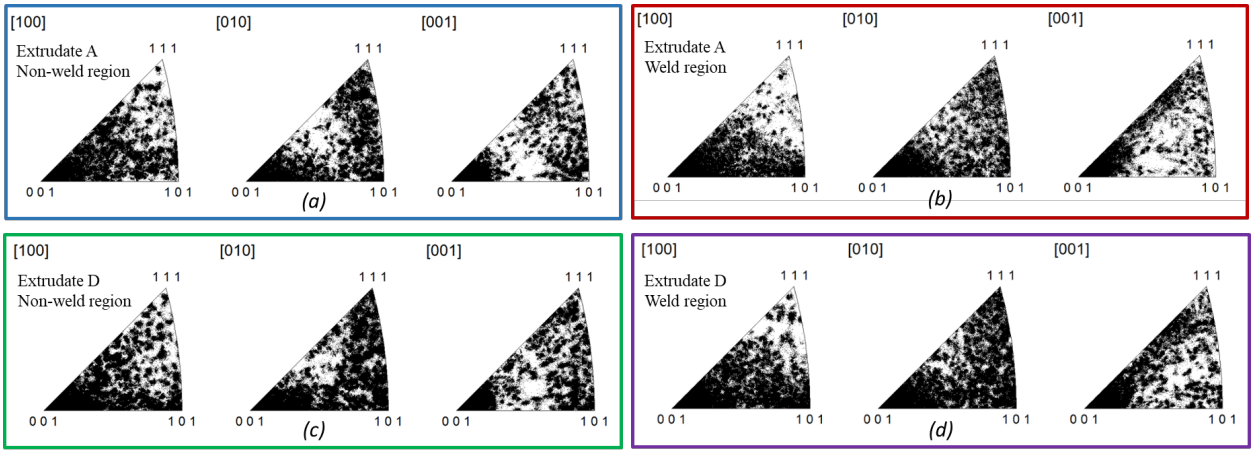

Fig. 5. Inverse pole figures for both Extrudate A (a, b) and Extrudate D (c, d).

Summary

Electron backscatter diffraction was utilized as a characterization method to analyze the localized microstructural texture, grain size, and metal flow of hot extruded AA6005 hollow profiles and to verify FEM predictions of exit temperature and plastic strain distribution. The average grain size decreased from 95.6 µm to 83.7 µm within the *non-welded* region and increased from 66.5 µm to 82.8 µm as the extrusion exit speed doubled. The increased grain size within the *welded* region was likely due to abnormal grain growth, but its cause was yet to be confirmed in this study. Similar die exit temperatures >500°C were recorded for both extrudates using the FEM simulations. Literature has shown this may have likely contributed to the PCG structure found throughout both extrudates. Local crystallographic texture varied across the core to surface, but remained consistent between both extrudates, with a strong [100] texture within the core regions, transitioning into a [101] texture along the surfaces. The varied texture from core to surface validated the plastic strain FEM simulations, which predicted the presence of strain gradients across the wall thickness.

The consistent texture profile between both extrudates implied that an increase in exit speed had no significant effect on the resultant microstructural orientation. But, without a clear difference in exit temperature between both profiles, an assumption cannot be made if it has any effect on the resultant texture. Overall, EBSD proved to be sensitive to local deformation conditions, detecting differences between the core and surfaces of the extrudate and can be used for the analysis of extrudate quality.

Keywords: Aluminum, Full Forward Impact Extrusion, Chevron Cracking, Heat Treatment

Abstract. In addition to the growing demand for energy efficiency, the current and future legal emission limits in the transport sector lead to an increasing demand for weight-reduced components. By substituting conventional materials with weight-reduced components, such as the aluminum alloy EN AW 7075 (AlZn5.5MgCu), emissions during vehicle service life can be reduced. Chevron cracks, also called internal cracks, can be caused by a variety of reasons during cold extrusion processes and pose a great, non-visible challenge for product quality [1]. However, the cause effect relations between the heat treatment condition and the tribological system in regard to damage development have not yet been sufficiently analyzed. In order to examine these relations, the first forming step of a ball pivot was investigated using full forward impact extrusion. Experiments with different tribological systems were investigated by varying lubricant and die treatment with regard to friction and wear reduction. In addition, the effect of the workpiece formability on crack formation was examined by comparing the T6 and soft annealed state of EN AW 7075 as workpiece materials. During this study, the microstructure of both conditions was investigated to highlight differences. A validated FE process simulation using the simulation software Forge NxT 3.2 accompanied the process in order to evaluate the stress state during the full forward impact extrusion process and its relation to the occurrence of chevron crack formation. In the experiments conducted during this study, chevron cracking occurred during full forward impact extrusion of EN AW 7075 in state T6, while in soft annealed condition none appeared. Unlike the heat treatment condition, the tribological system had no impact on the occurrence of chevron cracking but on the severity of the cracks.

Introduction

The cold impact extrusion (CIE) process is an established, resource saving manufacturing process. CIE plays an important role in the cost-effective production of complex and ready-to-install components that are produced in large quantities. There is a large spectrum of possible component geometries that can be produced by CIE. Those are used in a wide range of applications, especially in the automotive industry [2]. Due to a growing demand for the CIE of high-strength products with lightweight properties, especially the production of parts using higher priced, lightweight materials like aluminum alloys becomes increasingly attractive. In many cases, the process limits of forming technologies, which are primarily determined by the material formability [3], are already exploited to their maximum. Exceeding the material formability limit can result in workpiece defects. These defects occur as surface or internal cracks, also called chevron cracks or

Materials Research Proceedings 28 (2023) 445-454 https://doi.org/10.21741/9781644902479-49

central bursting. While surface cracks can be easily and quickly detected, as they can be seen by visual inspection, chevron cracks pose a much greater challenge for product quality [1]. Thus, the topic of chevron cracking has been part of many studies in recent years, and a variety of reasons was presented for the occurrence of these defects during the extrusion process. McVeigh and Liu showed that low friction between workpiece and tool leads to the increased occurrence of chevron cracking since the hydrodynamic stress increases with decreased friction [4]. In addition, unsuitable material hardening behavior [4], hard, brittle microstructural phases or non-metallic inclusions [3], as well as unsuitable or improper heat treatments of the workpieces [5] can lead to an increased occurrence of chevron cracks. As follows from McAllen et al. [6], different geometrical properties of the reduction die, for example larger shoulder angles, can also cause defects in form of surface and chevron cracks. However, the correlation between the tribological system (TS) and the occurrence of chevron cracks has not yet been sufficiently analyzed.

Consequently, the aim of this work is to investigate this correlation by determining the material behavior of aluminum alloy EN AW 7075 during full forward impact extrusion (FFIE), which is a process variant of CIE, in order to avoid chevron cracking. FFIE experiments with two different heat treatment conditions (T6 and soft annealed), three different lubricants and three different reduction die treatments were performed and subsequently analyzed in order to investigate the cause effect relations between these parameters and the occurrence of chevron cracking. All experiments were repeated three times to increase statistical value. The experiments were performed using a full factorial design.

Methods, Machines and Materials

Workpiece, tool material and experimental setup.

The experiments were conducted using full forward impact extrusion. The tools for the full forward impact extrusion, which consist of a punch, reduction die and shaft die, are shown in Fig. 1 (b). As tool material, high speed steel HS 6-5-2C (material number 1.3334) as well as the carbon steel G52 (no AISI equivalent) were used and hardened to 62 HRC. The reduction dies were provided with a shoulder opening angle of $\alpha = 45°$, had an initial diameter of $d_a = 31.4$ mm and a taper diameter of $d_{i1} = 20.6$ mm, see Fig. 1 (b). In order to prevent the sample from clinging to the inner wall of the die after taper, a heel was provided to increase the diameter to $d_{i2} = 20.7$ mm.

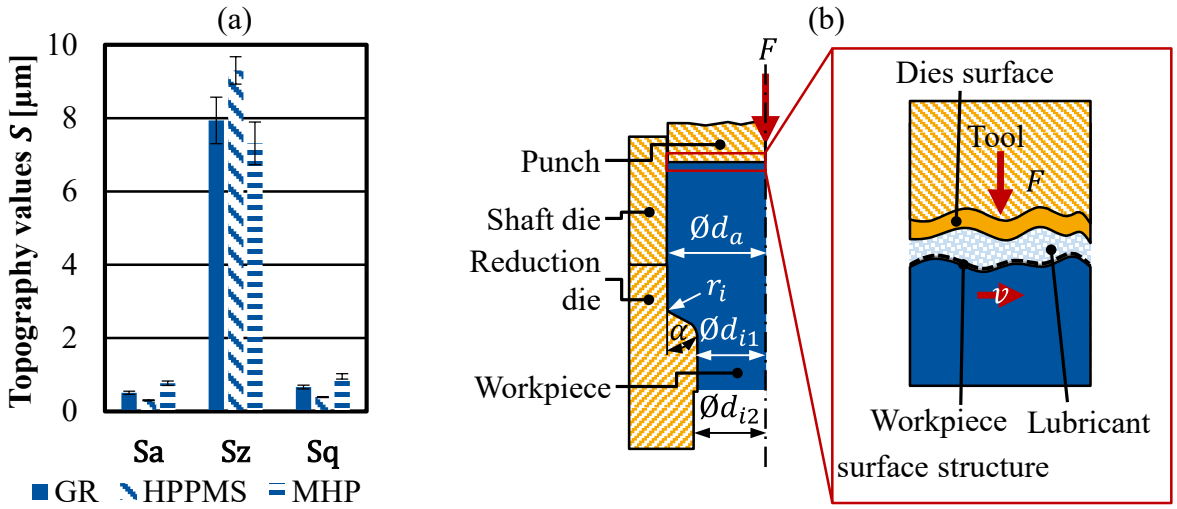

Fig. 1. Topography values of the dies according to ISO 25178 (a) and schematic illustration of the used tools (b).

The reduction die surfaces were finished by means of three different treatments. The first die was provided with a CrAlN-MoSx coating using high power pulsed magnetron sputtering (HPPMS) and were subsequently polished (Rz = 1 µm). The second die was processed by machine hammer peening (MHP) in order to increase wear resistance due to residual compressive stresses and to form lubricant pockets at the same time. The last die was ground (GR) after the manufacturing process. After treatment, the surface roughness was measured according to DIN EN ISO 25178 using a combined roughness and contour measurement system Hommel Etamic nanoscan 855 by Jenoptik AG. The results of these measurements are shown in Fig. 1 (a).

The experiments were carried out using the Schuler AG hydraulic press HPX-400. The press has a maximum pressing force of F_{max} = 4000 kN and was adjusted to a constant velocity of v = 12 mm/s. The punch path was kept constant at s = 12 mm. The results were partly evaluated using statistical methods of Design of Experiments (DoE), including main effects calculation. For DoE, adjustable parameters, also called factors, and their settings are determined, while the other process parameters remain constant. During the experiments, all combinations between the settings of the adjustable parameters are tested [8]. As adjustable parameters, die treatment (A) and lubricant (B) were chosen.

As workpiece material, the aluminum alloy EN AW 7075 was used, which is a widely used material for cold forming processes [7]. It is a hardenable wrought alloy, which provides high to highest static strength properties [6]. In order to transfer the material from the T6 condition to the soft annealed condition, the material was heat treated, see Fig. 2 (a). As can be seen in Fig. 2 (b-c), the texture was reshaped and showed a finer appearance in the soft annealed state. Before and after the treatment, microsections were etched using nitric acid n_{HNO_3}, hydrochloric acid n_{HCl}, hydrofluoric acid n_{HF} and water n_{H_2O}. Before the experiments were conducted, all workpieces were turned, ground and then shot-peened with aluminum granulate to improve lubricant bonding.

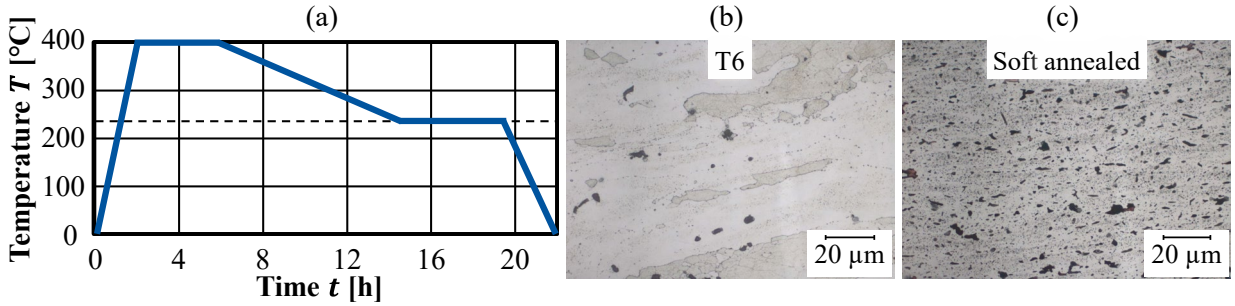

Fig. 2. Time table of heat treatment (a) and microsections of heat treatment condition T6 (b) and soft annealed (c).

Three different dry lubricants were applied on the workpieces. The application was carried out according to the recommendations of the lubricant manufacturer. The first lubricant (S1) was a water-soluble, low-dust lubricant for dry or wet treatment of aluminum workpieces prior to forming. It is used as an alternative to zinc stearate powder and wax systems. The lubricant was dissolved in distilled water with a solid content of 20 g/l and afterwards applied on the workpieces using a lubricant bath. The second lubricant (S2) was an aqueous polymer dispersion with a solid content of 20.5%, which forms a transparent, non-slip film and was applied on the workpieces using a lubricant bath with a 35% concentration. The third lubricant (S3) was an aqueous suspension of solid lubricants with a solid content of 26%. It was applied using a lubricant bath with a 45% concentration.

Numerical setup.

The experiments were accompanied by a finite elements (FE) simulation model using Forge NxT 3.2. The workpiece was modelled as an elasto-plastic, deformable volume. The punch and die were assumed to be rigid, non-deformable bodies. To reduce the required computing power and the calculation time, only one twelfth of the rotationally symmetrical components was implemented, see Fig. 3 (a). In post processing, these components were combined in order to analyze the complete workpiece. The velocity of the punch v as well as the punch path s were set to $v = 12$ mm/s and $s = 12$ mm to reflect the conditions of the experiments. For modelling the friction, a coupled friction model as a combination of Tresca's and Coulomb's friction models was used, see Fig. 3 (b).

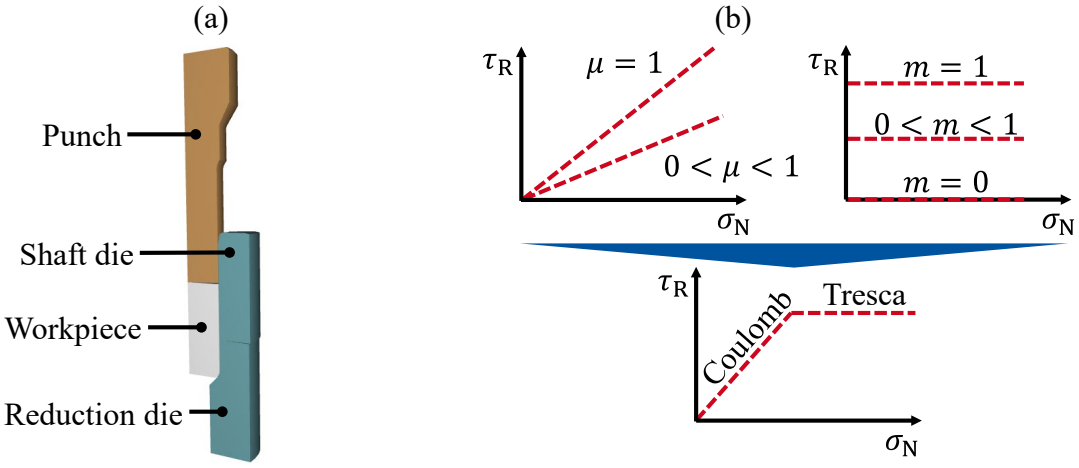

Fig. 3. Image of simulation model (a) and used friction model (b).

In order to represent various tribological conditions during forming, different coefficients of friction μ and friction factors m were used during the simulations. These are listed in Table 1.

Table 1. Coefficients of friction μ and friction factors m of implemented frictions laws.

Description	**Coefficients of friction μ / friction factors m**
Low friction	0.02 / 0.05
High friction	0.2 / 0.4

The meshing was carried out with the triangulation method, in which the geometry of the components was simulated using triangular facets. In order to reduce the calculation complexity on the one hand and to lower the error level on the other hand, a convergence analysis was carried out. Starting from a coarse mesh, the elements were reduced in size until the results of the simulation (punch force, stress distribution) converged. The mesh determined by the convergence analysis defined the edge length to a minimum mesh size of l_{min} = 0.02 mm.

Experimental and Numerical Results

Experimental results.

The diagram in Fig. 4 (a) displays the punch force-time-graphs of the first stroke of the different test pairings. Comparing the graphs reveals a similar course of each test pairing. At first, the punch force F increased quadratically until a linear progression was established, which continued until the maximum punch force F_{max} was achieved. With the exception of the TS that is induced by

HPPMS and S1, the gradient of the punch force-time-graphs reached a continuous, decreasing negative value after reaching the maximum punch force F_{max} and before the end of the FFIE process where the punch force F dropped to F = 0 kN. However, in the course of the TS consisting of HPPMS and S1, the gradient of the punch force-time-graph underwent a change of sign after reaching the maximum punch force F_{max}. The punch force F increased to a local maximum before the end of the FFIE process. The drop in the force curve can be explained by sudden stress relief after the occurrence of a chevron crack. Besides the similar course of each punch force-time-graph, different maximum punch forces F_{max} were achieved in each experiment. The highest punch force F_{max} = 751 kN was achieved by using S3 and the HPPMS treated die. The use of the HPPMS treated die and S1 required the lowest punch force F_{min} = 619 kN. The punch force F did not increase or decrease systematically with increasing stroke number. Thus, wear effects that occurred during this study can supposedly be neglected.

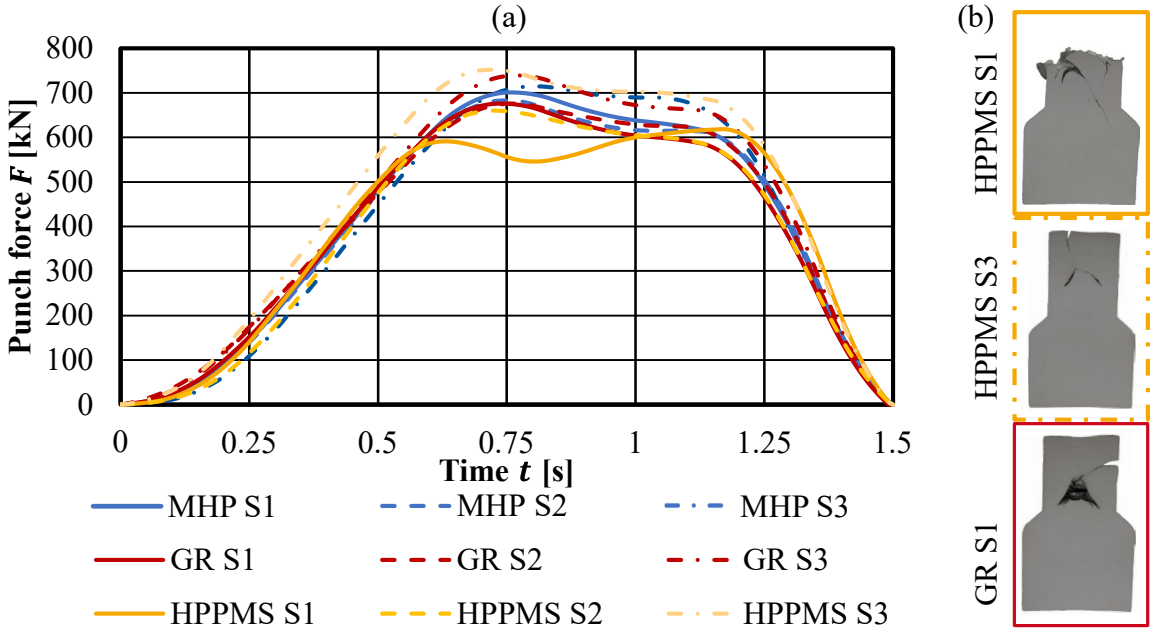

Fig. 4. Punch force-time-diagram of first stroke using different tribological systems and heat treatment condition T6 (a) and severity of chevron cracking depending on friction (b).

As can be seen in Fig. 4 (b), the severity of the chevron cracking varied regarding the TS. A dependency of chevron cracking and punch force can be postulated since the characteristics of the chevron cracks became more distinctive with lower punch force F, as the hydrostatic stress in the center of the workpiece was reduced with lower friction [5], although there were exceptions from this rule. The GR treated specimen had less critical chevron cracks during this study. In the lubricated state, the punch forces were lower than under dry conditions. While using S3, a MHP surface finish in the lubricated state decreased the punch force compared to a HPPMS surface finish. This can be explained by the formation of lubricant pockets, which lead to reduced friction behavior. Although with S1 and S2, this effect was reversed. On this account, hydrodynamic and hydrostatic effects could occur, which decreased friction and therefore the punch force. On the contrary, the very homogenous surface of the HPPMS process seemed not to grant hydrodynamic effects. As a result, the lubricant effect E_B was lower when using HPPMS-finished surfaces.

Table 2 summarizes the results of the evaluation using DoE. All the effects shown were calculated with the ground die (A- setting) and no lubrication (B- setting) as a reference. HPPMS or MHP were used as the A+ setting, and S1, S2 or S3 as the B+ setting. For each effect calculation,

all possible combinations of the *plus* and *minus* settings of A and B were considered. The effects of all combinations of the parameter settings A and B were calculated in comparison to the reference state. The effect of each factor was calculated as the difference between the average maximum force F_{max} in the experiments when the factor had the *plus* setting and the average maximum force F_{max} when the factor had the *minus* setting. As an example, the effect E_A was calculated by

$$E_A = \frac{F_{max,A+,B+} + F_{max,A+,B-}}{2} - \frac{F_{max,A-,B+} + F_{max,A-,B-}}{2} \quad (1)$$

For the calculation of effect E_{AB}, the setting of AB is given by the multiplication of the settings of factors A and B. So, for the combination of settings A- and B- or A+ and B+, the AB+ setting would be assumed, whereas for A+ and B- or A- and B+, AB- would be assumed. The effects in dependency of the *plus* or *minus* setting of the other factor were calculated as follows:

$$E_{A(B\overset{+}{-})} = E_A \overset{+}{-} E_{AB}. \quad (2)$$

As the force for the forming process does not significantly change between the experiments, the effects can be mostly explained by increased or decreased friction behavior. Regarding the main effects, the results indicate that the use of lubricants had a positive effect E_A on the maximum punch force F_{max} independently of the die treatment. The MHP treated die, on the other hand, showed a negative effect E_B on the maximum punch force F_{max}, while the HPPMS treated die had a positive effect E_B on the maximum punch force F_{max}. Considering the main effects E, the HPPMS treated die showed a positive effect $E_{A(B-)}$ on the maximum punch force F_{max} when dry pressing. The MHP treated die had the opposite effect $E_{A(B-)}$ and showed a negative effect on the maximum punch force F_{max}.

Table 2. DoE effects maximum punch force F_{max} of die treatment (A) and lubricant (B).

Effect E	HPPMS			MHP		
	SS1	SS2	SS3	SS1	SS2	SS3
E_A [kN]	-98.17	-85.65	-62.81	66.61	54.60	47.70
E_B [kN]	-307.92	-268.07	-205.89	-405.65	-390.34	-357.89

Fig. 5 compares the punch force-time-graphs using workpiece material in T6 and soft annealed heat treatment conditions with the ground die and lubricant S1. The test pairing was chosen for further analysis due to its average damage value regarding the severity of chevron cracks. By comparing the two courses, it can be seen that the maximum punch force F was significantly lower when in soft annealed than in T6 condition. Furthermore, the punch force-time-graph of the soft annealed heat treatment condition showed no drop in punch force F but a nearly linear progression after reaching the maximum punch force F_{max}. Moreover, the gradient of the punch force-time-graph for the soft annealed condition was smaller compared to the T6 condition during the rise and

fall of the punch force F during of the process. Using the soft annealed condition, no chevron cracks emerged during pressing. The workpiece was free of defects.

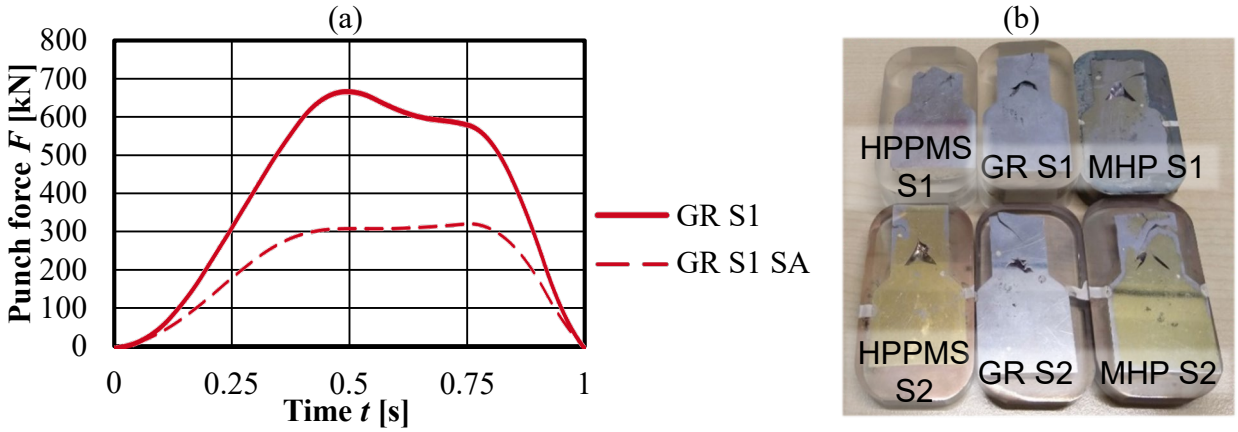

Fig. 5. Punch force-time-diagram of first stroke soft annealed and heat treatment condition T6 (a) and typical chevron crack formation during the experiments (b).

Numerical results.

In order to validate the simulation model, the punch force during FFIE and the geometry of the finished workpiece were compared to the simulation results. Fig. 6 (a) shows this comparison. The simulation was conducted using only the Hensel Spittel parameters [10] of EN AW 7075 in the soft annealed state, as the parameters for the heat treatment condition T6 were not available during this study. Regarding the punch force, the experimental data were comparable to the simulation data using low friction conditions. Both the experimental data and the simulation with low friction conditions reached a similar maximum punch force of about 300 kN. The maximum punch force during the experiments was about 8% higher than the punch force in the low friction simulation. The simulation model with low friction conditions shared a very similar gradient with the experimental data at the beginning of the FFIE process. The key difference was the negative force gradient at the end of the process, which decreased slower in the experimental data, which was the result of the reduced punch velocity at the end of the experiments. Furthermore, the lode parameter as well as triaxiality were investigated in order to evaluate the workpiece damage [9]. The triaxiality η is defined as

$$\eta = \frac{\sqrt{2}\cdot(\sigma_1+\sigma_2+\sigma_3)}{3\cdot\sqrt{(\sigma_1-\sigma_2)^2+(\sigma_1-\sigma_3)^2+(\sigma_2-\sigma_3)^2}} \tag{3}$$

where σ_1, σ_2 and σ_3 are the principal stresses [10]. The Lode parameter $\underline{\theta}$ is described by

$$\underline{\theta} = 1 - \frac{2}{\pi}\cdot arccos\,(\xi) \tag{4}$$

where ξ is the normalized third deviatoric stress invariant [11]. Using the lode parameter, areas of tensile and compressive stress can be identified in a simulation model. Fig. 6 (b) shows that most chevron cracks during the experiments occurred in the areas where areas with high compressive stresses met areas with high tensile stresses. The stress tensor in material flow direction in the center of the peg was characterized by large compressive stress values, while the surrounding area was characterized by large tensile stresses. The tensile stress values on the inside of the peg increased during the process, and lead to material failure in this area, which resulted in the occurrence of a chevron crack. Afterwards, tensile stress values continued to grow until another

chevron crack occured. Chevron cracks and cracks that started at the surface of the peg mostly seemed to grow alongside the areas where tensile and compressive stresses met.

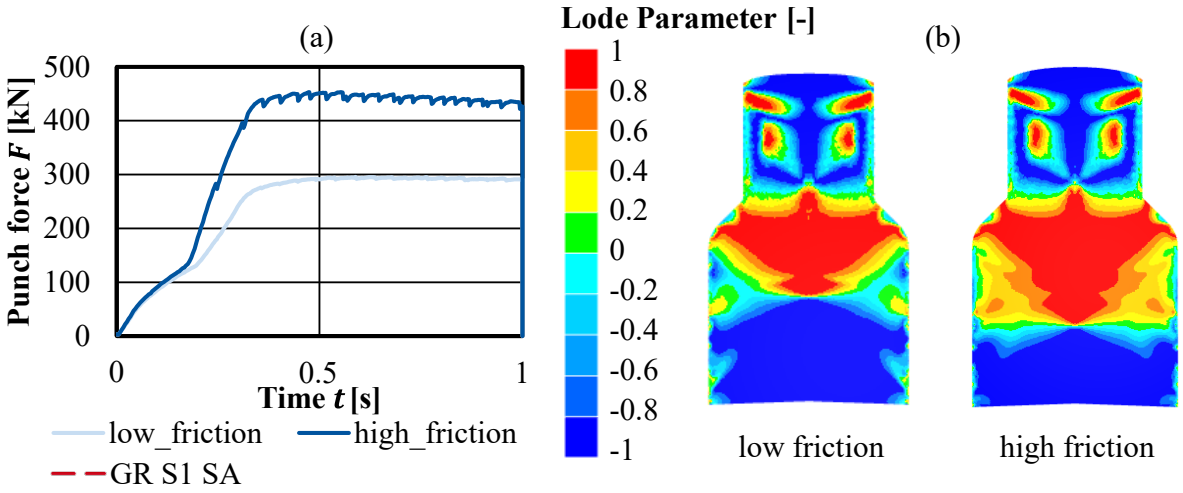

Fig. 6. Punch force over time during simulation (a) and Lode parameter during forming (b).

In Fig. 7 (a), the triaxiality at the end of the forming process is shown. Using both low and high friction conditions, tensile stress could be found near the surface of the peg, while the center was largely influenced by compressive stress. In the center of the extruded shoulder, which coincides with the area where most chevron cracks occurred, sheer stress was dominating and the highest von Mises stress values occurred. Right above this zone, the von Mises stress values decreased significantly, which lead to material failure in this specific area.

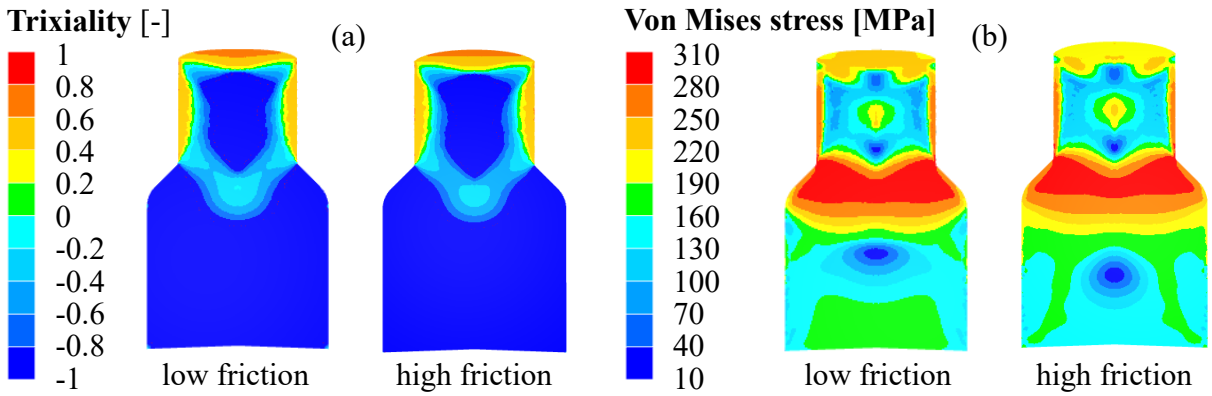

Fig. 7. Triaxiality during forming (a) and von Mises stress during forming (b).

Regarding the simulation of chevron cracks during the FFIE process, simulations in Forge were carried out using the normalized Latham-Cockcroft damage criterion, which is the most commonly used damage criterion in cold forming [12] and has already been proven to be suitable for the analysis of chevron cracks in cold extrusion processes [13]. For cold forming, a critical damage parameter of 0.5 is suggested. No chevron cracks occurred in the experiments that use the process parameters presented in this paper while using specimen in the soft annealed state, which was confirmed by the simulation results. Nevertheless, in order to investigate the growing process of chevron cracks during the forming simulation without changing the material behavior of EN AW 7075, the critical damage parameter was set to 0.2. In this theoretical case, the formation of chevron cracks started early during the FFIE process in the center of the reduction shoulder. Throughout the crack growth, the area between the crack itself and the lateral surface of the

workpiece showed an increased value for the Latham-Cockcroft damage criterion when compared to the rest of the specimen. Once the first chevron crack reached a certain width, another chevron crack occurred in the same area that the first one occurred in. During the experiments, multiple chevron cracks only appeared in a few specimen. On the other hand, the chevron cracks grew larger than in the simulation model, which can be explained by the different heat treatment condition. Furthermore, the resulting damage parameter was largely influenced by the friction conditions used during the simulation. By using high friction parameters, the occurrence of chevron cracks during the FFIE process was significantly reduced, which confirms the experimental results. It should be noted that, unlike in the experiments, the occurrence of chevron cracks during the simulations did not affect the punch force-time-diagram.

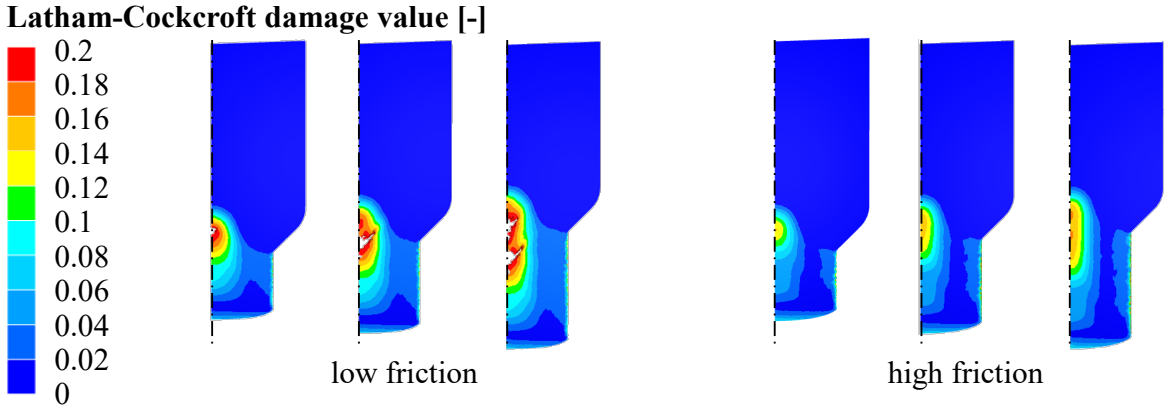

Fig. 8. Latham-Cockcroft damage value during FFIE simulation.

Summary

Within the present study, extensive analyses were carried out to investigate the cause-effect relations between heat treatment condition, damage development and tribological system. For this purpose, FFIE experiments were executed with workpieces made of the aluminum alloy EN AW 7075 in the different heat treatment conditions T6 and soft annealed as well as different tribological systems. The key findings of this study are as follows:

- A dependency between friction and chevron crack characteristics was shown. With increasing maximum punch force $\boldsymbol{F_{max}}$ and thus with increasing friction, the chevron crack characteristics that occurred in heat treatment condition T6 became less distinctive. These findings were also confirmed by the numerical investigations of this study.
- It was shown that the punch force-time-graph at the occurrence of chevron cracks had a different characteristic than that of defect-free components. All courses showed a drop in punch force $\boldsymbol{F}$ in form of a buckling after reaching the maximum force $\boldsymbol{F_{max}}$. This buckling did not occur in other experiments without chevron cracks with the same tool geometry and experimental parameters [13]. The buckling of the curve became increasingly apparent as the chevron cracks became more distinctive and is considered as a result from the sudden stress relief due to bursting of the material.
- The simulation model with low friction showed a mostly similar force curve to the experimental data using the soft annealed state of EN AW 7075. Simulations showed that chevron cracks occur in the areas where high tensile and high compressive stresses met.

Abstract. In this study aluminum-graphene-composites were manufactured applying a powder metallurgical approach. After graphene exfoliation and mechanical mixing, powders were disc milled, compacted and extruded into round rods. Two different sources of commercial graphene nano platelets (GNP) (by 1. Sigma Aldrich (SA) and 2. Alfa Aesar (AA)) were investigated with the main difference being their specific surface area. One subject of the study was to investigate the effect of disc milling processing on the mechanical properties of Al/GNP composites. Results indicated that micro hardness as well tensile yield strength (TYS) and ultimate tensile strength (UTS) were not improved significantly or only slightly when SA-GNPs and a disc milling duration of 1min were applied. Varying the extrusion ratio from R=9:1 to R=14:1 and R=31:1 as well as applying conic or flat face dies for extrusion did not have a significant effect on the mechanical properties. But when disc milling duration is extended to 5min, significantly increased micro hardness (up to 30%), TYS (up to 17%) and UTS (up to 26%) were observed. Application of AA-GNPs as a second source of commercial GNPs also resulted in significantly increased micro hardness (up to 49%), increased TYS (up to 16%) and UTS (up to 27%) when disc milling of 5min is conducted in the powder processing stage. SEM analysis indicated that after 5min disc milling aluminum particles were deformed from spherical into a plate-like shape. Additionally, GNP exfoliation and its dispersion in the Al matrix seemed to be improved by the longer milling duration and could be a reason for the enhanced strengthening effect of GNPs.

Introduction

Graphene is a 2-dimensional carbon-based material ideally consisting of planar carbon monolayers, where carbon is sp^2-hybridized. It was first synthesized successfully in 2004 [1]. Due to exceptional high intrinsic strength and elastic modulus [2] monolayer graphene is highly attractive to be applied as strengthening additive for composite materials such as aluminum-graphene-composites. But due to high van der Vaals forces, graphene layers tend to agglomerate which is detrimental to the mechanical composite properties [3]. Thus, graphene exfoliation and its homogeneous dispersion in the matrix material are key for achieving a high strengthening effect. Furthermore, the formation of carbides can be a reason for decreasing strength and ductility [4]. The current study investigates a processing approach of graphene sonication (for exfoliation), disc milling, cold compaction and indirect extrusion to manufacture aluminum-graphene-nanoplatelet(GNP)-composites. In a prior study, aluminum and graphene powders were mixed mechanically only, then compacted and extruded. This approach did not lead to significant

strengthening. The main reason for that was assumed to be GNP agglomeration, as GNPs were found to be aligned in relatively thick layers around aluminum particles, especially for high GNP contents [5]. Thus, for the current study disc milling was added to the process chain. Disc milling is a method usually applied to reduce the size of particles through compression, shearing and friction forces. Thus, with disc milling a high amount of energy can be introduced into the powder mixture, aiming to decrease the GNP agglomeration around aluminum particles and improve GNP dispersion. Furthermore, in this study two different commercial graphene sources were applied and the resulting mechanical properties of the Al/GNP composites are compared.

Materials and Methods

In this study Al/GNP composites were prepared via a powder metallurgical route. Same pure (99.7%) aluminum powder as in a previous publication [5] was applied as matrix material. Aluminum with mean particle size of 49µm was provided by TLS Technik GmbH & Co. Spezialpulver KG, Germany. In the first part of this research the effects of GNP-content, extrusion ratio, die angle and milling duration on micro hardness and tensile properties were investigated exemplarily. In order to study the general relationships between processing parameters and the material properties for each condition one rod was extruded. Micro hardness was tested on one rod cross section extracted from the middle length of each rod, three samples were cut from the middle to end region of the rod and tested in tensile tests. For the first part of the study GNPs provided by Sigma Aldrich were applied. All extrusion experiments were carried out on a small scale 0.5MN extrusion press with a container of 30mm diameter at Extrusion R&D Center TU Berlin. Billets were prepared by first GNP exfoliation through sonication (Branson Sonifier 450) in ethanol for 10min. The GNP/ethanol solution was then added to aluminum powder in an Eirich intensive mixer and batches with GNP-contents of (0.25%), 0.5% and 1.0% were prepared. Mechanical mixing was performed for 360s at 1800rpm. Subsequently powders were dried in a vacuum furnace for 16h at T=50°C. Powder mixtures were then disc milled applying the milling tools given in Fig. 1 rotating at 1000rpm for 1min and exemplarily for 5min. Milling batch size was 100g, respectively. Due to significant heat generation overall milling duration of 5min was split into 5 steps of 1min each with cooling breaks of a couple minutes in between. The weight of the tools (2 rings and 1 disc) rotating within the milling die was 9.2kg (Fig. 1). Milled powders were then sieved with mesh size of 172µm and subsequently cold compacted with 200MPa into solid discs for better specimen handling. Compacts were then extruded at 300°C in indirect extrusion mode applying different extrusion ratios of R=9:1, R=14:1 and R=31:1. Additionally, two different die angles ($2\langle$=180° flat face die and a conic die with $2\langle$=130°) were applied for selected samples to investigate its effect on the composites' properties, exemplarily.

In the second part of the investigation an alternative graphene source, provided by Alfa Aesar, was applied. The Alfa Aesar (AA)-GNPs especially featured a significantly higher specific surface area of 529m^2/g than the Sigma Aldrich GNPs (108m^2/g). In order to characterize their qualities both graphene sources were investigated by Raman spectroscopy. The effect of AA-GNP content as well as the effect of powder mixing or mixing with additional disc milling for 5min on the mechanical properties was studied. Extrusion of the 5min disc milled material with AA-GNPs was carried out applying the conic die ($2\langle$=130°) with diameter 8.0mm (R=14:1). Effects of extrusion ratio, milling duration and die angle variation were not investigated for AA-GNPs.

Results and Discussion

Powder characterization.

In a first step the initial powders were investigated via SEM in as received condition. Results are displayed in Fig. 2. The pure aluminum powder is given in Fig. 2a. The powder predominantly is of spherical shape with varying size between 5µm and 70µm. Mean particle size was 47µm. Fig. 2b presents the GNPs provided by Sigma Aldrich. These GNPs were mostly found attached to each other and had a very flat shape with sharp edges. In contrast, the GNPs provided by Alfa Aesar consisted more of spheric particles with very fine platelets on their surface (Fig. 2c).

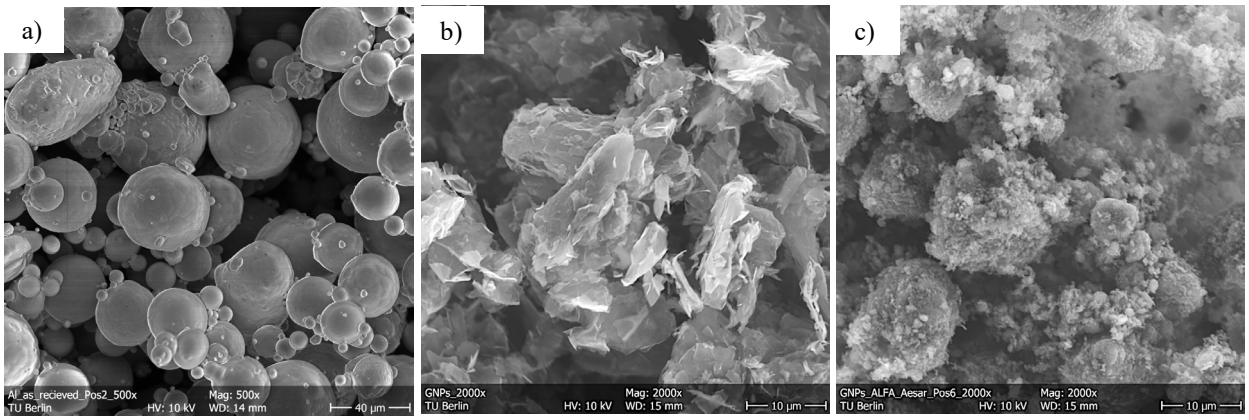

Fig. 2. SEM images of as received a) pure Al powder (99.7%), b) Sigma Aldrich (SA)-GNPs c) Alfa Aesar (AA)-GNPs.

In order to investigate the effect of each powder processing step on morphology and GNP dispersion, the composite powders with GNP content of 1% were selected exemplarily. SEM images are given in Fig. 3. Al-particles remained their initial spherical shape after mechanical mixing for 6min at 1800rpm as shown in Fig. 3a. SA-GNPs seemed to be relatively well distributed in the powder as no larger agglomerates were found. Although, often a few GNPs were stacked on top of each other. After 1min of disc milling first effects of the high energy input due to the milling process can be noticed (Fig. 3b). The surface of aluminum particles became rougher and their shape mostly was not as ideally spheric as in the initial state. After 5min of disc milling, due to the high impact energy through friction and shearing in the mill, aluminum particles were found to be deformed into plates with a rough surface (Fig. 3c). The results after 5min of disc milling seemed

to be comparable to the deformation of aluminum powder after 1h of ball milling presented in [6]. Thus, applying disc milling instead of ball milling could be an option to produce composites since milling time and thus cost could be reduced significantly.

After mixing, the AA-GNPs were found to be attached to Al-particles in form of small chunks as indicated in Fig. 3d. But after disc milling for 5min they were found in a very thin, flat shape and reduced in size (Fig. 3e). Hence, it can be concluded that the high energy input throughout the disc milling process had a positive effect on the dispersion of AA-GNPs in the composite powder.

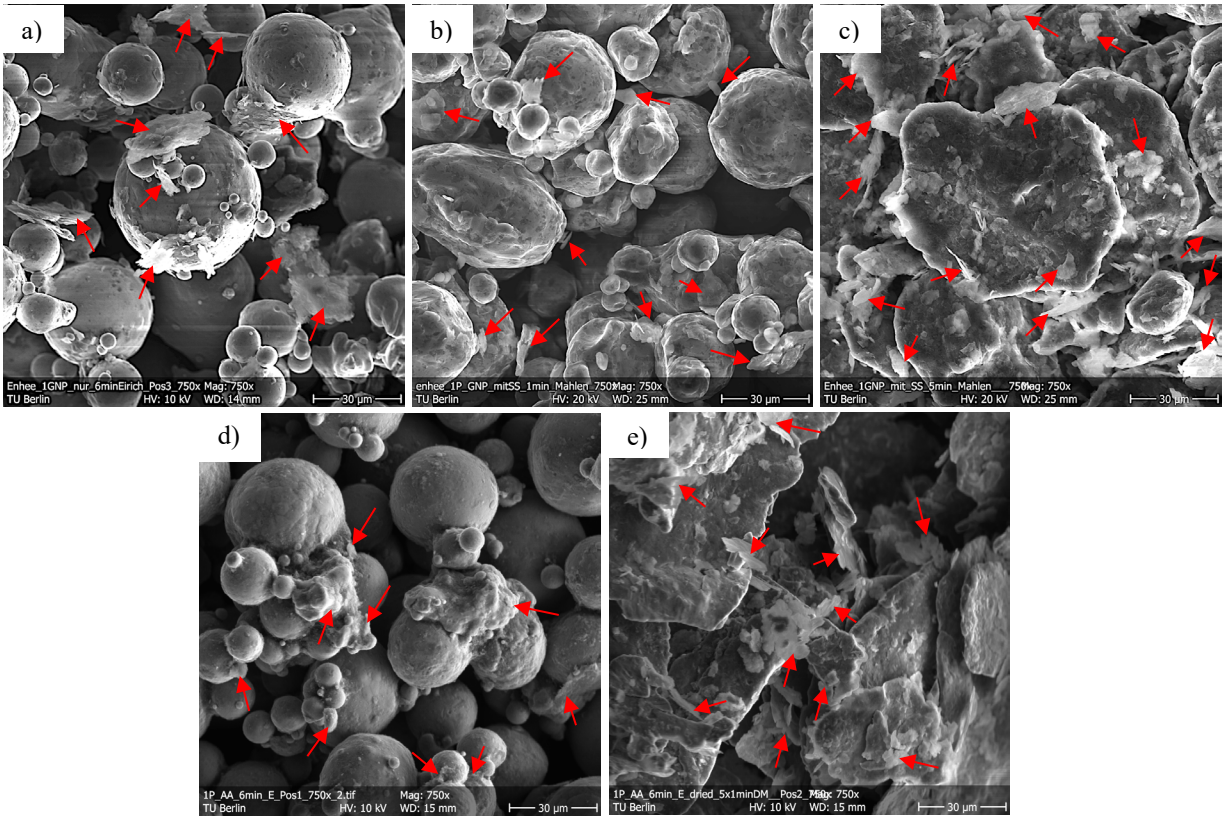

Fig. 3. SEM images of composite powders a) 1% SA-GNP after mechanical mixing, GNPs exemplarily indicated with arrows b) 1% SA-GNP after 1min disc milling c) 1% SA-GNP after 5x1min disc milling d) 1% AA-GNP after 6min of mechanical mixing e) 1% AA-GNP after 5x1min disc milling.

Raman spectroscopy is a fast, nondestructive method with high-resolution that can be applied for the characterization of e.g. lattice structure of carbon-based materials and thus provides information on the morphology and quality of GNPs [7]. The Raman spectra of the applied two different commercial GNPs are given in Fig. 4a and Fig. 4b. In both spectra the presence of the three prominent peaks namely D-band at ~1325cm^{-1}, G-band at ~1565cm^{-1} as well as 2D band at ~1650cm^{-1} were observed. The G-band corresponds to intrinsic in-plane C-C vibration modes of graphene and is characteristic for carbon-based compounds [8]. The D-band relates to the magnitude of defects or disorder in the crystal structure of graphene [9]. The 2D-band is related to number of graphene layers in the GNPs [10]. The defect density of GNPs can be predicted with the intensity ratios of D-band and G-band (I_D/I_G) and the number of graphene layers in the GNPs with the ratio of 2D-band to G-band (I_{2D}/I_G) [11].

Hence, the presence of both, G band as well as 2D band on the specific wavelength positions and the fact that the 2D intensity is much lower than the G-band (I_{2D}/I_G) leads to the conclusion that both GNP sources can be characterized as multilayer graphene. Furthermore, the ratio of I_D/I_G

leads to the conclusion that both GNPs contain defects and are disordered at least to some extent. By comparing the two GNP sources it can be stated that the AA-GNPs seem to be of better quality since the I_D/I_G ratio as a measure for defects and disorder is lower (Table 1). Additionally, the I_{2D}/I_G-ratio is higher for AA-GNP, which indicates that it consists of a fewer number of layers [10, 11]. Thus, both quality criteria were found to be in favor of the AA-GNPs.

Table 1. Results of Raman spectroscopy on both graphene sources.

	Sigma Aldrich (SA) GNPs		**Alfa Aesar (AA) GNPs**	
Peak	wavelength [1/cm]	Intensity [a.u.]	wavelength [1/cm]	Intensity [a.u.]
D band	1329	223	1317	159
G band	1571	1090	1560	515
2D band	2652	279	2649	258
I_D/I_G		0.80		0.62
I_{2D}/I_G		0.26		0.50

Characterization of mechanical properties.

Mechanical properties of the Al/GNP composites were characterized in terms of micro hardness and tensile testing properties in dependence of graphene content and relevant process parameters. The basic assumption for the effect of GNP-addition to the aluminum matrix material would be that if no agglomerates are formed, the mechanical properties of the composite should increase because of graphene's excellent mechanical properties.

Table 2a and Fig. 5a summarize the results of micro hardness testing on extruded composites with respect to the three SA-GNP contents (0%, 0.5% and 1.0%) as well as for the three different extrusion ratios (R=9:1, R=14:1 and R=31:1) when disc milling was conducted for 1min.

It can be noticed that the addition of SA-GNPs to pure aluminum did not lead to significantly increased hardness values. The only slight increase was observed for the 0.5%-SA-GNP-composite extruded at R=14:1. In that case hardness improved from 37.7 HV to 39.7HV (+5%). But a further increase of GNP content to 1.0% SA-GNPs resulted in a hardness of 37.3HV and thus, basically was the same as for pure aluminum. The effect of the extrusion ratio on micro hardness was limited as well but slightly more significant compared to the effect of SA-GNP content. For pure aluminum

the effect was insignificant. But for SA-GNP contents of 0.5% and 1.0% an increasing tendency of micro hardness with increasing extrusion ratio could be observed (Fig. 5a). The highest effect was found for the 0.5% SA-GNP composites by extruding with R=14:1 instead of R=9:1. By that hardness was increased from 35.7HV to 39.7HV (+11%). In case of the 1.0% SA-GNP composites hardness increased by 7% when extruding with R=31:1 instead of R=9:1.

Table 2b presents the effect of extrusion die angle (2〈) on micro hardness. For pure aluminum hardness increased by 5% from 37.7HV to 39.5HV when a flat face die (2〈=180°) is applied instead of a conic one with 2〈=130°. For the composite material with 0.5% SA-GNPs the opposite effect was found as hardness decreased by 8% when the flat face die was applied instead of the conic one. For the 1% composite there was no effect at all. Hence, a clear systematic effect of the die angle on micro hardness was not observed.

Table 2c and Fig. 5b represent the hardness values of SA-GNP-composites after t_{DM}=1min of disc milling and after 5min (5x1min). Hardness of pure aluminum increased by 5% from 37.7HV to 39.5HV after 5min. As the Al-particles are deformed into plates at the longer milling duration (Fig. 3c & Fig. 3e), strain hardening is assumed to be the main reason for the increased hardness. In case of the 1% SA-composite the increase in micro hardness was 30% as it increased from 35.3HV after 1min to 45.7HV after 5min. This was the first and only real significant effect in all the micro hardness testing of SA-GNP containing composites. Hence, as presented in Fig. 3c the longer milling duration seemed to have improved exfoliation of SA-GNPs and maybe even decreased their size leading to a better SA-GNPs dispersion in the composite. Through its improved dispersion the graphene was more effective in increasing the micro hardness of the composite.

Table 2. Micro hardness of extruded composites containing SA-GNPs a) effect of extrusion ratio R and GNP content b) effect of die angle for R=14:1 after 1min disc milling c) effect of disc milling duration at R=14:1.

a) GNP content	R	HV0.5
0%	9:1	36.8±0.4
0.5%	9:1	35.7±0.4
1.0%	9:1	35.8±0.6
0%	14:1	37.7±0.6
0.5%	14:1	39.7±0.2
1.0%	14:1	37.3±0.4
0%	31:1	37.7±1.3
0.5%	31:1	38.1±0.2
1.0%	31:1	38.3±0.3

b) GNP content	die angle 2α [°]	HV0.5
0%	130	37.7±0.6
0%	180	39.5±0.6
0.5%	130	39.7±0.2
0.5%	180	36.4±0.2
1.0%	130	37.3±0.4
1.0%	180	37.3±0.6

c) GNP content	t_{DM}	HV0.5
0%	1min	37.7±0.6
0%	5min	39.5±0.6
1.0%	1min	35.3±0.5
1.0%	5min	45.7±1.6

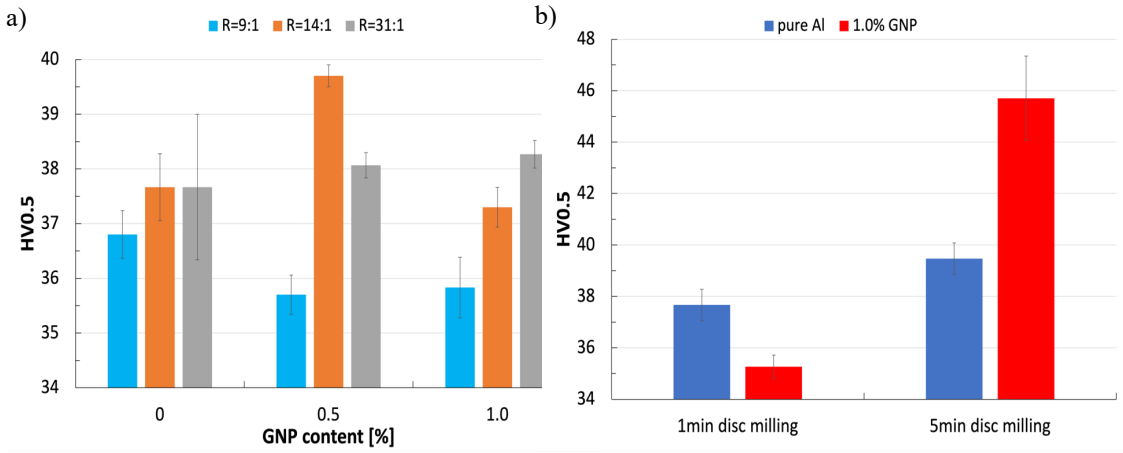

Fig. 5. Micro hardness of extruded composites containing SA-GNPs, a) processed via 6min mechanical mixing and 1min disc milling, extrusion at R=14:1 with conic die (2α=130°) b) effect of disc milling duration, applying R=14:1 and 2α=130° for extrusion.

Similar to the data representation of micro hardness, the results of tensile testing on the extruded SA-GNP composites are given in Table 3 and visualized in Fig. 6.

As observed before for the micro hardness, the tensile yield strength (TYS) did not change drastically with SA-GNP content nor with extrusion ratio. Values between 85MPa and 92MPa were measured for all composites that included disc milling for only 1min. The same can be stated for the ultimate tensile strength (UTS) since values varied between 110MPa and 116MPa. Even for the fracture strain no significant effect of the GNP content was measured. Values were between 25% and 29%. As can be noticed in Table 3b the effect of extrusion die angle (flat vs. conic) also did not have a relevant effect on the tensile properties of 1min disc milled SA-GNP composites.

Lastly, the effect of disc milling duration was investigated in tensile testing. Results are given in Table 3c and Fig. 6. In case of pure aluminum, a longer milling duration led to a reduction in TYS from 94MPa to 84MPa (-10%) while an increase in UTS from 116MPa to 126MPa (+9%) was observed. A reduction of TYS seemed to be very surprising since longer milling duration should lead to higher amount of deformation (generation of dislocations) in the Al-matrix and thus a work hardening effect. Hence, these experiments will be repeated in the future to figure out if that finding was a real effect that could maybe be related to softening by recovery or recrystallization due to significant heat generation during the milling process. For the 1.0%-SA-GNP composites an extension of milling duration resulted in increasing TYS from 81MPa to 95MPa (+17%) as well as increasing UTS from 112MPa to 141MPa (+26%). The fact that composite strengths increased could be related with improved SA-GNP dispersion in the composite (Fig. 3c) and hence a more effective strengthening effect of the graphene.

Table 3. a) Tensile test results for composites containing SA-GNPs, processed via 6min mechanical mixing and 1min disc milling, extrusion with conic die (2α=130°) b) Effect of die angle for R=14:1 after 1min disc milling c) effect of disc milling duration (t_{DM}).

1.0%	5min	95±1	141±1	17±3

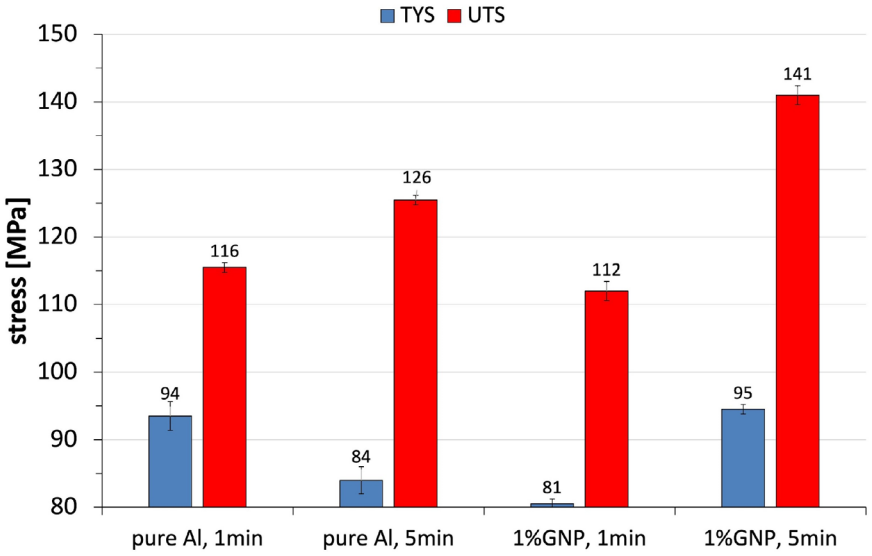

Fig. 6. Effect of disc milling duration on TYS and UTS of pure aluminum and 1%-SA-GNP composite rod materials.

When the strengths values of pure Al are compared to those of the 1% SA-GNP composite produced with same milling duration, it has to be noted that the addition of 1% GNP decreased TYS from 94MPa to 81MPa (-14%) after 1min of disc milling. UTS remained about constant and fracture strain decreased from 28% to 23%. Microstructural analysis with SEM will be carried out on the extruded rod material soon in order to investigate if maybe GNP agglomerations have formed locally for the relatively high graphene content of 1% and if those could be the reason for the detrimental YS. However, after a milling duration of 5min the addition of 1% SA-GNPs resulted in increased TYS from 84MPa to 95MPa (+13%) and UTS from 126MPa to 141MPa (+12%). Again, this could be due to improved GNP dispersion in the aluminum matrix after the longer milling duration and thus, an improved strengthening effect of graphene.

Since the results for SA-GNP composites were not as good as expected an alternative graphene source produced by Alfa Aesar (AA) was applied for the second part of the study. The effects of increasing AA-GNP content on micro hardness and tensile properties were investigated, after

applying powder processing via mechanical mixing only on the one hand and additional 5min disc milling on the other hand.

Fig. 7a presents the effect of AA-GNP content on micro hardness. In case of extruded composites produced from powders that were mechanically mixed only, increasing the AA-GNP content did not affect micro hardness as it remained about constant around 35HV. But powder processing via 5min of disc milling step, significantly increased hardness of extruded rods from 36HV to 43HV (+20%) in case of the 0.25% AA-GNP composite. The addition of a higher AA-GNP content of 1.0% increased micro hardness even further to 54HV, which means an increase of 49%. However, hardness decreased to values comparable to pure Al when AA-GNP content was 0.5%. This result could not yet be explained. If upcoming microstructure analysis with SEM should not show significant GNP agglomeration these tests will be repeated for verification.

In Fig. 7b the results of TYS and UTS are presented in dependence of GNP content and powder processing approach. Very similar to the prior micro hardness findings, composites where powders were processed via only mechanical mixing prior to extrusion, the TYS and UTS values did not change significantly with increasing AA-GNP content. TYS remained about constant in the range between 76MPa and 82MPa. UTS values varied only slightly between 105MPa to 113MPa. Fig. 7c presents the results of the measured fracture strains. For the composites no effect was observed when AA-GNP additions of 0.25% and 0.5% were applied as fracture strain remained about constant at 28%. But increasing AA-GNP content to 1.0% resulted in significant reduction to a fracture strain of 18%. As a reason for that decrease the formation of GNP agglomerates is assumed.

When the effect of AA-GNP content is studied for the approach including the 5min disc milling step, it can be noted that TYS increased from 79MPa (pure Al) to 92MPa (+16%) for the 0.25% composite. The UTS also increased from 112MPa to 142MPa (+27%). The increase in composite strength is supposed to be based on the improved AA-GNP dispersion that was noticed in Fig. 3e. Fracture strain of 5min disc milled samples were found to decrease with increasing AA-GNP content it was found to be reduced from 32% (pure Al) to 21% for 0.25% AA-GNP and to 26% for 0.5% AA-GNP. As previously noticed for micro hardness values, the material with an AA-GNP content of 0.5% also featured a low TYS of only 77MPa and a UTS of only 112MPa, which is comparable to pure aluminum. This value marks a significant drop when being compared to the 0.25% AA-GNP composite (92MPa). This again is a reason to repeat the tests for this condition. Unfortunately, the samples with the highest AA-GNP content of 1.0% could not be characterized by tensile testing since the extruded rod featured significantly cracking and it was impossible to manufacture samples for tensile testing. Hence, this condition will also be part of upcoming investigations again.

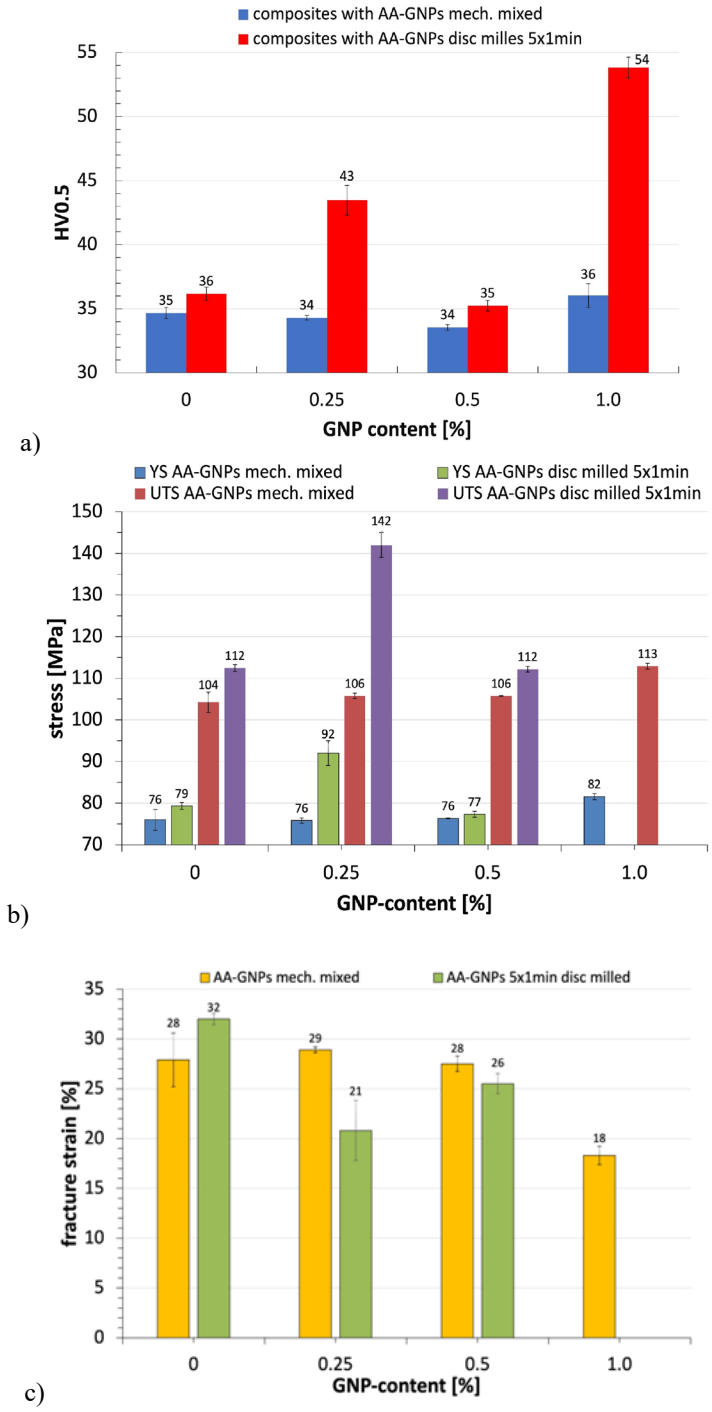

Fig. 7. Mechanical properties of extruded Al/GNP composite rods with different contents of AA-GNPs and initial powder processing via mechanical mixing only vs. additional 5min disc milling a) micro hardness b) TYS and UTS c) fracture strain.

Finally, when initial powder processing via mechanical mixing only is compared to the approach that featured the 5min disc milling, increased strength values were observed. For pure aluminum the increase in TYS was very low from 76MPa (mixed) to 79MPa (5min disc milled) and UTS from 104MPa to 112MPa (+8%). However, for the 0.25% AA-GNP composite 5min disc milling increased TYS from 76MPa to 92MPa (+21%) and UTS from 106MPa (mixed) to 142MPa (+34%). As previously assumed, the main reasons for increased strengthening are strain hardening of aluminum through plastic deformation during disc milling as well improved dispersion of GNPs in the aluminum matrix and thus an enhanced strengthening effect of the graphene additive.

Summary

The present study applied two different commercial graphene sources to investigate the disc milling process as a step in the powder metallurgical production chain for the manufacture of Al/GNP composites and the effects of process parameters on the mechanical properties. From the results the following conclusions can be drawn:

- When 1min of disc milling is applied, the addition of up to 1.0% of SA-GNPs did not significantly affect the mechanical properties of composites.
- Additionally, the application of either flat face die (2⟨=180°) or conic die with 2⟨=130°, as well as variation of extrusion ratio from 9:1, 14:1 and 31:1 did not have a significant effect on the mechanical composite properties.
- However, increasing the disc milling duration to 5min led to plate-like shaped Al-particles, a better exfoliation and dispersion of SA-GNPs and thus to increased micro hardness of up to 30%, increased TYS up to 17% and UTS up to 26%.
- Composites containing AA-GNPs improved in micro hardness by up to 49% (for 1% AA-GNPs) compared to pure Al, increased in TYS by up to 16% (for 0.25% AA-GNPs) and in UTS by up to 27% (0.25% AA-GNPs) when powders were disc milled for 5min.

Keywords: Aluminum Extrusion, Thermo-Mechanical History, Work Hardening

Abstract. The mechanical properties of extruded AlMgSi alloys are affected by the applied thermo-mechanical parameters employed during the entire production process. In the following, the effect of different extrusion speeds and homogenization conditions paired with either air or water quenching, is examined on four different sets of rectangular hollow AA6082-T4 profiles. These profiles were fabricated and extruded under industrial conditions and selected cross sections of each profile were examined by optical microscopy to determine the microstructure and level of recrystallization. Uniaxial tension testing was used to explore the effect of homogenization conditions and extrusion cooling rate on mechanical properties. Tensile tests showed that the water-quenched extrusions had a higher yield and ultimate strength compared to air-quenched extrusions. Moreover, samples that had a recrystallized microstructure typically showed a larger standard deviation of mechanical properties, which may lead to product quality and consistency issues for metal forming operations. Overall, the present work provides a more in-depth understanding of how the selected thermo-mechanical parameters affect the resulting properties of such profiles. This can further contribute to expanding the potential for effective accommodation of extrusion parameters for zero-defect products.

Introduction

Aluminum alloys, such as the AlMgSi alloys, are commonly used for structural applications in the form of extruded products as they allow for customizing cross sectional geometry with efficient use of material. This allows the profile geometry to be tailored for the specific application area, and the production process tailored to the geometry [1]. The resulting mechanical properties of such aluminum profiles are affected by the entire production process, including the alloy chemical composition and the applied thermo-mechanical history, from casting to final product [2]. As industry pushes towards the goals of reducing climate impact, increasing process adaptability and product customization, deeper understanding of the interactions of different manufacturing process-steps is required to fully utilize the favorable properties of aluminum extrusions.

Stretch bending of aluminum profiles is a commonly used forming method for producing lightweight products [3]. However, a variety of challenges are related to such forming processes particularly for industrial applications; e.g., springback, tool wear, and geometric defects [4]. In order to improve the fabrication process and the prediction of the material response during stretch bending, there is a need for an accurate model of the work hardening behavior. Moreover, an accurate model is critical for predicting geometric recovery such as springback after forming, allowing for adaptive processes which can compensate for this behavior. Recently, Ma et al. [5], have shown that an accurate prediction of the forces during forming is possible provided the material hardening behavior is known. With this information, tool wear can be modeled and maintenance schedules can be developed. Moreover, Ma and Welo [6] have recently used

analytical methods to assess the springback problem for aluminum profiles. In their work, they have shown how springback calculation can become quite complex for complicated bend geometries with variable stress states along the profile length. In their analysis, the stress state is a function of position along a cross section with stress gradients developing through transition zones and becoming stable in a uniform bending zones. When the forming process reaches the point where the entire material cross section is in the plastic state, the stress gradient will decrease as the flow stress curve approaches the saturation stress of the model [6]. Thus, once a specific part geometry is considered and the material hardening behavior is properly modeled, Ma and Welo's method can be applied in combination with finite element methods to predict springback and final part geometry of stretch bended aluminum extrusions.

Using process and property models which can account for the thermo-mechanical history to determine production parameters can allow for optimization of material and energy use by more holistic design methods. Furu et al. [7] propose a modeling framework which connects several independent models of separate process steps together. Thus, optimization of certain AlMgSi alloys, such as AA6082, by simulation is now possible with respect to several key factors such as properties and cost. Accurate prediction of dispersoid development during homogenization is critical to prediction of material structure, properties, and thus responses to later process steps with models by Dons et al. [8] and Dons [9] predicting these material characteristics. For example, the strength of AA6xxx alloys is affected by dispersoid size and density as it can determine the precipitation development during both natural (NA) and artificial aging (AA) as shown by Myhr et al. [10, 11]. This framework can also account for work hardening effects due to dislocation strengthening from pre-strain as shown by Granum et al. [12], and it is possible that this modeling family can be expanded to more accurately predict the hardening behavior of AlMgSi alloys.

However, the deformation experienced during extrusion also lead to further effects on properties. Schikorra et al. [13] divided extruded material into shear intensive zones (SIZs) or a main deformation zone (MDZ), with the higher strain and strain rates of the SIZ leading to higher potential for dynamic recrystallization during extrusion. Per Zhang et al. [14], during dynamic recrystallization grain size is a function of temperature and strain rate, and Schikorra et al. argued that this is a result of a critical strain value being reached, while Van Geertruyden et al. [15] suggests that it is based on deformation energy stored in the material from the extrusion process. Both the previous works are focused on PCG surface layers, but work by Wang et al. [16] shows that internal weld seams behave similarly. Extrusion bridge designs which increased strain also increased recrystallization of an AA6082-type alloy, consistent with the work on PCG surface layers. Similarly, work by Birol [17] shows that by increasing the number density of dispersoids (by increasing Cr and Zr) recrystallization was reduced along weld seams of extruded 6082 tubes.

The effects of homogenization parameters on dispersoid density are not limited to recrystallization, as dispersoid density effects the response of 6xxx series aluminums to aging. Work by Rakhmonov et al. [18] explains how a higher density of smaller dispersoids then resulted in an increase in β'' particles after AA, and thus improved strength. The developed as a result of alloying elements still present in solid solution, rather than in non-strengthening dispersoids. This understanding is in line with the reduction in quench sensitivity with NA found by Strobel et al. [19] in a study focused on high dispersoid density 6xxx series alloy. Alternatively, it was shown by Frodal et al. [20] that lower cooling rate decreases yield strength, due to an increase in the size of precipitate free zones around dispersoids and grain boundaries in multiple T6 aged 6xxx series alloys.

In short, variations in early extrusion production steps, such as homogenization treatment, cooling after extrusion and ageing conditions, may change the material response to downstream processes like subsequent forming operations. This work seeks to provide an example data set for the process modeling community where critical details of the material history and process

parameters are known, the mechanical properties measured, and potential impacts on downstream processes considered. The current work will show how process steps, which change the microstructure of extruded profiles, result in changes to the mechanical behavior of the material. As a result, this work will present data necessary for the process and property modeling community to move forward.

Methods

Homogenization and Extrusion.

Four sets of AA6082.26 profiles were extruded at Benteler Automotive Raufoss AS, employing differing homogenization and extrusion parameters, as listed in Table 1. and shown schematically in Fig. 1. All profiles are extruded from a single log with the composition measured at casting, as listed in Table 2. Sample sets are labeled based on their homogenization parameters and extrusion speed (either S or L) and the quenching fluid after extrusion (either A or W). Billets were homogenized for either 2.25 hours at 530°C (samples S) or for 12 hours at 590°C (samples L) before extrusion. The profiles used for this study are taken from four extrusions, with 2 prior extrusions used to ensure that all equipment was at stable operating temperature and providing stable operation conditions. Prior to extrusion, billets are heated to 470°C and then extruded at either 7 m/min (samples S) or 10 m/min (samples L). After extrusion, either forced air quenching (samples A) was applied over 40 meters after extrusion exit or water spray quenching (samples W) over 10 meters, with all extrusions reaching a temperature near 65°C after these processes. All extrusions had an extrusion ratio of 55, and the profile nominal cross-section dimensions are 60 × 40 mm with a wall thickness of 3 mm. A schematic of the profile cross section is shown in Fig. 2. Note that the extruded profiles under four sets of parameter combinations are labeled individually as SA, LA, SW, and LW.

Table 1. Homogenization and extrusion parameters for materials used for this study, all extrusions are AA6082.26.

Extrusion	1	2	3	4
Homogenization Temp [°C]	530	590	530	590
Homogenization Time [hours]	2.25	12	2.25	12
Extrusion Speed [m/min]	7	10	7	10
Quenching Fluid	Air	Air	Water	Water
Sample Label	SA	LA	SW	LW

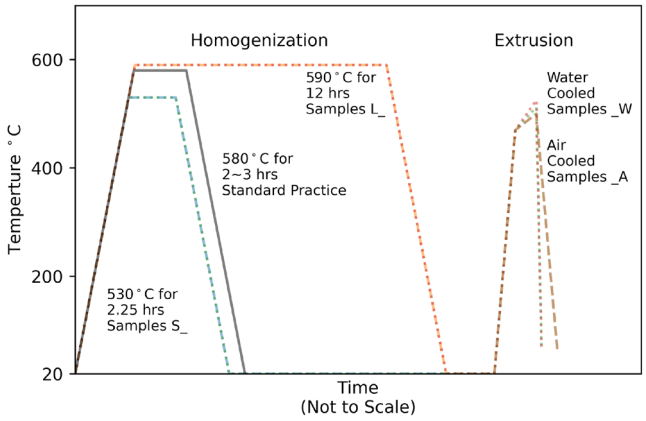

Fig. 1. Schematic of homogenization and extrusion temperatures over time with specific parameters varied for this study shown (dashed lines, also given in Table 1), in comparison to industry standard process parameters [21] shown with the solid line.

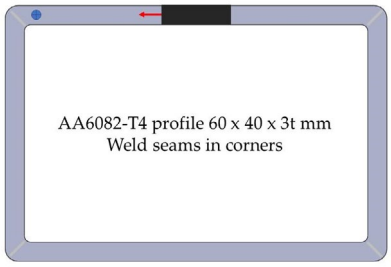
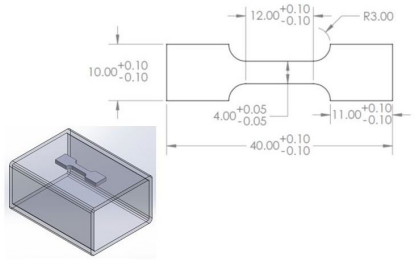
Microscopy.

Optical microscopy (OM) was done to characterize the level of recrystallization. OM imaging was done on corner sections of the extrusion cross section, with the extrusion direction normal to the image plane using a Zeiss Axio Vert Inverted Light Microscope with a 5x lens. Fig. 2 shows the image plane position and orientation with respect to the extrusion direction. OM surfaces were polished to 1 µm and anodized at room temperature in Baker's reagent (10 ml HBF_4 (48%) + 400 ml distilled water) for 90 seconds before imaging. OM images have a resolution of 0.685 µm/px, with image stitching used to show the full cross sections.



(a) Hollow Rectangular Profile Cross Section



(b) Mechanical Test Sample Dimensions and Position

Fig. 2. Cross section of rectangular hollow extrusions (a) and location of samples within cross section with dimensions of uniaxial tension samples (b). The blue arrow in (a) indicates the surface normal of the OM images of extrusion cross sections.

Tensile Tests.

Subsize tensile test samples were machined from the profiles with a so-called dogbone geometry, having a nominal cross-section of 3 x 4 mm and a gauge length of 12 mm. The position of the samples with respect to profile geometry is according to the schematic shown in Fig. 2. In order to determine possible variation, 3 samples along the same flange of a profile were used for testing. Uniaxial tension tests of the samples were done with an initial nominal strain rate of 0.001 1/s using an Instron ElectroPuls E10000 servo-electric load frame. Digital image correlation (DIC) [22] *in-situ* measurement of material deformation was used with Correlated Solutions VIC-Snap 8 and VIC-2D 7 software. Strain measurement was done using virtual extensometers within the

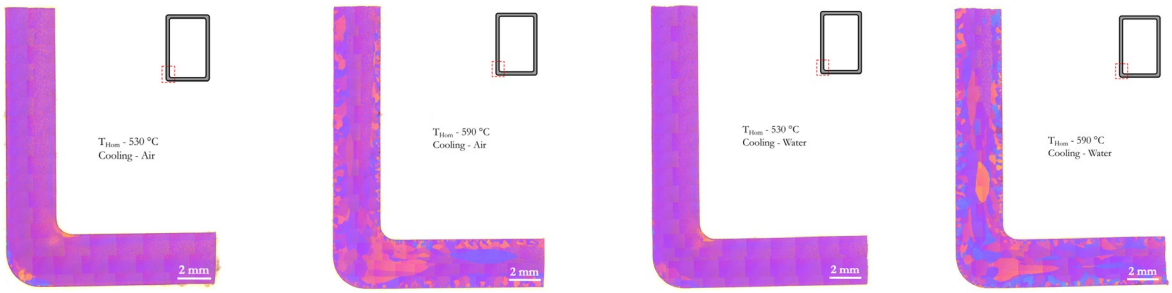
DIC data set. The engineering strain is used for determining uniform elongation, ultimate tensile strength (UTS), and an offset strength (OFS) at 0.002. This offset is chosen for ease of comparison to the Voce initial stress value explained below. The true plastic strain is calculated, with the elastic strain component removed using a Young's modulus of 70 GPa [23]. As AA6082 shows soft knee yielding and determining individual moduli per sample is highly sensitive to experimental setup and selection of data points, the single reference value was used for all samples. A Voce-type hardening model (Eq. 1) is then fit to the material behavior up to 20% plastic strains, ϵ^p, as given by:

$$\sigma_{True} = K + Q * \left(1 - e^{(-b\epsilon^p)}\right) \quad (1)$$

where σ_{True} is true flow stress, K is the initial stress value, Q is the saturation stress value, and b is the hardening exponent.

The plastic anisotropy ratio, r, is calculated at ϵ^p = 5% in the loading direction and is thus r_0, not to be confused with normal and planer anisotropies $\underline{R}$ and ΔR respectively. The calculation uses the nearest measured longitudinal plastic strain to ϵ^p = 5% and the corresponding measured lateral plastic strain. From these measured strains, the thickness plastic strain is calculated assuming incompressibility. 5% plastic strain was chosen as a representative point considering the range of plastic strains experienced during stretch bending [24].

Results



(a) Extrusion SA (b) Extrusion LA (c) Extrusion SW (d) Extrusion LW

Fig. 3. Optical microscopy imaging of the cross sections of AA6082.26 with variable extrusion histories as given in Table 1. Extrusion direction is out of the image plane.

Microstructure.

OM images of the cross sections are presented in Fig. 3, and show a fibrous grain structure is present in some part of all extrusions, with a peripheral coarse grain (PCG) layer in both the LA and LW extrusions. There is PCG growth in the corners of SA and SW, though it does not extend through the profile thickness along the weld seams. Note that the depths of the PCG layer for the LA extrusion are not symmetric on the inner and outer surfaces of the profile. The level of recrystallization in the LW cross section resulted in a thicker PCG layer in comparison to the LA extrusion. The difference in the recrystallization behavior between the T_{Hom}=530°C (S) and T_{Hom}=590°C (L) extrusion pairs is consistent with expectations based on dispersoid density after their respective homogenization parameters. Differences in recrystallization between extrusion pairs based on cooling method are still noticeable in Fig. 3, though less significant. As stated above, a fibrous-grained core is still present in both LA and LW samples. For the LA and LW cross sections, there is also recrystallization of the core within the profile corner with a PCG layer consisting of grains that are smaller than the recrystallized core. So, a PCG layer covers both the interior and exterior surfaces of the L extrusion profiles over 2 "core" areas with a fibrous core in the central areas of the webs and flanges and a recrystallized core in the corners.

Materials Research Proceedings 28 (2023) 467-476 https://doi.org/10.21741/9781644902479-51

Mechanical Properties.

The experimental flow stresses (σ_{True} vs plastic true strain ϵ^p) sorted by extrusion are shown in Fig. 4 with the curves ending at UTS. As expected and shown in Fig. 4, the material response varied based on both homogenization and cooling parameters. Water quenched extrusions; i.e., those with a higher cooling rate, showed a higher initial flow stress as reflected in both the stress-strain, $\sigma_{True} - \epsilon^p$, curves of Fig. 4 and the Voce initial strength K shown in Fig. 5 (d). The average OFS of the water-quenched extrusions (162.2 MPa and 152.1 MPa, for extrusions SW and LW respectively), as shown in Fig. 6 (a), is higher than the air-quenched extrusions (137.7 MPa and 139.3 MPa for extrusions SA and LA respectively). This difference is not dramatic, but with a variance ratio (between group variance/within group variance) of 17.34 it is greater than the difference between samples from the same extrusion. UTS showed a more significant difference between the water-quenched samples (258.6 MPa and 248.5 MPa for extrusions SW and LW respectively) and air-quenched samples (221.2 MPa and 232.8 MPa for extrusions SA and LA respectively), as shown in Fig. 6 (a). The UTS variance ratio is 46.14, which reflects a stronger relationship between an extrusion's thermo-mechanical history and UTS compared to OFS. This trend is also reflected in the saturation stress Q of the Voce model, shown in Fig. 5 (b).

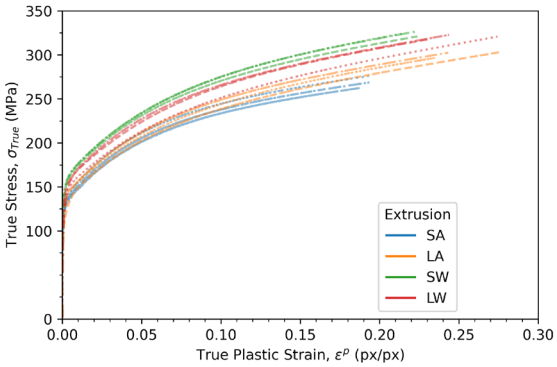


*Fig. SEQ Figure * ARABIC 4. Experimental true stress vs plastic true strain of AA6082.26 with varied thermo-mechanical histories as explained and labelled in Table 1.*

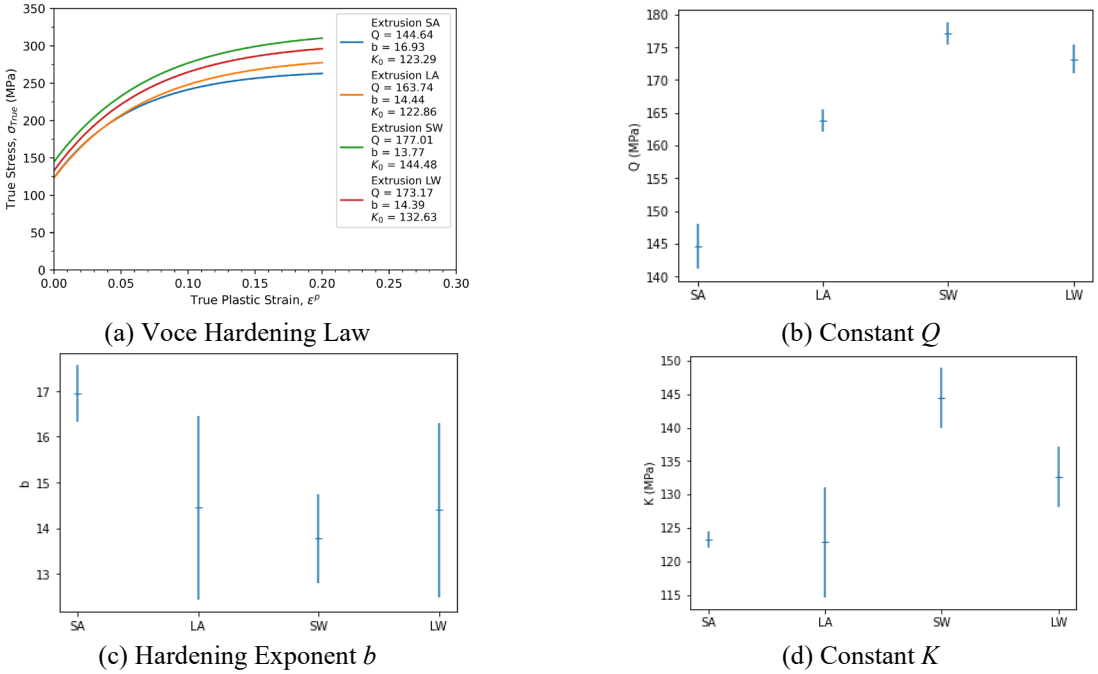

(a) Voce Hardening Law (b) Constant Q

(c) Hardening Exponent b (d) Constant K

Fig. 5. Fit of a Voce like hardening law to experimental true stress vs plastic true strain data of AA6082.26 with varied thermo-mechanical histories as given in Table 1. The Voce like hardening law is plotted for each extrusion in (a) using the constant Q (b), hardening exponent b (c), and constant K (d).

In contrast to strength, the ductility of the samples is better sorted by homogenization parameters than by cooling rate. The uniform elongation, as shown in Fig. 6 (b), is higher for both L sample sets, but the standard deviation (SD) is larger. In contrast, the level of consistency in both UTS and flow stress curves shown in Fig. 4 for both S extrusions is notable. It is important to observe that this trend is however not reflected in the strain to failure, in comparison to uniform elongation. The SW extrusion had similar failure strains as that of the L samples, implying significant elongation after UTS.

Discussion

As shown in the results section higher extrusion speeds in combination with homogenization parameters, and thus a lower number density of dispersoids, increases the recrystallization in AA6082 extrusions. On thin wall profiles, such as hollow rectangular extrusions, this can result in a significant portion of the cross section being PCG or recrystallized. This difference in material microstructure changes mechanical behavior, especially initial yielding, plastic deformation, and work hardening, due to the influence of grain size and texture on these properties.

Considering the recrystallization of the L extrusions, primarily within the different portions of a cross section, recall the work of Schikorra *et al*. [13]. Their framework is helpful to understand the differences between the PCG around the surface of the L cross sections, the fibrous core, and the coarser recrystallized grains in the corners as shown in Fig. 3. The higher recrystallization in combination with the higher extrusion speeds of the L samples is consistent with understandings presented above in [14], [15]. However, these results suggest that the material making up the corners does not fit cleanly within either SIZ or MDZ categories. Also, material which is within the same category of SIZ on the internal and external surfaces are not similar thicknesses, which is consistent with the different deformation histories of each. Thus, further work is needed to investigate the material flow path within this particular toolset to clarify the link between

deformation history and recrystallization. Based on Wang et al. [16], it is reasonable that the higher strain experienced by the material from the MDZ in the corners is resulting in the coarser grain growth. It also explains why there is also recrystallization in the S cross section corners, while the majority of the cross section retains a fibrous microstructure. In short, the PCG layer recrystallization is driven by strain history as part of the SIZ of the extruded material which is consistent around all surfaces. In the corners, a recrystallized core from the MDZ develops as a result of a longer flow path than the fibrous core. Thus it is also possible that the material making up the corners does not fit within either SIZ or MDZ categories.

As stated in the results section above, the mechanical characteristics of the profiles have a stronger relationship to the extrusion cooling rate than the homogenization parameters. However, it is clear from both the literature and differences between the SW and LW extrusions that the homogenization parameters have an effect. This work examines NA AA6082, and as such β' particles develop at nucleation points (which are often dispersoids [19]). Alloying elements which would have developed into β'' particles during AA remain in solid solution, strengthening the material. While Frodal et al. [20] was of AA rather than NA 6xxx series, it is consistent with this understanding of the results. The SW samples had higher UTS and OFS than LW samples, as well as higher average Voce constants Q and K as shown in Fig. 6 (a), Fig. 5 (b) and (d) respectively.

It is also interesting to note from these figures that both recrystallized extrusions LA and LW had higher uniform elongations and r at 5% ϵ^p, likely due to the recrystallized grain structure within these extrusions. Both characteristics suggest the LA and LW extrusions would have better formability, as r approaching 1 implies more isotropy and higher uniform elongations imply a larger allowable strain range for forming before localization. However, for both of these characteristics, the SD of the tested samples are larger than for the S samples (and in the case of r for LA, larger than the LW samples) which suggests possible production consistency issues. While these characteristics might imply better forming performance, recrystallized profiles tend to have an "orange peel" like surface texture which may cause issues for parts and profiles that must meet surface quality requirements for either paint or appearance for surfaces visible to the end user. It is also important to note that while the mechanical properties of initial flow stress and UTS of the LW samples were higher than both SA and LA samples, the SW extrusions are the best performing for applications where maximum mechanical strength is needed based on the extrusions tested.

Summary

Four sets of AA6082.26 rectangular hollow profiles are produced using industrial equipment and methods, using differing homogenization and extrusion parameters. Both microstructural characteristics and mechanical properties of the extruded profiles were examined. The influences of thermo-mechanical history on the property of extruded profiles were discussed. The main conclusions are summarized as follows:

- Extrusions with longer time and higher temperature homogenization resulted in higher levels of uniform elongation and more isotropic plastic deformation regardless of extrusion cooling rate.
- Higher extrusion cooling rates led to higher strengths overall (both ultimate and offset strengths), with this effect being larger in extrusions with shorter homogenization time.
- The hardening behavior of the material up to 20% plastic strain can be represented regardless of homogenization or extrusion parameters using a Voce like hardening law for the flow stress behavior.
- Extrusions with longer time and higher temperature homogenization showed higher standard deviations across a number of mechanical parameters, including hardening exponent b, plastic ratio r, and uniform elongation.

Based on these results, the extrusion cooling rate is more critical to control than recrystallization with respect to mechanical characteristics. For process modeling, homogenization effects on

ductility due to microstructural composition and the effect of extrusion cooling rate on strength are the primary effects of each process which then interact to result in the hardening behavior. Further work can proceed along two lines, either via investigation of the material or investigation of the subsequent forming process. Investigation of the material would involve TEM imaging and measurement of dispersoid size and density, as well as β' precipitate development during natural aging. Work proceeding along the forming process would show the impact of these property variations on dimensional accuracy of formed parts.

Abstract. The microstructure of Al-Mg-Si alloys is gaining nowadays an increasing industrial interest because it influences the strength, crash, corrosion and esthetic properties of the extruded profiles. In order to investigate and predict the recrystallization behaviour in the extrusion of 6XXX aluminum alloys, experimental and numerical activities are still needed. In this work, the extrusion of an industrial-scale AA6060 aluminum alloy hollow profile was carried out. An innovative recrystallization model was developed and optimized by comparing the microstructural data experimentally acquired with the outputs of the simulation performed using the Finite Element commercial code Qform Extrusion. A good correlation between numerical prediction and experimental data was found, thus proving the reliability of the proposed AA6060 recrystallization model.

Introduction

The microstructure of 6XXX aluminum alloy extruded profiles is of primary interest for extrusion companies since it affects the product performances [1,2]. To date, the relationship between process parameters and grain structure evolution is not fully understood due to the high number of factors that affects the final microstructure of the profile. For this reason, the scientific community is pooling efforts to investigate the recrystallization of aluminum alloys during the extrusion process. Moreover, in order to control the final microstructure at a die design stage without performing expensive experimental trial and errors, it is mandatory the development of reliable models for the recrystallization prediction to be implemented into FE (Finite Element) codes.

In Fig. 1, a typical microstructural evolution during the extrusion of 6XXX aluminum alloys is shown. Two different types of structures can be detected. In the fibrous structure (Fig. 1b,d), grains are deeply elongated and they are characterized by a length (the dimension along the extrusion direction) several times greater than the width and thickness. Instead, in the recrystallized structure (Fig. 1c,e), grains have a spherical equiaxed shape (Fig. 1a) so that they can be characterized by a single average grain diameter. The fully recrystallized state is always detectable in the billet material as consequence of the casting phase and further homogenization process. Immediately after the die exit, the profile always shows a fibrous microstructure (immediate profile quenching) due to the strain field applied during the extrusion process. If the profile is not immediately quenched and its temperature remains higher than the alloy recrystallization temperature for a sufficient amount of time, the structure may recrystallize (fully or partially Fig. 1c,e). If the energy stored in the material during the deformation process is lower than a certain critical level, the microstructure of the profile still remains fibrous (Fig. 1d).

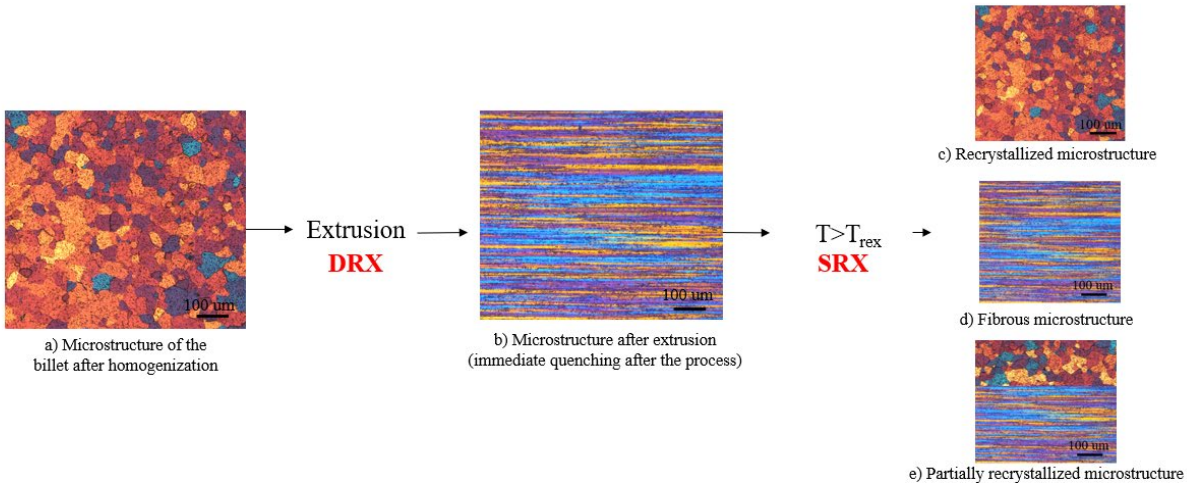

Fig. 1. schematization of the microstructure evolution during the extrusion process of a 6XXX aluminum alloy.

During and after the extrusion of 6XXX aluminum alloys, two main recrystallization mechanisms can be distinguished: the first, called dynamic recrystallization (DRX), occurs while the material is deforming [3]. This phenomenon is related to the material strain field and involves, for low stacking fault materials (LSFE), nucleation and grain growth or, for high stacking fault materials (HSFE as aluminum alloys), other different behaviours that are still under debate in the research community.

The second main recrystallization mechanism is the static recrystallization (SRX), which occurs after the hot deformation and causes the rearrangement of the microstructure through nucleation and growth [4]. Several studies have been made to investigate the SRX in the hot deformation processes of aluminum alloys also using finite element model simulations [5-7]. However, many of these works were performed using laboratory-scale or simple-profile extrusions as experimental campaigns. Moreover, none of the investigated models has been extensively tested on extrusions of industrial-scale cases or on complex geometry profiles, thus limiting the strain and strain rate fields for the modeling validation.

In this work, an industrial-scale extrusion of AA6060 aluminum alloy hollow profile was investigated. Numerical activities involving Finite Element (FE) simulation of the extrusion were performed with the commercial Qform Extrusion code. Moreover, an innovative recrystallization model was developed, comparing the achieved results with the microstructural data experimentally collected for the industrial-scale profile. The final aim of this work was to propose a reliable model able to accurately predict the microstructural behaviour in the hot extrusion of AA6060 aluminum alloy profiles.

Experimental Procedure

The geometry of the profile under investigation is reported in Fig. 2. It was produced by the Profilati SpA plant of Medicina (Italy). The production batch involved the extrusion of 17 billets and the data about profile exit temperature and extrusion load were acquired during the whole process and used to validate the numerical simulation results. The analyzed sample comes from the extrusion of the seventh billet in order to have steady-state conditions in the tool-die set.

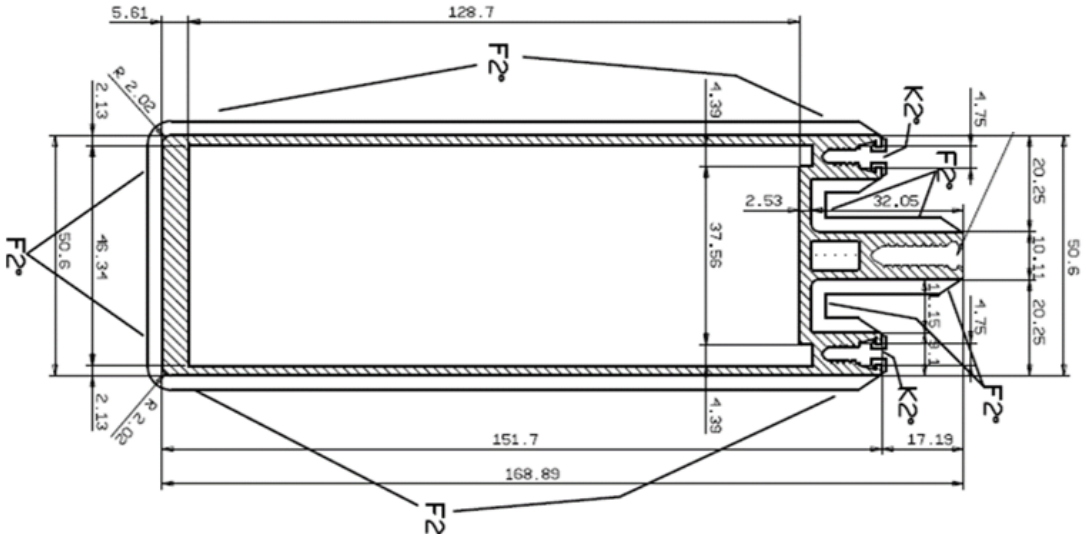

Fig. 2. Geometry of the extruded profile.

In Table 1, the extrusion process and the geometry parameters of billet and tools are reported.

Table 1. Process parameters and geometry tolerances.

Process parameters and geometry tolerances	**Profile**
Aluminum alloy	AA6060
Extrusion ratio	27
Ram speed [mm/s]	8
Container temperature [°C]	430
Billet temperature [°C]	480
Die temperature [°C]	510
Ram acceleration time [s]	5
Billet length [mm]	950
Billet diameter [mm]	203
Container diameter [mm]	211
Billet Rest length [mm]	44

The microstructure of the profile is reported in Fig. 3b-g. The investigated samples were grinded, polished and etched with electrolytical etching. The images of the etched samples were acquired by using polarized light microscopy Zeiss AXIO and the measurement of the average grain dimension was carried out according to the ASTM-E112 regulation. The images of Fig. 3 clearly show a fully recrystallized microstructure, within an average dimension range of 45 μm to 110 μm. The analysed samples were taken at the middle length of the extrusion profile, corresponding to a ram stroke of 475 mm. From the entire cross-section of the profile, six zones were selected (Fig. 3b-g). From each zone, 10 random points were extracted and, in each of these, the dimensions of the statically recrystallized diameter were measured. Half of these grain sizes were used for the model calibration and the other half for the validation. During the calibration, these values were used to find the material constants of the recrystallization model while, during the validation, the values were used to assess the accuracy of the model predictions.

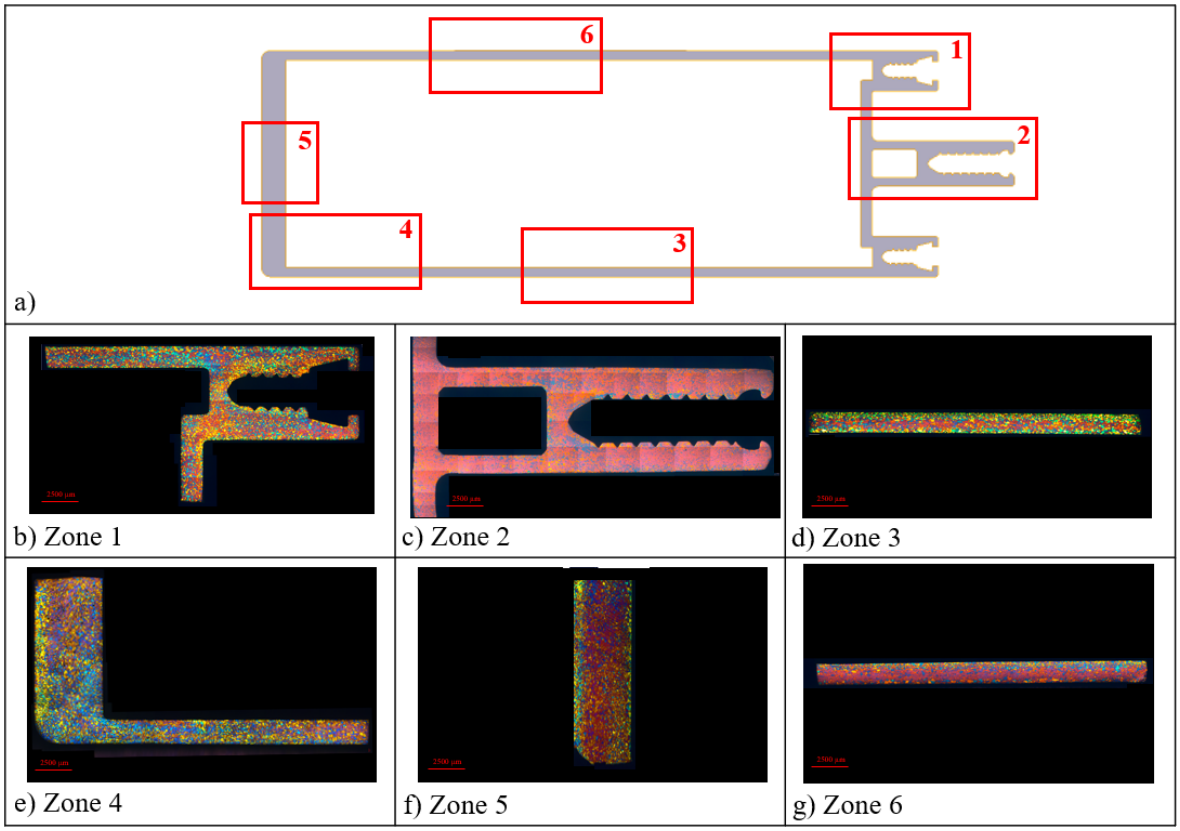

Fig. 3. Microstructure of the investigated AA6060 profile.

Modeling

The static recrystallization kinetic was modeled according to [8]: the average diameter of the static recrystallized grain D_{rex} was calculated as following:

$$D_{rex} = X_{rex} * N^{-1/3} \quad (1)$$

where N is the nucleation density and X_{rex} is the fraction of recrystallized material. The X_{rex} value was considered equal to 1 since the acquired images show a completely recrystallized microstructure. In order to determine N, different nucleation contributions must be considered [8]:

$$N = N_{PSN} + N_{GB} + N_C \quad (2)$$

where N_{PSN} is the nucleation occurred from deformation zones around particles larger than a critical size. It is often the main nucleation mechanism in 6XXX aluminum alloys which contains large undeformable particles, and involves the growth of nuclei in turbulent deformation zones with random orientations. N_{GB} is the nucleation from old grain boundaries and N_C is the nucleation from retained cube grains which survived the applied deformation. These three contributions can be calculated as following [8]:

$$N_{PSN} = C_{PSN}\, exp\left(\frac{-A_{PSN}}{(Pd-Pz)}\right) \quad (3)$$

$$N_{GB} = C_{GB}\, \delta\, A(\varepsilon)\, S_{GB} \quad (4)$$

$$N_C = C_C\, \delta\, A(\varepsilon)\, S_C \quad (5)$$

where C_{PSN}, A_{PSN}, C_{GB} and C_C are the material constants which need to be calculated in order to optimize the model for the investigated AA6060 aluminum alloy. Pd is the Stored Energy, driving force for recrystallization which act in the form of dislocation substructures and concentrations of vacancies [9]. Pz is the Zener Drag Pressure, retarding force for recrystallization which depends on the dispersoids size and density and alloying elements in solid solution [10].

$$Pd = \frac{Gb^2}{10}\left[\rho i(1 - ln(10b\rho i^{0,5})) + \frac{2\theta}{b\delta} * \left(1 + ln\ ln\ \left(\frac{\theta c}{\theta}\right)\right)\right] \quad (6)$$

where G is the material shear modulus (2.05x10^{10} Pa), b the Burgers vector (2.86x10^{-10} m), ρi the dislocation density, δ the subgrain size, θ the misorientation angle and Θc the misorientation angle limit (15°). The dislocation density ρi and the misorientation angle θ were calculated according to [9] as a function of the strain rate $\dot{\varepsilon}$, the temperature T and the strain ε (Fig. 4a,b).

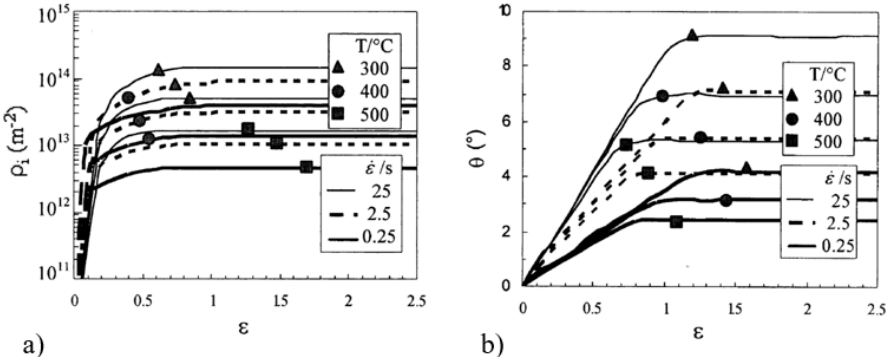

Fig. 4. a) Dislocation density [9], b) Misorientation angle [9].

The subgrain size and the Zener-Hollomon parameter were calculated according to [11]:

$$\frac{1}{\delta} = C\ (lnZ)^n \quad (7)$$

$$Z = \dot{\varepsilon}\ exp\ \left(\frac{Q}{RT}\right) \quad (8)$$

where C=3.36x10^{-9} m^{-1}, n=5.577, Q is the activation energy of the AA6060 (161000 J/mol*K [12]), R is the universal gas constant (8.341 J/mol) and $\dot{\varepsilon}$ is the maximum strain rate for each point of material flow during the extrusion deformation path.
$A(\varepsilon)$ is the grain boundary area per volume at a given strain and S_{GB}, which can be assumed as S_{GB}=S_C=S [13], is the number of subgrain larger than a critical subgrain size δ^*, calculated as followed:

$$\delta^* = \frac{4\gamma}{Pd - Pz} \quad (9)$$

According to what reported in literature [8], $A(\varepsilon)$ was modelled as:

$$A(\varepsilon) = \frac{1}{D_0}[(exp\ exp\ (\varepsilon)\ + exp\ exp\ (-\varepsilon)\ + 1)] \quad (10)$$

where D_0 represents the average grain size in the billet material after the homogenization process. According to the work of [10], the Zener Drag pressure is calculated as following:

$$Pz = \frac{3 * f * \gamma}{4 * r} \quad (11)$$

where f and r are the fraction area and the mean size of the dispersoids, respectively, and γ is the grain boundary energy (0.3 J/m^2 [13]). As an approximation, values of f and r were taken from the work of [14], where the distribution of dispersoids were analysed in different AA6060 aluminum alloys (f= 0.013%, r= 125 nm).

Numerical Investigation

The simulation of the analysed extrusion process was performed using Qform Extrusion, a commercial ALE (Arbitrarian Lagrangian Eulerian) FE code. The constitutive model used for the description of the AA6060 flow stress was proposed by Hensel-Spittel [15]. According to the proposed equation (Eq. 12), the material flow stress $\underline{\sigma}$ depends on the contribution of strain $\underline{\varepsilon}$, strain rate $\underline{\dot{\varepsilon}}$ and temperature T:

$$\underline{\sigma} = A \cdot e^{m_1 T} \cdot \underline{\varepsilon}^{-m_2} \cdot \underline{\dot{\varepsilon}}^{-m_3} \cdot e^{\frac{m_4}{\underline{\varepsilon}}} \cdot (1+\underline{\varepsilon})^{m_5 T} \cdot e^{m_7 \underline{\varepsilon}} \cdot \underline{\dot{\varepsilon}}^{m_8 T} \cdot T^{m_9} \quad (12)$$

The values of the Hensel-Spittel constants ($m1$-$m9$) used for the simulation of the AA6060 aluminum alloy, reported in Table 2, were taken from the Qform material database.

Table 2. Hensel-Spittel and for the AA6060 aluminum alloy.

Parameters	AA6060
A	280 [MPa]
m1	-0.00461 [K^{-1}]
m2	-0.16636
m3	0.12
m4	-0.02056
m5	0.00036 [K^{-1}]
m7	0
m8	0 [K^{-1}]
m9	0

The friction conditions between workpiece and tools were also taken from the software database according to the default values optimized for extrusion (Table 3). The values of the material properties used in the simulation are reported in Table 4.

Table 3. Friction conditions.

Surface	Friction condition
Billet-Container	Sticking condition
Billet-Ram	Sticking condition
Billet-Die	Sticking condition
Bearings	Levanov model (m = 0.3, n = 1.25)

Table 4. Material parameters for the AA6060 aluminum alloy.

Material Properties	AA6060
Density [Kg/m3]	2690
Specific heat [J/kg K]	900
Thermal conductivity [W/m K]	200
Thermal expansivity [m/K]	2.34*10-5
Young's modulus [GPa]	68.9
Poisson's ratio	0.33

In order to validate the results of the simulation, the values of the numerical extrusion load and profile exit temperature were compared to the experimental ones. With regard to the extrusion load, the experimental peak value was found at 23.4 MN while the numerical one at 23.3 MN. Consequently, the numerical error in the extrusion load prediction was under the 1%. Moreover, the experimental exit temperature of the profile (recorded by using a pyrometer fixed at the exit of the die) was found at 557°C while the numerical one at 562°C, with a prediction error close to the 1%. As a result, the average error in the extrusion load and temperature prediction was found below the 1%, thus proving the reliability of the simulation.

Results and Discussion

The material constants of the recrystallization model were obtained by applying the Levenberg-Marquardt non-linear regression algorithm [16], implemented in Matlab®, using as input data the "calibration set" of points in which the grain size was experimentally calculated. For each considered point, the values of temperature, strain and maximum strain rate were calculated by the simulation using Qform software. A different set of points ("validation set") were used to validate the results of the numerical microstructure prediction.

Considering the trend of eq. 10, since this equation was investigated in rolling processes which typically have stain values considerably lower than 10 [8], it has been noticed that for values of strain higher than 10 (Fig. 5a), typical of industrial-scale extrusions, the formula returned unreasonably high values of $A(\varepsilon)$ and, consequently, of N_{GB} and N. For this reason, $A(\varepsilon)$ has been calculated according to eq. 13, limiting the growth of the parameter to a maximum value (Fig. 5b):

$$A(\varepsilon) = \frac{1}{D_0}\left[p_1 - p_2\, e^{p_3\, \varepsilon^{p_4}}\right] \tag{13}$$

where p_1, p_2, p_3, p_4 are material constants. These values were added to the other material constants and optimized using the Levenberg-Marquardt algorithm mentioned above.

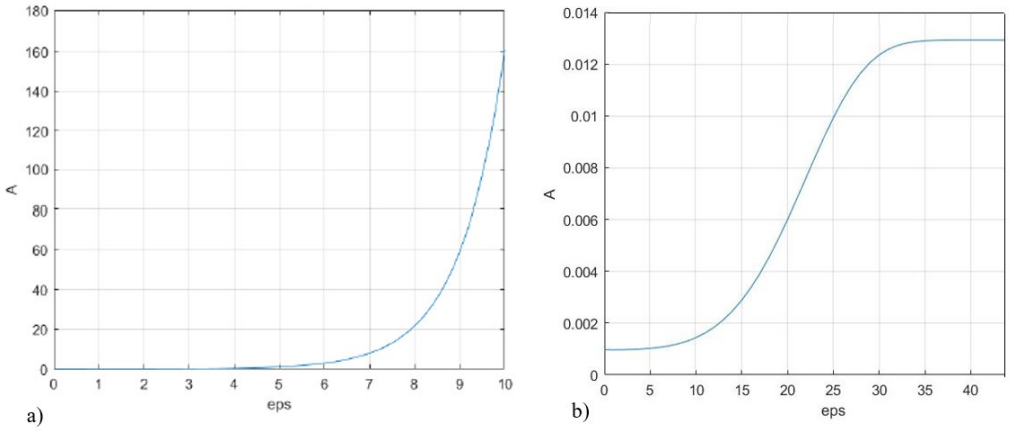

Fig. 5. a) A(ε) calculated according to Eq. (10), b) schematization of A(ε) calculated according to Eq. 13.

The outputs of the non-linear regression method are summarized in Tab. 5. After acquired these values, the model was implemented into Qform Extrusion and used to calculate the average grain size of the extruded profile.

In Fig. 6, the numerical simulation of the grain size after the complete SRX is reported. Red and blue areas correspond to the part of the profile in which the grain size have higher and lower dimensions, respectively. The numerical range of grain size dimension resulted between 52 μm and 96 μm.

Table 5. Recrystallization model material constants AA6060.

Material constants	**AA6060**
C_{PSN}	5.00021 e^{13}
A_{PSN}	872954
C_{GB}	0.0002145
C_C	0.0002145
p_1	1.9
p_2	1.06
p_3	1 e^{-7}
p_4	6

Fig. 6. Numerical average grain size of the investigated extruded profile.

In Fig. 7, the comparison between experimental and numerical grain size calculated in the "validation set" of points is reported. In details, the x-axis represents the diameter of grains experimentally measured while the y-axis represents the numerical predicted dimensions. Consequently, if the numerical measure perfectly matches the experimental one, the point is expected to be exactly on the 45° green line.

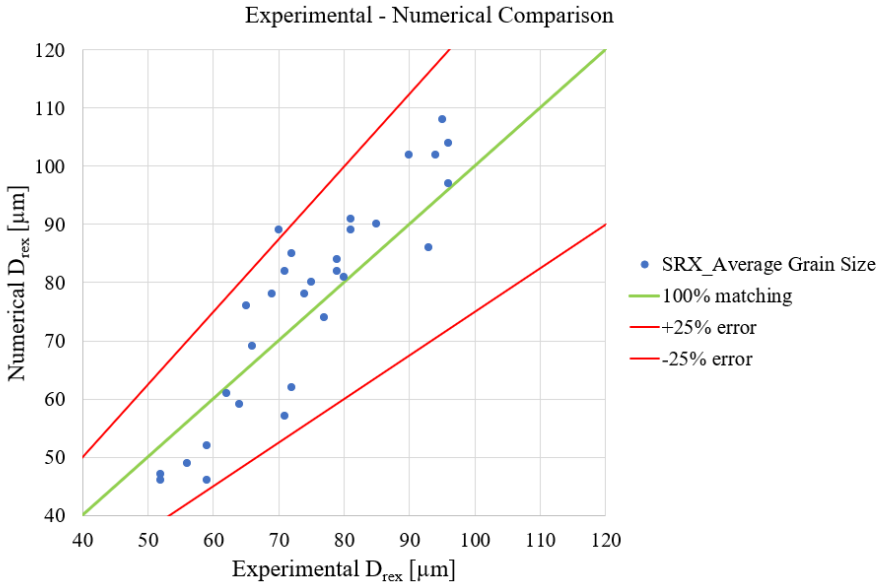

Fig. 7. Comparison between experimental and numerical grain size.

In order to facilitate the understanding of the prediction accuracy, two additional red lines were reported corresponding to a ± 25% of error. Since the high number of both process and

metallurgical factors affecting the final grain size, the industrial complexity of the analysed extruded geometries and the approximations deriving from the selected measurement methodology for the experimental analysis of the grain dimension, the range of ± 25% of error, also used by Donati L. et al. in [11] for the analysis of a laboratory-scale extruded profile, should be considered as a range of excellent prediction accuracy. As can be seen in Fig. 10, over the 95% of the blue dots fall within the red lines, thus proving the accuracy of the developed recrystallization model.

Summary

In the present work, the development of the recrystallization model of the AA6060 aluminum alloy was carried out together with the FE simulation using Qform Extrusion code. The microstructural analysis of the profile was performed and the collected data were used for the validation of the proposed model. The main outcomes of this work can be summarized as following:

- An innovative static recrystallization model was developed and optimized using the data experimentally acquired from the investigate AA6060 extruded profile.
- The prediction error of the average grain size in over the 95% of the analysed points remain below the ± 25% thus proving the good experimental-numerical agreement and the reliability of the proposed model. Further investigations are still needed to investigate the model accuracy in different AA6060 extruded profiles.

Abstract. The friction extrusion (FE) process is a solid-state material processing technique in which a translating extrusion die is pressed against a billet/feedstock material in a rotating extrusion container to produce an extruded rod or wire. A key aspect of FE is the generation of severe plastic deformation and frictional heat due to the relative rotation, leading to an improved microstructure. Numerical simulations of FE are highly complex due to contact between the tool and the workpiece, and the interplay between thermo-mechanical conditions and the present severe plastic deformation. In the present work, a three-dimensional finite element model is developed to study the material flow behavior for different extrusion ratios for a 60° die angle during friction extrusion. The developed model is numerically validated against experimental data. The spatial temperature and strain distributions illustrate the effect of extrusion ratio on the deformation characteristics of the extruded aluminum alloys, thereby assisting in understanding the material flow behavior.

Introduction

Extrusion is a solid state forming process in which a metal feedstock is forced through an orifice or die opening in order to obtain a reduction in diameter and increase in length of the feedstock. In direct extrusion, the extruded metal is forced to flow in the direction of applied force, while in indirect extrusion, the metal flows in the opposite direction. The friction extrusion (FE) process is a relatively novel approach compared to conventional extrusion because of the added rotational motion. This process was developed and patented in 1993 by The Welding Institute, UK [1]. An illustration of the indirect FE setup and mechanism of operation are shown in Fig. 1.

FE involves relatively high pressure and relative rotation to force the metallic feedstock in the container through the die, resulting in a fully consolidated extrudate. As a result, reshaping billets into rods, tubes, and wires is possible through FE. Based on the process features, FE is capable of meeting the increasing demand of producing materials with improved mechanical properties [3] for application in automobile and aircraft industries. FE also provides a suitable alternative for material processing thus lower force and energy are required since more heat is generated via friction and rotation as compared to conventional extrusion where preheating the feedstock before extrusion is necessary in order to minimize the force required for extrusion.

The quality of the extrudate has been associated with a number of factors. In FE experiments, the extreme changes observed in processing characteristics and microstructural evolution have been attributed in particular to the friction condition [4], where the friction condition controls the introduced strain and thermal evolution [2,4]. For instance, Peng et al. [5] ascribed the formation of hot cracks during extrusion to the material flow governed by the temperature gradient across the wire diameter. Furthermore, the work from Yu et al. [6] showed that the die angle has a significant influence on the material flow, where the die surface geometry affects the frictional heating at the contact region. Therefore, it is of interest to study the influence of variable extrusion ratios on the material flow behavior.

A fundamental understanding of the mechanism of heat generation and related material flow during a friction-based process is of high significance because it can minimize the number of trials and therefore cost of experiments. Numerical models can help significantly in this regard, where a suitable description of the friction conditions is essential for processes like FE to achieve correct simulation predictions. Often, a constant friction value with a suitable friction law is used in numerical calculations, especially in friction-based processes performed using finite element method (FEM). The commonly adopted friction models in FEM are shear and Coulomb friction models. Shear friction models with constant friction factor have been applied in FE [7], friction stir welding (FSW) [8,9] and refill friction stir spot welding (refill FSSW) [10], whereas the Coulomb friction model is less frequently applied [11]. One example includes the application of a temperature-dependent friction coefficient in a simulation of refill FSSW [12]. Furthermore, to model the material response during thermo-mechanical processing, a constitutive model is also necessary, which accounts for the thermal and mechanical effects. One of the simplest models in this regard is the Arrhenius constitutive model, which is widely employed to describe the relationship between flow stress, strain rate and temperature at elevated temperatures in metallic materials [13].

In the present model, the effect of extrusion ratio on the process and thermo-mechanical conditions is studied. The process parameters used are deduced from a force-controlled FE experiment. The description of the experimental setup, the numerical method and the simulation inputs are presented in the following section.

Experimental Setup and Finite Element Method

The FE process is performed on the FE100 (Bond Technologies, IN, USA), a dedicated friction extrusion machine. The tooling setup consists of a rotating 42CrMo4 steel container with charged AA2024 billet and an X40CrMoV5-1 die, featuring a 60° die angle and 10 mm die bore sizes as shown in Fig. 2(a). The experiment is conducted only for the 10 mm die bore with one billet, serving as validation data for the numerical simulation. The experiment is performed force-controlled, where a constant extrusion force of 300 kN and spindle rotation of 90 rpm are applied. The temperature was recorded via a K-type thermocouple at two-thirds of the die radius within the die, located 18 mm from the die face, as shown in Fig. 2(a). In experiment, the feedstock material in the as-cast condition is machined to have a based cylindrical shape of 50 mm length and 49.50 mm diameter, with a chamfer of 60° angle and 5 mm height at the edge, see also Fig. 3(a). The billet is locked against rotation towards the container. For initiating FE, a program step with higher rotation and lower force (300 rpm, 50 kN) is used to ensure defined contact between the die and feedstock to avoid torque overload.

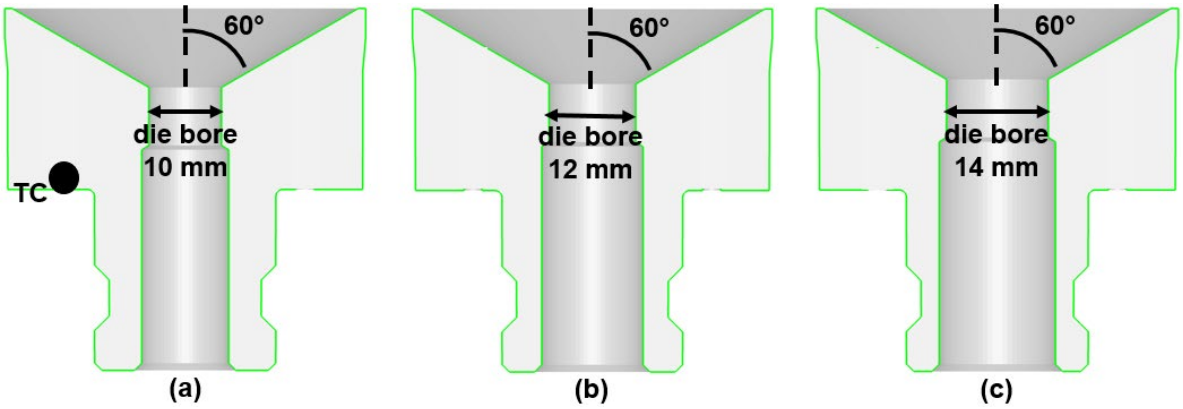

Fig. 2. Schematic extrusion die showing angle, including the location of the thermocouple (TC). Variable die bores are investigated, leading to different extrusion ratios: (a) ER = 25.0, (b) ER = 17.36, and (c) ER = 12.25.

The numerical model is set up in DEFORM 3D. The rotating extrusion container and the translating extrusion die, Fig. 3(b), are modeled as rigid and meshed with approximately 20,000 elements each to account for thermal conduction. The workpiece is modeled as rigid-viscoplastic material, where an adaptive mesh with approximately 50,000 elements with variable size is applied to resolve the thermo-mechanical properties at the contact region with the die as depicted in Fig. 3(c).

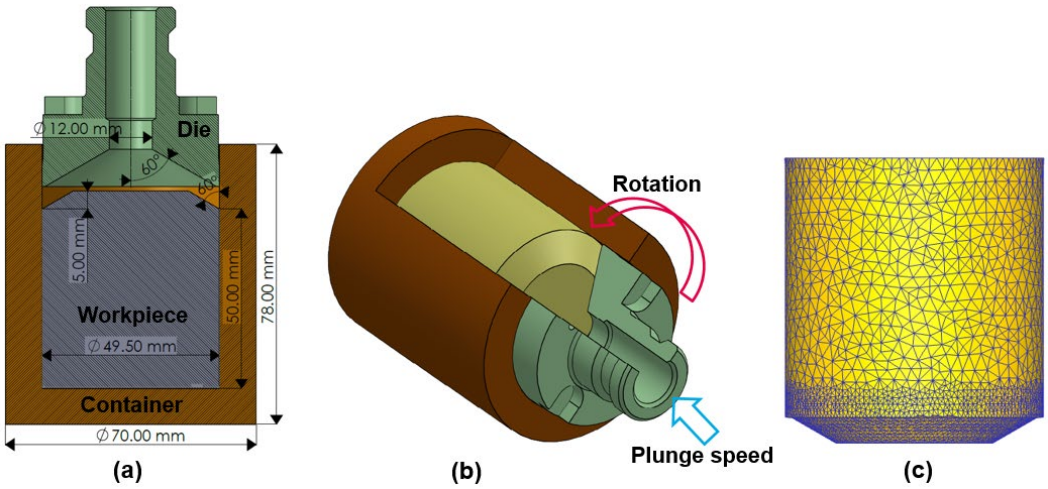

Fig. 3. Process model geometry: (a) Simulation set up and object dimensions; (b) Operational mechanism of FE and; (c) Workpiece showing adaptive mesh and a 60° angle at the edge to improve initial contact conditions.

The Arrhenius equation, relating strain rate, flow stress and deformation temperature, is applied to capture the material behavior during FE [14]. Based on a hyperbolic sine function, the Arrhenius equation can be written as:

$$\underline{\dot{\varepsilon}} = A[sinh\ sinh\ (\alpha\sigma)\ ]^n exp\left(-\frac{Q}{RT}\right) \quad (1)$$

where $\underline{\dot{\varepsilon}}$ is the strain rate, Q is the activation energy due to thermal deformation, n is the stress exponent, A and α are material constants, R is the gas constant, T represents the temperature and σ the initial flow stress. Flow stress data of AA2024 alloy are deduced from a hot compression test conducted at deformation temperatures between 200°C and 500°C under strain rates of 0.001-10 s^{-1} [15, 16]. The following parameters are used: $A = 1.96 \cdot 10^8$ s^{-1}, $\alpha = 0.016 MPa^{-1}$, $n = 4.27$ and $Q = 148$ kJ mol^{-1}. Non-isothermal process conditions are applied for all objects with reference temperature at 20 °C. Other values used in this simulation to relate different thermal interactions between the objects are: 0.02 N s^{-1} mm^{-1} C^{-1} for convection between tools and environment, and 11 N s^{-1} mm^{-1} C^{-1} for conduction between workpiece and tools as recommended for DEFORM 3D forming operations.

After several investigations on the two friction models, i.e. shear and Coulomb, a significant better agreement between experiment and simulation was obtained by modelling the mechanical interaction between the translating die and the rotating container with the workpiece via a Coulomb friction model, where a temperature-dependent friction coefficient μ is used [12], see Table 1.

Table 1. Friction coefficient as function of temperature [12].

Friction coefficient	0.5	0.36	0.3	0.26	0.2	0.1	0.08
Temperature (°C)	20	160	200	300	400	500	600

Although the experiment is performed force-controlled, due to numerical stability reasons, the simulation is performed displacement- or velocity-controlled, respectively. The die speed applied in the simulation is deduced from the die velocity during the FE experiments with the FE100 as shown in Fig. 4, and a rotational speed of 90 rpm is applied on the die.

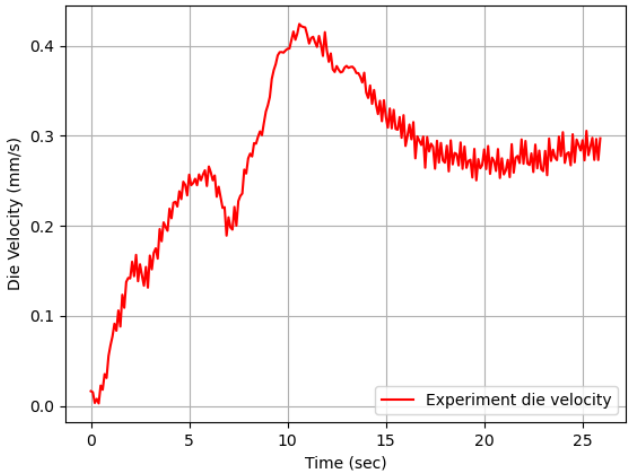

Fig. 4. Experimental die velocity obtained from the force-controlled experiment for ER 25.0 with FE100, which is used as simulation input.

Results and Discussion

As shown in Fig. 5, the results of the velocity-controlled simulation are in good agreement with the force-controlled experiment for both force and thermal history. During the deformation, the rapid increase in force and temperature at the onset of the process is related to the initial "cold" state of the workpiece, i.e. deformation resistance, and filling of the die angle cavity before extrusion. After the initial ramp-up, the process force shows a quasi-steady state due to sufficient material softening achieved.

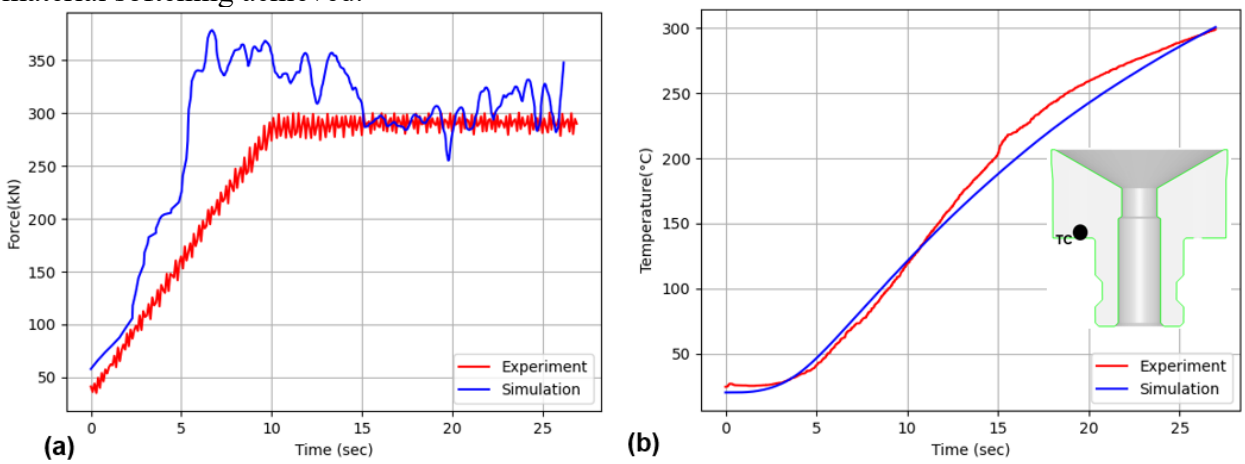

Fig. 5. Comparison between experimental and simulation results for (a) process force and (b) thermal history for ER 25.0.

The generated heat is directly related to the temperature; therefore, material softening depends on the contact condition and mechanical interaction between the workpiece and the extrusion die. Fig. 5 shows the calculated spatial temperature distribution at the interface between the workpiece and extrusion die. The maximum temperature is obtained at the contact layer to the die as shown in Fig. 6, because of the direct interaction between the rotating workpiece and translating extrusion die. The maximum temperature decreases with decreasing extrusion ratio viz, 551°C, 525°C, and 511°C, see Fig. 6(a), (b) and (c), respectively. This effect is attributed to less frictional heat with decreasing extrusion ratio, which is consistent with the findings of Baffari et al. [7] for a 90° die.

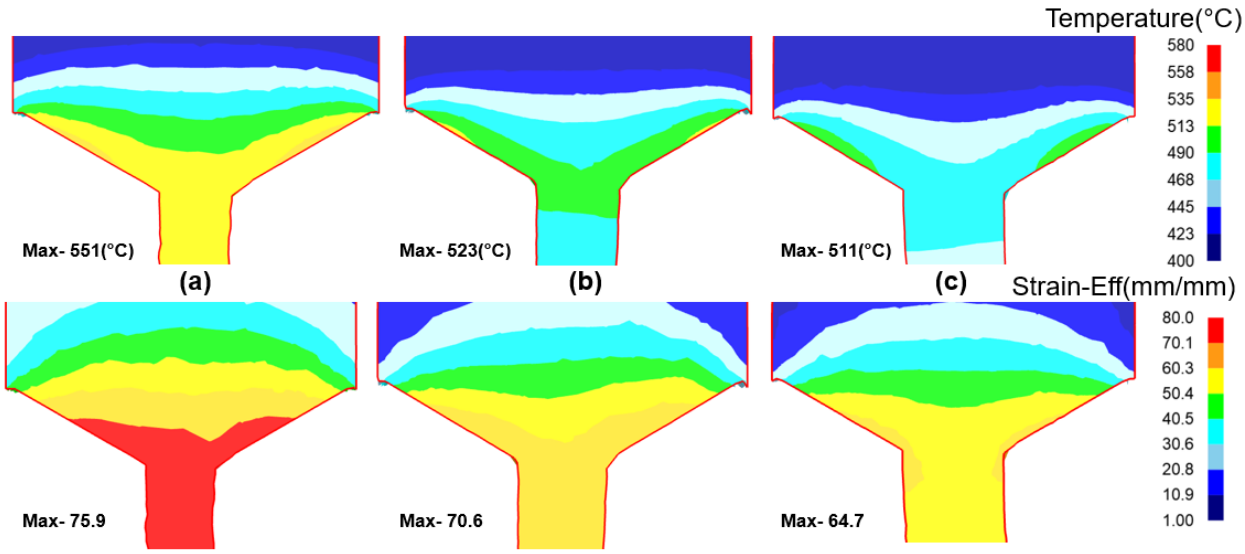

Fig. 6. Spatial temperature and strain distribution results for different extrusion ratios: (a) ER 25.0, (b) ER 17.36 and, (c) ER 12.25.

Next to the temperature, the resulting material deformation plays a crucial role in terms of the resulting microstructure and quality of the extrudate. Fig. 6 depicts that strain values close to the die orifice are higher compared to the rest of the workpiece. This is due to the edge of the die orifice, which induces severe plastic deformation on the workpiece during processing. Consequently, higher extrusion ratios induce more severe plastic deformation leading even to maximum strain values of 75. It is evident that the strain distribution is less homogeneous with decreasing extrusion ratio; see Fig. 6.

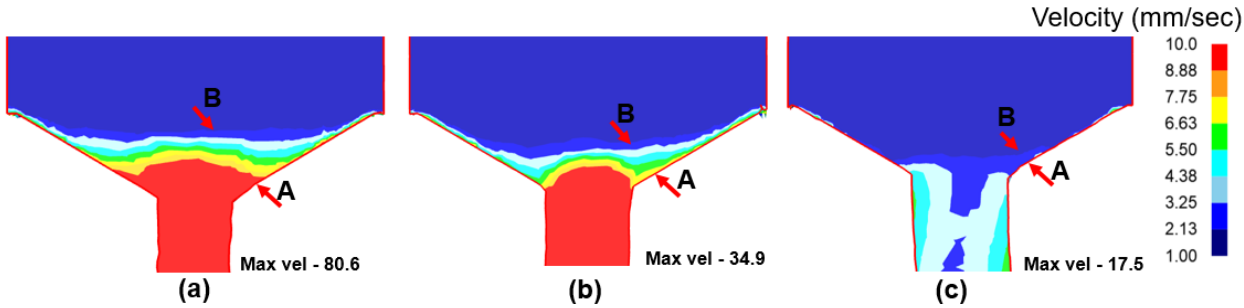

Fig. 7. Material flow velocity for different extrusion ratios: (a) 25.0, (b) 17.36 and (c) 12.25.

In FE, the mechanical interaction between the die and workpiece leads to thermo-mechanical conditions as described above, which are strongly influenced by the transition between the container and die, in particular, the die orifice. A homogeneous material flow is assumed to occur due to homogeneous deformation and, in this regard, better mechanical properties. As illustrated in Fig. 7, a higher probability of homogeneous material flow is observed at high extrusion ratios. The origin of the homogeneous material flow for high extrusion ratios can be traced to more severe plastic deformation induced. As depicted in Fig. 7, the velocity distribution region marked by points (A) and (B) decreases as the extrusion ratio decreases. The non-homogeneous material flow for the low extrusion ratio in Fig. 7(c) is attributed to less deformation due to sliding tendencies between the workpiece and the die.

Summary

The process simulation of the friction extrusion (FE) process accurately predicts the force and thermal history occurring in the force-driven FE experiment. The following conclusions are drawn:

- The maximum temperature is predicted at the contact region between the die and the workpiece for all cases due to direct mechanical interaction.
- Die geometry has a profound effect on the resultant thermo-mechanical conditions.
- A higher extrusion ratio leads to more uniformly distributed and higher values of maximum strain due to increased severe plastic deformation.
- At high extrusion ratios, the material flow is more homogeneous, and therefore a superior properties of the extruded rod could be anticipated.

Abstract. Cold forging processes, such as cold extrusion and in particular the Samanta process, provide a considerable potential for improvement in gears production. The method behind the Samanta process is based on the principle of cold extrusion in stacks. After partial forming of a workpiece, another workpiece is inserted into the die in order to eject a completely formed gear in the direction of the punch movement. Although this operating principle offers great potential for high-volume production, the industrial relevance of this process is limited by disadvantages such as high tool loads, limited gear accuracy and deformations on both face ends of the gear wheel. In order to overcome the technological challenges associated with the Samanta process, the die geometry was adapted. In this case the die operating surface was modified in terms of an extended forming zone length combined with an undercut in the tooth cavities of the die. In this paper the numerical results for this novel process regarding the correlations between geometric die parameters and resulting process data, such as punch force, contact pressure and die filling, are presented. The spline-based tool was methodically varied between one linear and two square (concave, convex) designs and was numerically evaluated using Deform 3D™ software.

Introduction

As an integral part of the modern automotive and mechanical engineering industry, gears are used in a wide variety of drive systems. Due to the high demands placed on gears in terms of performance, operational reliability and smooth running, they are usually manufactured using machining processes [1,2]. Machining processes, especially for gear production, are time and material consuming. Due to the ecological disadvantages of machining processes, it is important to find better alternatives in the long term. Cold forming is an alternative with a high potential for substituting machining processes. Cold extrusion in particular offers the possibility of producing gears with high output and improved material utilisation. In addition, the gears benefit from process-related strain hardening and an uninterrupted fibre structure [3]. The most common process for cold extrusion of gears is the Samanta process, in which the blanks are pressed in stacks through a toothed die. In this process, the workpiece is partially formed, then the punch is retracted and a new workpiece is inserted into the die. By extruding the second workpiece, the partially formed and thus toothed workpiece is ejected downwards out of the die, enabling the manufacture of a fully toothed workpiece [4]. Due to the established die geometry in this process, there are some process-specific disadvantages, such as an extreme tool load, shape and dimensional deviations of the gearing and deformations on the face ends of the workpiece. To overcome these disadvantages, a new process based on the Samanta process was developed at the Institute for Metal Forming Technology in Stuttgart, Germany. The so-called Guided Material Flow (GMF) process differs from the Samantha process by means of a modified die operating surface. Main feature of this redesign is an extended extrusion shoulder and thus forming zone. This extended forming zone is hypothetically intended to distribute the required forming work over a longer stroke and therefore reduce the die load. An improved accuracy of the extruded gear is expected.

Extending the extrusion shoulder increases the friction surface between the workpiece and the die. Hence, an undercut was added into the die cavity as a second feature in order to compensate the increase in friction surface.

Cold Extrusion of Gears

Samanta process.

The Samanta process is a special process in the field of cold extrusion which can be performed with full and hollow blanks. The special feature of the process is the characteristic process principle, which is shown schematically in Fig. 1a. Blank 1 is placed in the die and partially formed by means of the hollow punch and the mandrel in the first phase of the process. For the second phase, the hollow punch and the mandrel are retracted until blank 2 can be loaded. Due to the partial forming of blank 2, blank 1 is completely pressed through the toothed active surface of the die. Thus, the toothed workpiece is dropped out the die on its lower side, eliminating the need for an ejection process [4]. No ejection simplifies the tools, eliminates the risk of ejector marks and offers the potential for higher production output [5]. Using the Samanta process a gear accuracy with a tolerance class between 10 and 11 for helical and straight gears can be achieved. However, the automotive sector demands gear accuracies of IT 6 or better [6]. In addition, gears formed using the Samanta process exhibit typical features such as partial tooth underfilling (inflow area) on the bottom side and "crown-shaped" deformation on the top side of the gears (see Fig. 2b). Both of these areas necessitate material removal by machining, which reduces material utilisation of the process and also calls for additional production steps [7].

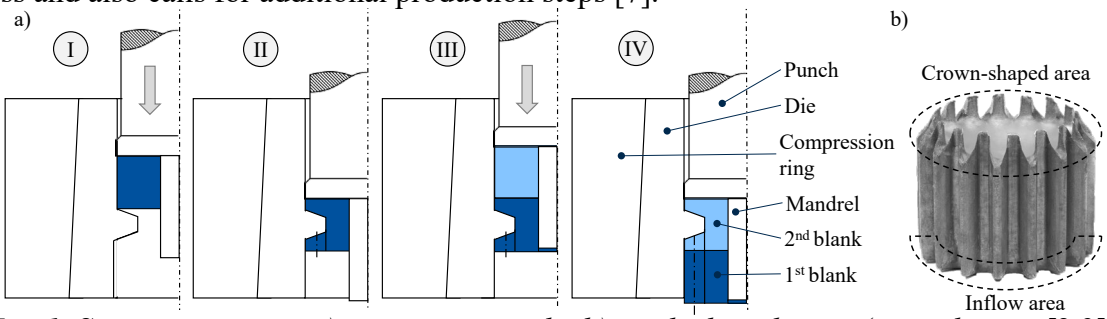

Fig. 1. Samanta process, a) process principle, b) toothed workpiece (according to [8,9]).

Guided Material Flow (GMF) process.

Based on the process principle of the Samanta process, a novel process for the cold forming of gears was developed at the Institute of Metal Forming Technology. The GMF process is a cold extrusion process for full and hollow blanks. It differs from the conventional Samanta process in the design of the operating die surface. Fig. 2a shows the sectional view of the tooth cavity in the GMF process and Fig. 2b a comparison of the die design between the two related processes.

Comparing both designs, two decisive features appear crucial: Characteristic 1 consists in the significantly extended length of extrusion shoulder and thus forming zone of the die. This has the effect of distributing the required forming work over a longer stroke, which on the one hand decreases the maximum punch force and on the other hand increases the friction surface between the die and the workpiece. In order to compensate the increased friction surface, the die cavity was modified by an undercut. Therefore, characteristic 2 consists of an undercut in the die cavity located at the area of the tip circle diameter of the toothing. This undercut highlighted with purple colour in Fig. **2**a serves to induce a contact separation between the die and the workpiece in the area of the tooth tip of the formed gear. Through this new design of the die active surface in the GMF process, the maximum punch force could be reduced by about 38% compared to a similar Samanta process [10]. Decreasing the maximum punch force leads to a reduction of elastic die deflection and thus to an improved accuracy of dimension and shape of the gearing as well as to a

reduction of tool wear. All geometric die parameters in the design of the die operating surface of the GMF process were determined based on practical experience in the field of cold forming within the scope of preliminary investigations. The complex die surface was designed by simulative evaluation and iterative adaptation of the individual contours (see Fig. 2) on different levels along process direction. Since the tooth cavity varies steadily in process direction, the material flow is controlled systematically, which finally led to the name of this novel process.

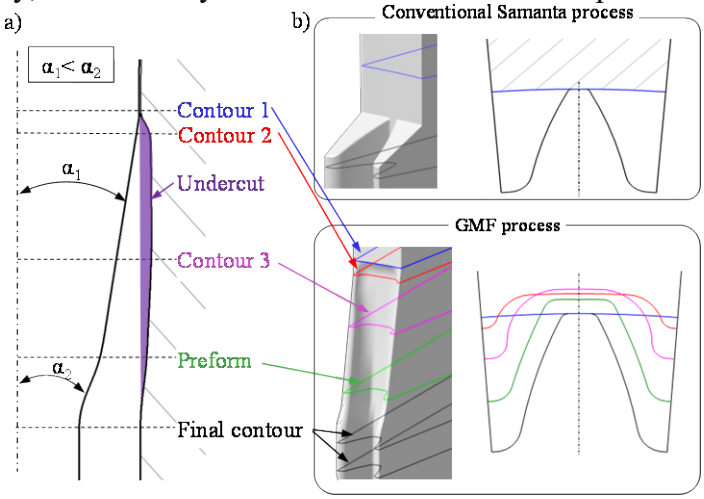

Fig. 2. GMF process, a) sectional view of die cavity, b) comparison of die design with Samanta process.

The initially designed die model was not suitable for the performance of comprehensive numerical investigations within the scope of a research project. The reason for this is the large number of geometric parameters and thus process influencing variables. Therefore, the number of geometric die parameters was significantly reduced in a new die model. Main objective of this simplification was performing a numerical analysis more effectively in order to identify relationships between geometrical die parameters and relevant process data in the GMF process. New design of the die used in the GMF process was achieved by means of splines and mathematical functions, as shown in Fig. 3. As boundary conditions for the adaptable design of the GMF die, the tip and root diameters of the involute toothing were selected. These two boundary conditions located at the respective ends of the forming zone enabled the geometrical profile of the extrusion shoulder to be implemented as a polynomial function *f(z)*. Corresponding polynomial function $f(z)=a_n\text{-}z^n+a_{n-1}\text{-}z^{n-1}+...a_1\text{-}z^1+a_0$ allows the variation of the geometric profile of the extrusion shoulder by changing the exponent.

This paper presents the numerical results for the linear and quadratic versions of the extrusion shoulder geometry in the GMF process. Aim of the numerical investigations was to determine the effect of different extrusion shoulder geometries on relevant process data during cold extrusion of gears in the GMF process. For this purpose, the toothing to be formed was kept fixed and the shape and length of the extrusion shoulder were varied for each version. The variation of the linear extrusion shoulder version was based solely on the forming zone length, since in this case the extrusion shoulder angle results from the gear data. In the case of the quadratic extrusion shoulder, there are two types - convex and concave. They differ in terms of the sign of the coefficient for the highest order of polynomial in the polynomial function. In the evaluation of the simulation, the geometric modification of the quadratic polynomial function is based on the angle α at the vertex of the parabola (see Fig. **3**).

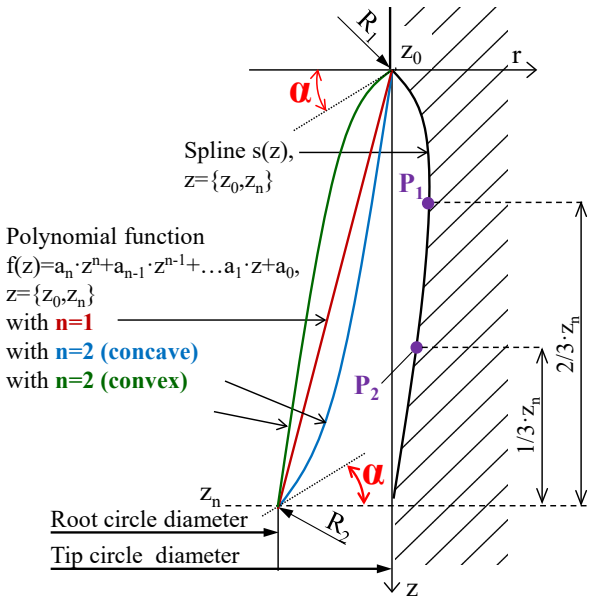

Fig. 3. Sectional view of re-designed die cavity in the GMF process with variation of extrusion shoulder profile.

The undercut in the area of the tip circle diameter of the gearing was designed with a spline as a guide curve. This spline was approached by four points as boundary conditions. The first point was at the beginning (z_0), the second at the very end of the forming zone (z_n) and thus also define the starting and end points of the spline. Two further points are located at 1/3 and 2/3 of the forming zone's length. The radial position of the two points along the spline was defined in relation to the tip diameter of the teeth. Point P_1 was defined 0.1 mm and the point P_2 0.3 mm larger than the tip diameter of the toothing.

Numerical Investigations

The numerical investigations were intended to determine any effects of geometric changes on the die operating surface in the GMF process and on significant process parameters. Analysis was performed by variation of design of the extrusion shoulder and numerical computation of the punch force, the contact pressure on the die and the die filling. By adjusting the coefficients of the polynomial function within most suitable intervals, a methodical evaluation could be conducted. Through numerical preliminary investigations, suitable range of intervals for the polynomial coefficients were determined for the very first practical trials. The geometric profile of the undercut was not varied in this FE analysis.

Simulation setup.

Fig. 4a shows the general setup of the simulation model in software Deform 3D™. All simulations within the numerical analysis were conducted according to this depicted simulation setup. In order to perform a DOE study based on 3D models, a corresponding simulation had to be set up for each process variation. Here, only the die models were replaced. Punch and die in simulation were implemented as rigid objects. The hollow workpiece segment of 4,615 ° (half tooth) has a height of 25 mm was defined as a plastic object made of material 16MnCr5. Workpieces were modelled with 80,000 mesh elements and simulatively deformed at room temperature at a punch speed of constant 40 mm/s. The friction in the simulation was defined as shear friction with a friction factor of 0.12 [11]. All dies were designed for extrusion of the same gear geometry. The simulated gear has involute teeth with a modulus *m* of 1 mm and a number of teeth *z* of 39. Dimensions of gear and utilized simulation data are listed in Fig. 4b. In the DOE, the extrusion shoulder geometry was varied between a linear and two quadratic (concave, convex)

geometries. Also, the length of the extrusion shoulder and therefore the forming zone length as well as the tangent angle α at the apex of the quadratic extrusion shoulder were varied between 30°, 50° and 70° within predefined intervals.

Results and Discussion

This chapter presents the numerical results for geometrically varying extrusion shoulder versions in the GMF process in relation to relevant process parameters. Relevant process parameters in cold extrusion do include the punch force, the contact pressure onto the die active surface and the die filling of the toothing. A comparison with the conventional Samanta process for forming the same gear (see Fig. 4b) also was performed.

Linear design for extrusion shoulder in GMF process.

As shown in previous publication [10], the highest contact pressure onto the die surface is located in the area of the extrusion shoulder and thus at the root circle diameter of the formed toothing.

Fig. 5 shows the numerical results for the DOE study with a linear extrusion shoulder. The red dashed line in the diagram represents the numerical reference results obtained from simulation of the conventional Samanta process with an equivalent simulation setup. Based on preliminary numerical investigations, the forming zone length was varied between 2 mm and 13 mm for analysis objectives. Beyond this interval, no complete die filling or increased process forces were detected using the linear extrusion shoulder in the GMF process for forming this gear. The results in Fig. 5 indicate that the die in GMF process having a linear extrusion shoulder design in every case is exposed to lower loads compared to the conventional Samanta process. The conventional Samanta process requires a maximum punch force of 430 kN, and, in contrast, the linear design of die in GMF process requires 415 kN (2mm length of forming zone) with a decreasing tendency as the forming zone length increases. This shows that when extending the forming zone length from 2 mm to 9 mm, the maximum punch force can be reduced from 415 kN down to 270 kN. In case of lengths of forming zones beyond 9 mm, the peak punch force converges to this measured value. Also, underfilling in the tooth tip occurs at a forming zone length of 13 mm. Comparing the results with the conventional Samanta process reveals that with the linear design of die in the GMF process for forming this gear, a punch force reduction of approx. 38 % can be achieved. In addition, it can be observed that the contact pressure in the die also decreases as the forming zone length increases. Thus, the maximum contact pressure decreases from 2,920 MPa (length of forming zone equals 2mm) to a value of 2,150 MPa (length of forming zone equals 12 mm). Compared to the

conventional Samanta process, a reduction in die contact pressure from 3,000 MPa to 2,150 MPa also was achieved, which equals a drop by approx. 28 %.

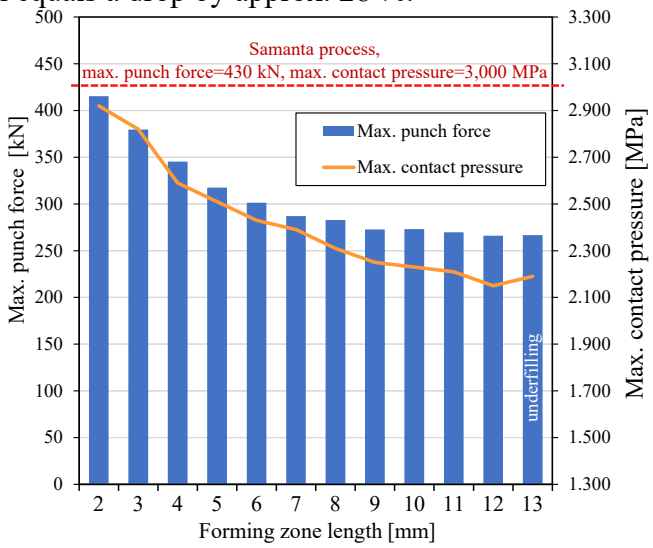

Fig. 5. Numerical results for linear extrusion shoulder geometry in GMF process.

Quadratic design of extrusion shoulder in GMF process.

In this chapter, the numerical results for a concave and a convex extrusion shoulder design being used for the GMF process are presented. The geometry of the extrusion shoulder with a quadratic polynomial function was varied based on the angle α. Here, the numerical investigation was performed at three different angles α - 30°, 50° and 70° (as shown in Fig. 3). In addition, the forming zone length was varied between 15 mm and 40 mm by 5 mm increments.

Concave extrusion shoulder design.

The chart in Fig. 6 summarizes the numerical results of the GMF process with a concave extrusion shoulder at an angle α of 30° and 50°. For the concave design with a tangent angle α of 30° (see Fig. 6a), obviously, the maximum punch force appears independent from the length of forming zone. Also, a maximum punch force of approx. 280 kN was determined. Thus, almost the same punch force reduction can be achieved with this process as with the linear extrusion shoulder design. Furthermore, the maximum contact pressure with this concave extrusion shoulder (α=30°) was observed at the same level as in the conventional Samanta process. Fig. 6 b shows the numerical results for the GMF process with concave extrusion shoulder design having an angle α of 50°. By increasing the tangent angle α at the vertex of the parabola from 30° to 50°, the level of the maximum punch force decreases marginally. Also, analogous to Fig. 6a no dependence was found between the forming zone length and the maximum punch force when using an angle of 50° at the concave extrusion shoulder. In this figure the maximum punch force consistently remains at a level of approx. 268 kN. It was found also, that the maximum contact pressure in this process was calculated as high as in the conventional Samanta process. As the forming zone length increases, underfilling of the toothing occurs, starting at a forming zone length of 20 mm. Such underfilling was also found in the process variant with a tangent angle α of 70°, regardless of the forming zone length. This underfilling was always found in the area of the tooth tip, since the corresponding extrusion shoulder design achieved insufficient material displacement in radial outward direction.

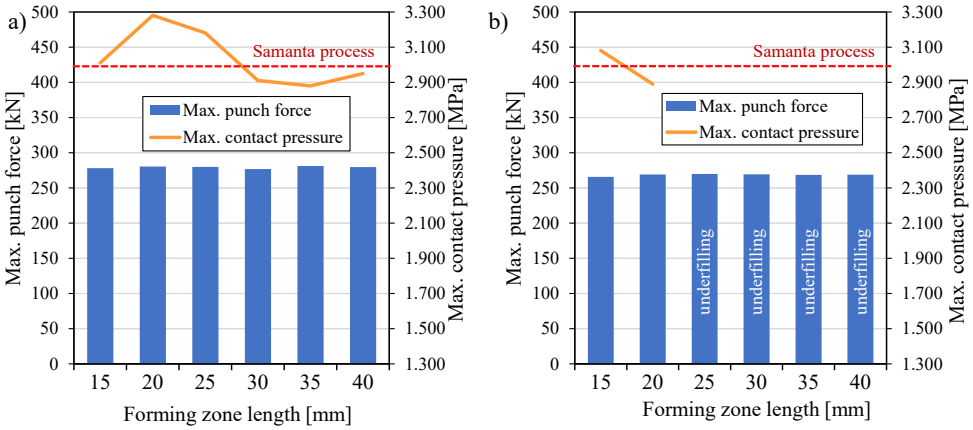

Fig. 6. Numerical results for concave extrusion shoulder geometry in GMF process, a) α=30°, b) α=50°.

Convex extrusion shoulder design.

The diagrams in Fig. 7 summarise the results of the convex extrusion shoulder in the GMF process with tangent angle α at 30°, 50° and 70°. Fig. 7a illustrates the results of the convex process version with angle α at 30°, indicating a significant reduction of the maximum contact pressure compared to the conventional Samanta process. The contact pressure of this extrusion shoulder design seems to correlate inversely with the maximum punch force. While the maximum punch force may reach a local maximum at a forming zone length of 25 mm, a local minimum of the maximum contact pressure appears here. In addition, the maximum punch force for this convex extrusion shoulder design appear remarkably lower than in the conventional Samanta process, irrespective of the forming zone length. However, even the lowest value of the maximum punch force in this process variant is higher than the lowest in the process variants having a concave design. Furthermore, underfilling also occurs at the toothing tip starting at a forming zone length of 35 mm.

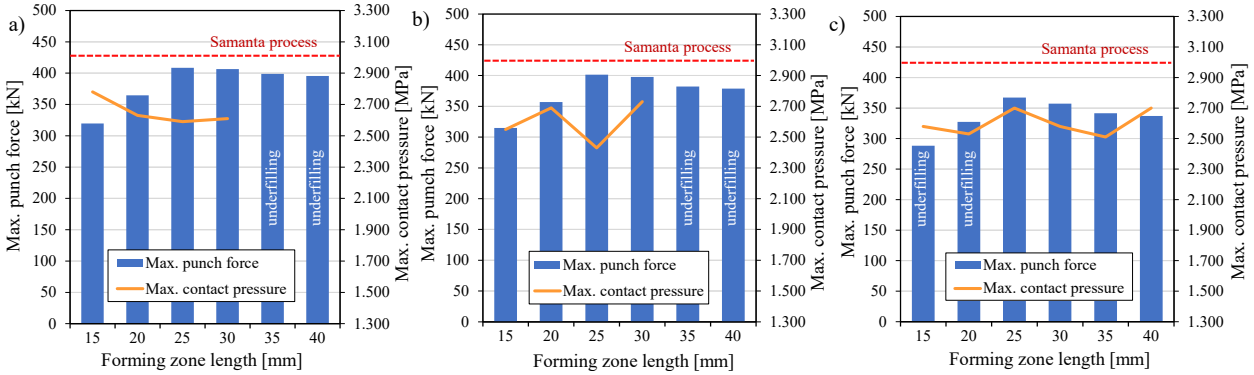

Fig. 7. Numerical results for convex extrusion shoulder geometry in GMF process, a) α=30°, b) α=50°, c) α=70°.

Fig. 7b shows the numerical results for the convex extrusion shoulder design in the GMF process with an angle α of 50°. The results are almost identical to the results for the convex version with a tangent angle of 30°. One difference however is observed: the maximum contact pressure does not show a clear correlation with the maximum punch force. Fig. 7c shows the numerical results of the convex extrusion shoulder in the GMF process having an angle α of 70°. By increasing the tangent angle α up to 70°, an underfilling of the tooth tip already occurs at a forming zone length of 15 mm. This underfilling also occurs at a forming zone length of 20 mm. A further increase of

the forming zone length results into complete die filling. Increasing the angle to 70° also leads to a general reduction in the maximum punch force for the convex extrusion shoulder variant. In addition, a local maximum of the maximum punch force at a forming zone length of 25 mm was observed. Maximum contact pressure was calculated at a level of 2,500 to 2,700 MPa and therefore was found lower than the maximum contact pressure occurring in the Samanta process. Hence, the maximum contact pressure appears nearly independent from the tangent angle α for the convex extrusion shoulder design in the GMF process.

Analysis of material flow.

An analysis of the material flow in Fig. 8 shows that the geometric shape of the extrusion shoulder has a significant influence on the material flow. Blue dots in that figure indicate contact areas between workpiece and die.

Linear extrusion shoulder design.

The linear extrusion shoulder design as depicted in Fig. 8a results into a steady increase of the friction surface between workpiece and die during the process. Friction surface at the tooth flanks increases only slightly when increasing the forming zone length, resulting into a reduction of the maximum punch force due to the forming work distribution. In Fig. 8b a difference in flow velocity of the material in the cavity and at the centre of the blank can be detected. The difference of about 5 m/s consists at a horizontal level on the blank. Due to this fact, there is a temporary reduction of the tooth height during the process. Here, the reduction of the tooth height is hindered by any effects of friction between the workpiece and the die in the area of the tooth flank. When enlarging the forming zone length, the axial material flow near the centre of the blank dominates, which evidently reduces the tooth height and finally results in underfilling of the toothing.

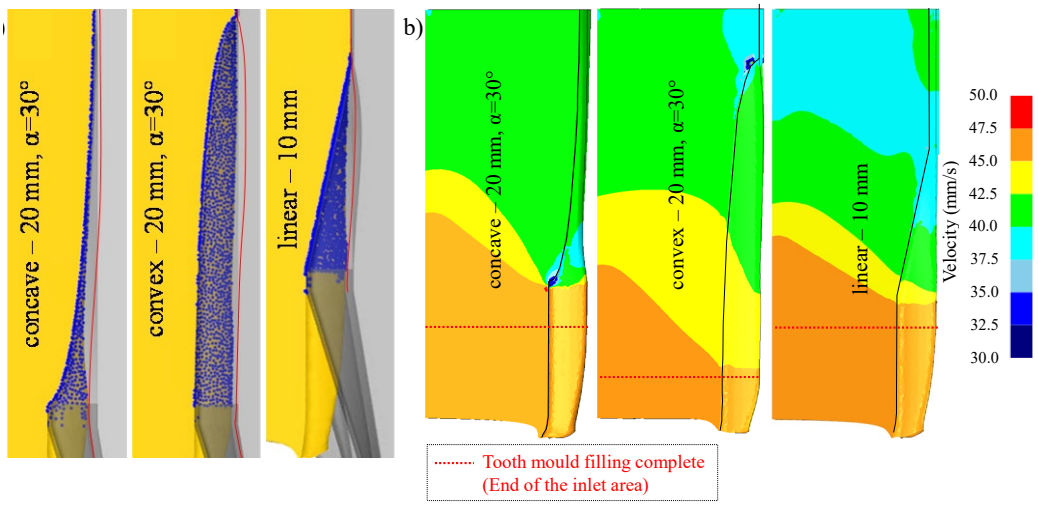

Fig. 8. GMF process at steady condition, a) contact area, b) material flow velocity.

Concave extrusion shoulder design.

Due to its shape, the concave extrusion shoulder design leads to a radial displacement of the material into the tooth cavity mainly at the lower end of the extrusion shoulder. This means that the effect of the undercut is barely noticeable and that the friction surface between workpiece and die in the area of the tooth flanks becomes minimal. Therefore, the friction surface and thus also the maximum punch force appear almost independent of the forming zone length. In the upper area of the concave extrusion shoulder, the low angle of the extrusion shoulder leads to a very slight deformation of the teeth. The material flows in an axial as well as radially inward direction, which causes the instantaneous workpiece in the toothing area to become temporarily smaller than the original blank diameter (blank diameter equals tip diameter). The temporary reduction of the tooth height results from the different flow resistances in the process along process direction, which

results into different flow velocities on the inner and outer diameter of the workpiece. In Fig. 8b, the maximum difference in flow velocities in process direction is observed around 10 mm/s. The low friction surface between the workpiece and the die in the area of the tooth flank favours the reduction of the tooth height, as the accumulated material can flow unhindered into the centre of the blank. As the forming zone length increases and the angle α increases, the reduction of the tooth height dominates, resulting into underfilling of the toothing.

Convex extrusion shoulder design.

In the convex shoulder design, depicted in Fig. 8, the main part of the tooth forming occurs in the upper area of the extrusion shoulder. As a result, the material in the upper area of the extrusion shoulder increases marginally in diameter compared to the original blank diameter. This means, the cavity is filled with material at the start of the process and the friction surface between the die and the workpiece increases rapidly. Due to the gradual tapering of the cavity in process direction, the die cavity was completely filled towards the end of the stroke. However, at mid-height of the extrusion shoulder, it can be observed that the material flows in a radially inward direction, causing the tooth height to temporarily decrease. Reason for this is also the differing flow velocity of the workpiece material in process direction. Enlarged friction surface between workpiece and die in the area of the tooth flank hinders the reduction of the tooth height, since the accumulated material is held in the die by the friction forces and the die tapering. Therefore, the tooth height reduction is less prominent in this process. When using the convex extrusion shoulder designs at 30° and 50°, a complete die filling was not achieved as the forming zone length increases. The more the forming zone length increases, the more material flows in the radially inward direction and thus the tooth height decrease seems to dominate. The reduced volume of workpiece material in the cavity cannot be compensated by tapering the tooth cavity to a complete die filling. In case of the process with a tangent angle of 70°, a complete die filling could not be achieved at small forming zone lengths. The reason for this is the big tangent angle in the upper area of the die shoulder. This steep design in the upper part of the forming zone results into a low radial displacement of workpiece material. Less material is thus displaced into the cavity at the start of the process. Moreover, the shortened forming zone length prevents any further displacement of material volume into the cavity. The material in this process variant is not formed sufficiently towards the cavity into the toothing area, which is why the axial material flow dominates here. As a result, despite the taper of the cavity in process direction, the die is not completely filled. An extension of the forming zone length results into complete die filling, as more material can be formed into the cavity through a longer path of the extrusion shoulder.

Summary

In this paper, the newly invented GMF process was numerically investigated under variation of the extrusion shoulder design. The extrusion shoulder design was modelled internally by linear as well as quadratic polynomial functional splines. Using this model, a three-dimensional simulation was performed to form the required gearing shape, whereby the geometric parameters of the extrusion shoulder were varied. In this way, the model of die was modified in the simulation between the two extrusion shoulder types (linear, quadratic), the forming zone length and the tangent angle α at the vertex of the quadratic polynomial function. As a result, the influence of these parameters on the maximum punch force, the maximum contact pressure acting internally in the die and the die filling of the gearing could be determined. In summary, it can be stated that a significant reduction of the maximum punch force can be achieved when using the new GMF process compared to the conventional Samanta process. In the case of a linear extrusion shoulder design, a steady decrease in the maximum punch force was observed when enlarging the forming zone length from 2 mm up to 12 mm. Overall, a reduction of the maximum punch force by approx. 38% was achieved compared to the conventional Samanta process. For the concave extrusion shoulder design, it was found that the maximum punch force remains almost independent of the

forming zone length. A reduction in the maximum punch force equal to that of the linear extrusion shoulder design was also achieved here. Maximum contact pressure was calculated at the same level as with the conventional Samanta process. With the convex variant, only a slight reduction in force and contact pressure was observed. Authors as next will focus on progressive optimisation of the die´s active surface, since a reduction of the maximum punch force by somewhat 50% was detected compared to a corresponding Samanta process design. The numerical results have also shown that the different extrusion shoulder geometries lead to different flow velocities of the material in the cavity and near the centre of the blank. This effect strongly influences the underfilling of the tooth at the lower end of the gear. Although the linear and concave shoulder designs show extremely low process forces, the inlet area was found extended in these variants compared to the concave shoulder design. This in fact results into a higher loadable gear height when applying the convex shoulder design, so, more effort will be put on further numerical investigations to assess the tooth underfilling in the inlet area. Therefore, future developments will consider the loadable gear height in order to analyse the grade of material utilisation in these processes.

Abstract. Crystallographically and magnetically textured but dimensionally limited NdFeB permanent magnets produced by hot deforming processes such as die-upsetting and back-extrusion have been extensively researched in the past [1]. In order to investigate the possibility of producing longer magnets which can subsequently be cut to the required length, the extrusion of permanent magnets was investigated as a further hot deformation process. For this purpose, the process control with regard to the tools used as well as the process parameters were modified from the common forming processes for extrusion. Therefore, a praseodymium-substituted NdFeB powder was encapsulated in steel and extruded by varying the extrusion ratio (9.9:1 & 13.9), the billet insert temperature (800°C & 850°C) and the extrusion speed (0.6 - 10.5 mm/s). In addition, the glass lubrication system was changed during the experiments. Since the resulting magnetic properties for hot deformation depend on the produced anisotropy, texture analyses were also carried out in the first step by means of X-ray diffraction on the cross-sections of the produced strands. For the parameter variation, strands could be realized with the applied concept. However, cracks were found in the magnetic material for all tests. Based on the texture analyses, anisotropy could be generated in the magnet material for all strands.

Introduction

Permanent magnets based on NdFeB are widely used in further areas due to their excellent magnetic properties in the form of high energy product $(BH)_{max}$. For anisotropic magnets, this is based on an alignment of the hard magnetic $Nd_2Fe_{14}B$ phase during the manufacturing process. In addition to the sintering route, in which a magnetic field must be applied during the manufacturing process for alignment, anisotropy can also be achieved by hot deformation (Figure 1). The advantage of this is that no magnetic field is required [1]. In order to improve the coercivity of sintered magnets, neodymium is often substituted in parts with dysprosium in many alloys. However, this is characterized by low availability and a high price. As a further substitution variant, it is possible to add praseodymium to the powder alloys without strongly affecting the magnetic properties. The lower purchase price compared to neodymium plays a decisive role in this case [2-4]. Another approach to improve the coercivity is to keep the grain size of the magnets as small as possible [5,6]. Due to the production method of the powder for the hot- deformation processes, these are especially distinguished for this purpose.

Here, the magnetic powders for further processing are produced by the melt-spinning process. In this, the molten starting material is applied to a wheel at high rotational speeds. The material spun off undergoes very rapid cooling and grain sizes in the sub-µm range are achieved. In the final powder, the grains are present in the platelet-shaped particles without crystallographic preferred orientation. Die-upsetting and back-extrusion are two forming processes that have already been intensively researched and applied in practice [1,7]. They can be used to produce

block magnets or ring magnets with high magnetic properties. As already mentioned, these high magnetic properties are based on the formation of a suitable texture by hot-deforming. In the die-upsetting example, the powder is first hot compacted. This step is carried out in an argon atmosphere, since the powder tends to oxidize at the high operating temperatures. The pre-compacted blank is then hot-deformed. In this process, the formation of anisotropy is based on the fact that a liquid phase is formed at the grain boundaries and the grains undergo preferential grain growth in the a-axis direction of the tetragonal NdFeB unit cell. The grain growth is thereby fed by diffusion processes in the liquid phase [8-12]. Fig. 1 compares the manufacturing processes for sintered magnets and for the hot-deformed magnets (die-upsetting and back-extrusion) with the manufacturing approach studied in the experiments. In addition, the anisotropy achieved for the hot-deformed magnets is shown based on the C-axis orientation of the $Nd_2Fe_{14}B$ phases.

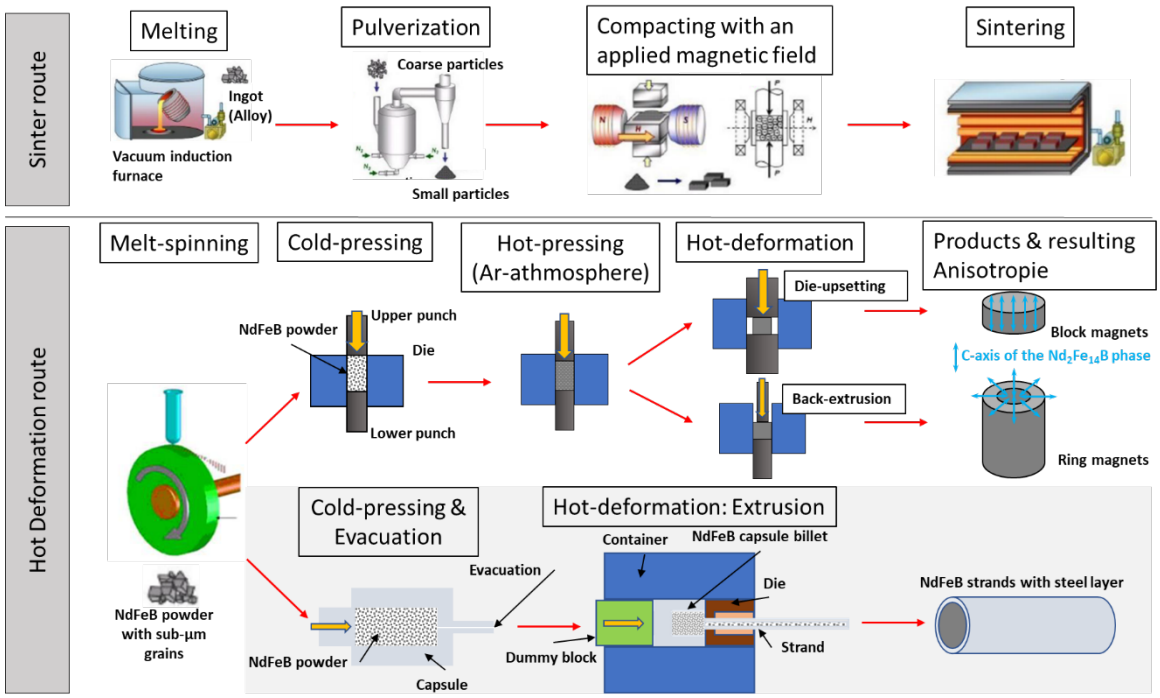

Fig. 1. Manufacturing processes of NdFeB magnets via sintering and hot-deformtion as well as the chosen investigation approach via extrusion [13].

The present investigations are intended to provide initial information on the conditions under which the extrusion of Pr/NdFeB is possible. For this purpose, in contrast to die-upsetting, the process control is adapted in such a way that pre-compaction at high temperatures is avoided and the powder is thus pressed directly. In order to obtain a first impression of the magnetic properties, texture measurements are carried out on the samples according to the correlation between these and the anisotropy achieved in the material.

Experimental Procedure

A Dy-free powder alloy with Nd substituted by Pr was used for the tests. The alloy composition is shown in Table 1. This was produced by the company Magnequench by means of the melt-spinning process for further processing by hot-deformation. Furthermore, Table 1 shows the particle size distribution of the powder used.

Table 1. Alloy composition and particle size distribution of the powder used.

Direct extrusion was selected as the process for hot-deforming. For this, the set-up shown in Fig. 2 consisting of die (Hot work tool steel 1.2367) with ceramic ring insert (Al2O3), inlet ring (1.2367) with half die angle of α = 60°, glass pad, evacuated capsule billet with applied glass lubrication (slurry) and dummy block (1.2367) in a container with a diameter of 85 mm was used. The extrusions were carried out on the 8 MN extrusion press of the Extrusion Research & Development Center (TU Berlin).

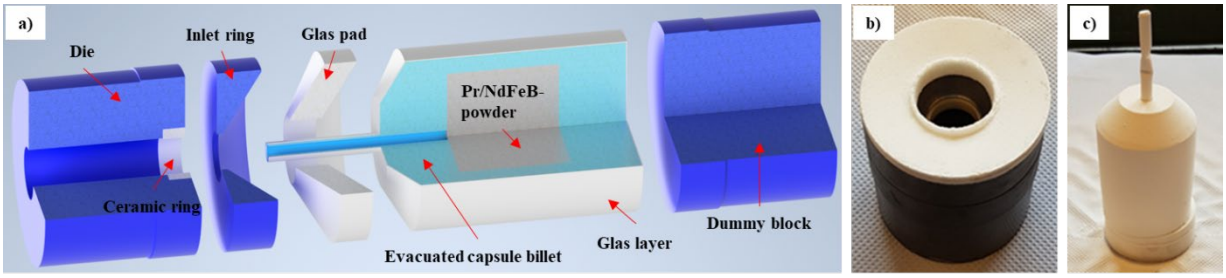

Fig. 2. a) Illustration of the experimental setup; b) Assembly of die, ceramic ring, inlet ring and glass pad; c) evacuated capsule billet with glass layer.

The powder was extruded in the encapsulated and evacuated form shown above, since the powder tends to oxidize at the forming temperatures applied. Accordingly, a capsule was first manufactured from mild steel (1.0577) with an outer diameter of 80 mm and a wall thickness of 8 mm, and then filled with the powder. In order to increase the output, the powder was also cold pre-compacted before evacuation. Furthermore, a two-part glass-based lubrication system, consisting of a glass pad and a glass layer sprayed onto the billet, was used for the extrusions. The purpose of this is to minimize friction and provide thermal insulation against the tools (container, die with ceramic ring, inlet ring and dummy block). The operating temperature of the mentioned tools was set to 500°C for the experiments. In the direct extrusion process used, the NdFeB billet together with the capsule material is pressed through the die by the dummy block and tapered to form a strand. Here, the inlet ring serves to improve the material flow into the deformation zone. The final cross-sectional geometry of the strand is determined by the ceramic ring, which represents the bearing channel of the die. In the best case, this remains intact throughout the entire extrusion.

For the tests, the billet operating temperatures, the diameter of the bearing channel, the ram speed and the type of glass lubrication system (Reimbold & Strick Handels- und EntwicklungsGmbH) used were varied (Table 2).

Table 2. Used experimental parameters.

	Billet operating temperature [°C]	Diameter oft he bearing channel [mm]	Extrusion ratio [-]	Ram speed [mm/s]	Glass lubrication system with application temperature range
#1	800	27	9,9:1	8,8	Pad: RS2745 0,1-0,4 (780 °C -1140 °C) Slurry: RS2745/10,063 (780 °C -1140 °C)

#6	850	22,8	13,9:1	0,6	as in #5

For the qualitative investigations of the extruded strands, visual inspections of the strands were carried out on the one hand, and metallographic analyses in the form of X-ray diffraction (XRD) were performed on strand cross-sections to show the obtained textures on the other hand. When preparing the samples for XRD analyses, they were first grounded with a grit size of 4000 and then polished with diamond suspensions at 6 µm, 3 µm and 1 µm levels. The texture measurements were performed on the polished cross-sections of the strands in the center and in the edge region of the magnetic material. The measurements were carried out at the Department of Metallic Materials at the TU Berlin on a diffractometer from the Huber company using a location-sensitive detector OED 50 M from M. Braun GmbH. These involved monochromatic Co-Kα radiation (λ = 0.17887 nm), an accelerating voltage of 40 kV, a current of 25 mA, and a collimator with a diameter of 1 mm, and the crystal orientations {004}, {310}, {313}, {410}, {411}, and {006} were measured. For the measurements, the samples were rotated azimuthally (φ) in 5° steps from 0° to 355° and repeated for tilt angle steps (Ψ) of 5° ranging from 0° to 55°. The program MTEX was used to determine the orientation distribution functions (ODF) and create the pole figures.

Results and Discussion

Fig. 3 shows the resulting strands of the test extrusions. It can be seen that for all test parameters, strands could be extruded which also contain magnetic material. In addition, Table 3 summarizes the extrusion forces measured during the tests as a function of the stepwise parameter adjustments. The total force to be applied by the extrusion press is the sum of the die force and the friction force. The forces are determined by load cells which are coupled to the container for the friction force and to the die for the die force. In the case of the used container (diameter of 85 mm), the total force is also restricted to 6.5 MN in order to avoid exceeding the critical yield stresses of the used tools.

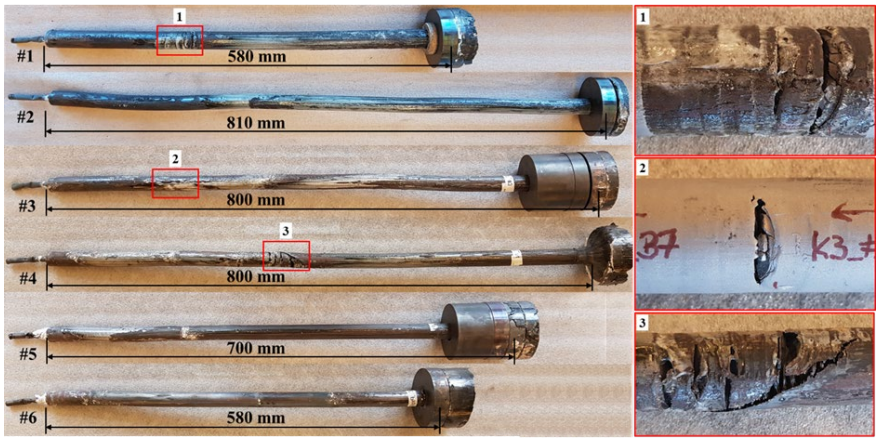

Fig. 3. Strands of tests No. 1 to No. 6 (left); 1-3) Pressing defects.

Table 3. Measured extrusion forces as function of the stepwise parameter adjustments.

	#1	#2	#3	#4	#5	#6
Parameter adjustments		Increased extrusion ratio Increase Ram Speed	Increased billet Temperatur Decreased Ram speed	Decreased Ram speed	Changed Glass lubrication system Decrease Ram speed	Decrease Ram speed
Die Force [MN]	4,1	4,9	4,8	5,1	4,4	4,0
Friction Force [MN]	1,0	1,3	1,5	1,2	0,4	0,3
Total force [MN]	5,1	6,2	6,3	6,3	4,8	4,3

For test No. 1, the required die force and the friction force between billet and container were measured to be 4.1 MN and 1.0 MN, respectively. By increasing the ram speed and decreasing the bearing channel diameter, the die force increased as expected to 4.9 MN. The friction force was measured at 1.3 MN, resulting in a total force of 6.2 MN to be provided by the extrusion press. This results in very high stresses for the ram and the used tools. To counteract these, the billet operating temperature was increased and the extrusion speed reduced for test No. 3. However, despite the adjustments, 4.8 MN and 1.5 MN were measured for the die and friction forces, respectively. It can be assumed that the adjustment of the extrusion speed is not sufficient to achieve sufficiently high differences in the mean logarithmic forming speeds which can be calculated according to the formula [14]:

$$\underline{\dot{\varphi}_g} = \frac{(V-1)\cdot 2\cdot tan\alpha}{D_0 \cdot D_S} \quad (1)$$

Here V is the extrusion ratio, α is the die angle, D_o is the container diameter and D_s is the strand diameter. The determined small reduction from 7.5 1/s to 6.3 1/s could therefore not be sufficient to achieve a relevant reduction in the flow stresses of the material. For test No. 4, the ram speed was further reduced. Here, too, no relevant deviations from the values of test No. 2 could be observed with 5.1 MN and 1.2 MN. This could equally be attributed to a still slight reduction of the mean logarithmic forming speed to 4.9 1/s. In addition, it could be considered for the tests that manual loading oft he billet can lead to delays in the extrusion process.

This means that even short time differences can lead to strong cooling of the billet due to the high temperature gradient between the container and the billet, which can also lead to an increase in the flow stresses in the deformation zone. In order to further reduce the forces, a new lubrication system suitable for use at lower temperatures was used for tests No. 5 and No. 6. At the same time, the ram speed was further reduced for test No. 5. As a result, the die and friction forces were significantly reduced to values of 4.4 MN and 0.4 MN, respectively. The reduction in the friction force, which is measured by load cells attached to the container, can thus be attributed to the reduced friction between container and billet surface. The lower die force can also be explained by a reduction in friction. In this case it is due to the reduced friction between the billet and die, since the measured values for the forming force are recorded via load cells on the die, i.e. decoupled from the friction force. The improved material flow at the die, i.e. facilitated by the more suitable lubrication system, also improves the formability. For test No. 6, a further reduction in the ram speed also resulted in lower values for the die and friction forces of 4.0 MN and 0.3 MN in the steady-state of extrusion. In contrast to the previous tests, however, this billet could not be extruded completely, which resulted in an increase in the total force to a maximum acceptable value of 6.5 MN for the test setup, above which forming was no longer achieved with the corresponding extrusion force. In this case, it can be assumed that the set low ram speed during the extrusion results in excessive cooling of the billet and thus freezing of the billet. Figure 3 also

Materials Research Proceedings 28 (2023) 505-514 https://doi.org/10.21741/9781644902479-55

shows the strand lengths obtained. For tests No. 1 to No. 5, the theoretical lengths calculated via the volume consistency (approx. 600 mm for ER. 9.9:1; approx. 800 mm for ER. 13.9:1) could be achieved, whereby the deviating strand length for test No. 5 is due to a shortened capsule cover of 10 mm. In accordance with the not completely extruded billet in test No. 6, a reduced strand length of 580 mm was realized here. Also extrusion defects for strands No. 1, No. 3 and No. 4 are shown in Figure 3. These are cracks in the shell material of the strand areas with magnetic core, which are perpendicular to the extrusion direction. The magnet material in these areas is also characterized by strong transverse cracks, in some cases also beyond the areas of the shell cracks (see Figure 3, detail view 2). Figure 4 shows the theoretical positions of the magnet material as well as the real cutting positions for removing the relevant magnet areas in the resulting strands for the two different extrusion ratios. The strand sections shown in Figure 5 were extracted according to these cutting positions. For reasons of equivalence with respect to strand No. 2, strands No. 3 and No. 4 are not shown.

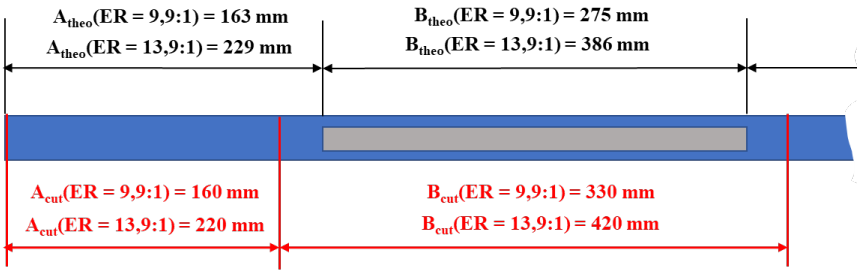

Fig. 4. Theoretical position of the magnetic material in the strand (black); removal positions for the magnetic material (red).

In addition, Fig. 5 shows the sections through the magnet-filled areas in order to compare them with the theoretical material flow.

While for the experiments No. 1 to No. 5 the section lengths of 330 mm and 420 mm given in Fig. 4 were observed due to the complete extrusion of the billets, only a section of 340 mm could be taken for experiment No. 6. The cross-sections also show that the magnetic material is present in different proportions over the length of the sections. Thus, for all tests, there is a pronounced back-end defect at the end of the section, in which the capsule bottom material flows forward in the middle of the strand and the magnetic material is therefore present in a ring shaped area in the cross-section. On the other hand, a variable area fraction of the magnetic material can also be seen in the areas without back-end defect, whereby this decreases over the extrusion. In the case of tests No. 5 and No. 6, it can be seen that magnetic material is already present in the strand before the theoretically determined position. In the case of test No. 5, it can be assumed that the shortened capsule cover is the cause of the displaced position of the magnet. In the case of test No. 6, it could be assumed that, due to the low extrusion speed, the flow stresses for the steel are higher than for the magnet material as a result of the rapid cooling of the billet. This would result in a pre-flow of the magnet material in the center of the strand. Furthermore, in Fig. 5, cracks can be seen in the magnet material along the entire strand length for all tests, not just in the defect areas shown in Fig. 4. On the one hand these could be explained by insufficient matching of the forming properties of the material composite and on the other hand by the difference in the thermal expansion coefficients of the two materials.

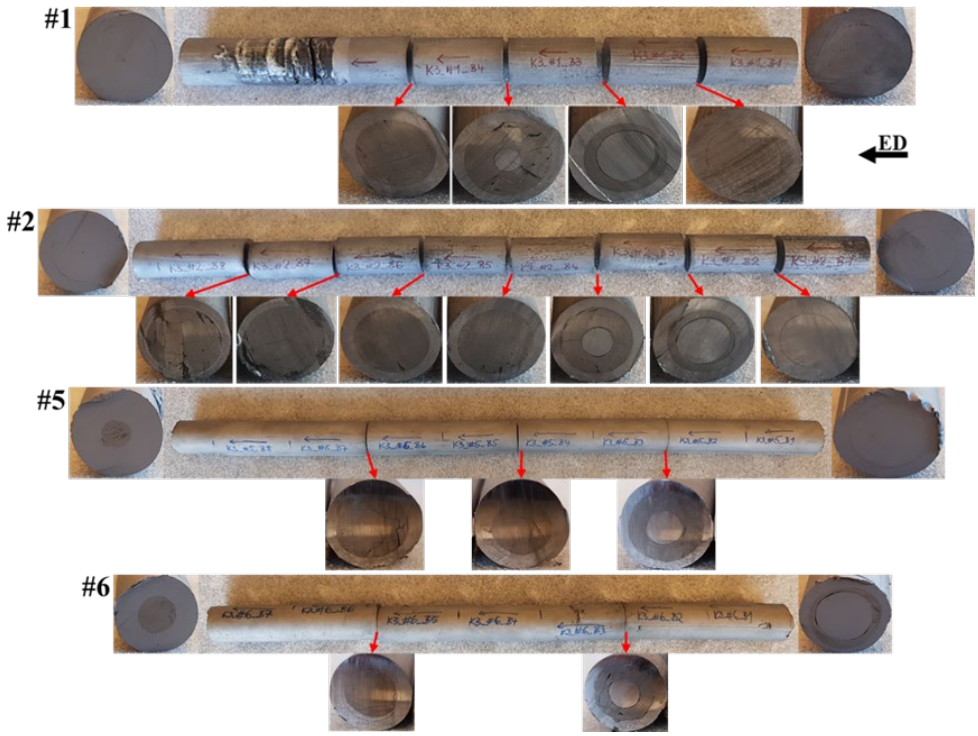

Fig. 5. Resulting strands and strand cross sections.

Fig. 6 shows the pole figures determined by XRD for selected tests at the edge and in the center of the magnetic material. For the investigations, sample cross-sections were considered in which the area fraction of the magnetic material was the largest. Since the pole figures for tests No. 2 to No. 5 do not show any decisive differences, these are represented for the edge by test No. 2 and for the center by test No. 3.

In general, an orientation of the lattice structure can be determined for all tests, both at the edge and in the center, in which the (002) planes are preferably perpendicular to the cross-sectional plane and rotated with respect to the extrusion direction. The (100) planes are primarily oriented in the cross-sectional plane or perpendicular to it. According to these orientations, the (110) planes are thus preferably rotated by 45° to the orientation of the (100) planes, as can be seen in Fig. 6. Furthermore, it can be seen that a certain proportion of the (001) planes are oriented horizontally in the cross-sectional planes, especially in the measuring positions at the edge. This indicates that an theoretically expected anisotropy is more pronounced in the center regions. In theory, the hot-deforming of Pr/NdFeB results in an anisotropy in which the (002) planes are perpendicular to the applied pressure direction. This can be seen in the die-upsetting and back-extrusion processes (Fig. 1). Consequently, in the process used here, a radial orientation of the c-axes of the tetragonal unit cell, corresponding to the anisotropy in back-extrusion magnets, would ideally be expected in the cross-sectional area of the strand.

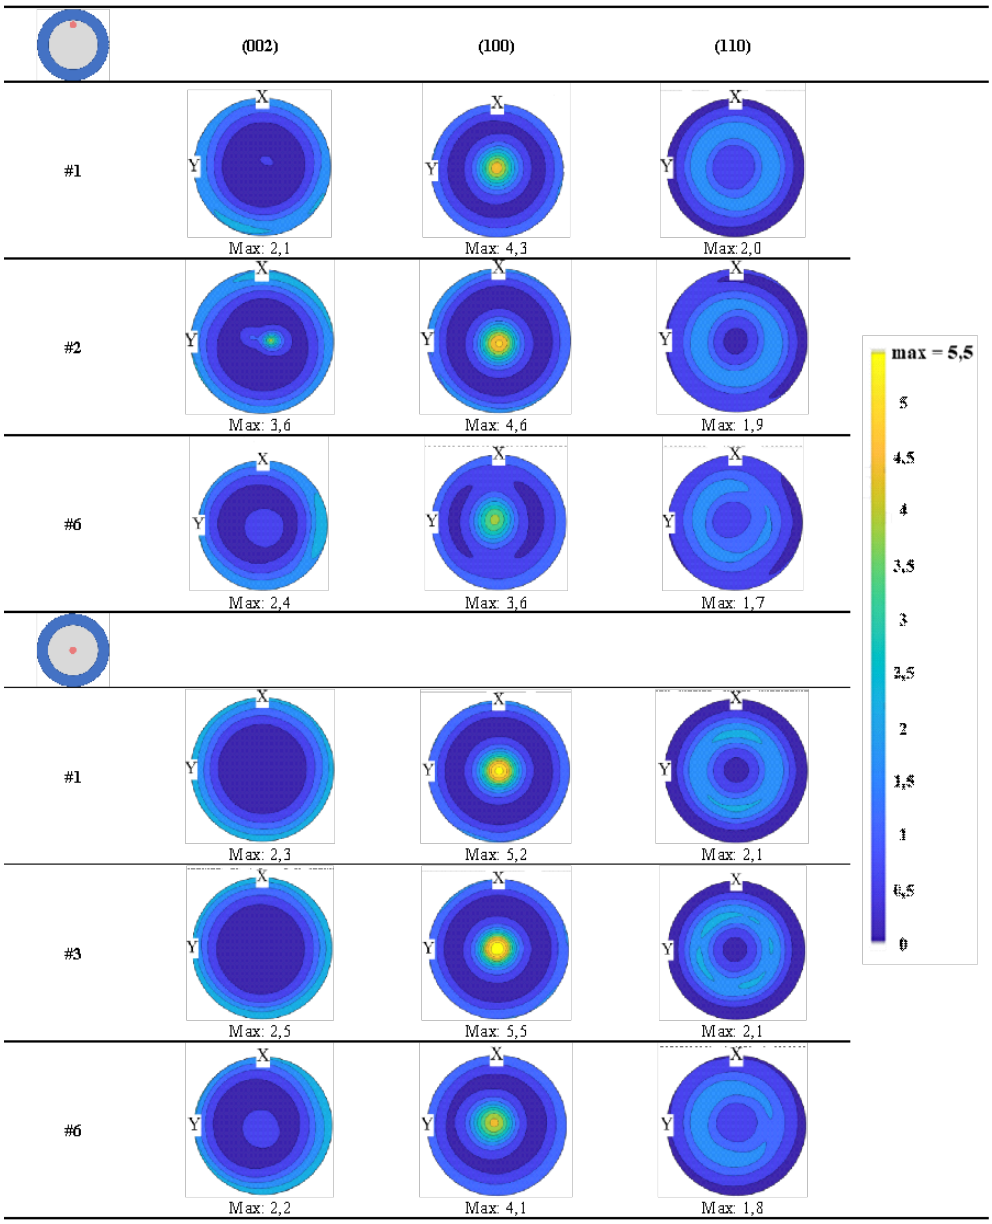

Fig. 6. Pole figures determined by XRD at the edges and in the center of the strands; the colored legend represents the intensity range of the displayed pole figures.

For the occurrence of the perpendicular to the extrusion direction orientated (002) planes in the edge region, it can be assumed that, due to too rapid cooling of the magnetic material, no sufficient rotation of the grains in the liquid phase required for hot deformation is possible at the extrusion speeds used because of the large temperature gradient between the container and the billet. Consequently, the temperatures in this area could drop too quickly into the temperature range of the solidifying temperature of the liquid phase. A similar argument can be made for test No. 6 in the center of the strand. Here, the possibly too slow pressing speed for the experimental setup could lead to a rapid cooling of the billet down to the center of the material and thus cause the observed superimposed anisotropy. Furthermore, it can be assumed that the not achieved radial anisotropy can be explained by insufficient shear of the material based on the possibly too low selected extrusion ratios. In general, it should be noted that for further tests to optimize the

anisotropy, the tools must be adapted with regard to realise a constant Temepratur in the billet over the entire extrusion.

Summary

With the selected test setup for direct extrusion of encapsulated magnetic powder, strands with magnetic material or at least partial strands (Test No. 6) could be processed for all parameters. A pronounced back-end defect was observed for all strands. For some strands, partial cracks of the strand shell and and in these areas strong cracks in the magnetic material perpendicular to the extrusion direction could be observed. In addition, the magnet material was riddled with finer cracks in all tests. In future, consideration can be given here to adapt the capsule material in order to better match the flow properties to the magnet material in the temperature range used.

Furthermore, a comparable texture was produced in the edge areas and the centers of the magnet material in all tests. In this, the c-axes of the Pr/NdFeB unit cell were preferably perpendicular and rotated with respect to the extrusion direction. Purely radial anisotropy of the magnet material could not be generated.

In summary, it can be assumed that the excessive temperature gradient between the tools and the magnetic billet led to an unfavorable cooling for the process. For further tests, it is useful to develop a concept that allows higher operating temperatures to be realized for the tools in order to counteract the decrease in Temperature of the magnetic material during extrusion. In addition, to enhance shear and thus anisotropy, an increase in the extrusion ratio may be considered.

Keywords: Friction Extrusion, Solid-State Processing, Aluminum, Powder Consolidation

Abstract. Friction extrusion (FE) is a solid-state process categorized as an energy-efficient process, utilizing the intrinsic friction-induced heat to plasticize and manufacture fully consolidated extrudate from various feedstocks, i.e. solid billet, chips and powder. Friction in the relative motion between the feedstock and the non-consumable die generates heat as well as imposes severe plastic deformation; this combination enables dynamic recrystallization and refinement of the microstructure. This study demonstrates the feasibility of directly extruding aluminum alloy powder into fully consolidated wire in a single step process. The extrudate is free of noticeable defects and shows predominantly homogeneous microstructure along the cross-section of the wire. The powder evolution upon passing through the die orifice was investigated in terms of morphology and microstructure. Additionally, the mechanical properties of the extrudate, i.e. microhardness and ultimate tensile strength, were compared to solid billets of AA7075 in different temper states and shows adequate mechanical properties without possible post-heat treatments.

Introduction

Friction extrusion (FE) process, developed and patented by Thomas et al. [1] in 1993, is used to extrude diverse materials, i.e. aluminum [2], magnesium [3] and copper [4] alloys. FE, schematically shown in Fig. 1, differs primarily from classical extrusion in the relative rotational motion, utilizing the well-established concept from friction stir welding (FSW). Friction occurs at the interface of the feedstock and the die, which introduces shear deformation and elevated temperature, resulting in the initiation of recrystallization and grain refinement. Three essential control factors in FE, i.e. axial force, rotational speed and die geometry, determine the extrudate properties and geometry, which have been extensively studied in the literature for different materials. The effect of the rotational speed and extrusion force was investigated and the rotational speed as the critical process parameter determined [5,6]. The die geometry not only defines extrudate shape but also affects the material flow prior to extrusion. Darshell et al. [7] and Halak et al. [8] discussed the influence of different die profiles and angles, respectively.

The FE from powder feedstock has attracted particular interest in the past few years, as it demonstrates the ability to extrude rod and tube directly from powder precursor [9,10] and led to better mechanical properties, such as ductility and electrical conductivity, compared to conventional analogous processing techniques [11]. Additionally, friction consolidation (FC) process that can be viewed as the FE without a die orifice, revealed the formation of the supersaturated solid solution of the immiscible alloy, which initiates the potential to achieve novel

properties [12]. Strain and strain rate prior to FE are the decisive factors of the extrudate properties and have been studied using marker materials in solid billet feedstock [13]. In contrast to a solid billet feedstock, additional consolidation is necessary for powder FE. Furthermore, the influence of powder flow ability on strain and strain rate needs to be considered. Despite the numerous advantages of using powder as feedstock in FE and the possibility of accomplishing novel properties, the material flow of powder in front of the die is still rarely studied.

To understand the consolidation and deformation of the powder feedstock during FE, the present study analyzes the powder evolution within the residual feedstock, in particular of the powder shape alteration and the elimination of powder boundaries. In addition, the microstructure and properties of the extrudate are studied.

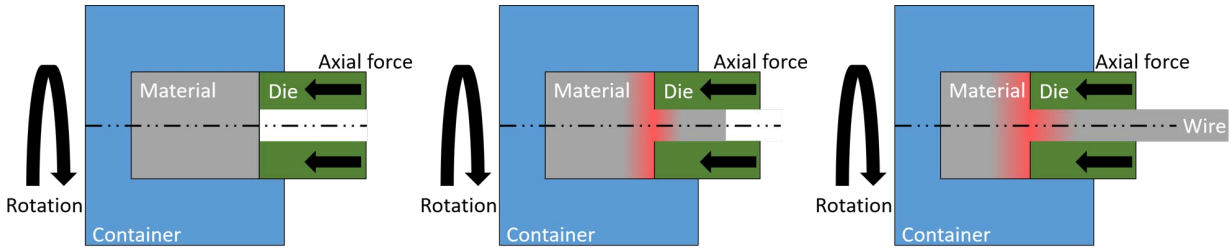

Fig. 1. Illustration of the FE process, including two machine parts, container and die.

Materials and Methods

Aluminum gas-atomized 7075 powder with a particle size smaller than 106 µm, stored in dry air, was used in this study. The dedicated friction extrusion machine FE100 manufactured by Bond Technologies was used. The machine allows forces up to 1000 kN, torques of 3500 Nm and rotational speeds of 1000 rpm. Along with high-speed data acquisition, FE100 enables the exploration of broad parameter combinations. The two essential tooling parts, shown in Fig. 1, namely a rotating powder container machined from 4140 steel with an inner diameter of 50 mm and a hydraulically driven extrusion die with a flat face from H13 steel with a 10 mm die orifice, were applied in the current study, which resulted in an extrusion ratio of 25. The temperature was recorded via type-K thermocouple embedded 1 mm from the extrusion die surface at a radius of 16.5 mm. The powders of ~ 150 g were filled in the powder container with a 0.6 mm AA7075 plate placed on top and pre-compacted with 100 kN to prevent powder spill before extrusion. The initial stage of the process applied a rotational speed of 300 rpm with 55 kN to establish complete contact between the extrusion die and the material. After the extrusion die advanced for 1 mm, the transition to the force-controlled friction extrusion process was conducted via a 10 s ramp. The constant 100 kN force with the powder container constantly rotating at 200 rpm were denoted as the process parameter in this study.

After extrusion, the extruded wire and the residual feedstock were sectioned transversely and longitudinally to the extrusion direction, respectively, and prepared following standardized metallography procedures. The microstructure of the wires was subjected to an additional electrolytic etching with Barker's solution at 20 V for 80 s and inspected with a Leica DMi8 optical microscope. In contrast, the microstructure of residual feedstock was analyzed by an FEI Quanta 650 field-emission scanning electron microscope (SEM) equipped with EDAX Apollo X energy dispersive X-ray spectroscopy (EDX). Furthermore, microhardness was tested with an EMCO-TEST Durascan 70 G5 with a load of 0.2 kg and ultimate tensile strength (UTS) was measured by an Imprintec i3D BVR according to DIN SPEC 4864. The mechanical properties of the extruded wire were compared with the as-received AA7075-T651 bar material and the annealed sample by heat treating the sample at 404 °C for 150 minutes followed by oven cooling.

Results and Discussion

The microstructure overview in the cross-section of the extrudate, processed at 100 kN and 200 rpm, is shown in Fig. 2. No noticeable defects and a fine-grained microstructure were observed in the core of the wire, indicating the powder is fully consolidated after FE. Grains, with grain size smaller than 10 µm, are predominantly present through the full cross-section of the wire, while at the periphery, larger grains up to 50 µm and defects can be noticed. The reasons might refer to the extensive residual heat in the die bearing promoting grain growth and the relative rotating motion between the extrudate and the die.

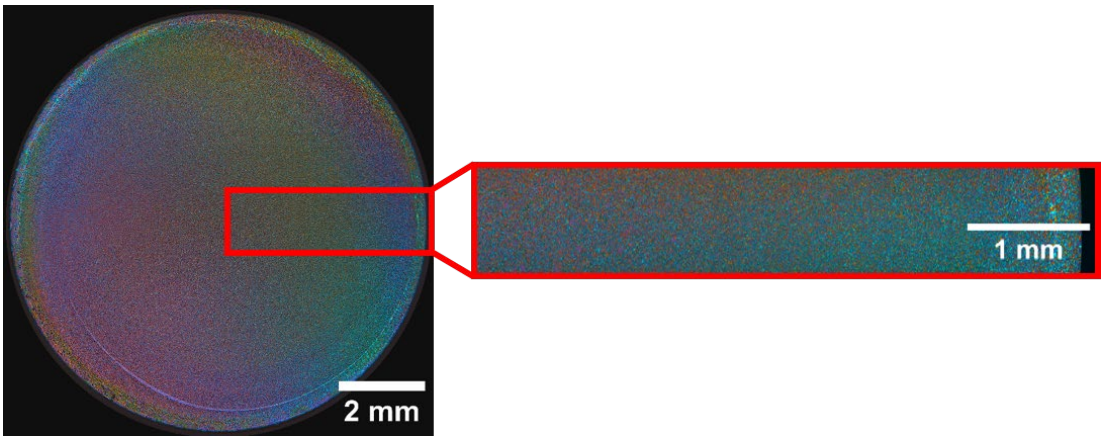

Fig. 2. Micrograph of etched cross-section of the wire extruded at 100 kN, 200 rpm, including enlarged section at the position highlighted by the red frame.

The powder evolution analysis is conducted on the residual feedstock after FE. The overview geometry of the specimen can be seen in Fig. 3(a). The left up and down corners of the specimen were fractured. Spherical raw powders, Fig. 3(b), have been found within the fracture area, indicating that the pre-compaction stage has not affected the powder in these regions prior to FE. Several positions at the center of the residual feedstock have been subjected to SEM for a powder evolution study. Fig. 3(c-g) reveals the evolution of powder during the FE process. High porosity has been identified as highlighted by white circles in Fig. 3(c) in form of void volume between as well as pores within individual powders, which is regarded as the starting condition of the powder after pre-compaction. The morphology of the powder alters gradually by approaching the die orifice and accompanies by the pores removal due to the extrusion force combined with the rising temperature and completed in Fig. 3(d). In Fig. 3(e), approximately 6 mm advanced entering the die orifice, the powders have been elongated in the extrusion direction, indicating the mechanical effect of the tooling has contributed to the FE. The powder boundaries begin to fade, suggesting the merge of the powder is potentially under the diffusion route with a much lower temperature, maximum 503 °C according to temperature measurement, compared to the conventional sintering temperature (580 – 620 °C) for AA7xxx alloys [14]. In Fig. 3(f), the large amount of powder boundaries vanishes and suggests that the powder consolidation nearly finished prior to entering the die orifice and material flow onwards can be considered similar to FE from a solid billet feedstock. However, the different strengths and the flow ability among the pre-compacted powder, solid billet or chips have a tremendous impact on the initial heat generation and the heat dissipation,

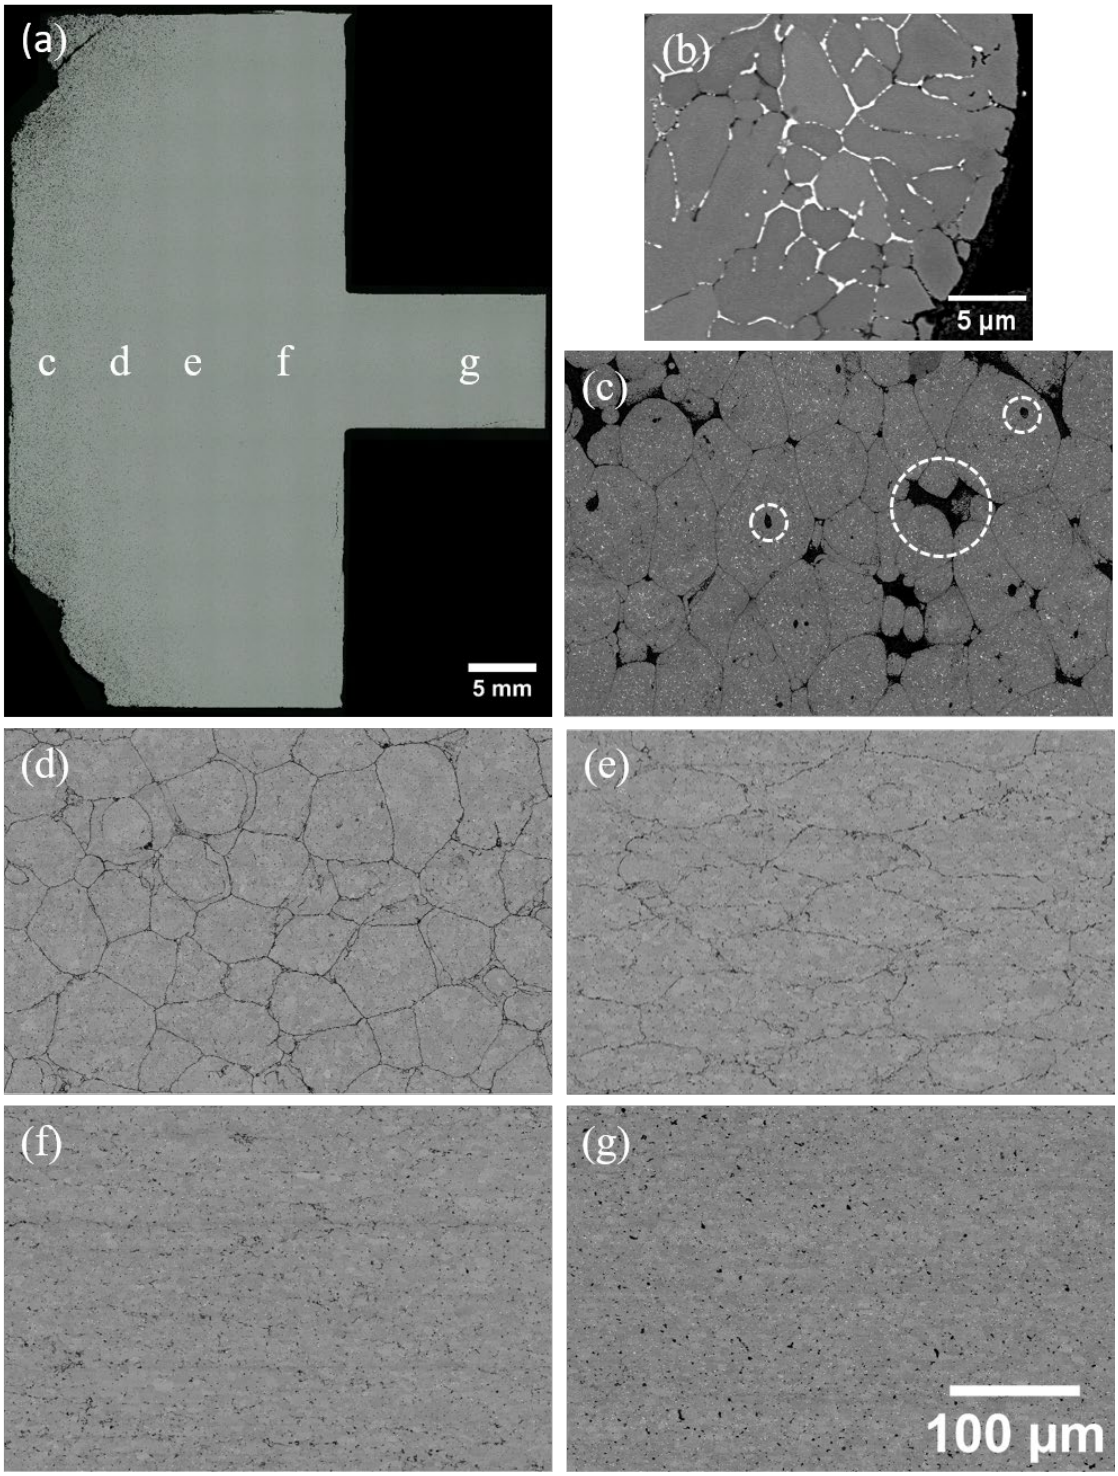

Fig. 3. Overview of residual feedstock (a), base powder (b) and powder evolution in the center from the left of the specimen (c) to the extrudate (g).

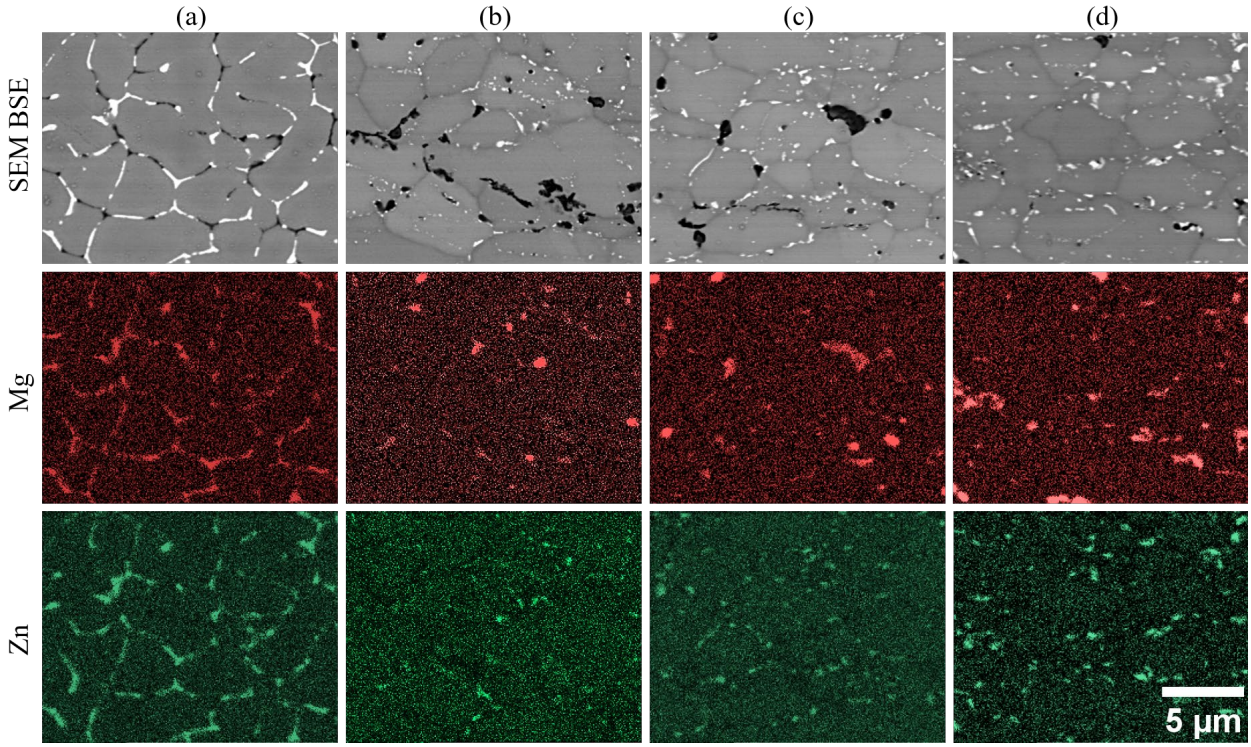

Fig. 4. SEM backscatter images from base powder (a) and different distance to the die orifice, i.e. 6 mm (b) and 4 mm (c) advanced and 10 mm (d) retreated, and the corresponding EDX mapping of Mg and Zn.

which hinder the direct implantation of the strain and strain rate found in the literature for solid billet as well as chips feedstock into the powder [13, 15]. After passing through the die orifice, the microstructure of the extrudate transforms into the final microstructure as shown at the position of 10 mm, Fig. 3(g), after the die orifice. No powder boundary has been found, indicating the powder is fully consolidated after the FE and further confirming the previous finding in Fig. 2.

In the aluminum alloy AA7075, two major alloying elements, magnesium and zinc, form the $MgZn_2$ phase at the grain boundary, which is observed in all the SEM images as white particles. Therefore, the residual feedstock is subjected to EDX to disclose and complement the powder evolution in the FE before entering the extrusion orifice. The EDX mapping of the Mg and Zn as well as the corresponding SEM backscatter images are shown in Fig. 4(a-d). In the base powder, Fig. 4(a), most of the $MgZn_2$ phases are larger and located at the grain boundary, which is the typical behavior of this phase in AA7075. The discontinuity observed in the EDX mapping can be explained by the re-melting of solid particles [16]. Approaching the extrusion die, the $MgZn_2$ phases are fragmented into smaller particles under shear and longitudinal deformation or diffuse into the grains as reported that FE can form a forced supersaturated solid solution [12]. By comparing the different grain orientations in the raw powder, Fig. 3(b), and near the extrusion die, Fig. 4(b-d), the transformation of the randomly distributed grains aligned in the extrusion direction can be observed, indicating the effect of the deformation. In Fig. 4(b), the capture position is adjacent to the powder boundary, where the $MgZn_2$ phases are rarely found, which corresponds to the observation of the unprocessed base powder. The reason could be that the rapid solidification rate of gas-atomized powder impedes the diffusion behavior of alloying elements on the powder surface [16]. Since the melting point of $MgZn_2$ phases is much below the processing temperature of FE, the incipient melting of existing phases may occur before the die orifice and could explain

the smaller defects observed in Fig. 4(c). However, the huge defects may be due to the isolated pores that typically find in powder metallurgy materials [17]. It needs to be mentioned that the grain size observed in the SEM images is also below 10 µm and comparable to the base powder.

The microhardness was evaluated over the cross-section for a part in the middle of the extrudate, see Fig. 5(a). The FE extrudate shows a relatively homogeneous hardness, 115.6 HV, except for the outer ring with slightly larger grains. At the lower part of the mapping, one region with significantly lower microhardness is supposed to be a defect, as observed at the periphery of the cross-section in Fig. 2. By comparing the extrudate to AA7075 alloys in different temper states, T6 and O, Fig. 5(b), the hardness is 67 % of AA7075-T6 and 80 % higher than the annealed state. AA7075 is a precipitate hardenable alloy, and T6 temper is the peak artificial aging. Therefore, the lower hardness after high temperature exposure during FE (maximum measured temperature of 503 °C) is expected due to the dissolution of strengthening precipitates.

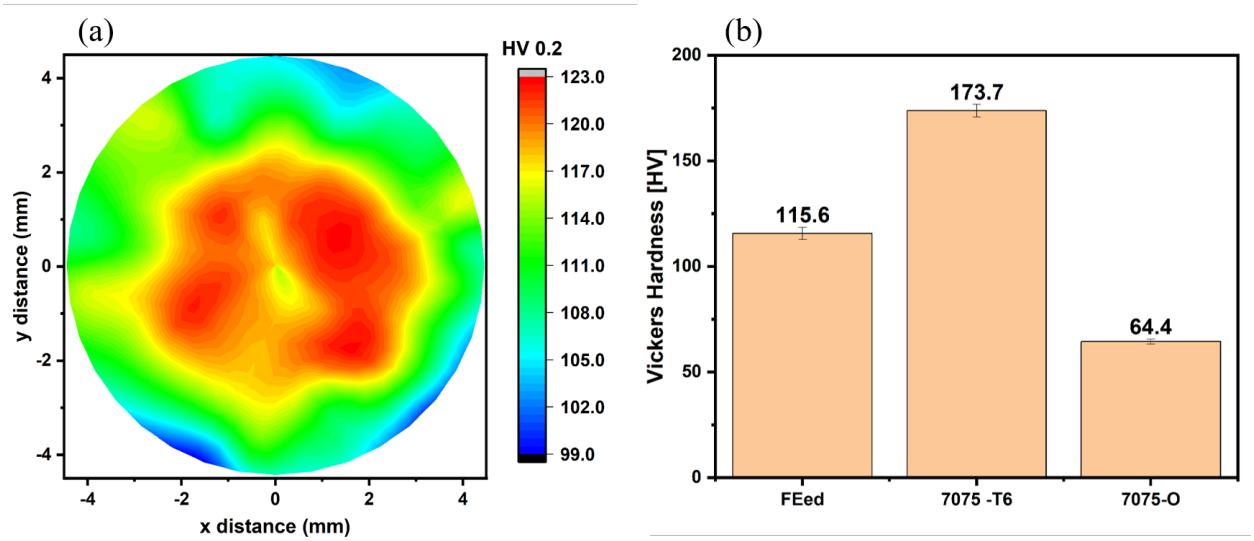

Fig. 5. Microhardness mapping of the cross-section for the extrudate (a) and comparison to the base material in different temper states.

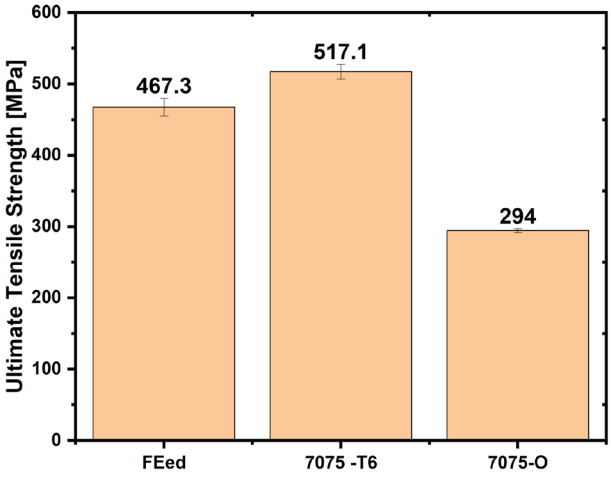

Fig. 6. Ultimate tensile strength for the extrudate and comparison to the base material in different temper states.

The UTS of the FE extrudate as well as for AA7075-T6 and AA7075-O is shown in Fig. 6. The extrudate UTS is 467.3 MPa, which shares the same trend as the microhardness, with 90 % of the T6 state and 59 % more than the annealed state. The recrystallization and the grain refinement enabled the improvement of the mechanical properties; however, the precipitate strengthening effect dictated the mechanical properties of 7075 alloys, and the further increase of UTS after artificial aging has been proven [18]. The UTS value is comparable to the FE from AA7075 solid billet feedstock [8, 18], indicating full consolidation of the powder during FE.

Summary

In the present study, friction extrusion based on powder material was investigated in terms of extrudate microstructure as well as powder evolution in front of the extrusion orifice. The fully consolidated wire was successfully extruded directly from the powder feedstock. Additionally, the mechanical properties of the final extrudate were analyzed. The main findings are summarized as follows:

- Fully consolidated wire with predominantly homogeneously distributed fine grains and no noticeable defects in the core is successfully extruded from powder feedstock without a complex powder metallurgy procedure. Larger grains and defects are observed at the periphery of the wire; hence, a cooling system has been planned to introduce to prevent the grain coarsening issue.
- The combination of pressure and elevated temperature leads to extensive porosity removal within the powder feedstock, followed by the elongation of powder particles in the extrusion direction as well as the elimination of powder boundaries finally forming the consolidated extrudate.
- Adequate mechanical properties without post-heat treatment, comparable results to extrusion from solid billet feedstock, and the potential to improve the properties by applying artificial aging are achieved and demonstrated.

Keywords: Copper Extrusion, Plastic Die Deformation, 3D Scanning, Numerical Analysis

Abstract. In copper extrusion, the dies are continuously subjected to high thermo-mechanical stress. This results in elastic and plastic die deformation as well as extensive wear. To estimate the strain of possible hard phase surface modifications during service, knowledge of the deformation behavior of the extrusion dies is required. Therefore, the plastic deformation of dies made of four different tool materials was investigated in the present study. The applied tool materials were hot-work tool steel 1.2367, special hot-work tool steel CS1, nickel-based alloy 2.4668 (Alloy 718) and cobalt-based alloy 2.4775 (Stellite 1). 3D scans of the dies were created, both in the initial state and after each of three extrusion cycles, utilizing structured-light scanning. The extrusion trials were carried out using an 8MN extrusion press configured for direct extrusion and billets made of commercially pure copper Cu-DHP (CW024A). By evaluation of the 3D scans, the progression of plastic die deformation was determined in dependence on the tool material. Finally, the results were compared to corresponding numerical investigations on die deformation.

Introduction

In the product portfolio of copper extrusion plants, semi-finished products such as rods and tubes represent one of the largest items. The processing temperatures of copper-based alloys are usually in the range of 600-1050°C, which is why the extrusion tools are subjected to high thermo-mechanical stresses [1]. This results in elastic and plastic die deformation as well as extensive wear [2]. In order to counteract plastic tool deformation, high-temperature nickel- and cobalt-based alloys are used as tool materials in addition to the widely used hot-work tool steels [3]. One possible approach to reduce adhesive and abrasive wear is the application of hard phase surface modifications like coatings or diffusion layers [4]. These can offer good resistance to abrasion and adhesion due to their great hardness and possibly high chemical inertness [5]. However, some of these surface modifications also exhibit quite brittle deformation behavior, which entails the risk of cracking or ablation when the substrate is overly deformed.

To estimate the strain of the surface modifications during service, knowledge of the deformation behavior of the dies is required. For this purpose, tool deformation was investigated in a previous study by means of FEM-based numerical analyses [6]. In the present study, the extrusion dies were 3D scanned to determine the actual die deformation and to compare it with the results of the simulations. One die each made of the tool materials hot-work tool steel 1.2367, special hot-work tool steel CS1, nickel-based alloy 2.4668 (Alloy 718) and cobalt-based alloy 2.4775 (Stellite 1) was 3D scanned in the initial state and after each of three extrusion cycles using structured-light scanning. Evaluating the 3D scans, the progression of plastic die deformation was determined in dependence on the tool material. In conclusion, the experimental results were compared with those of the numerical investigations.

Experimental Procedure

In order to investigate the plastic deformation behavior of dies during copper extrusion, a die was designed according to literature [1] and four pieces were manufactured using different tool materials. A CAD-model of the die design is given in Fig. 1. The applied tool materials were hot-work tool steel 1.2367, special hot-work tool steel CS1, nickel-based alloy 2.4668 (Alloy 718) and cobalt-based alloy 2.4775 (Stellite 1). Due to the low toughness of the cobalt-based alloy and the resulting high risk of cracking, an insert (Ø60 x 20 mm) was shrink fit into a holder made of 1.2367. Furthermore, all dies were equipped with a thermocouple to measure the profile exit temperature. Billets were prepared from copper alloy CW024A (Cu-DHP) and extrusion trials were carried out on the 8MN extrusion press of the Extrusion Research & Development Center. The extrusion press was configured in direct extrusion setup and the extrusion forces were recorded with integrated load cells. The applied extrusion parameters as well as die and billet dimensions are listed in Table 1.

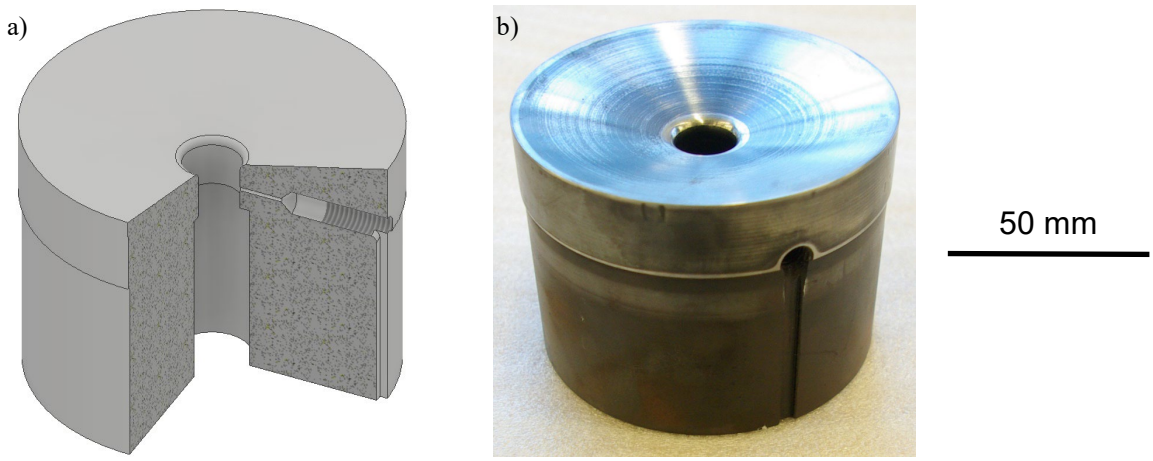

Fig. 1. Illustrations of the die geometry: a) CAD model and b) photograph.

Table 1. Die dimensions and extrusion parameters.

Semi die angle	Outer Diameter	Bearing channel diameter	Bearing channel length	Inlet radius
75°	95 mm	15 mm	10 mm	2 mm
Ram speed	Extrusion ratio	Billet temperature	Billet dimensions	Tool temperatures
20 mm/s	40.1 : 1	850 °C	Ø92 x 300 mm	500 °C

Structured-Light 3D Scanning.

The creation of virtual copies of the dies enables the study of the progression of plastic deformation and the comparison with numerical analyses. Therefore, the dies were scanned using an AICON smartSCAN-HE structured-light scanner. The test volume was 161 mm x 208 mm x 130 mm and with a test distance of 397 mm the resulting average distance between measuring points was 0.064 mm. To keep measurement time and data volume low, only the upper third of the dies, which contains the functional surface, was scanned (see Fig. 2, a). Each die was scanned in

the initial state to set a benchmark and after each of three extrusion cycles. Prior to each scan an anti-reflective coating was applied to the dies to avoid interfering reflections. The 3D scans generated surface meshes, which were imported in the software GOM Inspect 2019 for further analysis. In order to determine the plastic deformation of the dies after individual extrusion cycles, a scan of a die in its current state was superimposed on the scan of the initial state in each case (see Fig. 2, b). Using the local-best-fit function of the software and the thermocouple receptors as reference point, an accurate positioning of the two surface meshes was achieved. Subsequently, an area comparison was performed, in which the distance to the nearest point of the mesh in the current state is output for each point of the benchmark mesh (see Fig. 2, c).

Results and Discussion

Extrusion Trials and Structured-Light 3D Scanning.

As basis for the investigation of the progressive tool deformation, a reference scan was made of each of the four dies in their initial state. Subsequently, a total of twelve extrusion trials with consecutive 3D scans was carried out using the four dies made of different tool materials and performing three repetitions per die. On average, the maximum die force was 3.4MN and the highest temperature measured in the bearing channel was approximately 800 °C [6]. The results of surface comparisons of the die made of hot-work tool steel 1.2367 are presented in Fig. 3. Detail a) of Fig. 3 depicts the comparison between the benchmark scan and the state after the first extrusion cycle. Considering the lateral surface, an expansion of approx. 0.03 mm is observed. Since the dies were manufactured with an undersize of 0.25 mm with respect to the container bore, at least elastic expansion of the lateral surface is to be expected during the extrusion process. However, the measured expansion suggests that the yield strength of the material has been exceeded and plastic deformation has occurred. Corresponding to the radial expansion of the lateral surface, a significant lowering of the outer area of the conical face was observed (0.02-0.04 mm). This lowering diminishes towards the center of the die. Inlet radius and bearing channel also exhibit a plastic change in geometry. On average, a diameter reduction of approx. 0.02 mm and 0.01 mm is found at the radius and in the bearing channel, respectively. This deformation is due to an exceeding of the yield strength, considering the very high temperatures present in the bearing channel (superficially above 800°C). A more detailed discussion of the acting forces and resulting deformations is provided in a later section of this study by means of numerical investigations. The comparison between benchmark scan and the state after the second extrusion cycle is shown in

Fig. 3, b). No significant differences can be observed on the lateral surface compared to the state after the first extrusion cycle. There are two reasons for this. On the one hand, plastic deformation induces strain hardening at small strains, as is shown in Fig. 4. Thus, the stress required to cause further plastic deformation is higher than in the first extrusion cycle. However, since the process conditions and therefore the acting forces are approximately equivalent for all extrusion cycles, the stress present in the material is not sufficient to cause further plastic deformation. On the other hand, the deformation of the die in this area is geometrically limited by the inner diameter of the container bore. At the inlet radius and bearing channel, a slight diameter enlargement was measured. This does not correspond to the expected material behavior, since an increase in plastic deformation is to be expected due to the high temperatures and stresses. One possible explanation is the mechanical post-processing of the dies functional surfaces in preparation for the respective 3D scan. Due to the strong adhesion of copper to the die materials, it was necessary to remove adhering copper and lubricant residues (graphite-based) using fine sandpaper and polishing fleece. A slight removal of tool material could not be completely avoided. Following the third extrusion cycle, this phenomenon can also be observed on the lateral surface of the die (see Fig. 3, c). In the area of the bearing channel, in turn, a significant increase in plastic deformation and thus reduction of diameter was measured. This amounts to approx. 0.02-0.03 mm after three extrusion cycles.

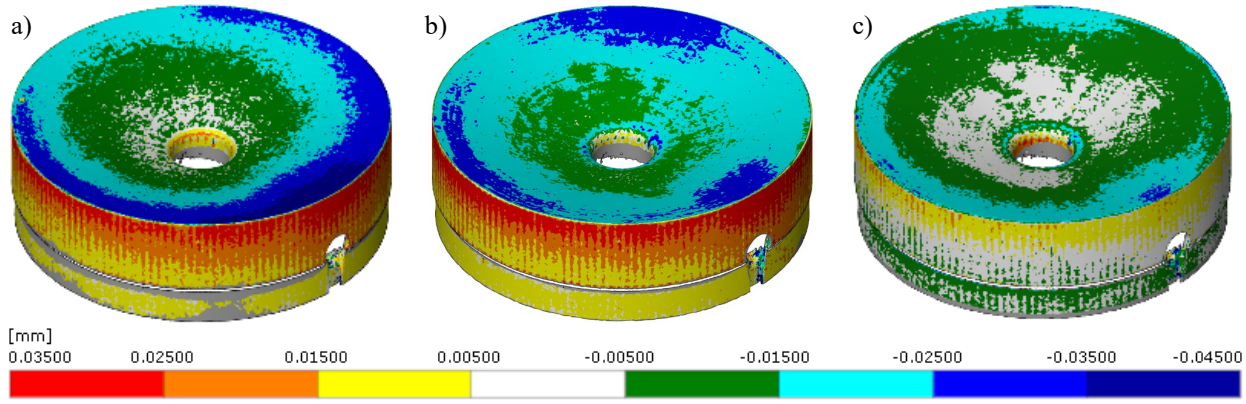

Fig. 3. Surface comparisons for the die made of hot-work tool steel 1.2367 in different states: a) after one, b) after two, and c) after three extrusion cycles.

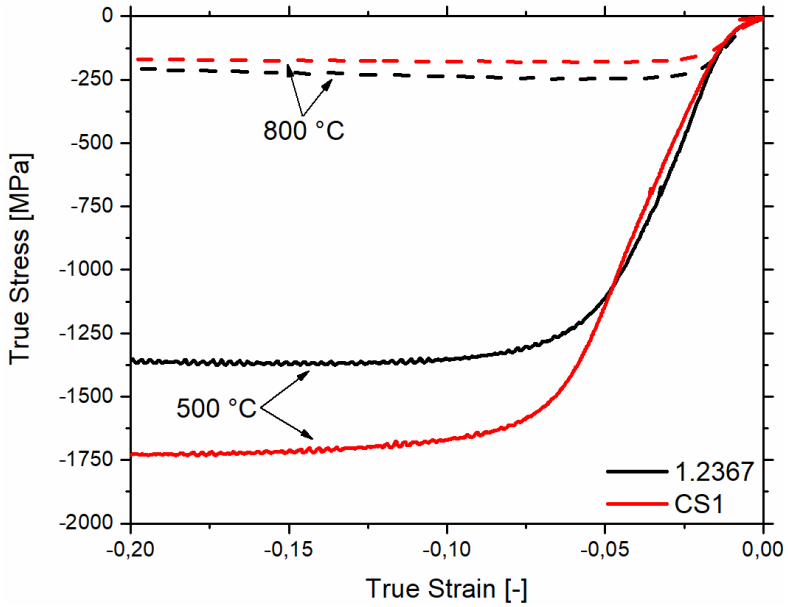

Fig. 4. True stress-true strain curves of hot-work tool steel 1.2367 and special hot-work tool steel CS1 at 500°C and 800°C, obtained by means of hot compression tests at a strain rate of 0.005 s^{-1} [6].

Compared to the hot-work tool steel 1.2367 shown so far, the lateral surface of the die made of special hot-work tool steel CS1 does not expand to any significant extent (see Fig. 5). This is due to the elevated hot strength of CS1 in the temperature range of 500-650°C (see Fig. 4). The slight decrease in lateral surface diameter can be explained, analogously to the die made of 1.2367, by the mechanical post-processing for cleaning the die. In the bearing channel, on the other hand, a strong increase in plastic deformation with the number of extrusion cycles is seen. As a result of the reduced hot strength at temperatures above 750°C, significantly greater deformation occurs in the vicinity of the inlet radius and bearing channel than with hot-work tool steel 1.2367. At the inlet radius, a mean lowering of 0.01-0.02 mm (1st cycle), 0.04 mm (2nd cycle) and 0.04-0.06 mm (3rd cycle) was observed. In the bearing channel, the diameter reduction after the first cycle is 0.01-0.02 mm on average with a local peak of 0.04 mm, followed by 0.02-0.04 mm (2nd cycle) and 0.05-0.06 mm (3rd cycle).

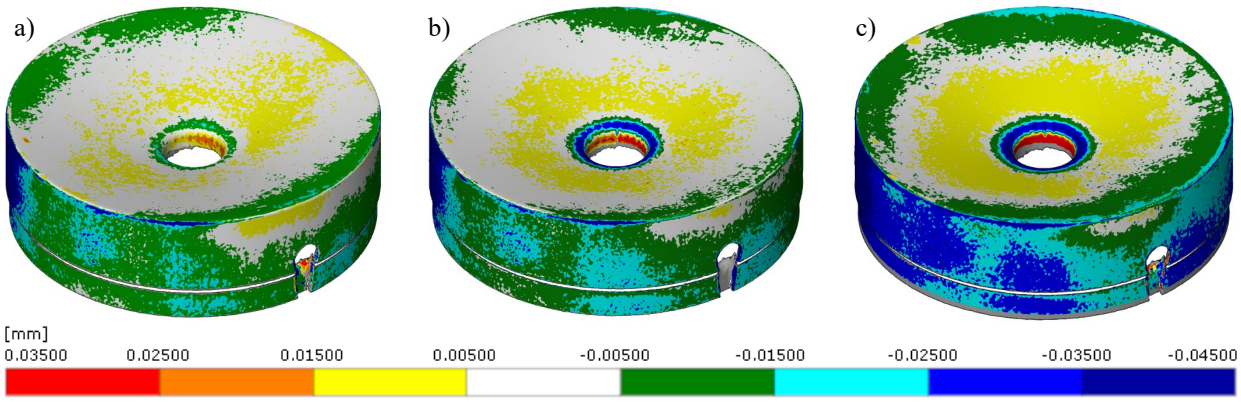

Fig. 5. Surface comparisons for the die made of special hot-work tool steel CS1 in different states: a) after one, b) after two, and c) after three extrusion cycles.

Materials Research Proceedings 28 (2023) 523-532 https://doi.org/10.21741/9781644902479-57

In contrast to the two hot-work tool steels investigated, the die made of the nickel-based alloy 2.4668 (Alloy 718) shows only very slight plastic deformation overall. As shown in Fig. 6, no remarkable increase in plastic deformation is observed over three extrusion cycles. The evaluation of the 3D scans showed only a diameter reduction of up to 0.02 mm in the bearing channel. At this point, the excellent high-temperature properties of the nickel-base alloy become apparent [7]. Due to almost invariant high-temperature strength up to temperatures of 700°C [6] and the work hardening occurring in the area of the inlet radius and bearing channel, the unchanged process conditions of the three extrusion cycles do not lead to any significant change in die geometry.

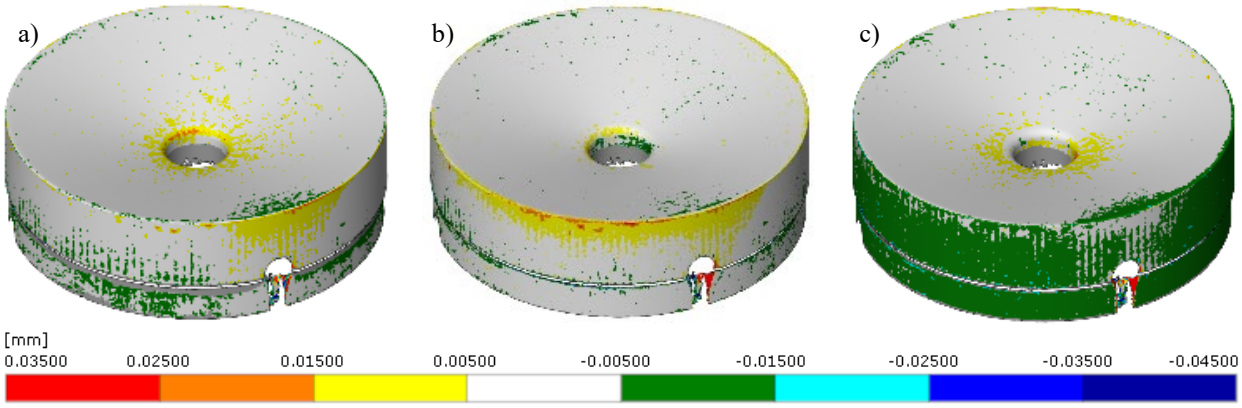

Fig. 6. Surface comparisons for the die made of nickel-based alloy 2.4668 in different states: a) after one, b) after two, and c) after three extrusion cycles.

The surface comparisons for the die made of cobalt-based alloy 2.4775 are shown in Fig. 7. With regard to the use of an insert in combination with a tool holder, there are some distinctive features to be considered when evaluating the 3D scans of this die. Since the shrink-fit of the insert was realized only by insertion and not by pressing, setting of the insert occurred during the first extrusion cycle. As the relative positioning of insert and tool holder no longer corresponds to the benchmark, the alignment of the surface meshes in the evaluation was carried out taking only the insert into account. Therefore, a strong displacement results for the tool holder, as can be seen in Fig. 7. The asymmetry of this displacement suggests that the insert was slightly tilted relative to the holder either in its initial state or after setting. For the insert a lowering of the conical face by 0.01 mm was detected in proximity to the tool holder. Furthermore, a large-area and uniform lifting of the area around the inlet radius by 0.01 mm, and a diameter reduction of the bearing channel by 0.01 mm were measured (see Fig. 7, a). These dimensional alterations remained unchanged over the course of the further extrusion cycles (see Fig. 7, b and c). Due to the excellent hot strength of the cobalt-based alloy [3], no measurable plastic deformation was expected in the material under the stresses and temperatures encountered. Rather, it is suspected that due to an inaccurately manufactured fit in the tool holder, the insert experienced a bending during setting, causing the outer area to lower and the area close to the center to raise.

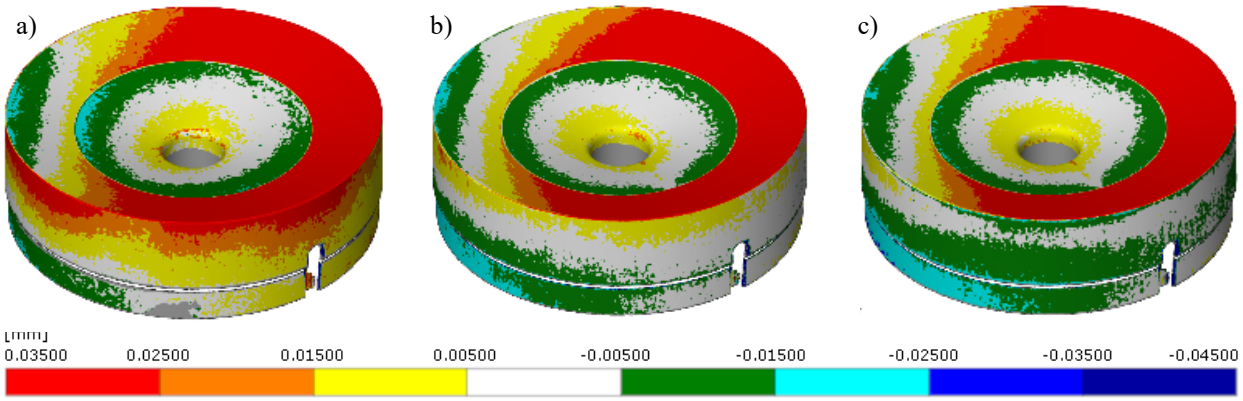

Fig. 7. Surface comparisons for the die made of cobalt-based alloy 2.4775 in different states: a) after one, b) after two, and c) after three extrusion cycles.

Comparison of Experimentally and Numerically Obtained Die Deformation Data.

In parallel to the extrusion trials, FE analyses were carried out in order to numerically model the die deformation. For this purpose, the FE-software DEFORM 2D was used and a rotationally symmetric model was built. The visco-plastic deformation behavior of copper was modeled using flow stress data gained by means of hot compression tests. In the first step of the FE analysis, which represents the extrusion process, the dies were modeled rigid. In the subsequently performed decoupled die stress analysis, elasto-plastic models were implemented to describe the material behavior of the different die materials. The identification of the required flow behavior of the tool and billet materials as well as model design and verification are described in detail in [6]. Since only very small deformations in the range of a few microns are predicted for the two tools made of 2.4668 and 2.4775, solely the two hot-work tool steels investigated will be discussed below. Fig. 8 and 9 illustrate the deformation of the dies estimated by the numerical analyses. The contour of the die in the initial state is represented by the green line and the deflection of the bulk material (magenta) has been scaled up by a factor of 10 for better visualization. The displacement after the third extrusion cycle is indicated by vectors. Fig. 8, b) and c) depict the total displacement at the edge between lateral surface and outer perimeter of the conical face. Analogous to the 3D scans of the extrusion dies, the simulation predicts a significantly pronounced plastic deformation of the hot work tool steel 1.2367 (0.017 mm) compared to CS1 (0.006 mm). While the value for 1.2367 is underestimated by about 40%, simulation and 3D scans match for CS1.

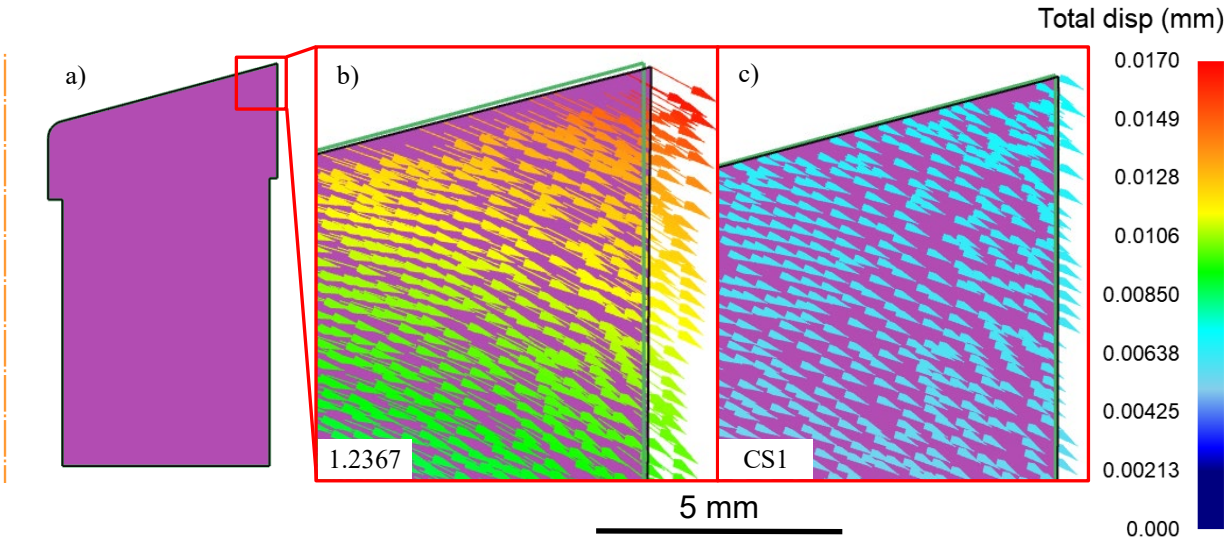

Fig. 8. a) 2D FE-Model of the extrusion die and estimated totals displacement at the lateral surface after three extrusion cycles for the use of b) hot-work tool steel 1.2367 and c) special hot-work tool steel CS1.

Fig. 9, b) and c) show the absolute displacement of the die material in proximity to the inlet radius and bearing channel. For hot-work tool steel 1.2367, the estimated lowering is approx. 0.02 mm. The diameter reduction of the bearing channel by 3 microns is negligible. This again reveals a considerable underestimation of deformation by the numerical model, since the measured diameter reduction was 0.02-0.03 mm. The same applies for CS1, which is estimated to have both a major lowering of the inlet radius (0.035 mm), and a noticeable diameter reduction of the bearing channel (0.016 mm). These values are again underestimated by up to 40% and 70%, respectively. One reason for the inaccuracy of the simulation is the underlying simplicity of the elasto-plastic material model chosen, since neither creep nor fatigue phenomena are taken into account.

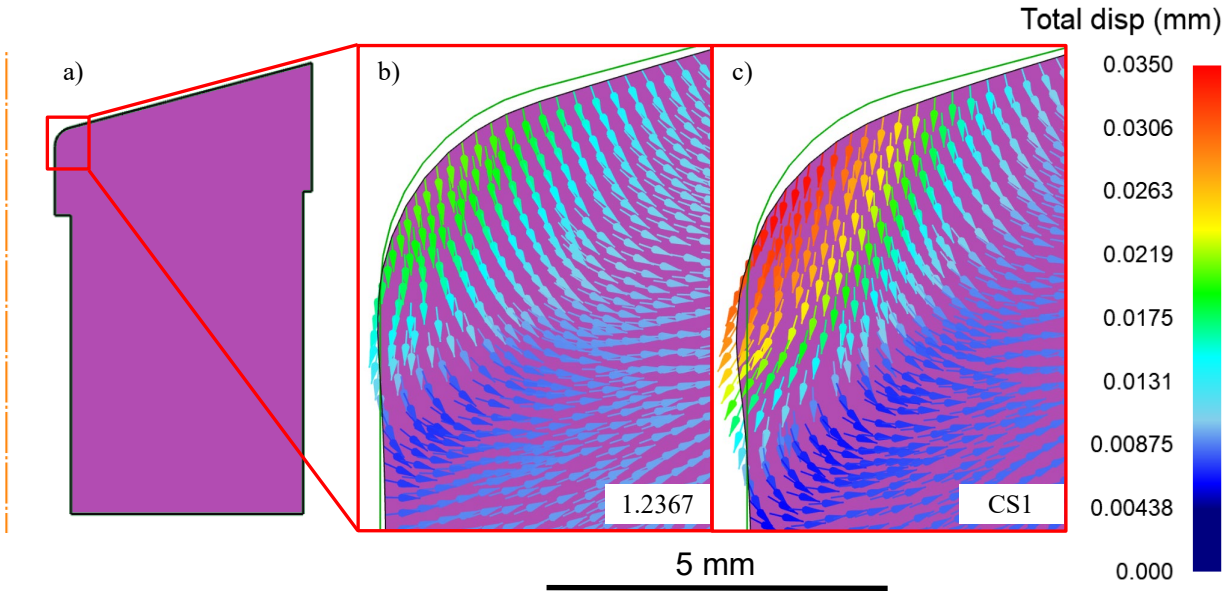

Fig. 9. a) FE-Model of the extrusion die and estimated totals displacement at the inlet radius after three extrusion cycles for the use of b) hot-work tool steel 1.2367 and c) special hot-work tool steel CS1.

The cause of the observed displacements are pressure differences in the extruded material. As illustrated in Fig. 10, the normal pressure acting on the die decreases from the conical face towards the bearing channel. Consequently, stress states are created in the die material which, if sufficiently intense, cause a plastic material displacement in extrusion direction and towards the die center. This effect is more pronounced for the special hot-work tool steel CS1, since its yield strength at temperatures above 750°C is lower than that of 1.2367 (see Fig. 4). At lower temperatures, strain-induced hardening would counteract the increasing plastic deformation as the yield strength shifts to higher stresses under repeated loading [8]. However, in the case of high temperatures, softening mechanisms take effect that counteract strain-induced hardening and prevent a significant increase in yield strength. Therefore, further plastic deformation occurs upon re-loading.

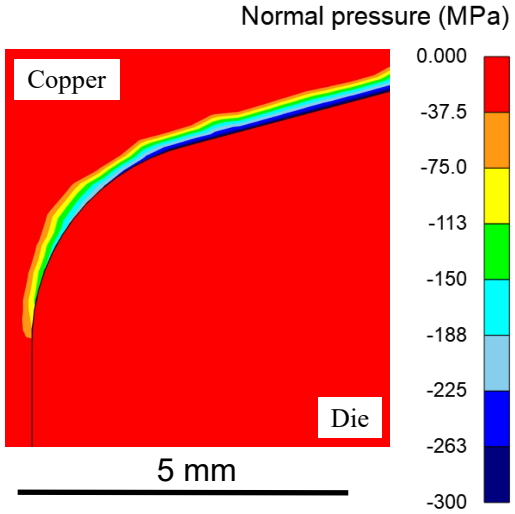

Fig. 10. Normal pressure acting on the die surface in proximity to the inlet radius.

Summary

For the purpose of studying the progression of plastic die deformation during copper extrusion, trials with dies made of four different tool materials were performed. Geometric measurement of the dies was conducted before and after each of three extrusion cycles using 3D structured-light scanning. The evaluation of the scans and the comparison with numerical investigations resulted in the following findings:

- Due to their limited hot strength in the temperature range above 600 °C, the hot-work tool steels investigated are subject to significant plastic deformation that progresses with the number of extrusion cycles.
- Both the nickel- and cobalt-based alloy exhibit very little plastic deformation, irrespective of the number of pressing cycles.
- The results of the numerical investigations indicate a very good agreement with the 3D scans. Both the direction of the displacement and the influence of the tool material can be reproduced accurately by the simulation. However, with the given material models, the absolute values of displacement are underestimated by the simulation.

Abstract. During the extrusion process, high temperatures are generated, due to friction and deformation works, potentially leading to profile and die defects. Among the suggested solutions aimed at controlling the thermal field of the process, the most accredited one involves the manufacturing of cooling channels at the mating face between the die and a third plate. Despite the proven efficiency of well-designed channels, the main drawback lies in the managing of the many variables involved that strongly affect the cooling efficiency and balancing. In this frame, aim of the work is to investigate the applicability of the topological optimization tool, proposed by COMSOL Multiphysics software, for the design of cooling channels in extrusion dies. To validate the tool, an industrial case study has been selected and results compared between not optimized and optimized cooling solutions.

Introduction

Temperatures developed during the hot extrusion of industrial aluminum profiles are frequently nearby critical thresholds that can be detrimental for the profile quality, the die lifetime and the overall productivity [1]. To face the issue, one of the most efficient solution lies in the flowing of liquid nitrogen in a channel milled and drilled in the mating surface between the die and a third plate, the backer, incorporated in the tooling set as support to limit the die deflections [2]. Even if the use of nitrogen nowadays represents a consolidated industrial practice due to its proved efficiency [3,4], the channel design still represents a challenge due to the many variables involved, strongly affecting the fluid-dynamic and thermal performances of the nitrogen flow [5]. To date, nitrogen cooling channels are still designed based on die makers experience and their effectiveness judged merely by observing the out coming profile, a practice motivated by the complexity and cost of a continuous experimental monitoring of cooling efficiency: a glossy surface states a good design, a matt one a poor design. However, the surface appearance is mostly related to the gaseous nitrogen flowing from the channel' outlets that creates an inert atmosphere around the profile reducing oxidation, rather than to the overall channel performances. Nevertheless, this drawback can be overcome by the adoption of reliable numerical models at the process and channel design stage able to return continuous maps, in space and time, of all the parameters required to properly judge the selected solution. In addition, the level of complexity force not only through numerical approaches, but also demands for automated, robust and comprehensive methodologies.

If many works have been reported on aluminum extrusion FE (Finite Element) modelling [6,7], stating the robustness and reliability of the approach, only recently Reggiani and Donati [8], and Pelaccia et al. [9,10] proposed a comprehensive numerical model for the prediction of the thermal

gradient during the extrusion process with nitrogen cooling. In addition, very promising results have already been achieved, by the same authors, by integrating the comprehensive FE model in an optimization platform able to change the channel sections iteratively and automatically along the path [11]. However, the main limitation of the procedure lies in leaving the optimizer free to vary only the cross-sections point by point, but not the path. More challenging and ambitious is the topological optimization applied to cooling channels that allows to attain any path within the design space, instead of dealing with a predefined configuration.

Currently, topological optimization is widely used in many engineering applications at the concept level of a design process, including the optimization of cooling channels in injection molds [12] and stamping tools [13]. However, to the best of the authors knowledge, a free-shape topological optimization has never been applied for the design of cooling channels in extrusion dies, thus motivating the proposed work.

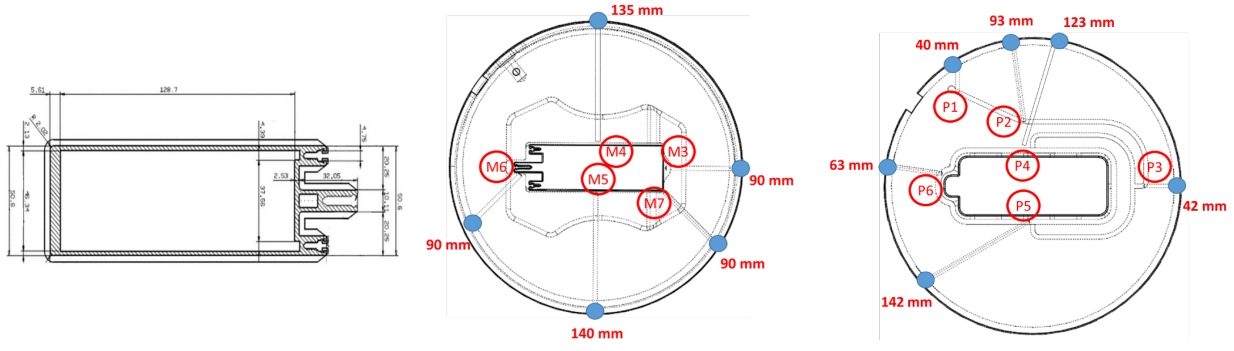
Therefore, in this context, an industrial case study previously investigated [10] has been selected to present and validate the approach. The process parameters and the experimental settings were selected as input for the subsequently numerical analysis. The original channel design, merely based on the die-maker expertise without the support of the simulation, was compared in terms of cooling efficiency with the new one designed using the numerical approach based on topological optimization.

Experimental Analysis

The Fig. 1 shows the tooling set composed by the mandrel, die and backer [10]. The mandrel with five portholes was designed to obtain the industrial hollow profile shown in Fig. 2a, while a planar cooling channel was manufactured in the backer surface in contact with the die (Fig. 1c).

a) b) c)

Fig. 1. The tooling set: a) mandrel; b) die; c) backer with the cooling channel [10].



a) b) c)

Fig. 2. a) Profile drawing, b) thermocouple locations in the die, c) thermocouple locations in the backer; dimensions in millimetres report the acquired depths of the thermocouple holes [10].

Eleven thermocouples were positioned within the tooling set (Figs. 2b and 2c) in order to monitor the temperature field during the whole extrusion process. Five thermocouples were placed in the die around the bearings where the highest temperatures were generated (M7 was broken during the trials), six in the backer by following the nitrogen path with the aim to evaluate the cooling channel performances. The experimental campaign consisted in the extrusion of seventeen AA6060 billets in different conditions of extrusion speed and nitrogen flow rate. In detail, four different conditions were evaluated, excluding the first billet used to warm up the tooling set: the extrusion process without nitrogen cooling using the standard ram speed of 8 mm/s selected by the extruder (billets 2-4), the extrusion process with nitrogen valve opened at 40% maintaining the standard ram speed (billets 5-8), the extrusion process with nitrogen valve fully opened maintaining the standard ram speed (billets 9-12) and the extrusion process at increased ram speed of 50% (12 mm/s) by continuing to use the maximum nitrogen flow rate (billets 13-17). The thermal history of the tooling set recorded by the thermocouples is reported in Fig. 3. At first, it is worth nothing the temperature difference of about 200°C already in the uncooled condition between the cooling channel plane and the bearings, a trend that highlights the great distance between the cooling channel and the area where the highest amount of heat is developed. In the die, the thermal field showed a rapid rise in temperature in all thermocouples during the extrusion of each billet and a subsequent temperature decrease during the dwell time for the billet change. On the other hand, the heat exchange between the hot die and the less warm backer made more stable the temperatures in the backer, showing minimal differences between the extrusion phase and the billet phase change.

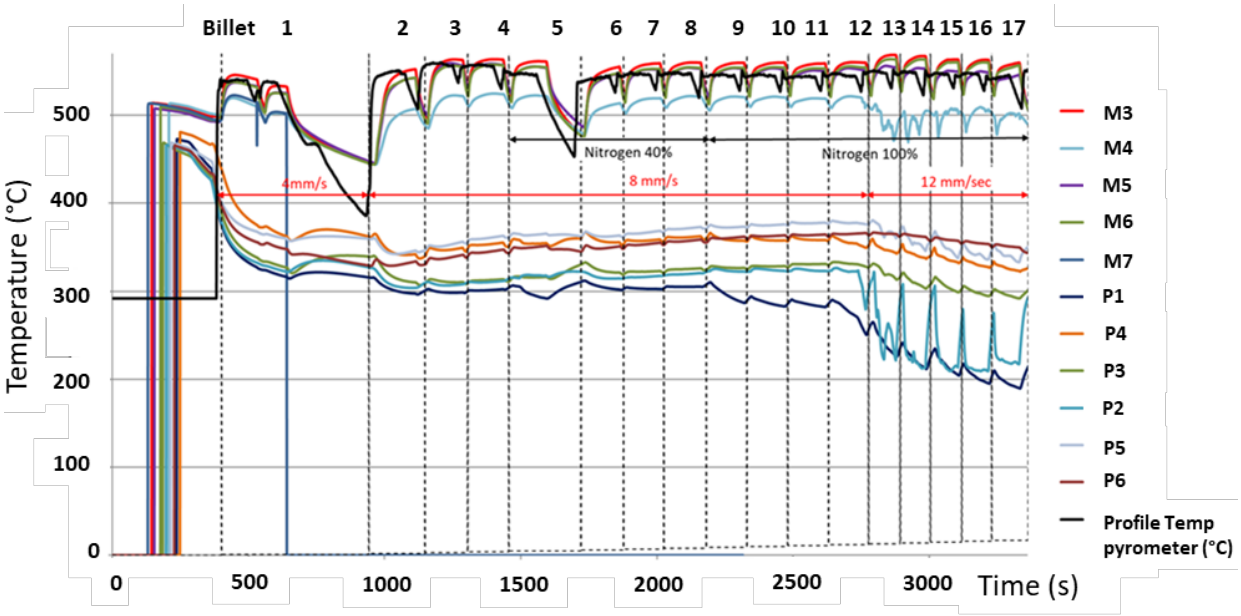


Fig. 3. Temperature history of the whole extrusion process [10].

By analyzing in detail the thermal history of the fourth billet (steady-state uncooled condition), it was detected the highest value of 565 °C in the bearings recorded by thermocouple M3, positioned closer to the short side of the profile without wings (Fig. 2b). Moreover, the thermocouples M6 and M5, positioned respectively near the wings and at the center of the lower side, acquired the same maximum temperature of 560 °C. The lowest temperature of 525°C was recorded by M4, located at the center of the upper side. In the backer, the lowest temperatures of 300°C and 311 °C were registered by the thermocouples P1 and P2 respectively, located along the initial portion of the cooling path. Thermocouples P3, P4, P5 and P6 were positioned in the die

and recorded temperatures of 313 °C, 355 °C, 360 °C and 345 °C, respectively. Notably, the higher radial distance of thermocouples P1-P3 than thermocouples P4-P6 from the profile exit was the cause of their temperature' differences.

Starting from the thermal field of the fourth extrusion, it is immediately clear the inefficiency of the cooling channel design since not significant change in temperatures was found both in the backer and in the die when the nitrogen valve was opened at 40% (billets 5-8). The same trend was obtained in the die from the ninth to the twelfth extrusion when the maximum nitrogen valve was used. Also during the last extrusion, after eight billets extruded with nitrogen cooling, the heat removal in the die had a limited effect visible only in the thermocouple M4 (from 525 °C of the uncooled condition to 505°C). When the nitrogen valve was opened at 40%, the combination of high-pressure drops induced by the channel design and the high thermal gradient between the nitrogen and the tooling set caused a formation of a large amount of gas nitrogen that congested the nitrogen flow within the channel (an increase of volume of 177 times occurs during the phase change). In addition, the selected channel design did not promote the gas purging, thus limiting the liquid nitrogen flow with a long transitory also when the nitrogen valve was fully opened (effective cooling only in P1 and P2 nearby the nitrogen inlet). Therefore, the experimental campaigns showed the limits of the selected channel design and confirmed the issues that can occur using a design approach based only on the experience. In the next paragraphs, after the validation of the numerical model of the extrusion process with nitrogen cooling, a first attempt of new design approach based on the topological optimization of the cooling channel is proposed and deeply assessed.

Numerical Model of Extrusion Process with Nitrogen Cooling

A full comprehensive numerical model of the extrusion process was implemented in the COMSOL Multiphysics code by modelling the extrusion process with a pure Eulerian approach. Therefore, the geometry of the material flow was in the already deformed configuration (Fig. 4a), the tooling set was merged into one solid tool to avoid the contact analysis, while the ram and the container, required only for a Lagrangian approach, were replaced by proper thermal and frictional boundary conditions. The cooling channel was replaced with a 1D cooling path that follows the middle line path of the real 3D channel and integrated within the 3D model of the tooling set (Fig. 4b). The numerical approach based on the 1D modelling of the nitrogen cooling was tested and validated in different previous works of the authors [8-11], proving the good accuracy of the achieved results at very reduced computational time if compared to the approach based on a full 3D model of the nitrogen flow. In this work, the accuracy of the numerical model was demonstrated by analyzing, in terms of temperature prediction, the experimental-numerical differences in both uncooled and cooled conditions.

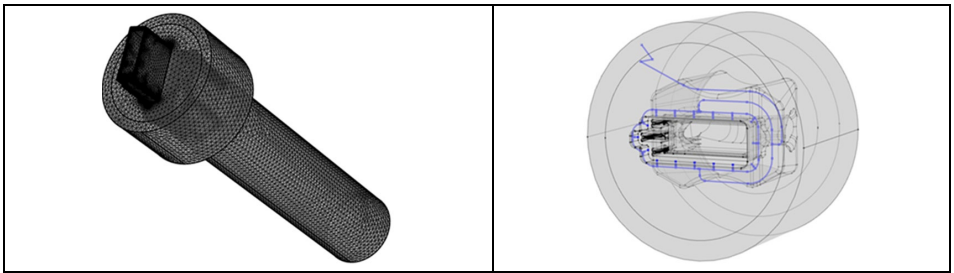

Fig. 4. The 3D model for the simulations: a) the billet and the die set, b) the tooling set combined with the 1D cooling channel.

Table 1. Process Parameters set in the comprehensive stationary simulations of the extrusion process.

Process Parameters	Billet 4	Billet 17
Billet Temperature	480 [°C]	480 [°C]
Die Temperature	520 [°C]	Starts from steady state uncooled simulation
Container Temperature	430 °C	Starts from steady state uncooled simulation
Ram Temperature	440 °C	Starts from steady state uncooled simulation
Temperature of backer surfaces in contact with press	280 °C	280°C
Ram Speed	8 [mm/s]	12 [mm/s]
Inlet Nitrogen Pressure		4.5 [bar]
Inlet Nitrogen Temperature		-196 [°C]

The numerical uncooled condition was compared with the fourth extrusion, while the stationary numerical analysis of the cooled condition was compared with the last extrusion where it was experimentally found a visible cooling effect in the tooling set. In Table 1 are reported the main parameters required to prepare the steady state 3D simulations of the extrusion process integrated with the 1D model of the cooling channel. About the nitrogen cooling, a model based on the Homogenous Flow approach [14] was implemented that allows to predict the pressure drops and the cooling channel inefficiency caused by the gas formation however avoiding the effective simulation of the phase change. Indeed, the physical properties of nitrogen (dynamic viscosity, density, heat transfer coefficient etc.) were replaced with expressions that depends on the nitrogen vapor title ω_g, not set constant but as a function of the heat exchange within the channel. The details about the model were presented and deeply discussed elsewhere [14]. Figure 5 shows the numerical comparison of the thermal field between the uncooled (billet 4) and the cooled (billet 17) conditions in the die and in the mandrel, specifically in the planes where the thermocouples were positioned. It is immediately clear that the simulation properly predicted the inefficiency of the cooling channel designed by the die maker: not significantly differences in temperature were obtained in the die, while the small cooling effect in the backer was localized at the entrance of the cooling channel nearby the thermocouples P1 and P2, confirming the experimental evidence.

In detail, Table 2 reports the experimental-numerical comparison in terms of thermocouple's temperature in the backer. Except for P2 and P4, the average numerical errors were below the 5%, thus confirming the accuracy of the implemented model and its capability to predict the cooling efficiency induced by the channel design and the nitrogen gas formation. In this way, the numerical testing of the cooling channel designed with the support of the topological optimization can be considered as trustworthy even in absence of an experimental testing.

Table 2. Thermocouple temperatures in the backer: Experimental vs Numerical results (Billet 4 and Billet 17).

	Thermocouples Temperature [°C]					
Billet 4	**P1**	**P2**	**P3**	**P4**	**P5**	**P6**

Topological Optimization

For the topological optimization of the cooling channel, only the backer surface was modelled (Fig. 6a) allowing the tool to "virtually milled" it by the nitrogen flow in order to satisfy the selected objective functions. In the topological optimization approach based on the density method [15], the nitrogen flow was modelled using the Darcy flow model in order to treat the backer as a porous media with the porosity and the other physical properties controlled with penalization functions [15]. Following this approach, the elements of the mesh with the porosity equal to zero were considered as solid with the physical properties of the steel, while the elements with porosity equal to one were treated as liquid nitrogen. The density approach was controlled by the output material volume factor θ having the following expression:

$$\theta = \frac{(\tanh(\beta(\theta_f - \theta_\beta)) + \tanh(\beta\theta_\beta))}{(\tanh(\beta(\theta_f - \theta_\beta)) + \tanh(\beta\theta_\beta))} \quad (1)$$

where θ_f is the filtered material volume factor, β the slope and θ_β the projection point. When θ was equal to one the material was considered liquid; on the contrary, it was considered solid with a zero value. The slope and the projection point were calibrated to control the interpolation through intermediate values (set equal to 1 and 0.5, respectively). The interpolation was then constructed such that the physical governing equations of fluid flow were solved wherever the control variable was equal to one, while equations associated with the solid material were solved where the control variable was equal to zero. In details, the permeability, conductivity, density and specific heat capacity were expressed by the selected formulations [15]:

$$c = c_l + (1-\theta)^3 * (c_s - c_l) \quad (2)$$
$$k = k_s + (1-\theta) * (k_l - k_s) \quad (3)$$

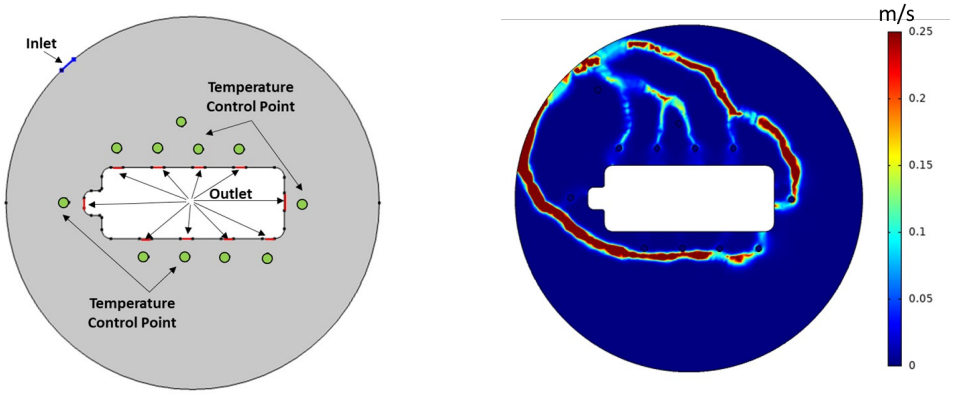
$$\rho = \rho_s + (1-\theta) * (\rho_l - \rho_s) \quad (4)$$

$$c_p = c_{ps} + (1-\theta) * (c_{pl} - c_{ps}) \quad (5)$$

where the subscript l indicates the properties of the liquid nitrogen, while the subscript s the properties of the steel. The Fig. 6a shows the initial setting for the topological optimization: one nitrogen inlet was selected close to the original one, ten outlets were selected instead of the sixteen of the original design in order to reduce the excessive pressure drops. The number of outlets were selected as input; however, further investigations will be focused on the possibility to include the choice of outlets as objective function. Eleven temperature control points were used to implement an objective function related to the temperatures balance around the profile exits. The latter was imposed as the minimization of the standard deviation with respect to the temperature control value of 250°C combined to the minimization of the differences in temperature between the control points:

$$\Delta T_{min} = \sqrt{\frac{\Sigma_{i=1}^{n} (T_i - T_{ref})^2 + \Sigma_{i,j=1\, i\neq j}^{n} (T_i - T_j)^2}{n + \frac{n!}{2*(n-2)!}}} \quad (6)$$

The temperature reference of 250°C was selected reasonable to avoid thermal shocks in the tooling set as well as to guarantee an adequate cooling in the bearings located away from the cooling channel. A convective heat flux perpendicular to the backer plane was defined as boundary condition (heat transfer coefficient of 11000 W/m^{2}K at a temperature of 550°C) with the aim to replicate, in a simplified way, the heat exchange between the backer and the hot die. As constraints, a maximum θ_{avg} of 0.25 was imposed, to avoid an excessive volume of channels (not feasible from a technological point of view), together with maximum inlet pressure of 5 bars, the maximum available for the nitrogen plant used during the experimental trials. The optimization problem was solved using the Method of Moving Asymptotes (MMA) [15-16].



a) b)

Fig. 6. Topological optimization: a) Problem setting, b) Velocity field of the nitrogen within the channel.

The Fig. 6b shows the velocity profile of the nitrogen flow after 280 iterations of the optimizer (computational time of 10h). The results obtained from the topological optimization was then used to design the new cooling channel. Fig 7 presents the comparison between the old and the new design. The L-shaped channel, that connected the external nitrogen pipeline with the backer surface, was imposed fixed in order to analyze the difference in terms of cooling efficiency of the sole planar path. The topological optimization suggested to split the channel in three different paths instead of just one with a lot of ramifications as in the original design. A rectangular cross-section was selected since the channel is commonly milled: the width of 8 mm was suggested by the results of the topological optimization, the depth was set variable in order to guarantee an adequate

nitrogen flow rate also in locations far from the inlet (for longer route, higher hydraulic diameter to reduce the pressure drops).

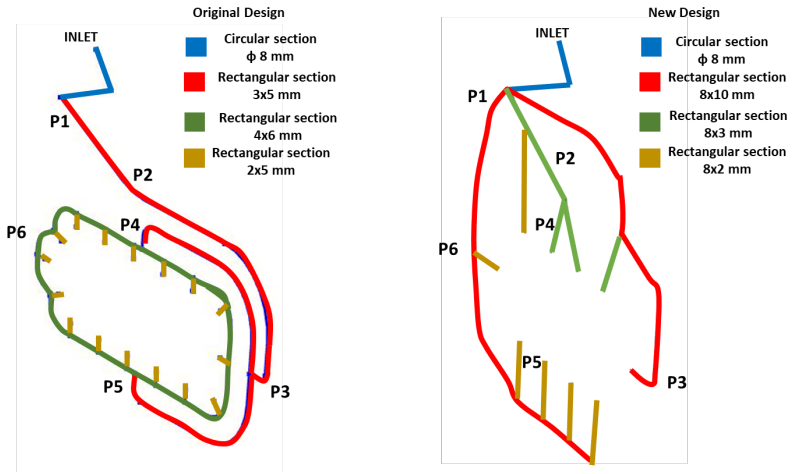


Fig. 7. The comparison between the old design and the new one.

Results and Discussion

The final step of the work was the testing of the new cooling channel design and the comparison with the old one in terms of cooling efficiency as predicted by the 3D model. The same process parameters and boundary conditions for the simulation of last extrusion were selected for both cooling channel designs (billet 17 in Fig. 3). In details, Fig. 8 evidences the differences in terms of cooling efficiency between the old design and the new one: a great cooling was achieved in the backer with the new design, highlighted by the large blue area around the profile exit, with a low cooling effect in the area near the right corner of the lower side, where the simulation properly predicted the gas formation. The great cooling effect obtained in the backer allowed to reduce the temperature around the bearings, detecting a minimum of 420°C in the thermocouple M4. The unbalance of the cooling in the backer caused the peak temperature difference of 45°C in the bearings (Table 4), thus suggesting the need for further investigation. Indeed, in this first optimization, the properties of the nitrogen within the Darcy fluid model were set constant and equal to those of liquid nitrogen, thus neglecting the effect of the phase change nearby the outlets of the longest cooling path. However, the achieved results clearly show the benefits of the proposed approach based on topological optimization of the cooling channel design, gaining a cooling efficiency significantly higher than that of the original design.

Table 3 Thermocouple temperatures in the Die: Old Design vs New Design (Billet 17).

Billet 17	Thermocouples Temperature [°C]

Summary

For the first time, an approach based on the topological optimization was implemented and tested for the design of the cooling channel in extrusion dies. The experimental campaign of the selected case study proved the limit of the design approach merely based on the experience without the support of numerical tools. The 1D model of the nitrogen cooling integrated with the 3D model of the extrusion process allowed to properly predict the cooling efficiency with an average experimental-numerical error of 6% in terms of temperatures, showing the poor performances of the original channel design. The new channel, designed on the basis of the topological optimization toolkit, guaranteed a great cooling in the backer and a significant decrease of temperature around the bearings (a maximum decrease of 104°C in the thermocouple M4). Further investigations will be focused on the integration of the nitrogen phase change in the topological analysis and on the testing of different objective functions in order to include, for example, technological constraints.

Keywords: Skin Contamination, Back-End Defect, FEM, QForm Extrusion, ALE Approach

Abstract. The paper presents an innovative approach implemented in QForm UK Extrusion FEM software to analyse one of the core defects encountered in profile extrusion known as billet skin defect. The validation of the algorithm has been performed based on a number of experimental case studies taken from the literature [1,2]. Additionally, the sensitivity of the accuracy of the results to the variation in initial parameters has been analysed for both types of profile shapes: solid and hollow. Based on this, practical recommendations have been formalised for the successful industrial use of the presented algorithm.

Introduction

Aluminium profile extrusion is a process that allows the production of numerous cross-sectional shapes: from simple solid forms to complex hollow shapes. Since these shapes are used for the most highly developed industries, they are subjected to strict requirements regarding geometrical and performance properties. In addition, the modern extrusion process has to be designed to provide high productivity combined with minimal material waste.

One of the typical defects inevitably formed during the direct profile extrusion process is the so-called billet skin defect which is a type of back-end defect. In general, the most critical form of this defect arises during the end of the process cycle if the inlet opening in the tool is incorrectly designed or if the discard length of the billet is too short. Eventually, it causes the penetration of the contaminated content into the profile (Fig. 1).

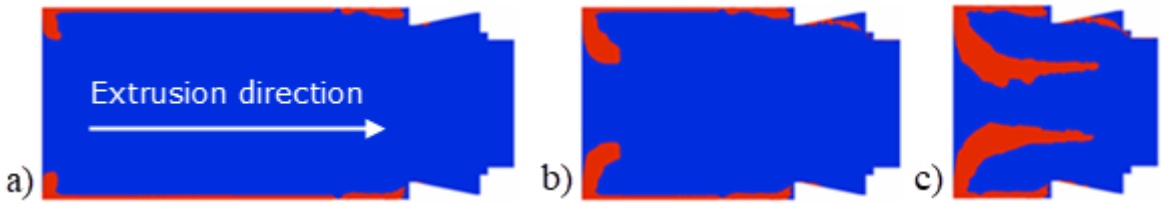

Fig. 1. Stages of extrusion: a) initial, b) intermediate, c) ending. Billet skin is marked by red.

In turn, this results in surface defects and a loss of durability in the finished product [3]. In technical literature it's common to distinguish two types of billet skin flow [2,3]. Flow type 1, also called inward flow, occurs when defective material flows into the tool ports along dead metal zones formed between the container and inlet surface of the tool. Since the material involved in such flow forms the outer shape of the profile, this flow may only lead to surface defects. Whereas, flow type 2, also called forward flow, occurs when the skin layer accumulated at the corner between the container wall and the contact surface of the dummy block starts to flow into the tool ports, causing the appearance of the defective material inside the wall of the profile cross-section.

Skin contamination of the profiles is a potential reason for increasing scrap in the aluminium extrusion process. However, it can be avoided if a proper discard length is chosen to sheer off all the accumulated contaminated material from the skin. The complexity of the process mechanics forcibly invokes the need for a numerical tool to accurately predict the optimal discard length. Even though the impact of the discard length significantly affects the overall process efficiency, few papers have been published on this subject. To the best of authors knowledge, only two studies were performed to investigate the skin defect on profiles of industrial complexity [4,5] where both front-end and back-end defects are analysed using numerical simulation with the Arbitrary Lagrangian Eulerian (ALE) approach. In [6], a Lagrangian approach was used for the simulation of the extrusion process and the skin propagation was checked by tracing the array of points located at the distance of the thickness of contaminated layer. On the one hand, the use of a pure Lagrangian tool resulted in an increase of the prediction accuracy but, on the other hand, it led to a considerable rise in computational time of the simulation.

Unlike the other case studies listed above, this paper aims to find a way to predict the billet skin defect in extruded profile's by means of ALE numerical simulation using an innovative method implemented in QForm UK Extrusion which combines high accuracy in the prediction with low computational time of the simulation.

Description of the Method for Simulation of Billet Skin Propagation

There are two basic ways to describe the motion of deforming material commonly used in numerical simulation, i.e., Lagrangian and Eulerian. Principal differences, limitations and other details of these approaches and their combinations are discussed in [7]. The method used in this paper for billet skin tracking involves points tracing over the Lagrangian-Eulerian mesh environment where points move based on the velocity solution achieved at every step of extrusion simulation of the entire billet.

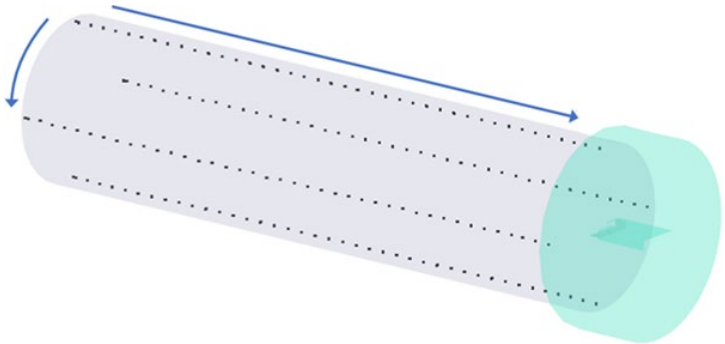

Fig. 2. Initial position of tracking points: 4 lines, 40 points per line.

The settings available as inputs for such kind of analysis are skin thickness, number of lines and number of points per line. Skin thickness value defines the points' radial offset from the upset billet's outer surface. The number of lines is the parameter that determines the number of sectors of the circle so that the points are created along the borders of these sectors. For example, if the number of lines is 2, then there are only two sectors 2x180° with lines located opposite each other,

if the number of lines is 4, then there are four sectors 4x90° (Fig. 2), etc. Additionally, there is a special continuous solid object built based on the specified points. Therefore, there are three different ways to plot the results of such kind of tracing, i.e., array of points, deformed continuous object and billet skin distribution presented in the same way as all the standard typical fields for FEM packages (Fig. 3). This kind of simulation is optional and performed in the post-processor by the implementation of a standard subroutine.

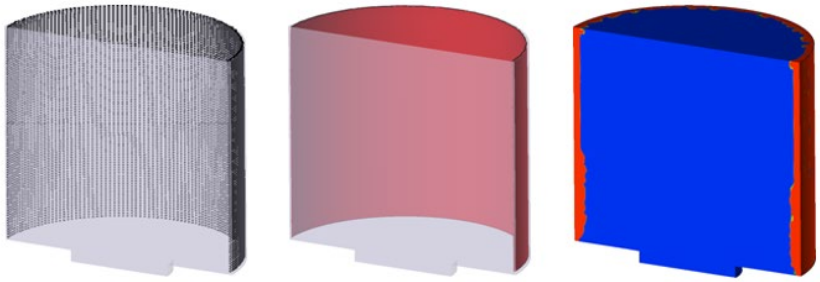

Fig. 3. Types of billet skin representation: array of points (left), continuous solid object (middle), field (right).

Description of the Case Studies

Solid profile.

The authors of the work [1] prepared the special billet with the core material of AA 6063 alloy and skin material of AA 3003 alloy. These materials have similar flow stress levels at high temperatures but react differently to the etching process, therefore billet skin propagation could be clearly recognised on the cross-cuts.

Table 1. Technological and geometrical parameters of the project.

Parameter	Value
Alloy	AA 6063
Extrusion ratio	5.5
Container temperature [°C]	Variable: 20, 500
Billet temperature [°C]	450
Tool temperature [°C]	450
Lubrication	Variable: with and without
Extrusion velocity [mm/s]	19
Billet length [mm]	91
Billet diameter [mm]	91
Container diameter [mm]	94
Ram stroke [mm]	69.5
Billet skin thickness [mm]	1

In this case study, the 40 mm bar was extruded through a flat die under different friction and temperature conditions. There were three experiments carried out, i.e., extrusion without lubricant with a cold container (room temperature), extrusion with a hot container (500°C) without lubrication, and extrusion using a hot container with a lubricated ram. This allowed the authors to obtain different results of metal flow patterns at the contact surfaces between the billet and tools, which eventually affected the shape of the contaminated layer. Process parameters and geometrical detail are listed in Table 1.

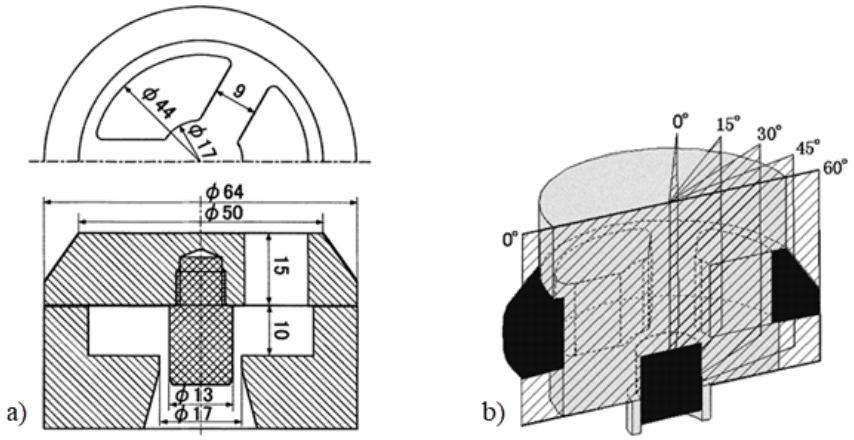

Fig. 4. Geometrical details of the second case study: a) tool scheme; b) cross-cut planes analysed in experiment (right).

Hollow profile.

In this case [2], AA 1100 alloy was used as a core material and AA 1050 as a billet skin material. Similar to the first presented case, the etching characteristics of the alloys differed, allowing qualitative identification of the billet skin propagation. For this purpose, the authors have designed a porthole tool with sixfold symmetry (Fig. 4a). The investigation was divided into two significant steps: analysis of the evolution of billet skin shape at different ram strokes for the case where no lubrication was used, and analysis of billet skin pattern depending on different friction conditions on ram and container. For both cases, the results of billet skin propagation were analysed for five different planes (Fig. 4b). Technological parameters and critical dimensions of the project are listed in Table 2. The authors of the work also performed tests using colloidal graphite lubrication but this part of the experiment isn't considered in the current paper.

According to the presented data, several simulations were done using a coupled thermomechanical task for the material flow domain and tools (Fig. 5).

Table 2. Technological and geometrical parameters of the project.

Parameter	**Value**
Alloy	AA 1100
Extrusion ratio	20.9
Container temperature [°C]	400
Billet temperature [°C]	400
Die temperature [°C]	400
Lubrication	Variable: no lubricant, boron nitride
Extrusion velocity [mm/s]	0.017
Billet length [mm]	50
Billet diameter [mm]	49.5
Container diameter [mm]	50
Ram stroke	Variable: from 35 to 46
Billet skin thickness [mm]	0.5

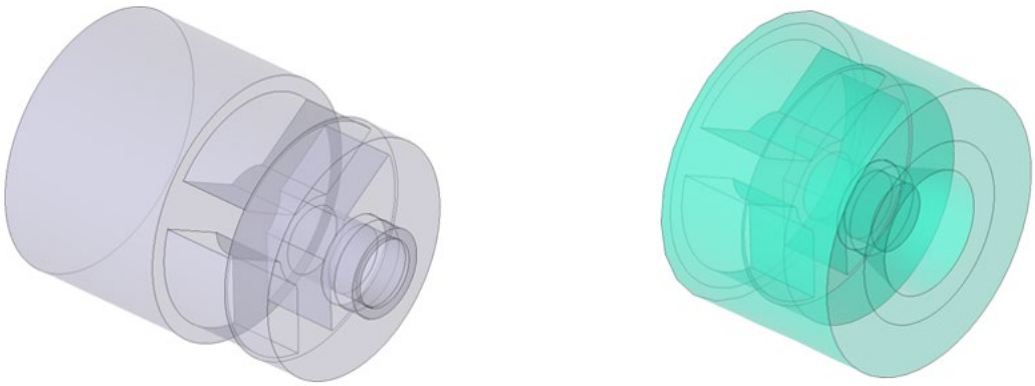

Fig. 5. Geometrical representation of the second case study: material flow domain (left) and porthole tool (right).

Description of the Models Used in the Simulation

Coupled task.

Material flow and temperature are simulated, taking into account the deformation of the tool and the temperature distribution in it. This means that tool deformation influences the material flow, while the tool distortion itself depends on the material's contact pressure. Similarly, temperature evolution in billet material is defined not only by heat generation due to plastic deformation and friction but also by heat exchange with the tool. Such a coupled solution is obtained through several iterations combined with automated remeshing of the flow domain. The heat flux between the billet and tooling set is specified by Newton-Richmann law in the following form:

$$q_n = \alpha(T_1 - T_2) \tag{1}$$

where α - heat transfer coefficient (by default equal to 30000 W/m^2K in QForm UK Extrusion), which takes into account the number of coefficients of heat transfer between the workpiece and lubrication and between lubrication and the tool, T_1 is the billet temperature, T_2 is the tool temperature.

Table 3. Hensel-Spittel parameters for AA 6063 and AA 1100.

Parameter	Solid design	Hollow design
A [MPa]	250.7	265
m_1 [K^{-1}]	-0.000498	-0.00458
m_2	0.126346	-0.12712
m_3	0.135122	0.12
m_4	-0.0052884	-0.0161
m_5 [K^{-1}]	-1.06775x10^{-6}	0.00026
m_7	0.00005655	0
m_8 [K^{-1}]	2.53717 x10^{-8}	0
m_9	0	0

Flow stress.

Hensel-Spittel equation (2) defines the dependence of the flow stress (σ_s) on the strain (ε), strain-rate ($\dot{\varepsilon}$), and temperature ($\boldsymbol{T}$) were used to describe flow curves for the billet material used in both considered projects. Table 3 contains values of the coefficients used in the simulation.

$$\sigma_s = A \cdot e^{m_1 T} \cdot T^{m_9} \cdot \varepsilon^{m_2} \cdot e^{\frac{m_4}{\varepsilon}} \cdot (1+\varepsilon)^{m_5 T} \cdot \varepsilon^{m_7 \varepsilon} \cdot \dot{\varepsilon}^{m_3} \cdot \dot{\varepsilon}^{m_8 T} \quad (2)$$

Friction.

Levanov friction law was used to describe friction between aluminium and steel. This friction model is a generalisation of the Coulomb and Siebel friction laws. When the normal contact pressure is low (typical for the bearing area), Levanov's shear stress is close to Coulomb's. When the normal contact pressure is high (which is typical for the rest of the billet usrface), Levanov's shear stress is close to Siebel's shear stress. According to the Levanov friction model, the shear stress (τ) on the contacting surface of the workpiece depends on the friction factor ($\boldsymbol{m}$), flow stress ($\sigma_{\boldsymbol{s}}$) of the workpiece material, normal contact pressure ($\sigma_{\boldsymbol{n}}$), and Levanov coefficient ($\boldsymbol{n}$):

$$\tau = m \cdot \frac{\sigma_s}{\sqrt{3}} \cdot \left(1 - e^{-n \cdot \frac{\sigma_n}{\sigma_s}}\right) \quad (3)$$

In QForm UK Extrusion the default value of Levanov coefficient that was used for all simulations is equal to 1.25.

Mesh.

To investigate the impact of initial mesh size, two different mesh variations were created for both hollow and solid profile designs, where an increased adaptation coefficient in the container area was used to make the mesh finer. The visual and quantitative differences between the initial and adapted mesh can be seen in Fig. 6 and Table 4, respectively.

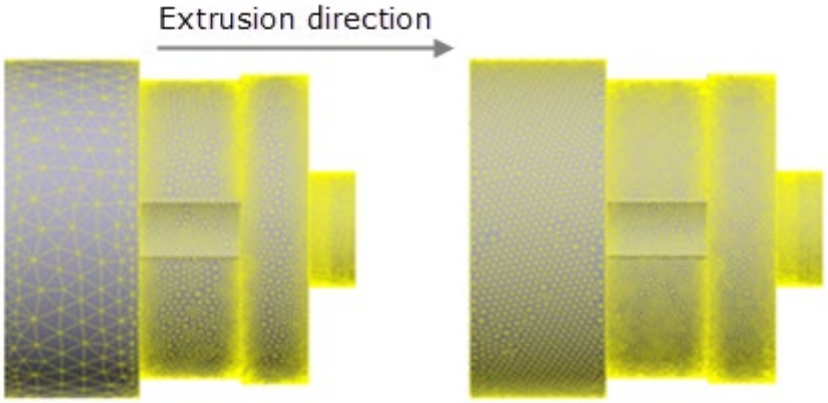

Fig. 6. Initial (left) and adapted (right) mesh for hollow profile.

It's been observed that for the proposed approach mesh density influenced the smoothness of the resulting skin shape but didn't significantly affect the qualitative picture of its propagation. Therefore, further analysis is presented for the cases with mesh generated with the default settings.

Table 4. Mesh properties.

	Initial mesh	**Adapted mesh**
Nodes, #	145586	174961
Surface elements, #	70958	91570
Volume elements, #	786554	931870

Results and Discussion

Solid profile.

The simulation of the extrusion process was performed using standard hot AA 1100 alloy available in the QForm material database. The total computational time for the simulation resulted in 2 hours. For the cases where no lubrication was used in actual experiments, the friction properties were selected according to the default extrusion settings, i.e., Levanov friction law with the friction factor equal to 1. For the experiment where lubrication was used, the friction factor (m) was assumed to be equal to 0.5 in simulation to evaluate the sensitivity of this parameter on the final result.

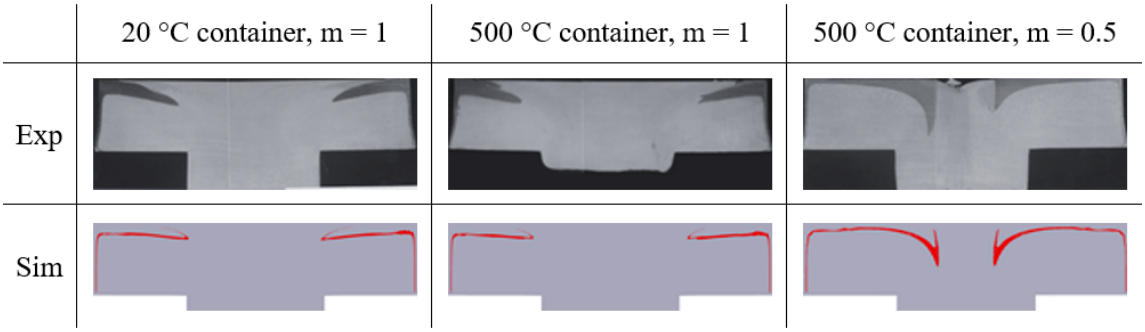

Fig. 7. Comparison of billet skin propagation in experiments with the solid profile.

As it can be clearly seen from Fig. 7, simulation has fully matched the experimental results. It's worth mentioning that the difference in container temperature (20°C vs 500°C) had no significant effect on the results of billet skin flow. Which is quite logical in this case since the design configuration is simple and difference in temperature doesn't affect the general behaviour of the flow pattern.

Nevertheless, the change in friction conditions on the ram surface led to a significant change in the billet skin shape. In this case, the use of lubricant worsened the flow pattern of billet skin since the contaminated material is located closer to the bearing exit of the tool.

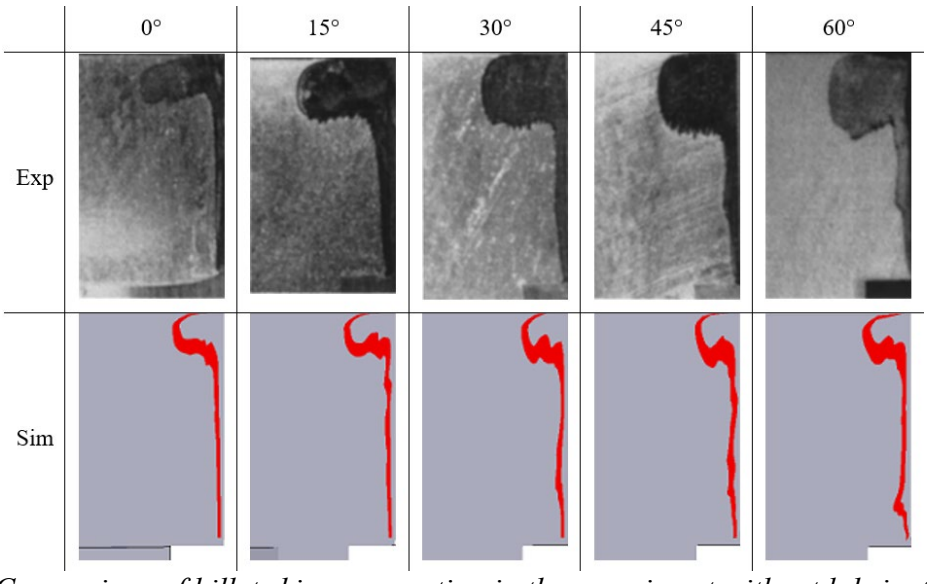

Fig. 8. Comparison of billet skin propagation in the experiment without lubrication and simulation for 35 mm ram stroke.

It can also be seen that the experimental result in the case of the lubricated contact surface of the ram is remarkably asymmetrical. It could be caused by different production factors such as inaccurate container alignment, an asymmetrical upsetting of the billet in the container, etc. In a simulation the asymmetry is also possible but mostly due to the difference in the mesh. In general, such kind of asymmetry can be minimised or even eliminated by making the mesh finer or by the use of symmetry planes.

Hollow profile.

In this case, the simulation was performed with standard extrusion AA 6063 alloy from the QForm material database. The total computational time for the simulation resulted in 3 hours and 30 minutes. As mentioned before, the first step of algorithm verification was to assess the evolution of billet skin shape at different ram strokes. For all the experiments where no lubrication was used, the friction conditions were set in accordance with the default extrusion friction available in the QForm database mentioned before.

Fig. 8 presents the results of the first test where the process was stopped at 35 mm ram stroke. It can be seen that the most intensive propagation of the contaminated layer is achieved on the cross-cut located in the middle of the port (60°). The area of billet skin decreases as you move away from this section reaching its minimum on the cross-cut plane (0°) placed right in the middle of the mandrel web (separation element of the tool). Simulation shows a similar trend of billet skin propagation qualitatively matching experimental results. For both practical and simulation results the origination of inward flow can be seen in sections 45° and 60°.

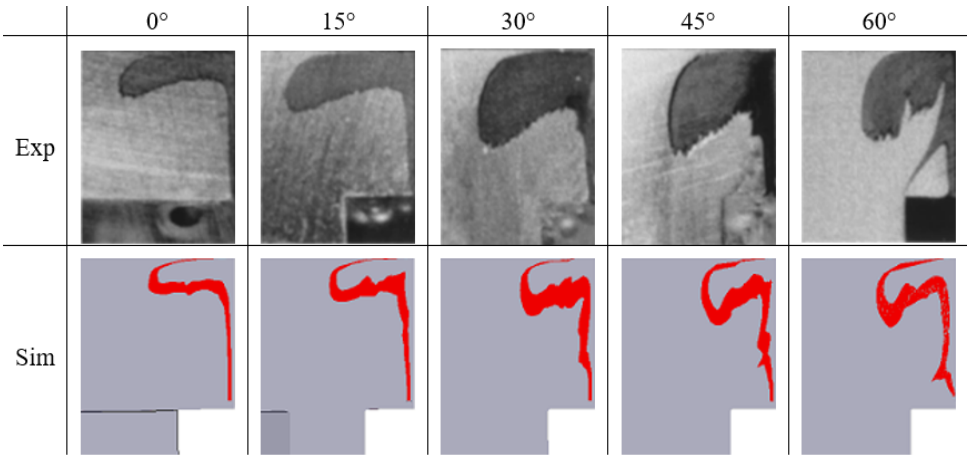

Fig. 9. Comparison of billet skin propagation in the experiment without lubrication and simulation for 41 mm ram stroke.

Fig. 9 compares the results of the same test but with the ram stroke equal to 41 mm. In this case, the inward flow is clearly defined for section 60°, which determines the intensive metal flow from the regions close to the container surface. Whereas the flow in section 0° that crosses the middle of the web has no sign of inward flow and billet skin propagates radially along the ram surface. For this stage of the process (41 mm ram stroke) simulation shows qualitatively the same result obtained in the practical experiment, which indirectly confirms the general correctness of the initial parameters used in the simulation. Slight deviations in inward flow might be caused by the sensitivity of this kind of back-end defect to the mesh size, specifics of the tracing algorithm or billet skin visualisation in the software.

In a similar way, Fig. 10 presents the results of the final moment of the extrusion process of the billet for the ram stroke equal to 46 mm. At this stage contaminated material flows into the ports for the sections 30°, 45° and 60°.

Another part of the investigation in this experiment was assessing the impact of lubrication on the flow pattern of billet skin. To simulate this influence, the friction factor was assumed to be equal to 0.9 on the contact surfaces of the ram and container. In this case, simulation matched the experimental result quite well (Fig. 11) with a minor deviation that adjustment of the friction factor

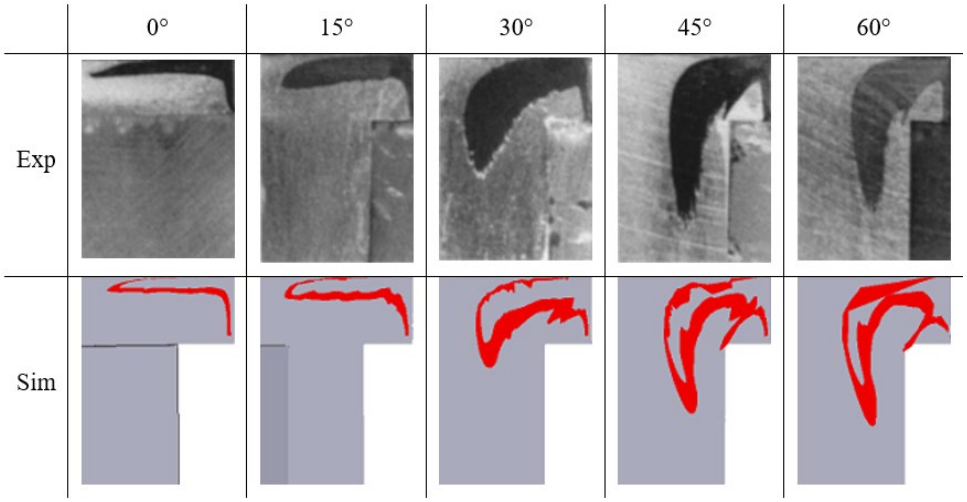

Fig. 10. Comparison of billet skin propagation in experiment without lubrication and simulation for 46 mm ram stroke.

can eliminate. In this case, if compared with the process that was carried out without lubrication for a similar ram stroke, it can be clearly seen that the volume of contaminated material approaching the ports is less, which indicates the positive influence of lubrication on billet skin propagation in contrast to the result obtained for the solid profile. However, it should be noted that containers of direct extrusion of aluminium profiles are generally not lubricated in industrial conditions.

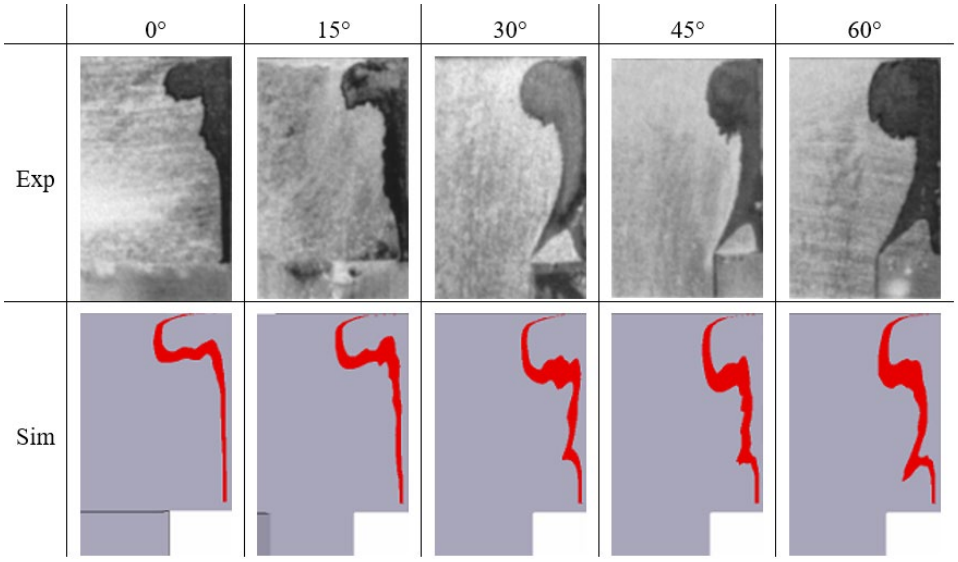

Fig. 11. Comparison of billet skin propagation in experiment with BN lubrication and simulation for 39 mm ram stroke.

Summary

In the present work, the innovative method of billet skin prediction implemented in QForm UK Extrusion was used and verified based on two experimental studies. It's worth noting that from a practical point of view, the results obtained in cases where no lubrication was used have a higher

value, since most industrial extrusion trials are performed without any lubrication of the container, ensuring the adhesion of billet aluminium to tool steel. The qualitative comparison was carried out for solid and hollow profiles extruded with different friction conditions. Parameters affecting the accuracy of this method have been varied to define the sensitivity of the applied approach.

As a summary, the presented research allows us to draw the following key findings:

- A good numerical-experimental matching was achieved on the skin contamination behaviour with and without lubrication.
- The total computational time for the two simulations (2 hours for the solid profile, 3 hours, and 30 min for the hollow profile) proved to be several times lower than the computational time reported in [6] without causing a decrease in the prediction accuracy. PC with Intel Core i9-9940X (14 cores, 4.20 GHz max. frequency) was used to obtain simulation results.
- Friction is a crucial parameter affecting the propagation of the contaminated layer.
- Default friction settings recommended for simulation in QForm UK Extrusion provided high accuracy of the results for experiments carried out without lubrication.
- Lubrication can lead to both positive and negative effects on the propagation of the contaminated layer.
- Even a significant change in container temperature has a minor effect on the flow pattern of billet skin in case of extrusion of simple solid bars.

Keywords: Crystal Plasticity, Twist Extrusion, Severe Plastic Deformation

Abstract. Severe plastic deformation (SPD) induced by conventional forming processes such as extrusion has a significant effect on texture evolution and strength of metals. Conventional twist extrusion (TE) process can be used to produce ultra-fine grained (UFG) structures without introducing any significant change in the overall dimensions of the sample. However, the commercialization for industrial usage has been limited because of production efficiency and non-uniform distribution of grain refinements. In order to overcome these difficulties a new process called nonlinear twist extrusion (NLTE) has been introduced recently where TE mold channel is modified to restrain strain reversal and rigid body rotation of the workpiece. Prediction of the texture evolution in these processes is crucial for mold design and process parameters. In this work, the texture evolution during NLTE and TE processes are investigated through crystal plasticity finite element method. Single copper crystal which has a billet form is fully extruded through the TE and NLTE mold models separately. In addition to spatial stress and strain evolution investigations, the orientation differences and texture evolution of extruded billets are examined for two different initial orientations of single copper crystal. Moreover, the deformation histories at different locations of the sample are analyzed with crystal plasticity finite element method (CPFEM) to compare the performance of both techniques.

Introduction

Severe Plastic Deformation (SPD) is an efficient manufacturing technique to produce ultrafine-grained (UFG) structures with high densities of lattice defects. In recent years, SPD methods have been popular with their capability for refining the grain size of materials to sub-micrometer and nanometer scales [1]. The strength and resistance to the plastic flow of polycrystalline materials depend on the grain size. Usually, UFG materials have several advantages compared to coarse-grained counterparts with their high strength and other superior properties, including potential use in super-plastic forming operations at elevated temperatures [2]. Various early reports describe interesting results from different SPD techniques to produce UFG structured materials. Equal channel angular pressing (ECAP) (see e.g. [3]), high-pressure torsion (HPT) (see e.g. [4]), accumulated roll bonding (ARB) (see e.g. [5]), multi-directional forging (MDF) (see e.g. [6]), and twist extrusion (TE) (see e.g. [7]) can be listed as the most popular SPD processes. All these methods have certain advantages and disadvantages compared to each other. ECAP process has some operational difficulties and produces excessive waste compared to the other SPD processes. A potential problem in HPT processing is the strain which varies across the disk specimen. Besides, HPT and ECAP processes do not apply to large bulk materials. ARB process also suffers in-homogeneity of strain distribution, and it requires multi-passes. The grain refinement ability of MDF is lower than all other SPD processes, and grain size reduction is not homogenous through the center of the sample. TE process has in-homogenous distribution characteristics, and strain

Content from this work may be used under the terms of the Creative Commons Attribution 3.0 license. Any further distribution of this work must maintain attribution to the author(s) and the title of the work, journal citation and DOI. Published under license by Materials Research Forum LLC.

distribution increases from the center to the periphery. It also requires multi-passes to increase the homogeneous distribution of grains through the workpiece.

In SPD processing, UFG formation is facilitated in deformation routes that involve high dislocation accumulation, and strain reversal or redundant strain reduces the rate of the dislocation accumulations and hence retard the UFG formation. Therefore, the non-linear twist extrusion (NLTE) technique has recently been developed by the authors (see [8]) based on TE, aiming to avoid strain reversal and rigid body rotation, which retard the UFG formation. Numerical analysis of the NLTE process shows the advantages of this process in terms of punching force and deformation distribution.

The numerical modeling of texture evolution during SPD techniques is crucial for understanding the grain refinement mechanisms. The results can be used for optimizing the process and mold parameters for SPD methodology. Nowadays, the crystal plasticity finite element method (CPFEM) is an effective tool for simulating texture evolution during SPD. In recent years, CPFEM simulations of some SPD methods have been performed in various studies. For example, the capability of the CPFE approach in predicting texture formed during ECAP and deformation heterogeneity of single crystal materials were examined (see e.g. [9]). The deformation history and texture evolution during TE were investigated (see e.g. [10]). Crystallographic texture evolution in simple shear extrusion (SSE) process was compared with experimental results (see e.g. [11]). Coupling of FEM flow and crystal plasticity simulations were conducted during the helical extrusion process (see e.g. [12]).

In this study, a single copper crystal with a billet form is fully extruded through the TE and NLTE mold models separately. In addition to spatial stress and strain evolution investigations, the orientation differences and texture evolution of extruded billets are examined for two different initial orientations of single copper crystal, i.e. (<111>and<100>) using crystal plasticity finite element technique. Moreover, the deformation histories at different locations of the sample are analyzed to compare the performance of both methods.

Finite Element Models

Fig. 1 shows the Abaqus finite element models of the twist extrusion processes. In the LTE process, a billet is pressed through a die with two straight channels separated by a section with helical geometry. Apart from being continually rotated in the helical part of the die, a cross-section of the billet normal to the extrusion axis stays unchanged during its translational movement. The mold model of LTE and punch are considered rigid bodies in CPFEM simulations. Encastre boundary conditions (u1=u2=u3=R1=R2=R3=0) were applied through mold geometry from its rigid body reference point (center of mass). Velocity boundary conditions (2 mm/s) were applied through punch rigid body reference point (center of mass). Similarly, the model forNLTE is also presented in Fig. 1.

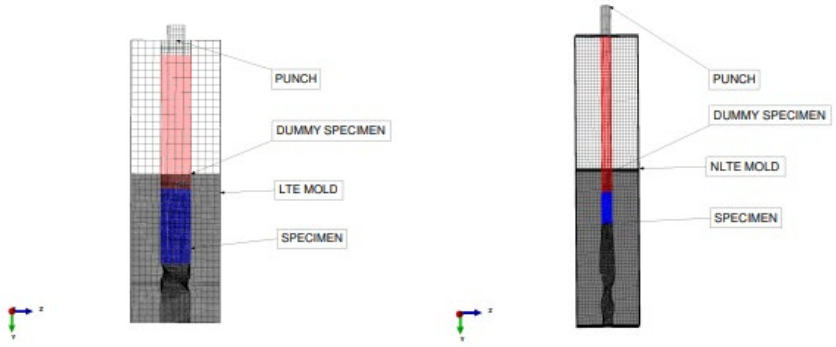

Fig. 1. LTE (left) and NLTE (right) processes FEM model.

Table 1. FEM model mesh parameters of simulated LTE and NLTE processes.

Model	Element Type	Element Family	Number of Elements
LTE Mold	Implicit-Tetrahedral-C3D4-Rigid	3D Stress	33777765
LTE Punch	Implicit-Hexahedral-C3D8R	3D Stress	925
LTE Specimen	Implicit-Hexahedral-C3D8R	3D Stress	159989
NLTE Mold	Implicit-Tetrahedral-C3D4-Rigid	3D Stress	419316
NLTE Punch	Implicit-Hexahedral-C3D8R	3D Stress	1679
NLTE Specimen	Implicit-Hexahedral-C3D8R	3D Stress	48750

The significant difference from LTE is that the billet is extruded, keeping rotation around the longitudinal axis so that the strain reversal is avoided. The mold model of NLTE and punch are considered rigid bodies. Boundary conditions are applied to the model same as in LTE simulations. Single copper crystal specimens are modeled with square and cylindrical shapes for LTE and NLTE, respectively. The square specimen dimensions were 20mm × 20mm × 50mm, and the dimensions of the cylindrical specimen were 20mm r = 10mm×30mm. Mesh properties of SPD models are presented in Table 1.

Crystal Plasticity Constitutive Model

This study utilizes a modified version of a crystal plasticity framework implemented as a UMAT (user-defined material model) subroutine [13]. In the classical crystal plasticity theory, the deformation gradient tensor **F** is multiplicatively decomposed into an elastic component $\boldsymbol{F^e}$ and a plastic component $\boldsymbol{F^P}$ [14] according to

$$\boldsymbol{F = F^e F^p} \tag{1}$$

According to Schmidt's Law, the resolved shear stress (τ^α) on a slip system is the leading cause of dislocation slip [15], which can be calculated by,

$$\tau^\alpha = \boldsymbol{\sigma}: \mathbf{s}^{*\boldsymbol{\alpha}} \otimes \mathbf{m}^{*\boldsymbol{\alpha}} \tag{2}$$

In Eq. 2, $\boldsymbol{\sigma}$ is the Cauchy stress tensor is projected on the slip systems where $\mathbf{m}^{*\boldsymbol{\alpha}}$ and $\mathbf{s}^{*\boldsymbol{\alpha}}$ are the slip direction and normal to slip plane in the current configuration, and α represents the slip system number. $\mathbf{m}^{\boldsymbol{\alpha}}$ and $\mathbf{s}^{\boldsymbol{\alpha}}$ are in the reference configuration,

$$\mathbf{s}^{*\boldsymbol{\alpha}} = \mathbf{F}^{\mathbf{e}}\mathbf{s}^{\boldsymbol{\alpha}} \tag{3}$$

$$\mathbf{m}^{*\boldsymbol{\alpha}} = \mathbf{m}^{\boldsymbol{\alpha}}\mathbf{F}^{\mathbf{e-1}} \tag{4}$$

The plastic velocity gradient, $\mathbf{L^P}$ is calculated by,

$$\dot{\mathbf{F}}^{\mathbf{p}}\mathbf{F}^{\mathbf{p-1}} = \mathbf{L}^{\mathbf{P}} = \sum_{n=1}^{\alpha} \dot{\gamma}^\alpha \mathbf{s}^{\boldsymbol{\alpha}} \otimes \mathbf{m}^{\boldsymbol{\alpha}} \tag{5}$$

The power law type rate-dependent formulation, which relates the slip rate on each slip system to the resolved shear stress τ^α and the slip resistance g^α is given in Eq. 6

$$\dot{\gamma}^\alpha = \dot{\gamma}_0 \text{sign}(\tau^\alpha) \left| \frac{\boldsymbol{\tau^\alpha}}{\mathbf{g}^{\boldsymbol{\alpha}}} \right|^{\mathbf{n}} \tag{6}$$

where $\dot{\gamma}_0$ is the reference shear strain rate, and n is the rate sensitivity parameter. The slip resistance g^{α} is calculated considering the latent hardening as presented below. The hardening moduli $h^{\alpha\beta}$ gives the rate of strain hardening on slip system α due to slip system β. The occurrence of self and latent hardening is phenomenologically described by Eq. 8, with q representing latent hardening matrix.

$$\dot{g}^{\alpha} = \sum_{k=1}^{12} h^{\alpha\beta} \left|\dot{\gamma}^{\beta}\right| \tag{7}$$

$$h^{\alpha\beta} = q^{\alpha\beta} h^{\alpha\alpha}(\gamma) \tag{8}$$

Pierce, Asaro, and Needleman [16] have used a simple form for the self-hardening moduli,

$$h_{\alpha\alpha}=h(\gamma)=h_0 \operatorname{sech}^2 \left|\frac{h_0\gamma}{g_s-g_0}\right| \tag{9}$$

where h_0 is the initial hardening modulus, g_s is the stage I stress, and γ is the Taylor cumulative shear strain on all slip systems in Eq. 10.

$$\gamma = \sum_{\alpha} \int_0^t |\dot{\gamma}^{\alpha}| dt \tag{10}$$

In the literature, there is a lot of inconsistent experimental data for single-crystal copper tension tests. Therefore, pure copper polycrystalline stress-strain data under tensile tests are used to calibrate single-crystal copper mechanical properties through homogenization. Symmetric boundary conditions are applied to representative volume element (RVE) cube composed of 500 hundred randomly oriented grains. RVE cube is illustrated in Fig. 2. Data and homogenization curve are illustrated in Fig. 3. The Parameters of a single copper crystal are given in Table 2.

CPFEM Simulation Results

Finite element simulations of LTE and NLTE processes are performed for initially <100> and <111> oriented single copper specimens. The simulations illustrate an initial quadratic increase of the load in LTE and NLTE processes when the specimen head enters the twist zone. After the sudden increase, the slope of the curve starts to decrease, and the punch force slightly increases throughout both processes. The required punch force is less than the LTE process for the NLTE process (Fig.4). This is one of the prominent advantages of NLTE. Black curves show the initially <111> oriented single copper crystal results, and green curves show the initially <100> oriented single copper crystal simulation results. In the LTE process, initially <100> oriented single copper crystal faces with more punch force compared to initially <111> oriented single copper crystal. On the contrary, in the NLTE process, initially <111> oriented single copper crystal needs more punch force throughout the process. Since the cross-section areas are different for both cases, punch pressures are compared for a better presentation. However, the punch forces are dependent on the frictional coefficient. In these calculations, the friction coefficient is set to be low (less than 0.01) due to the convergence problems of implicit solver in contact non- linearities and frictional discontinuities. If the fiction coefficient increases, the punch forces will also increase for both processes. The sharp increase in the LTE case is due to the sudden change in the cross-section, which does not exist in the proposed smoother non-linear process.

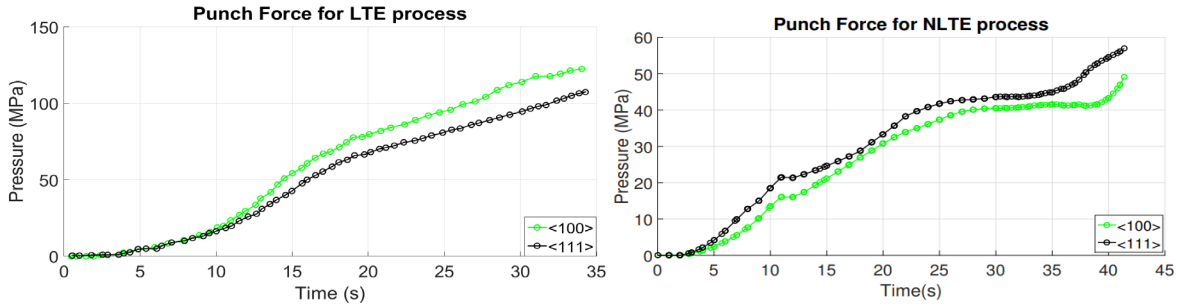

Fig. 4. LTE and NLTE processes punch forces according to the single-crystal copper initial orientation.

Von Mises stress contours are illustrated in Fig. 5 and Fig.6 for LTE and NLTE processes for initially <100> oriented single copper crystal, respectively. The stress values show an increase from the specimen center to the periphery, and maximum stresses can be observed at the edge of the surfaces. In the LTE process, stress evolution is more heterogeneous, and higher stress values are obtained in periphery regions. On the contrary, in the NLTE process, the stress distribution is more homogenous, and high-stress values are inspected in the periphery region and throughout the single copper specimen.

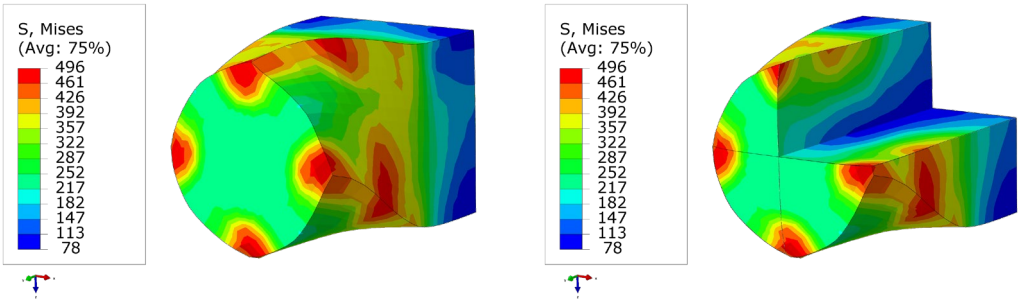

Fig. 5. Von Mises stress (MPa) results of <100> oriented copper single crystal after one pass of LTE (left) with section view (right).

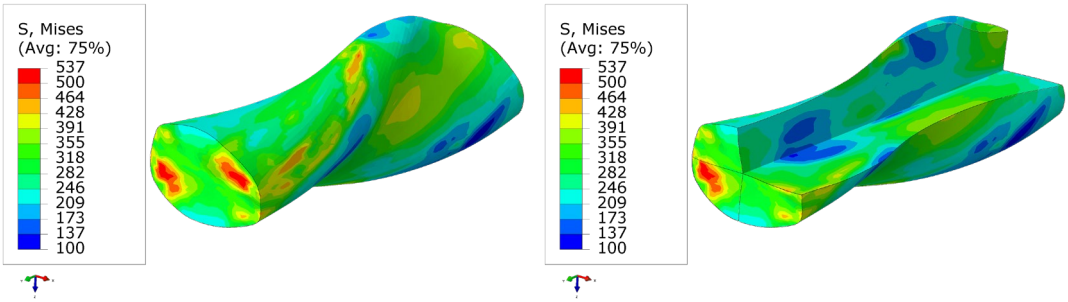

Fig. 6. Von Mises stress (MPa) results of <100> oriented copper single crystal after one pass of NLTE (left) with section view (right).

Fig. 7 and Fig.8 show the equivalent plastic strain distribution in LTE and NLTE processes, for initially <111> oriented single copper crystal, respectively. In the LTE process, a smaller magnitude of equivalent plastic strain evolves around the specimen center, and there is a gradual increase from the center to the surface of the specimen for both initial conditions. Distinctively, in the NLTE process, equivalent plastic strain evolves uniformly. Equivalent plastic strain distributions are more homogenous in the center when compared to the periphery region. Single copper crystal is subjected to much more plastic equivalent strain during the NLTE process. To show the deformation characteristics of LTE and NLTE processes, two typical elements of workpieces were chosen at the center and the periphery sections of the specimen distinctively. The selected elements are highlighted in Fig. 9.

Certain texture components of face-centered cubic (FCC) materials assist in understanding the final texture of a single copper crystal after deformation. Table 3 pole figures show the main texture components of FCC materials: Copper, Brass, Goss, and S orientations. It gives information about mechanical behaviors and physical and chemical properties of materials and is associated with the performance in their production and investigation in engineering applications. Hence, an accurate understanding of deformation mechanisms and precise control of texture evolution becomes a requirement for developing new materials [18].

Materials Research Proceedings 28 (2023) 553-562 https://doi.org/10.21741/9781644902479-60

Table 3. Texture components and pole figures for face centered cubic (FCC) materials according to [111], [110] and [100] plane respectively [19].

Components Name	Directions	Bunge Euler Angles (ZXZ)	Pole Figures of Components [111] [110] [100]
Cube	[001]<100>	0º 0º 0º	Goss	[011]<100>	0º 45º 0º	Brass	[0-11]<211>	35º 45º 0º	
Copper	[-211]<111>	90º 35º 45º	S	[111]<110>	60º 32º 65º	
FCC materials with high or medium stacking fault energy (SFE) grains tend to rotate toward the copper-type textures with increasing deformation, and dislocation slip has been recognized as the dominant deformation mechanism during the whole deformation stage. SFE plays an essential role in determining the dominant mechanisms of plastic deformation. In metals with high SFE (e.g., aluminum and copper), slip is the dominant deformation mode, and the rolling texture is composed of copper, brass, and S texture components. In materials with low SFE, the copper-oriented grains cluster at the prior deformation stage. However, with increasing loading, these grains rotate to the brass-type textures, and the latter dominates in the final textures' at large deformations. The rolling texture in these metals is known as alloy-type texture and is composed of a strong brass component and a minor Goss orientation [20]. After the first pass of LTE and NLTE processes, results for the center and periphery elements are illustrated in Fig.10, respectively. The initial orientation distributions significantly change by the processes for one pass. The distribution of the orientations in pole figures after the LTE and NLTE processes resemble the main orientation pole figures of copper and s textures orientation distributions. Thus, the pole figures of NLTE and LTE processes show that the elements of the single copper specimen face shear deformation during both processes, and their dominant deformation is dislocation slip. Moreover, after one pass, the center and periphery elements' orientation distributions are very close in the NLTE process compared to the LTE process.

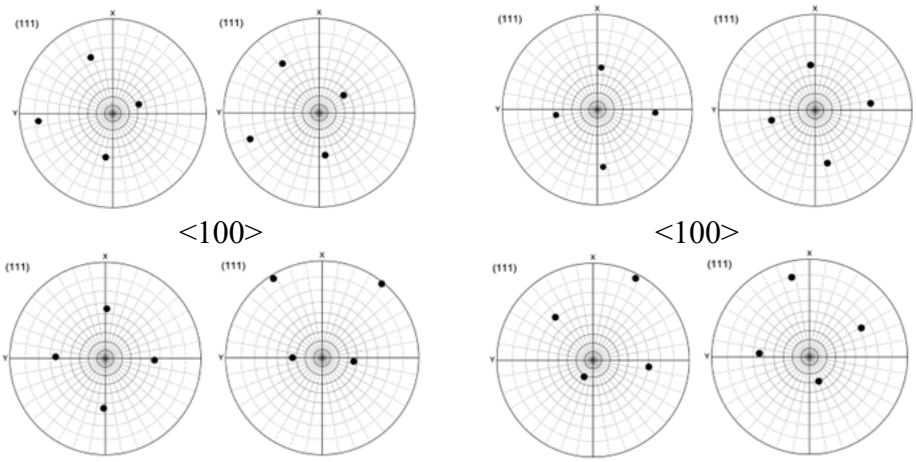

Fig. 10. Pole figures of center (left) and periphery (right) elements of single crystal copper specimen after LTE process according to the initial orientations (<100> and <111>) (Left) and pole figures of center (left) and periphery (right) elements of single crystal copper specimen after NLTE process according to the initial orientations (<100> and <111>) (Right).

Summary

In this study, simulations of a single copper crystal workpiece extrusion through both LTE and NLTE processes were performed for two different initial orientations of workpieces. In this way, a detailed comparative grain refinement performance by using crystal plasticity finite element analysis was addressed. The initial result reveals that the NLTE process has advantages in terms of punching force and deformation distribution. While the LTE process induces strain evolution, increasing from center element to periphery elements, more homogenous plastic strain distribution is examined in the NLTE process. In addition, the orientation distribution of the NLTE process is more homogenous when compared to the LTE process. The SPD analyses were performed under low friction coefficient and backpressure due to the convergence problems of implicit CPFEM UMAT code. For that reason, a more comprehensive analysis will be performed with explicit VUMAT code, and the results will be compared to experimental results as a next step.

Keywords: Metal Forming, Surface Quality, Wire Drawing Process

Abstract. Profiled wires manufactured by the drawing and rolling processes are widely used for production of industrial screens used in the particles separation processes. The main goals in the production processes of such screens are to obtain increased durability and surface quality due to its demanding working environment i.e. high abrasive wear and aggressive condition. The present studies were focused on the analysis of the effects of applied wire drawing and rolling processes on the mechanical properties and surface quality of the produced profile wires. The differences in the schedules of the metal forming processes as well as in the deformation inhomogeneities in the drawn products were analysed. As a result of the applied deformation methods, different surface quality and mechanical properties were obtained. The rolling process has been shown to provide better surface quality and a lower YS/TS ratio, which is critical for further deformations such as the bending process of round industrial screens. The investigations were preformed using austenitic stainless steel.

Introduction

Changes in the mechanical properties of the metallic materials are one of the main effects of plastic deformation processes. They become particularly important in drawing and rolling processes of the profiled wires where the effects of inhomogeneity of plastic deformation play a crucial role [1]. Controlling of the mechanical property distribution at the cross-section, especially in the case of profiled wires, creates new opportunities in the applications of such products. However, this requires a good knowledge of the relationships occurring between strain or strain rate and individual mechanical properties [2-4]. The development of such relationships is a part of the thermo-mechanical description of deformation process like drawing or rolling. Those can be considered as a crucial aspect in the case of multi-step deformation. The possibility of prediction of the level of yield stress (YS), tensile strength (TS) and the so-called yield ratio (YS/TS) [5] for the individual deformation steps have to be taken into account in the development of the metal forming processes [5-6]. Therefore, the main aim of the present work is to critically assess the effects of drawing and rolling on the mechanical properties, especially yield ratio, as well as the quality of precise profiled wires (Ra) aimed for filtration screens [7,8].

Experimental Procedure

In the present study AISI 304L austenite stainless steel was used in order to determine the differences in the mechanical as well as the microstructural behaviour of the material using different deformation process routes i.e. drawing and rolling processes. The chemical composition of the tested steel grade is presented in Table 1.

Table 1. Chemical composition of the tested steel [wt. %].

Material	C	Mn	Si	S	P	Cr	Ni	N
AISI 304L	0.02	1.54	0.37	0.006	0.035	18.16	8.10	0.075

The tests were focused on the analysis of the influence of the deformation method i.e. wire drawing and rolling processes, on the mechanical properties as well as the microstructure development. Additionally, both analysed effects cause changes in the surface quality, which is very important in the case of the profile wires due to their application [8]. Schematic presentation of the process is shown in the Fig. 1. The final shapes and dimensions of the wires were similar. The dimensions of the profiled wires are presented in Table 2.

Table 2. Dimensions of the final thin profile wire.

Shape	Initial wire rod diam. [mm]	A [mm]	B [mm]	α [°]	
28Sb	3.55/3.43	2.20	4.50	23	
The rolling process was performed in three steps while the drawing process was conducted as four step process. In the case of rolling, the first step was performed on a duo rolling mill with flat rolls, followed by profile rolls. In the case of drawing, the first step involved flattening the wire rod in a two-roll drawing machine, while the second and third deformation passes were carried out using profiled roller dies - the so-called Turks head [9]. The samples after the rolling and drawing processes were tested for mechanical properties in tensile tests on the Zwick Z250 tensile machine with a strain rate of $0.1s^{-1}$. Roughness of the surfaces was measured using optical profilometer VykoNT9800/9300 from Veeco. The roughness was measured in three to five places in order to obtain average values.

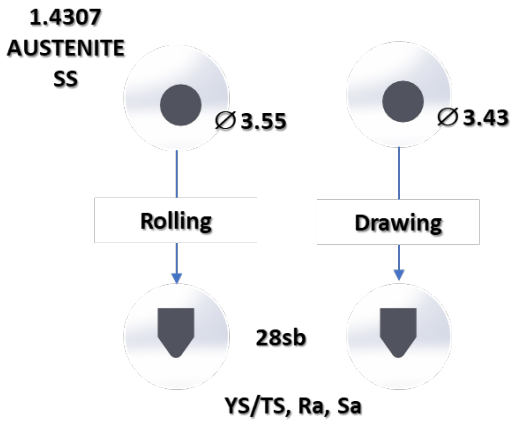

Fig. 1. Schematic presentation of forming schedule.

The microstructural changes were analysed using optical ZEISS Axio Imager M1m microscope. The microstructure analysis was performed in the initial wire rods and after last step of deformation, both in the drawn and rolled specimens.

Results and Discussion

The results of testing the mechanical properties of profiled wires obtained in the rolling and drawing processes are presented in Table 3. The profile wire was rolled from the initial diameter of 3.55 mm while the wire drawing process was conducted using initial wire diameter of 3.43 mm. The differences in diameters were caused by the conditions of the industrial process, where different diameters of wire rods were used in the rolling and drawing processes. The final mechanical properties of the finished products were measured to obtain the YS/TS ratio, since good formability is required for further bending of rounded filter screens. In both cases an increase of the mechanical properties was observed. The obtained results indicate that in the rolling process the YS/TS ratio was 91%, while in the drawing process it was 96%. These results clearly show that after the rolling process, the further stages of the screen manufacturing process (resistant spot welding and bending), especially in the case of cylindrical screens, will run more efficiently. In the case of drawn profile wires intended for further deformation (bending), an annealing process may be necessary to improve the ductility of more hardened materials.

Table 3. Mechanical properties of the AISI 304L stainless steel after rolling and drawing process.

Deformation Method	**Profile**	**YS** [MPa]	**TS** [MPa]	**YS/TS** [%]
Rolling	ϕ3.55 [mm]	637.0	863.8	73.75
	28sb	1313.1	1441.8	91.08
Drawing	ϕ3.43 [mm]	623.5	805.3	77.43
	28sb	1346.4	1399.9	96.18

The deformed wires were analysed both in terms of shape evaluation and microstructure development. Based on the analysis of the shape accuracy and macrostructure obtained from each stage of the drawing process (shown in Fig. 2), it can be observed that the plastic flow of the material, forced by the process conditions, gives the correct shape of the corners of the profile wires.

Fig. 2. Analysis of the shape of drawn profile wires after each stage of deformation.

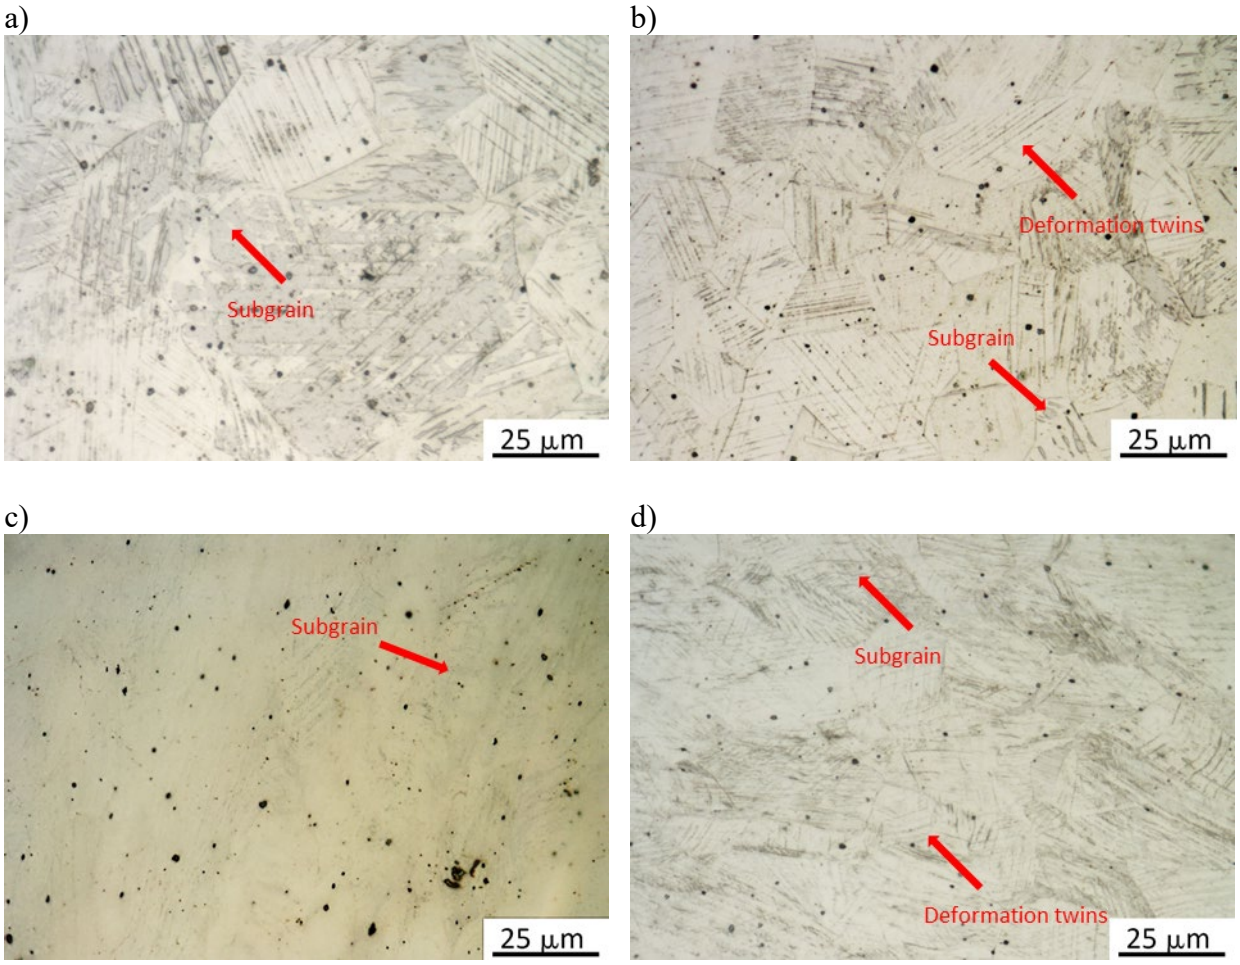

Fig. 3. Microstructures of the AISI 304L Austenitic Stainless Steel at the initial stage, in the centre -a) and close to the surface -b); profile wires after drawing process in the centre-c) and top surface of profile wired -d).

The initial material was characterized by equiaxial austenite grains with visible annealing twins. It was also observed that structural effects related to the martensitic transformation occurred (Fig. 3a, b). In the microstructures of the materials after drawing process it can be seen that the effect of the deformation caused forming the deformation twins (Fig. 3c). There are also visible areas where the deformation was initiated in two planes of slip (or twinning). However, no shear bands which are crossing grain boundaries can be observed. In the case of the near-surface areas of the layers, the microstructure of the deformed material indicates a more significant deformation, which can be estimated on the basis of a stronger deformation of grains and a larger amount of subgrains in the microstructure (Fig. 3d). Also, it can be seen that formation of the microstructure of the so-called lenticular structure, indicating a high degree of deformation of the material (about 80 %).

Materials Research Proceedings 28 (2023) 563-570 https://doi.org/10.21741/9781644902479-61

Fig. 4. Shape analysis of the rolled profile wires after each step of deformation.

The deformation degree during rolling process is significantly larger in each step of rolling due to higher reduction. The final shape, without deviations can be obtained in 3 step process (Fig. 4).

The microstructure of the initial wire rod is characterized by a high degree of homogeneity of austenitic structure (Fig 5a,b). In the microstructures of the material after rolling process, a slight degree of grain refinement can be observed, mainly in the central zone of the profile wire (Fig 5c). Final microstructure after rolling process in the top surface area of the profile wire can be characterized by high refinement of the grains without additional microstructural effects such as twinning or slip planes (Fig 5d).

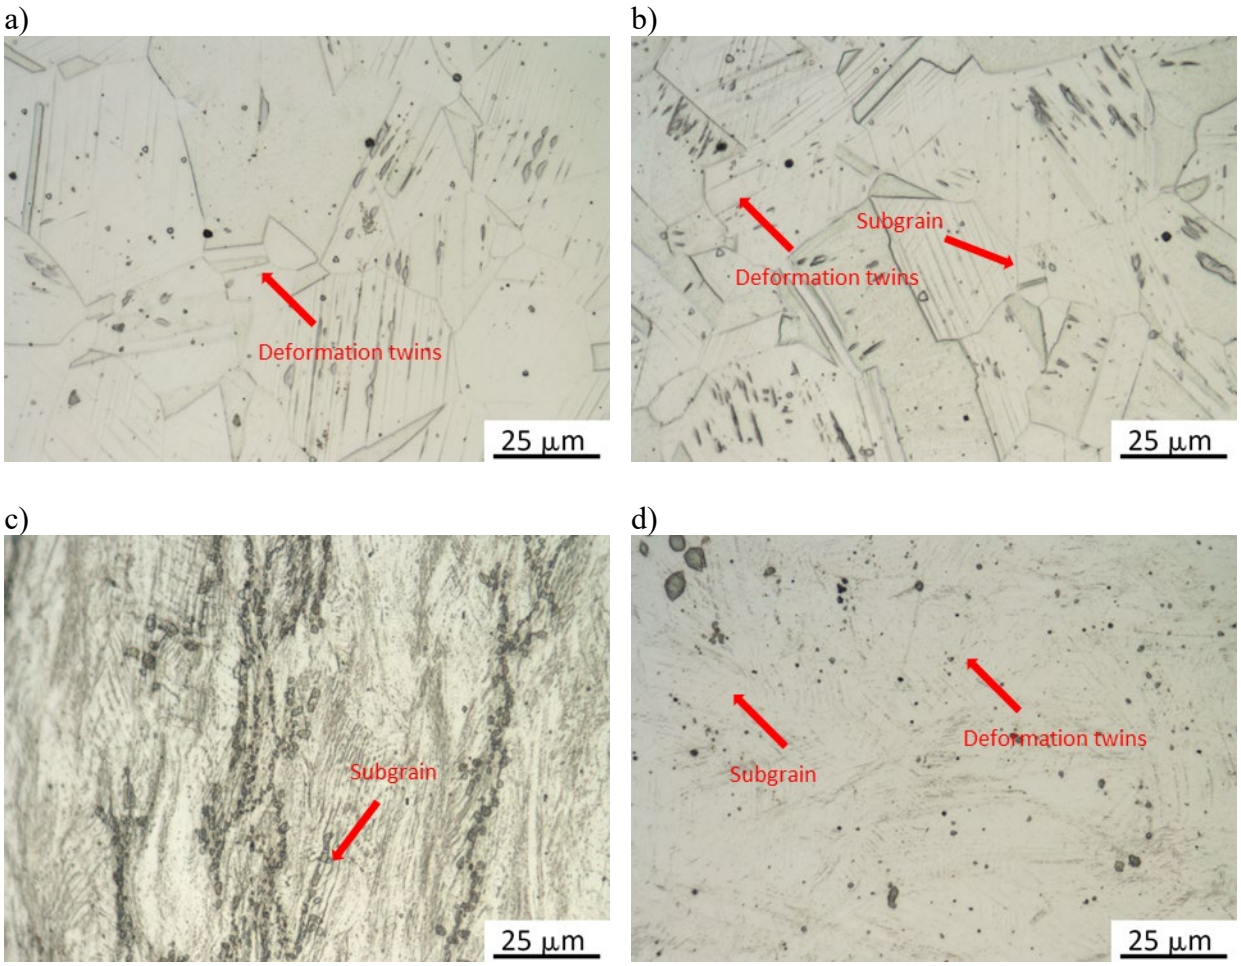

Fig. 5. Structure development of the AISI 304L Austenitic Stainless Steel at the initial stage, in the centre -a) and close to the surface -b); profile wires after rolling process in the centre-c) and top surface of profile wire -d).

According to customers' requirements the profiled wires used for industrial filtration screens must meet the requirements regarding the roughness of the surface, especially in the screens used in the offshore applications. The initial roughness Ra of the wire rod aimed for the rolling process was equal to 0.17 µm and in the case of wire rod aimed for the drawing process it was equal to 0.18 µm. After rolling Ra decreases to about 0.16 µm while after drawing process Ra increased to 0.25 µm. Such high increase was caused most likely by the low quality of die surface and the mechanical (stress and strain) state obtained in the drawing process. The obtained results suggest that the rolling process is more suitable for the profiles tested in the present study (28sb). All of the results of the roughness measurement are presented in Table 4.

Table 4. Surface roughness of the profile wires produced by two different metal forming processes.

Deformation Method	**Profile**	**Ra_{avg} [µm]**	**Sa_{avg} [µm]**
Rolling	ϕ3.43 [mm]	0.17±0,03	0.33±0,05
	Profile wire	0.16±0,01	0.51±0,04
Drawing	ϕ3.55 [mm]	0.18±0,03	0.34±0,03
	Profile wire	0.25±0,02	0.78±0,11

Summary

In the presented research results, the influence of two different metal forming processes on the surface quality, mechanical properties and microstructure of the produced profile wires was analysed. Based on the conducted research, it can be concluded that:
As expected, the applied metal forming process has a significant impact on the surface quality of finished products. Nevertheless, the presented studies have shown that in the current production conditions, the rolling process allows to obtain a lower, required surface roughness, mainly due to the mechanical state (state of deformation and state of stress) occurring during deformation. It should be expected that with sufficiently high surface quality of the tools used and changes in the deformation schedules (e.g. thanks to the use of the so-called smoothing threads - skin pass), these relationships may change. Such research will be the focus of further studies.

Abstract. The surface layer of hot forging tools undergoes local microstructural changes due to high thermo-mechanical and tribological loads. Tools made of hot working steel are usually pre-heated and experience extreme heating and cooling during each forging cycle, affecting their local wear behaviour significantly. Therefore, the analysis of these tool surface layers in die forging and their effect on wear behaviour is of great importance. The microstructural changes in the tool surface layer mainly depend on thermal loads, which are highly influenced by the tool cooling system. A process and a suitable tool system are developed to vary the thermal and mechanical loads on the tool surface layer and fundamentally examine the resulting microstructural changes.

Introduction

Tools in hot forging are exposed to high process related loads and stresses, for which a distinction can be made between thermal, mechanical, tribological and chemical loads. Thermal loads result from thermal expansion due to the increased base tool temperature. Additional thermal loads come from the frequent alternations between the rapid heating of the tool surface area during forming and the rapid cooling due to the relatively cold base material underneath. This is further increased by the cooling of the tools. The mechanical loads result from the forces on the tool during forging. Combined with the relative movement between the tool and the deforming work piece, these lead to tribological stress [1]. All of these loads can cause permanent damage to the tool surface area and ultimately lead to tool failure. The main reason for tool failure is predominantly the wear of the contours [2]. The loss of strength of the material in the tool surface layer is caused by the thermal loads and results in wear. During forging, peak temperatures in the thermally highly stressed tool areas exceed the tempering temperature of the tool material, thus softening the tool surface layer [3].

During forging the heated work piece is placed in the engraving, forged, taken out of the engraving, and subsequently cooled through convection and radiation by spraying the coolant and lubricant into the engraving. The temperature rises to its peak value during contact of the up to 1250 °C hot work piece and the tool with heat being transferred from the first into the latter. Following the forming process, there is a considerable drop of temperature in the engraving surface. The tool starts cooling with the warm work piece still in the die. Due to thermal conduction, the heat flows into the colder base material below the heated zone and thus reduces the contact temperature in the surface. After removing the work piece, the temperature of the engraving surface drops due to radiation and convection. Finally, the cooling lubricant is sprayed into the engraving which cools the tools below base temperature and thus exposes them to additional thermal stress. A considerable amount of heat is extracted from the tool by evaporation of the lubricant. As a result of the spraying process, the temperature in the tool surface area drops below the base tool temperature. Afterwards, the temperature of the engraving surface once again reaches the set base tool temperature and the next work cycle begins (Fig. 1, left) [4]. The base

tool temperature can mainly be adjusted by the billet temperature, the amount coolant applied, the overall length of a forging cycles and the tool pre-heating.

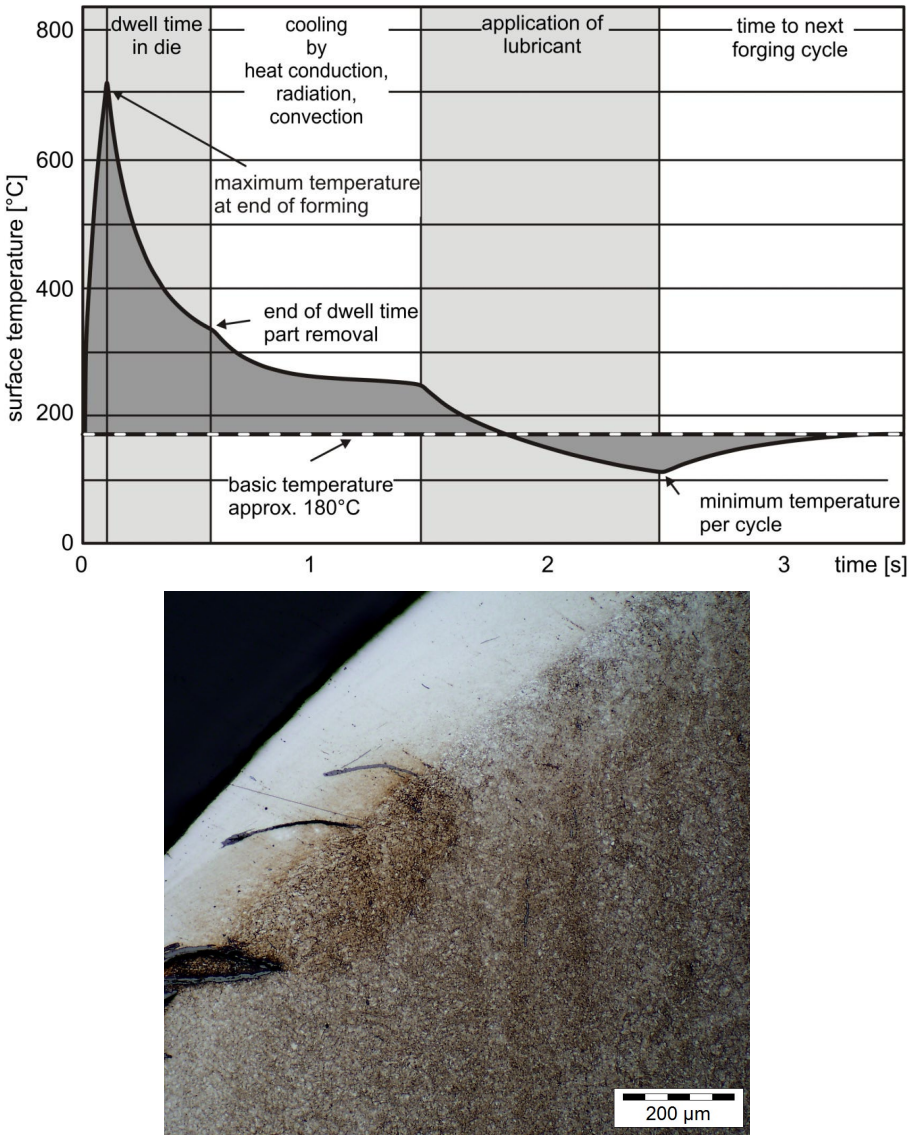

Fig. 1. Tool surface temperature during forging [4] and a tool surface layer with a white, rehardened zone.

The peak temperature in the tool surface area during a forging cycle depends mostly on the temperature of the work piece and the base tool temperature. The great differences between the work piece and base tool temperature lead to a high temperature increase in the tool surface layer during each forging cycle [4]. In metallographic analysis, rehardened tool surface layers often appear as white layers (Fig. 1, right). They form when the tool surface area is exposed to high temperature gradients exceeding the austenite start temperature in combination with cooling above the critical speed [5]. The effects of rehardened zones on the tool wear is controversially discussed in literature. Rehardened zones are often seen as component damage [6]. Some studies compare the rehardening of the tool surface layer as a heat treatment that strengthens the tool surface area [7] and refer to the potential of the special wear resistance when exposed to abrasive stress [8]. Due to engraving areas with convex radii being predominantly at risk of wear, structural changes in these tool edge areas have a decisive influence on the wear behaviour.

Separation of Lubricant and Cooling

To analyse the tool surface layer behaviour under different thermal conditions during forging, the tool cooling needs to be varied. In industrial forging, the lubrication is usually carried by the coolant. When applying a conventional water-graphite suspension to the tool surface area, the heat is dissipated by the evaporation of the water from the thermally sprayed tool areas and the friction conditions on the tool surface are improved by the remaining graphite. Since the cooling lubricant for the spray unit is usually premixed to ensure stable operation, a targeted control of the cooling by specifying a certain amount of water per area and time is not possible.

In order to enable targeted control of the cooling process, the cooling lubrication process has to be separated according to its functions into two independent processes, cooling and lubrication. Therefore, the cooling is carried out by an air-water mixture, which is applied to the tool surface via a spraying system by Gerlieva. The control unit of the supply system can be used to specifically regulate air-water spray parameters such as pressure and duration. The regulation of the spray parameters is to take place in such a way that different base tool temperatures are achieved. Next, the lubrication process is designed. Due to the functional separation of cooling and lubrication, the possibility of conventional lubrication, e.g. by means of a water-graphite suspension, is no longer applicable. For lubrication, the technology of electrostatic powder application is used with powdered boron nitride as the lubricant. Studies have shown that this type of lubricant application can significantly reduce tool wear [9]. Lubrication is applied by a powder coating system by ITW / GEMA Oberflächentechnik. Due to the functional separation of cooling and lubrication, the application is carried out in two stages. Cooling is stage I and lubrication stage II. The lubrication process is controlled by regulating the applied voltage potential, as well as the disperse duration and pressure.

Material Characterization

Steels of different strength are formed to determine the influence of the mechanical load on the tool surface layer. The yield strength of the materials have a direct influence on the mechanical stress on the tool, which in turn influences the transformation behaviour of the material in the tool surface layer. The AFP (Precipitation hardening ferritic-pearlitic) steel 38MnVS6 is selected due to its high-alloy content (Table 1). Because of this, comparatively high flow stresses at high temperatures and thus high mechanical loads on the tools during hot forming when compared to the low alloyed steel C45 are expected. The last mentioned steel is also picked for this study to represent a common forging steel with the option of heat treatment.

Table 1. Chemical composition of the materials under consideration according to the manufacturer's specifications (wt. %).

	C	Si	Mn	P	Cr	Mo	V	N
38MnVS6	0.34 – 0.41	0.15 – 0.80	1.20 – 1.60	0.025	< 0.3	< 0.08	0.08 – 0.2	0.01 – 0.02
C45	0.45	0.25	0.65	-	-	0.020 – 0.035	-	-
X37CrMoV5-1	0.41	0.97	0.32		4.77	1.30	0.46	

For a realistic numerical representation of the mechanical material behaviour of the steels, flow curves of both forging steels are needed at different strain rates and temperatures to calculate the loads on the tool during forging. Flow-curves are recorded through uni-axial cylinder compression tests, which are carried out at constant deformation rates of 0.1, 10 and 50 s^{-1} at process-relevant temperatures of 700°C, 1,000°C and 1,200°C. Tests are performed in the forming simulator

Gleeble 3800 GTC by DSi. The sample temperature is set by using controlled conductive heating controlled by type K thermocouples. To ensure statistical validation, at least three test repetitions are carried out. Based on the force-displacement curves obtained, the effective flow stress k_f is determined as a function of the equivalent plastic strain ϕ, the rate of deformation $\dot{\phi}$ and the forming temperature T. After the experiments, the flow curves are fitted and extrapolated using the Hensel-Spittel 1 model [10] for 38MnVs6 following methods already presented in detail in [11]:

$$k_f = A \cdot \varphi^{m_1} \cdot \dot{\varphi}^{m_2} \cdot \varphi^{-m_3/T} \cdot e^{m_4/\varphi} \quad (1)$$

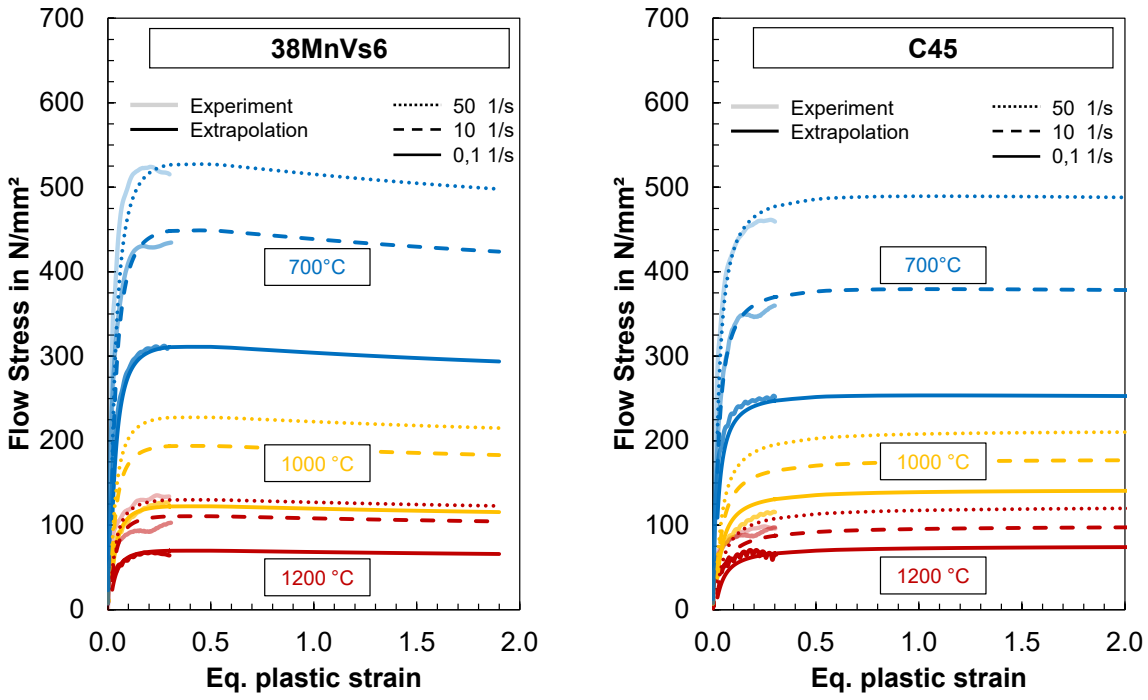
A = 2550, m1 = - 0.0028, m2 = - 0.076, m3 = 0.1 and m4= - 0.03

For C45 the GMT Model [15] was applied:

$$k_f = c_1 e^{c_2 T} \cdot \varphi^{n_1+Tn_2} \cdot e^{\frac{l_1 T+l_2}{\varphi}} \cdot \dot{\varphi}^{m_1 T+m_2} \quad (2)$$

C_1 = 3600, C_2 = - 0.038, n_1 = 0.000044, n_2 = - 0.05, l_1 = - 0.00003, l_2 = - 0.0006, m_1 = - 0.00009 and m_2 = - 0.02

The resulting flow curves are displayed in Fig. 2. The thicker drawn lines represent the mean experimentally measured flow curve, while the thinner lines represent the corresponding calculated curve from the fitted extrapolation model. As displayed, the flow resistance of 38MnVs6 steel is 10-20% higher, depending on the forming conditions. In the higher temperature range, a more pronounced strengthening of 38MnVs6 as a function of the strain rate is noticeable.



(a) (b)

Fig. 2. Recorded and extrapolated flow curves for the steels 38MnVs6 (a) and C45 (b).

Additionally, in order to be able to assess in the context of a numerical load study whether the tool can withstand the mechanical load during forging, the yield strength of the used tool steel

X37CrMoV5-1 (case hardness: 48+2 HRC) is also determined using uni-axial compression tests carried out with the Gleeble 3800 GTC forming simulatior at temperatures of up to 800°C. The yield strength $R_{p0,2}$ of the tool steel X37CrMoV5-1 is noted in Table 2 for different temperatures and determined according to the method presented in [13]. It becomes clear that a high strength is maintained at a temperature of up to 400°C. Stepping up to a temperature of 800°C, which can be reached in the tool surface layer [4], shows a strong decrease in the tool yield strength. Especially at this temperature, the expected risk of plastic deformation increases based on the measured yield strengths.

Table 2. Recorded yield strength $R_{p0,2}$ of X37CrMoV5-1 at process relevant temperatures.

	20 °C	**200 °C**	**400 °C**	**800 °C**
X37CrMoV5-1	1888 MPa	1703 MPa	1512 MPa	409 MPa

Tool Design

A rotationally symmetrical tool system, which experiences high thermal loads in the surface area during forging, is selected for easy adjustment of the thermal loads. The dies are to be made of hot working tool steel X37CrMoV5-1 (case hardened to 48+2 HRC). The geometry of the upper die has engravings, where locally different loads occur during forging (Fig. 3, left). In previous research results, it was shown that these tools display the essential structural changes and the associated wear due to abrasion and plastic deformation, which mainly occurs on the convex tool radius. Besides high surface pressures, a high thermal load is to be expected at these points due to the relatively long time of contact and the deep penetration of the tool into the work piece. To characterize the cooling behaviour, the tool temperature during forging is analysed. The temperature development of the near-surface edge areas is recorded by using thermocouples (TC) inserted into the tool. The recording takes place continuously over the entire forging process during the heating and cooling phases. Encapsulated Type K thermocouple with a 1.5 mm diameter are selected for which 1.6 mm diameter holes are integrated into the tools. The TC wiring is to exit the tools to the sides (Fig. 3, right). Thermal paste is used to increase the heat transfer and decrease reaction time between the tool and the TC.

Numerical Investigation of the Die Load

In order to enable a realistic prediction of the die load, an FE model of the forging process is set up using the FE application *simufact.forming 16*. Due to the complex tool geometry with six channels for the TC, a complete 3D model is necessary to theoretically derive a sink load in each channel (Fig. 3, right).

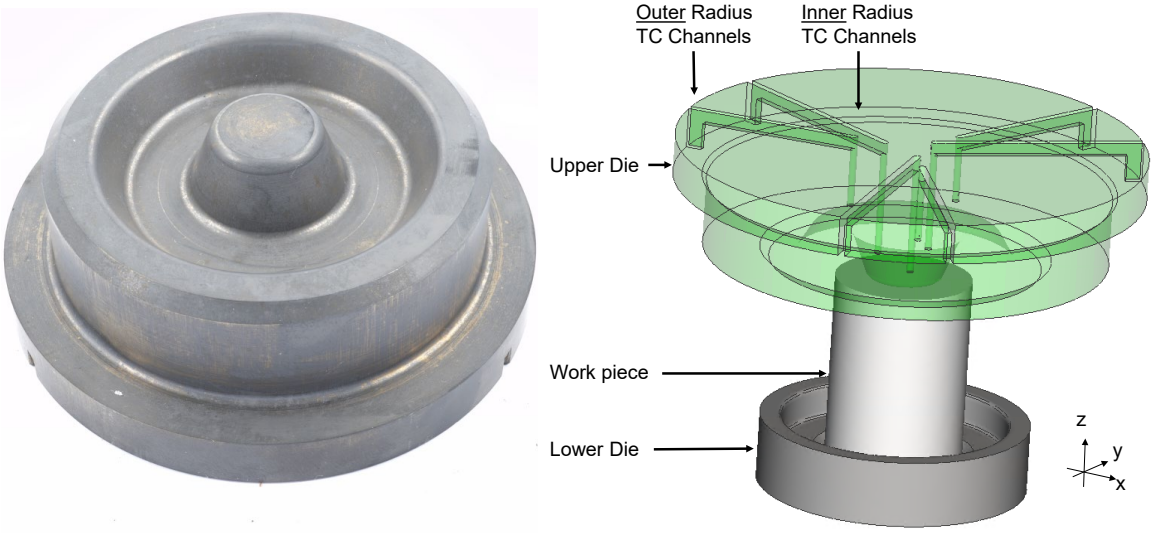


Fig. 3. Upper forging die (left) and CAD-view of the 3D-FE calculation model showing the Initial design of the upper die with channels for thermocouples (right).

For this purpose, the upper die is modelled fully thermo-mechanically coupled, while the lower die is set as an analytically rigid body. To reliably assess the tool stability, the most extreme parameter set is mapped in the process model, at which the highest thermo-mechanical load is expected. These are at a base tool temperature of 400°C, a work piece temperature of 1200°C, a friction factor of m = 0.6 and the material data set of the steel 38MnVs6. With these parameters, the stationary state during series forging is represented in the FE simulation. For a later evaluation of the temperature-time history, the return stroke and the subsequent cooling phase are taken into account in addition to the actual forming step. The influence of the spray cooling is taken into account by applying corresponding heat transfer coefficients, which were previously determined experimentally in [11].

To evaluate the numerical results regarding the thermo-mechanical loading, a sectional plane of the tool with the TC channels closest to the surface is shown in this study. In the following illustrations, the TC channels are also highlighted with a black or white outline for better visibility.

Fig. 4 shows the calculated temperature distribution at the end of the forming process before the removal of the part and spray cooling for the mentioned parameter set. This shows that a peak temperature of approximately 900 °C is reached in the mandrel radius of the die engraving. Based on this, a re-hardening of the tool surface layer can be expected after cooling. Furthermore, the heat-affected zone does not reach the tips of the channels during the forming process, which can be seen as advantageous for the structural die stability. However, this circumstance prevents the measurement from being able to resolve the direct surface heating caused by the work piece contact.

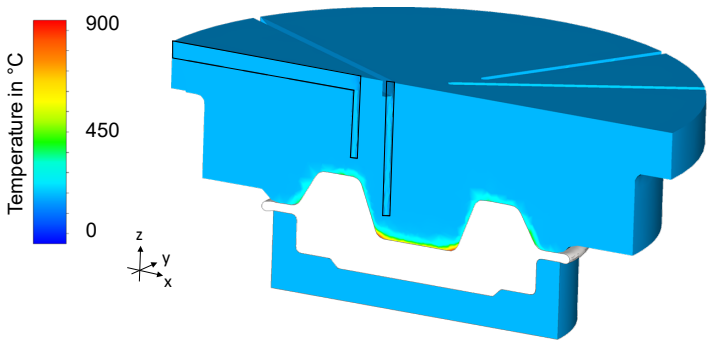

Fig. 4. Temperature distribution in the upper die at the end of forming.

For the evaluation of a possible crack risk, the common main normal stress hypothesis according to Rankine is applied, which can be used as a first assessment criterion for brittle fracture materials, such as the hardened tool steel used here [14]. In order to make crack-critical areas directly visible, only the 1st principal stress (tensile stresses) exceeding the experimentally determined yield strength at 400 °C is visualised in Fig. 5.

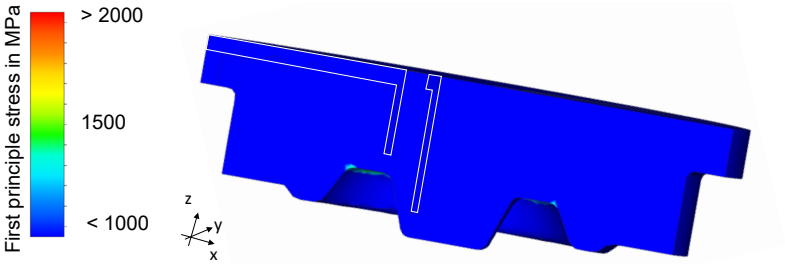

Fig. 5. First principle stress distribution on the upper die limited to the critical value range.

This allows for a clear assessment, that the areas around the TC channels are not under significant tensile load and thus uncritical with regard to a possible risk of cracking. Only in the area of the inner radii of the engraving slight cracking can be expected, which is also known from previous studies with this die geometry [7].

For the estimation of plastic deformation, the yield criterion according to von Mises is applied to compare the flow stress in the die with the experimentally determined values for the yield strength. It must be taken into account that the die load increases exponentially towards the end of the forming process. Thus, the von Mises comparative stress at three different stages of the forming stroke, characterised by the respective burr thickness subsequently measurable on the component, is shown in the following Fig. 6.

These different stroke lengths in respect to the burr thickness are chosen starting from the stroke at which a complete filling (burr thickness = 2.4 mm, Fig. 6, a) is achieved. Fig. 6, c) clearly shows that a critical condition is reached, when a burr thickness of 1.6 mm is formed, as the equivalent stress in the centre of the die exceeds the experimentally determined yield point at 400°C. In relation to the TC channels, an unwanted deformation of the channel walls would most likely occur at this stage of forming as well. Reducing the forming stroke length results in a reduction of the burr thickness to 2.0 mm (Fig. 6, b), with the burr being less strongly formed radially. By reducing the forming stroke, the loads on the tool decrease, as less material has to be displaced into the decreasing burr gap. At this stroke setting the von Mises stress does not exceed the given yield strength so there is a significantly reduced risk of deformation. Keeping in mind that the chosen

process parameters for this stability estimation represent the most extreme case, for further forging experiments, this forming stroke length will be used for experimental forging tests.

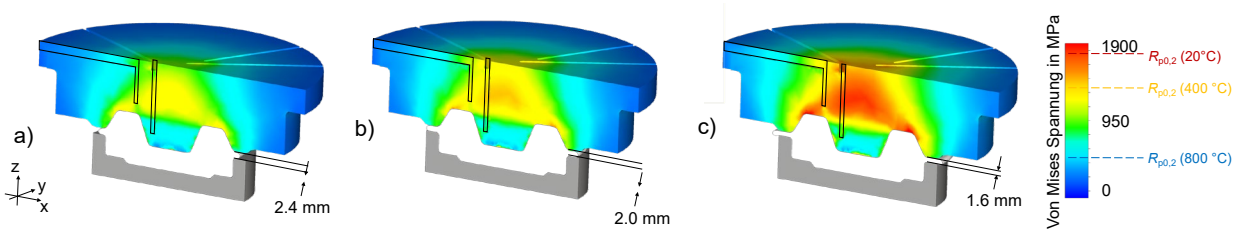

Fig. 6. Distribution of von Mises stress in the die at different stroke lengths.

Regarding the general die design, however, it became clear that the outer radius TC channel tips are located directly in a mechanical loaded area. This implies that the heath thermocouples used in the process are also subjected to mechanical stress. Since these cannot be represented and analysed within the framework of the FE analysis, it can be concluded from the results shown that damage to the measuring tip might not be completely ruled out. There is therefore a risk that no valid data can be recorded in the process without any recognisable signs of damage being visible from the outside resulting in invalid data. Furthermore, the simulation shows that the position of the TC channels is not close enough to the surface zone to record its heating phase. With this application, the temperature measurement can however be used to reliably validate the base tool temperature in the mandrel area. With regard to these two findings, it is concluded that the outer TC channels offer no added value and can therefore be assessed as an unnecessary risk. These channels are therefore removed in the following design update and the demonstration tools are manufactured accordingly (Fig. 7).

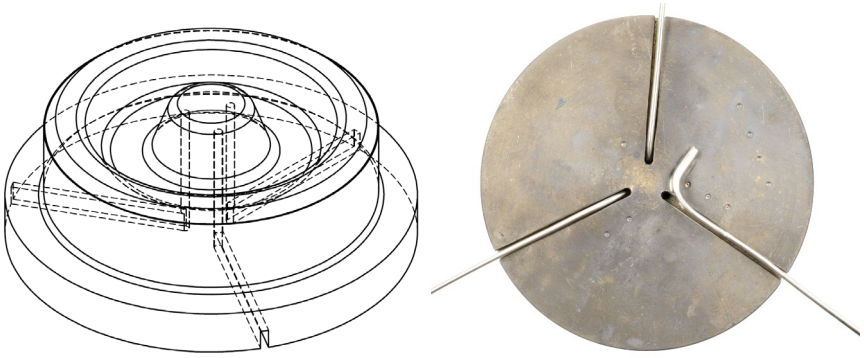

Fig. 7. Updated die Design for thermally loaded tool with channels for three mantled thermocouples.

A tool equipped with TC is then stressed in forging tests. The tool is pre-heated to 200°C. Cylindrical work pieces made of steel C45 are used with a diameter of 30 mm and a height of 40 mm. The billets are heated to 1200°C and forged with a forging cycle time of 8 s. Between each forging cycle, boron nitride powder is applied for lubrication and water is sprayed for cooling. Fig. 8 shows the comparison of the measured temperature curve with the numerically determined one during a forging cycle for a tool base temperature of 200°C. Here a characteristic deviation is recognizable, as the temperatures in the simulation are evaluated directly on the bottom of the channel wall, while in reality there is an additional heat transition from the channel wall to the mantle thermocouple. This reduces the measurement dynamics that can be achieved in reality and consequently shifts the measured temperature curve to lower and time-delayed values. In practice,

this deviation has no relevant influence on the validity of the die stress simulation carried out. In fact, the example of an excerpt from the recorded temperature-time curve shows that it was possible to achieve highly reproducible process execution.

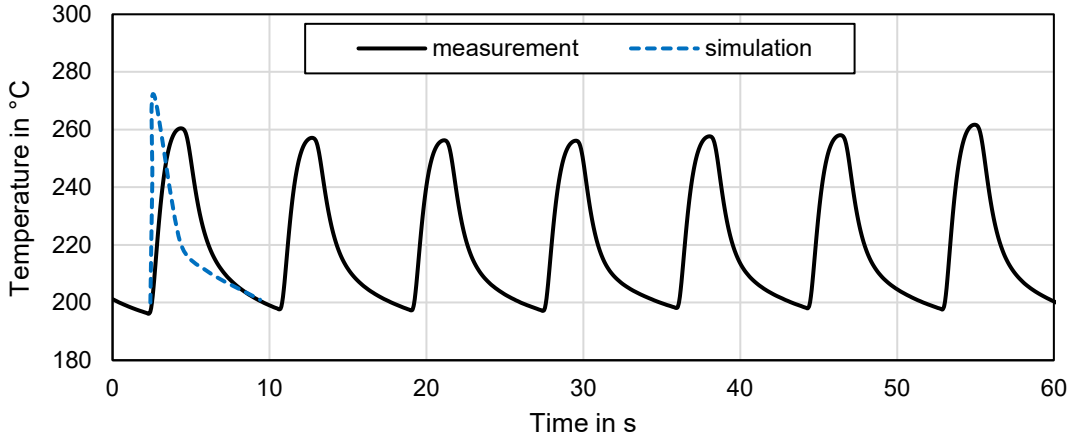

Fig. 8. Temperature measurement at the tool mandrel.

Summary

The main objective was to develop a process to investigate microstructural changes in the surface zones of hot forging dies under varying cooling conditions, as well as varying tribological and mechanical loads. A primarily thermally loaded tool system was investigated and equipped with multiple internal TC at predetermined positions for better regulation of the tool temperature. To ensure structural stability of the tool system, the thermo-mechanical loads on the die were calculated using a FE-model. The mechanical stresses on the dies will be altered by varying the forging steels of different flow resistance. The necessary material data regarding the mechanical behaviour was obtained by uniaxial compression tests using the forming simulator Gleeble 3800 GTC. To investigate the influence of thermal and tribological loading on the microstructure in the surface zone, cooling and lubrication strategies were developed, achieving different stationary die temperatures. Here, the separation of lubrication and cooling functions replaced the conventional lubrication with a water-graphite suspension by using boron nitride powder for lubrication and a water-air-combination for cooling. With these methods, temperature measurements at a short distance from the surface can be carried out and monitored during forging. During forging tests it was shown that for a base temperature of 200°C the peak temperature values after each forging cycle are consistently ranging around 260°C. Taking into account the aforementioned dynamic losses of the thermocouple measurement, this corresponds to an actual measured value of approximately 270°C at the selected measuring point.

Acknowledgements

The presented investigations are carried out within the project ID 349885770 “Influence of cooling of forging dies on the process-related microstructural changes in the surface zone and their effect on wear behaviour” of the German Research Foundation (DFG). We are thankful for the assistance provided.

Abstract. Hot forging dies are subjected to high loads, which can lead to early tool failures. Abrasive wear, plastic deformation and thermal softening of the surface layer can be counteracted in particular by a high surface hardness. Thermochemical diffusion treatments and coatings are established as wear protection measures. DLC coatings, which feature excellent frictional properties and high hardness, are commonly applied on cold forging tools. However, the low coating adhesion to steel and the thermal stability of the diamond bond limit the current range of application. In this study, DLC coatings are applied in metallic treatment atmospheres with the aim of increasing the diamond bond's temperature resistance. Furthermore, the influence of weak and intense nitriding to coating adhesion is investigated to reduce coating delamination. A pre-selection of modified DLC coatings for hot forging dies was carried out on the basis of hardness and scratch tests. The most promising tungsten DLC coating was tested in serial forging tests. Based on tool contour comparisons before and after forging, the potential as a wear protection measure for hot forging dies was determined. Tool wear was reduced by up to 29 % after 100 forging cycles with the tungsten DLC coating compared to the nitrided reference.

Introduction

Hot die forging is an economical process for the production of dynamically loaded high strength components in large quantities. About 15 % of the economic efficiency of forging processes is determined by tooling and setup costs [1]. An increased tool life can reduce these costs, enabling the forging industry to compete on an international market.

The primary limiting factor for the lifetime of hot forging dies is wear, which results from the high mechanical, thermal, tribological and chemical process-related loads. Abrasive wear describes the loss of material from the surface of a solid component caused by the contact and relative movement of an opposing object. In addition, these superimposed loads can cause plastic deformation and cracking [2]. The surface layer of the forging dies softens in contact with the hot blanks, which promotes abrasive wear and plastic deformation [3]. The use of cooling lubricants reduces the thermal tool load. However, the resulting cyclic temperature change leads to tensile and compressive stress changes in the tool surface layer, which can cause the formation of thermomechanical crack networks [4].

Common wear protection measures for hot forging dies aim to increase the hardness of the surface layer, to counteract abrasion, plastic deformation and thermal softening. Therefore, thermomechanical diffusion treatments such as nitriding are established processes. Diffusion of

the nitrogen into the tool surface layer results in the formation of a nitrided zone. It consists of a compound layer and a diffusion zone. The compound layer is a complete conversion of the steel surface in iron nitrides. In the diffusion zone nitride precipitations are formed. Coatings can be applied to further increase hardness and thus wear resistance. Duplex treatments are commonly used, i.e. the coating is applied on nitrided surfaces. Nitriding counteracts early coating cracking, which is associated with softer surface layers below the coating (also known as "egg shall" effect) [5].

In cold forming processes, diamond-like carbon coatings are used for wear protection of forging dies [6]. The amorphous hydrogen-containing layers exhibit stochastically distributed networks of carbon and hydrogen. Both sp^2- and sp^3-hybridized forms of carbon are simultaneously present [7]. The first form describes the graphite bond and is known for its excellent friction properties. In sp^3-hybridized form (diamond bond), the carbon atoms are arranged as a tetrahedron, resulting in a high hardness of 1500 – 3500 HV [8]. A major disadvantage of DLC coatings is their low adhesion to steel, which leads to an early coating delamination. This is related to an inappropriate residual stress condition due to the application process [9]. Li et al investigated the influence of the sp^3/sp^2-ratio on DLC coating adhesion. They determined that an increased sp^3 content increases the hardness, but also reduces the toughness and thereby the adhesion of the coating [10]. Another promising approach to increase coating adhesion is prior plasma nitriding, which results in a less precipitous hardness gradient [11]. Due to the diamond bond's low thermal stability, the field of applications of DLC coatings is limited, i.e. decomposition in air occurs at approximately 700°C and under loads earlier. According to Behrens et al, temperature resistance can be increased by metallic elements in the treatment atmosphere. This has been proven in particular for the element's chromium and tungsten [12].

In this study, modified treatment atmospheres for DLC coatings containing the previously mentioned and other metallic elements are investigated with the aim of delaying or shifting the coating decomposition to higher temperatures. Furthermore, a suitable nitriding to increase the adhesion of the coating is to be determined. This is intended to enable the coatings to withstand the loads from hot die forging (up to 1200°C, currently up to 700°C).

Methods

First, the procedure for specimen and tool fabrication is explained. Furthermore, the surface layer modifications are described. Appropriate coating characterization methods are used to determine the most promising DLC coating which is applied to hot forging dies. The DLC coated tools and nitrided references are used in serial forging tests. Wear behavior is investigated by high-resolution images, contour comparisons and metallographic analysis.

Specimen and tool fabrication.

All specimens (ø35 mm x 4 mm) and tools were made of hot work tool steel AISI H11 and quenched and tempered to a hardness of 48 ± 2 HRC. Prior to nitriding, the surface was blasted with glass beads and cleaned.

Surface modification.

The surface modification includes nitriding and DLC coating of specimens and tools. A pre-selection of suitable DLC coating systems for hot forging dies is determined on the basis of microhardness tests and scratch tests.

Nitriding.

Two different nitriding processes were applied to the specimens (co. Rübig Anlagentechnik, type PN 100/150). Both nitriding treatments were carried out at a temperature of 520°C and for a duration of 16 h. The pulse-pause ratio was 100 µs (pulse) to 500 µs (pause). A pressure of 300 Pa was adjusted in the treatment chamber. As a significant difference, the nitrogen content in the treatment atmosphere was varied (10 % and 80 % N_2), the other part of the atmosphere was hydrogen.

DLC-Coating.

In total, three metal-containing DLC coating systems were applied to previously nitrided specimens (10 % and 80 % N_2) with the aim of increasing temperature resistance. The DLC coatings were applied on a PACVD coating system. Niobium (40 %) and tungsten (30 %) were used as atmosphere modifying elements (Nb40 and W30), due to the high potential already identified in previous studies [12]. In addition, a combined DLC coating system containing the elements niobium (20 %) and chromium (20 %) was investigated (Nb20Cr20).

Layer characterization.

To determine the influence of the metallic elements in the treatment atmosphere on wear-reducing properties, such as high hardness, microhardness measurements according to Vickers were carried out. These were performed according to DIN EN ISO 6507 with a microhardness tester (co. Qness, type Q10A+). The hardness of the DLC coating was measured three times for each specimen and the standard deviation was determined. Furthermore, the Lc2 value was determined three times for each specimen after tempering the specimen at 600°C in scratch tests according to DIN EN ISO 20502 (co. Rtec Instruments, type SMT-5000), which describes the delamination of coatings.

Serial Forging Tests.

For characterization of the application behavior and qualification of DLC coated hot forging dies, serial forging tests were carried out on an eccentric press (co. Eumuco, type SP30d). A fully automated blank feeding system, forged part removal and spray cooling provide reproducible process conditions (Fig. 1, left). The blanks were made of the steel AISI 4140 with the dimensions ø30 x 40 mm. An inductive push-through heating system was used to heat the blanks. In one series of experiments, the blanks were heated to 1200°C and in another to 900°C. Between the forging cycles, a graphite-containing lubricant (co. Carl Bechem, type Berulit 906 HP) was applied in a ratio of 1:10 mixed with water. The forging dies were preheated to a temperature of 180°C.

In the serial forging tests, a highly tribological loaded forging die geometry was investigated, which is characterized by long material flow distances (Fig. 1, right). The forging dies were loaded up to 100 (900°C) and 1500 forging cycles (1200°C). Based on the layer characterization, the most promising coating DLC (W30) was applied to the previously quenched, tempered and nitrided (10 % and 80 % N_2) tool surfaces. In addition to the coated hot forging dies, quenched and tempered (unnitrided) as well as nitrided (10 % and 80 % N_2) reference tools were investigated.

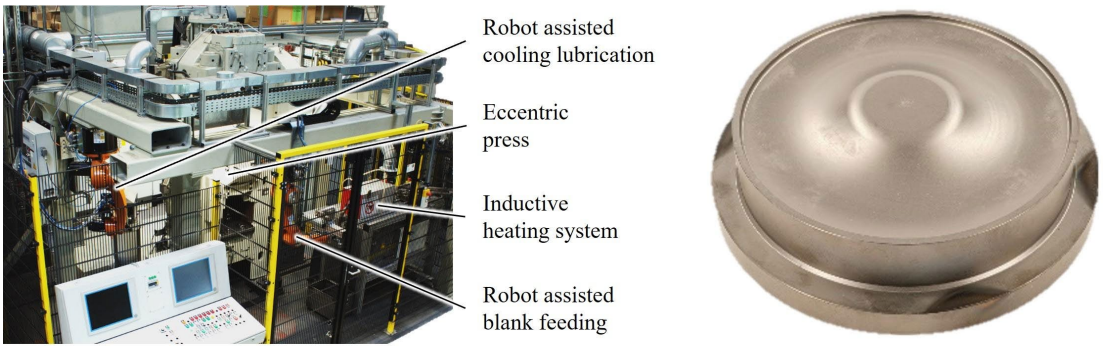

Fig. 1. Fully automated serial forging process (left) and high tribological loaded hot forging die (right).

Wear analysis.

The performance and wear progress were characterized in dependence of the forging cycles. For this purpose, high-resolution images of the wear-critical central elevated area were obtained (cf. Fig. 4) using a 3D profilometer (co. Keyence, type VR- 3200). Based on these images, an

initial wear analysis was carried out. Additional images were taken of non-critical wear areas, which were used to reference the tool contours before and after forging (cf. Fig. 5). The area between the profiles represents the planimetric wear which was determined according to DIN 50320. Six contour measurements were defined for each tool. Due to the focus depth, the area of analysis was limited to ±14 mm from the tool center. All specimens were metallographically prepared and etched with Nital to examine the microstructure and surface layer through light microscopy (co. Zeiss, type LEO 1530).

Results and Discussion

First, the characterization of the nitrided and DLC coated surface layers (microhardness measurements and scratch tests) is presented. Afterwards, the high-resolution images, contour comparisons and metallographic analyses of the forging dies are discussed.

Nitriding. Both determined hardness depth profiles for the nitriding processes 10 % and 80 % N_2 are shown in Fig. 2 (left). At a high nitrogen content of 80 %, a maximum hardness of approximately 1310 HV 0.005 was determined. In comparison, the hardness depth profile of the 10 % N_2 nitriding shows a maximum hardness of approximately 1170 HV 0.005. As a result of the increased nitrogen content, the precipitation behavior of nitrides is affected, leading to these differences. In addition, the diffusion of the nitrogen deeper into the material was enabled. This results in an approximately two times higher nitriding depth. A comparable hardness gradient can be seen for both nitriding processes, which can be explained by the identical treatment time and temperature. Furthermore, an increased nitrogen content results in additional diffusion processes, which leads to a homogeneous nitrogen distribution. Consequently, two nitriding processes with different characteristics are available for the subsequent application of the DLC coatings in order to investigate the influence on the coating adhesion.

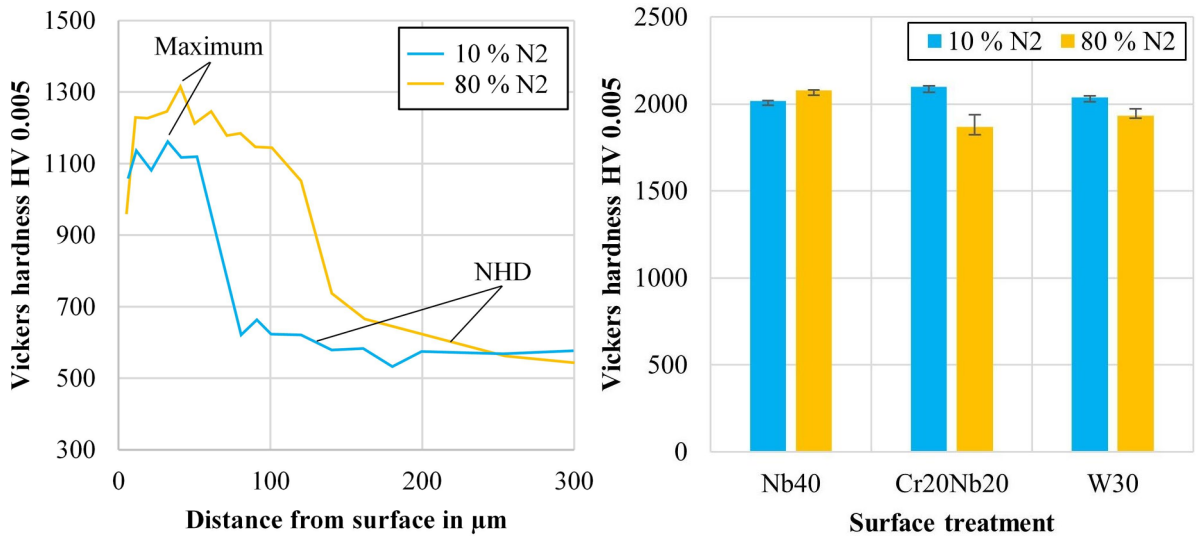

Fig. 2. Hardness depth profiles of the nitriding variants with a nitrogen content of 10 % and 80 % N_2 (left) and microhardness measurement on differently modified DLC coated specimens (right).

DLC Coating.

Cross-section microhardness tests were performed on the modified DLC coating systems Nb40, Cr20Nb20 and W30. The results are shown in Fig. 2 (right). It can be seen that the three DLC coating systems have a comparable hardness of approximately 2000 HV 0.005. Thus, for all variants, increased wear protection can be assumed compared to uncoated nitrided tools, if the DLC coatings withstand the thermal loads of hot die forging. Considering that the determined

hardness is comparable to conventional DLC coatings [8], no negative influence of the modified treatment atmosphere can be observed.

Scratch tests were carried out to determine the most appropriate modified DLC coating system for hot die forging, and the results are shown in Fig. 3. The results show that the DLC coating system Nb40 is prone to early coating delamination at a temperature of 600°C (which approximately represents the maximum temperature of thermally loaded regions on hot forging dies). This behavior can be improved through the addition of the element chromium. The DLC coating system Cr20Nb20 features two to three times higher resistance to coating delamination. By combining DLC (W30) with 10 % N_2 nitriding, the highest coating resistance was observed. Therefore, DLC (W30) can be assumed to have the highest resistance to the loads associated with hot forging processes.

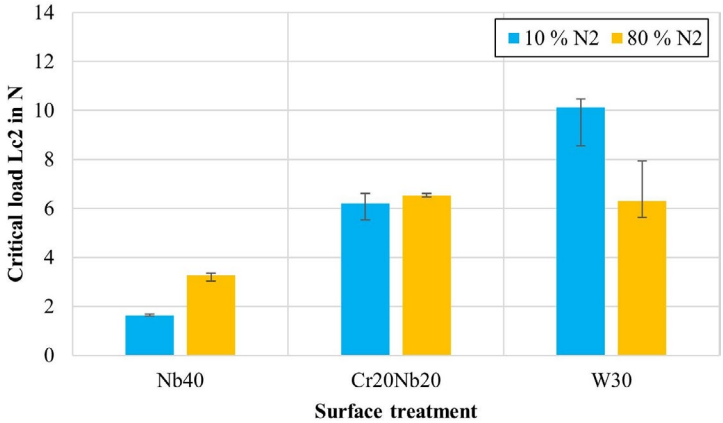

Fig. 3. Characterization of coating delamination at 600 °C of different metallic DLC coatings.

Wear analysis.

After the serial forging tests were carried out on the differently treated forging dies, high-resolution images were analyzed for the qualitative characterization of the wear behavior. The results after 1500 forging cycles are shown in Fig. 4. Maximum abrasive wear is present on the central elevated area radius of the quenched and tempered reference tool. In particular, the grooves in the direction of material flow are a characteristic feature of abrasion and a high tribological load. Due to the low hardness and significant thermal softening, this result was to be expected. Fine and coarse thermomechanical crack networks have formed in the middle of the central elevated area and near the radius. Intensively nitrided tools show an increased crack sensitivity compared to the 10 % N_2 variants. The DLC (W30) coated tools show finer crack networks than the nitrided reference tools and slightly reduced wear, therefore a coating removal can be assumed. This particularly affects the 10 % N_2 coated tool, since a lower hardness below the coating promotes cracking.

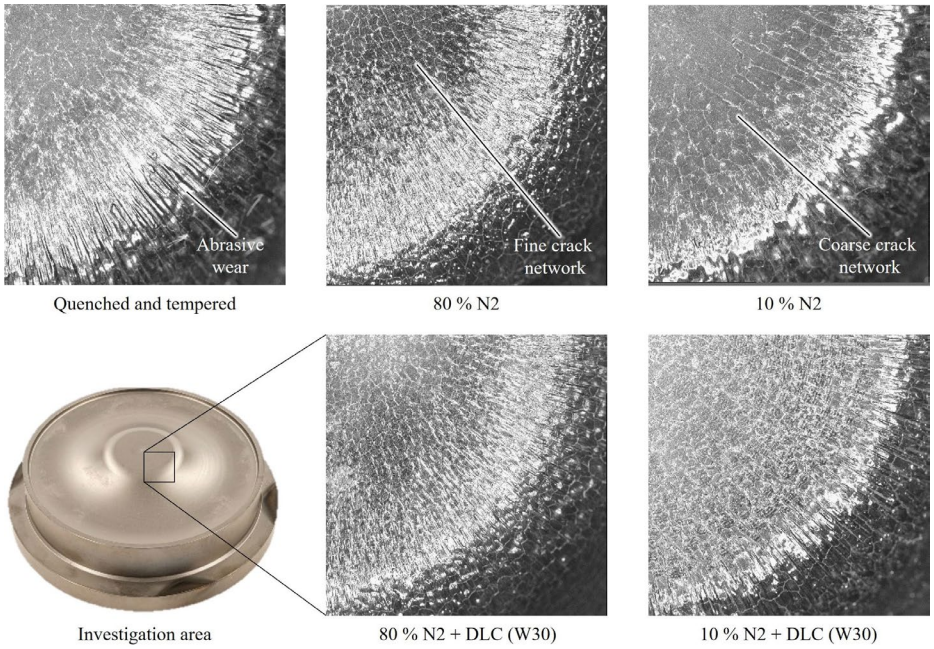

Fig. 4. High-resolution images of the differently treated hot forging dies after 1500 forging cycles.

Contour Measurement.

The profile comparisons (Fig. 5, right) show a negative geometry deviation, which means abrasion is the main wear mechanism. Since no positive deviations are detectable, plastic deformation and adhesive wear either did not occur, or were superimposed by abrasion. Compared to the 10 % N_2 nitrided reference tool, a wear reduction of approximately 23 % was measured for the DLC coated forging die after 1500 forging cycles (Fig. 5, left). This correlation cannot be determined for the 80 % N_2 nitrided and DLC coated variant. A possible explanation is the almost two times higher layer adhesion, which can be observed from the results of the scratch tests (Fig. 3). After 100 forging cycles, the DLC coated forging dies exhibit less material removal than the nitrided reference dies. Abrasive wear was reduced by approximately 28 % with the DLC coated 80 % N_2 variant. In general, the lowest planimetric wear was observed after 1500 forging cycles for the uncoated 80 % N_2 nitrided tool.

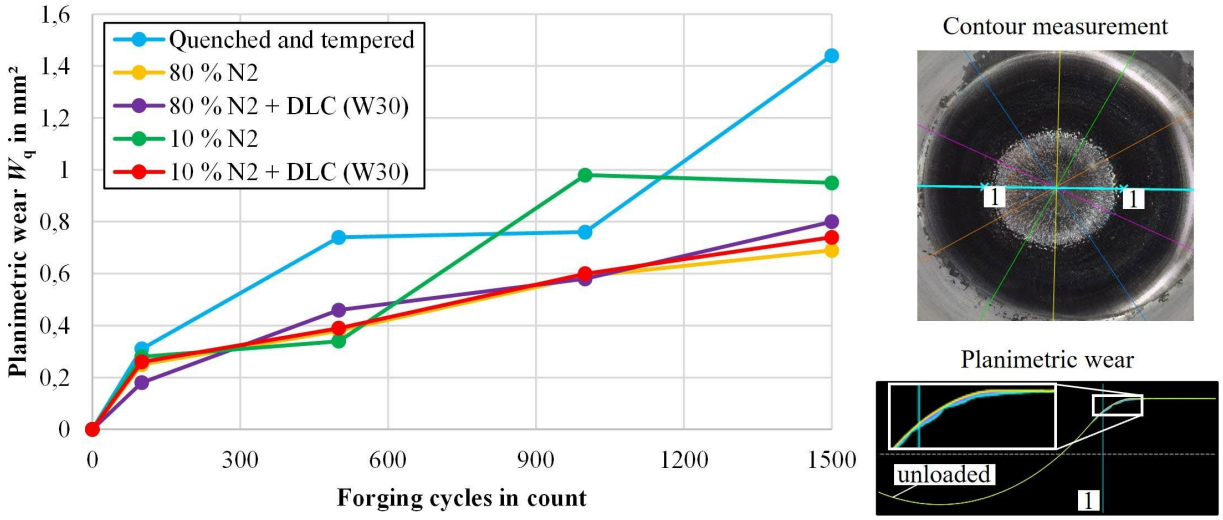

Fig. 5. Contour comparisons in dependence of the forging cycles of the differently treated forging dies.

Metallography.

Metallographic cross-sections (Fig. 6) of the DLC coated tools were prepared and analyzed after reaching 100 forging cycles (900°C) or 1500 (1200°C). At a blank temperature of 1200°C and after 1500 forging cycles, significant cracks are detectable in the surface layer. Crack initiation was promoted by the hard surface as a result of nitriding. In the light gray zone, the surface layer has been thermally softened and the nitriding zone below is visible. The 10 % N_2 nitrided forging die with DLC coating no longer shows a coating after 1500 forging cycles at a blank temperature of 1200°C. Considering the contour comparisons (Fig. 5), the DLC coating seems to be present up to 500 forging cycles. Similarly, no DLC coating was observed on the 80 % N_2 nitrided tool after 1500 forging cycles. Additional serial forging tests at 900 °C were carried out with 100 forging cycles to confirm the increased thermal stability of the DLC (W30) coatings. Fig. 6 shows the results of the metallographic analysis and for both nitrided DLC coated variants (10 % and 80 % N_2) a thin white layer is visible, which is assumed to represent the DLC coating. The thick layer beneath it, is probably the compound layer. Similar to the serial forging tests at 1200°C, a maximum wear reduction of 29 % was found (80 % N_2).

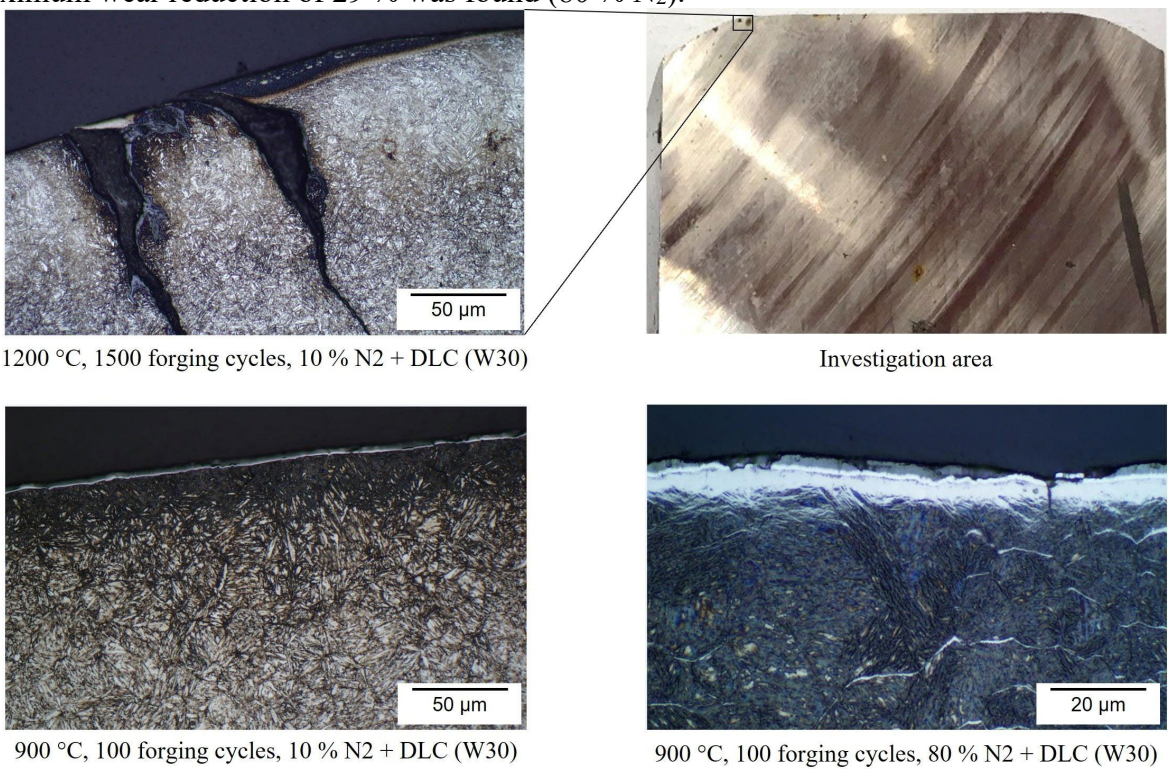

Fig. 6. Metallographic analyses of the forging dies subjected to different loads and treatments.

Summary

To qualify metallic modified DLC coating systems as wear protection measures for hot forging tools, Nb40, Cr20Nb20 and W30 were applied to differently nitrided (10 % and 80 % N_2) specimens. Vickers hardness tests did not indicate any reduction of wear reducing properties such as high hardness through the modification. Scratch tests showed the highest resistance to coating delamination at a temperature of 600°C for the DLC (W30) coating (10 % N_2). Serial forging tests were carried out using a high tribological loaded forging die with blanks heated up to 900°C and 1200°C. After 1500 forging cycles, high-resolution images showed slightly lower wear and increased crack sensitivity for the DLC coated tools compared to the nitrided references. Based on contour comparisons, it was found that the DLC coated tool with 10 % N_2 nitriding had approximately 23 % less planimetric wear than the nitrided reference tool after 1500 forging

cycles. A possible explanation is the increased layer adhesion, which was determined in the scratch tests. After 100 forging cycles and a blank temperature of 1200°C, a reduction in planimetric wear was observed for all DLC coated tools, which amounted to up to 28 %. Metallographic analysis showed no DLC coatings after 1500 forging cycles. Verification of higher temperature stability than conventional DLC coatings (700°C) was obtained through metallographic analysis of forging dies loaded with blanks heated to 900°C. Thin white layers are visible on these metallographic cross-sections, which are associated with an intact DLC coating.

Further destructive metallographic analyses are planned in the future to determine more precisely the layer degradation of the DLC coatings at a blank temperature of 1200°C. In addition, primary thermal loaded hot forging dies with modified DLC coatings are investigated to increase the range of applications.

Acknowledgment
The results presented were obtained in the research project “Investigations on the application of metal containing DLC-coatings as wear protection systems for forging dies” financed under project number 283898001 by the German Research Foundation (DFG). The authors would like to thank the German Research Foundation for the financial support.

Keywords: Friction Welding, Hot Forging, Tailored Forming, Joining Zone, Partial Cooling

Abstract. Hybrid material concepts enable the combination of beneficial properties of different materials to extend the limited potential of monolithic components. When it comes to steel and aluminium, a wear-resistant and a lightweight metal are combined to produce a weight-reduced high-performance component with load-adapted areas. A method to create hybrid gear shafts is a novel approach called Tailored Forming. The process chain consists of joining e. g. by friction welding and subsequent impact extrusion under elevated temperature. Before forming, an axial temperature gradient is set in the serial arranged semi-finished products to adjust the different yield stresses of the dissimilar materials through induction heating of the steel part. The subsequent forming is intended to positively influence the joining zone thermo-mechanically and geometrically. However, prior work indicated a limitation of the influence on the joining zone in forward rod extrusion. Therefore, approaches are being researched that enable a stronger formation of the joining zone geometry to influence the resulting bond qualities through surface enlargement. A forward rod extrusion process of friction welded hybrid semi-finished products made of 20MnCr5 (AISI 5120H) combined with EN AW-6082 (AA6082) was carried out experimentally. Complementary to prior investigations, in which mainly the aluminium section was reduced through the die angle followed by the steel, the forming sequence of the materials was reversed to increase the joining zone surface with variation of the forming path. Additionally, a cooling of the aluminium side was realized through an immersion cooling to adjust maximum temperature gradients and further equalize the different yield stresses. Hardness tests, metallographic and SEM images of cross-sections were taken to evaluate the bond quality with regard to the temperature influence, joining zone formation, occurring defects and the resulting intermetallic compound (IMC). Impact extrusion with initially steel formed followed by aluminium resulted in a spherical formation of the joining zone and consequently in greater surface area, but also lead to partial defects in the IMC. The partial cooling of the aluminium allowed higher temperature gradients to be set, thus reducing defects through improved material flow in the joining zone.

Introduction

An effective use of resources is becoming more crucial to deal with rising energy prices as well as increased environmental responsibilities. Monolithic components have their material-specific restrictions, thus new concepts and production techniques must be created to meet the rising standards. Monolithic materials cannot always meet the ever-more-complex and occasionally conflicting criteria put on lightweight constructions. One option to address these demands for lightweight concepts and attain a required load-adapted functionality is through hybrid components, which utilize different materials. In the case of steel and aluminium, the positive mechanical properties are combined to produce a high-performance component with low weight.

Using the example of a hybrid gear shaft, aluminium can serve as a structural element, while steel is used in a power transmitting area [1].

State of the Art

Within sheet metal forming, especially for the automotive industry, application-adapted hybrid semi-finished products called tailored blanks have been widely used since their development by ThyssenKrupp in 1983 [2]. Due to the local adaptations such as a local variation of the sheet thickness or sheet material, the components are optimised for a subsequent forming process or the end application [3]. This concept can also be applied to bulk metal forming. Contrary to compound forging of hybrid materials, where the joining is realised by forming [4-6], the hybrid semi-finished products are first pre-joined and then further processed by forming in order to positively influence the joining zone. The combination of joining and forming has been addressed by some studies for similar and dissimilar material pairings. For instance hot forging of cladded work pieces consisting of two different steel alloys using upsetting tests was investigated numerically and experimentally by Wang et al with regard to material distribution and the effect of friction [7]. Furthermore, in the studies by Foydl et al, an extrusion process was developed, in which aluminium profiles were reinforced by steel wires. For further processing into connecting rods, the components were cut to size and used as semi-finished products for a die forging process [8]. Basic research into joining by friction welding and subsequent upsetting of solid hybrid components made of copper and aluminium or steel and copper was carried out by Domblesky et al. The results obtained from upsetting indicate a good workability of hybrid materials [9].

Based on the concept of the studies mentioned, the new approach called Tailored Forming enables a production of load-adapted high-performance components by forming pre-joined hybrid semi-finished products. The process chain can differ in terms of joining processes used such as friction welding, lateral angular co-extrusion (LACE) or cladding and subsequent forming processes such as impact extrusion or die forging [10].

The joining zone of the two hybrid materials is usually the weakest area, where the failure of the component occurs. Therefore, the basic motivation is the enhancement of the weak point through suitable measures such as reducing tensile stresses and thus defects by a pressure superimposition [11-13], an adjustment of the yield stresses by a viable heating strategy [14] or improvement of the stress state by an inversed forming sequence [15]. The last two aspects mentioned have a direct influence on the shape of the joining zone, which results in an increase of bond strength and quality through surface enlargement [15] and influencing IMCs, which in general are characterised by their brittleness. The creation of a sufficiently sound bond is the setting of the lowest possible IMC thickness, which should not exceed a certain thickness. According to Herbst et al. sufficiently narrow IMC thicknesses smaller than 1 µm indicate high bond strengths, while for thicknesses greater than 1 µm, the strength decreases significantly [16]. A sufficiently sound bound can be achieved through a subsequent forming operation. During the impact extrusion of serially arranged hybrid semi-finished products, it is crucial that the yield stress differences between the two materials are as small as possible. In this way, a high local degree of forming can be achieved and influence can be exerted on the joining zone geometry. If the yield stress difference between steel and aluminium is too high, the local deformation is not sufficient and the different materials flow one after the other into the extrusion shoulder with only a parallel displacement of the interface. In previous work [17], the influence on the joining zone properties after friction welding and impact extrusion under elevated temperatures of steel-aluminium billets was investigated. In various forming processes such as backwards cup (full forward) extrusion or hollow forward extrusion, it was possible to geometrically influence the joining zone so that larger joining zone surfaces were created. In the case of forward rod extrusion, however, the joining zone did not change and remained flat, almost as it was after friction welding (see Fig. 1). Since in forward rod extrusion no additional compressive stress is initiated by forming tools as in the other

processes investigated, the axial temperature gradient is particularly important in the case in order to set the previously mentioned local deformations resulting in a spherical shape of the joining zone [17]. Due to this, a larger temperature gradient must be set in order to further equalise the yield stresses and also to influence the joining zone geometry. This is possible e. g. by actively cooling the aluminium.

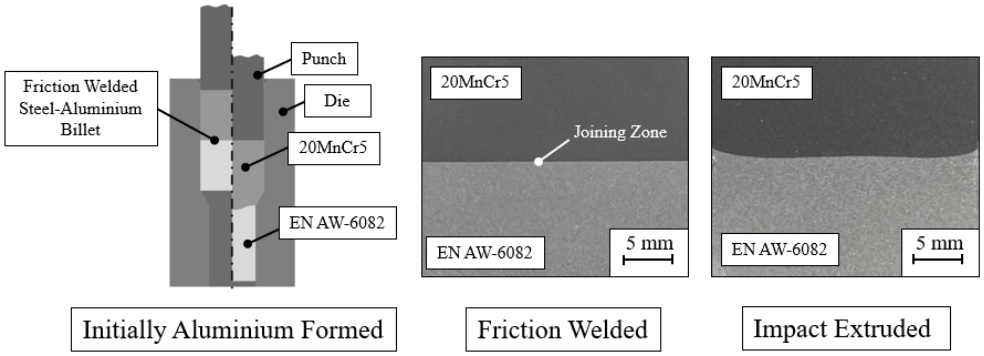

Fig. 1. Joining zone after friction welding and forward rod extrusion.

According to Gumm an increased flow rate of the centre material is observed if the harder metal undergoes the forming process first. In case the softer material is pressed through the die first, lower pressures in the forming zone and a formation of cavities in in the joining zone of compound forged components is observed [15]. Therefore, the sequence of materials is another crucial factor to further enhance the joining zone geometry through an improved stress state in the forming zone. Another aspect to reduce unwanted tensile stresses is the application of a pressure superimposition. Particularly in cold extrusion of hybrid materials, fractures occur inside the component due to differing yield stresses, which can be significantly reduced by this measure with the similar effect of the selection of material sequence [11-13]. However, this does not have any influence on the surface enlargement [17], but is required to ensure the reduction of defects.

Deriving from the state of the art, a pressure-superimposed forward rod extrusion with partial aluminium-side cooling is carried out within the scope of this study by means of Tailored Forming. Furthermore, contrary to the previous work, the material sequence is inverted so that the steel is formed first followed by the softer aluminium. In order to reproduce the formation of the joining zone and the resulting surface enlargement, the forming path is varied. The two heating strategies (without vs. with cooling) are compared with regard to the joining zone formation. The process changes enable an improvement of the mentioned joining zone characteristics. The friction welded and impact extruded steel-aluminium bonds are evaluated by means of metallographic images and hardness tests. Furthermore, the resulting IMC is characterised by SEM images and EDX analyses. The process changes enable an improvement of the joining zone characteristics.

Tailored Forming for the Production of a Hybrid Transmission Shaft

The process chain of Tailored Forming (see Fig. 2) first includes friction welding of the hybrid material pair consisting of steel (soft-annealed 20MnCr5) and aluminium (EN AW-6082 T6 condition) in a serial arrangement. Then the joined semi-finished products are formed in a forward rod extrusion process with prior inductive heating, which in the context of this study takes place both with and without immersion cooling. This is followed by machining to produce the final component, which is characterised by a load-adapted material distribution. The process chain of Tailored Forming has already been used in earlier work to create customised, hybrid machine parts in serial and coaxial arrangements like axial bearing washers or bevel gears [10].

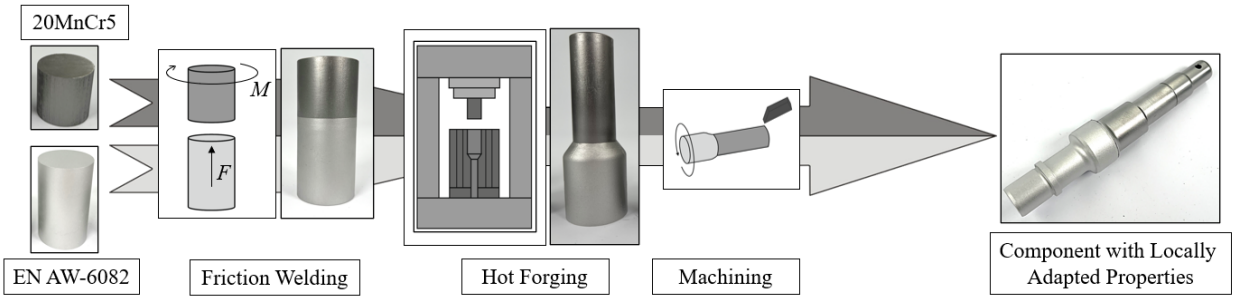

Fig. 2. Process chain of Tailored Forming for a hybrid shaft with reversed forming sequence.

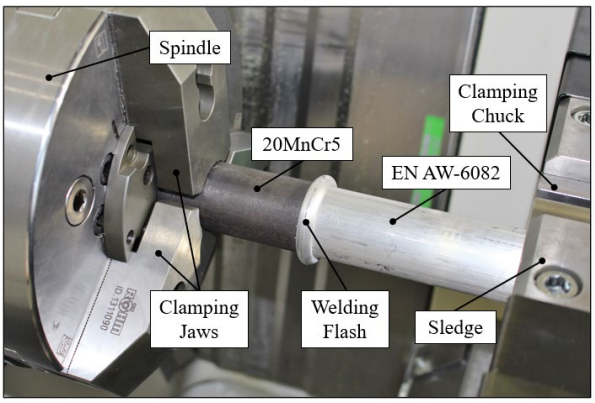
Rotatory Friction Welding

Before joining, the welding surfaces of both semi-finished products made of 20MnCr5 and EN AW-6082 are first machined and cleaned with ethanol to remove irregularities and impurities. After preparation, the materials are immediately joined on the KUKA Genius Plus friction welding machine with the experimental set-up and parameters shown in Fig. 3.



a)

Parameter	Value
Billet Diameter D	40 mm
Rotation speed n	1500 rpm
Relative Friction Path s_R	4 mm
Friction Pressure p_F	120 MPa
Upsetting Pressure p_U	200 MPa
Upsetting Time t_U	2 s

b)

Fig. 3. Rotatory friction welding: a) experimental set-up, b) investigated parameters.

The parameters were chosen according to the previous work [18] and are designed to prevent unnecessary shortening and to set low temperatures in order to keep the emerging intermetallic phase as small as possible. The steel rotates at a speed of n = 1500 rpm on the spindle side, while on the sledge side the aluminium is rubbed against it with a relative friction path of s_R = 4 mm at a friction pressure of p_F = 120 MPa. After completion of the friction phase, the upsetting phase takes place with an upsetting pressure of p_U = 200 MPa and an upsetting time of t_U = 2 s. The resulting welding flash consists of aluminium as only this material is plastically deformed in the process due to its lower strength compared to steel. After the process, the welding flash is removed by machining and the specimens are shortened to a length of 105 mm (42 mm steel, 63 mm aluminium) for the subsequent impact extrusion process.

Inductive Heating and Immersion Cooling

With the help of an induction coil, the friction-welded hybrid component is heated partially to equalise the significantly different yield stresses of steel and aluminium before the forming process. In order to achieve a favorable flow behavior, an inhomogeneous temperature distribution in the hybrid semi-finished product is necessary. According to simulations and material data, the yield stresses at steel temperatures of 900°C or higher and aluminium temperatures of 20°C are approximately the same level [14]. Due to the time required to heat up and process the component in combination with the thermal conduction during this time, it is not technically possible to reach this ideal equalisation for the forming process. The aim is therefore to achieve the largest possible

temperature gradient between the two materials. To investigate the influence of the temperature gradient on the material flow, the heating is carried out with and without partial cooling of the aluminium side before forming. During the heating phase, the steel side is in the induction coil, which consists of six rectangular windings. The magnetic field is generated by a 40 kW mid-frequency generator (TRUMPF TruHeat MF 3040) with a frequency range between 5 - 30 kHz. The edge of the aluminium part is at the same level as the lowest coil winding and is cooled by the surrounding water when used with immersion cooling (see Fig. 4).

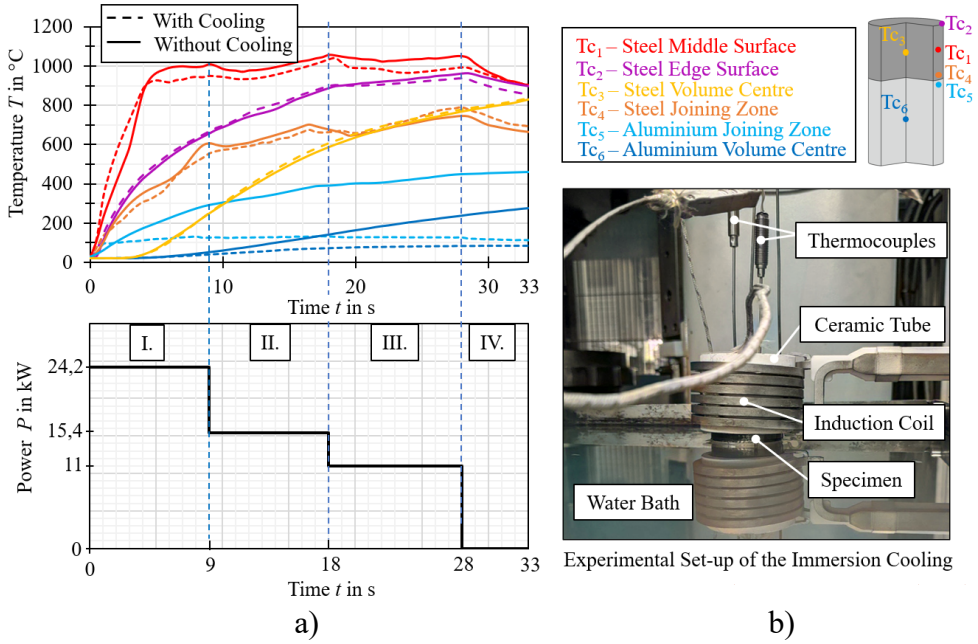


Fig. 4. Partial heating: a) measured temperatures during induction heating with and without immersion cooling, b) positions of the thermocouples (Tc) and experimental set-up.

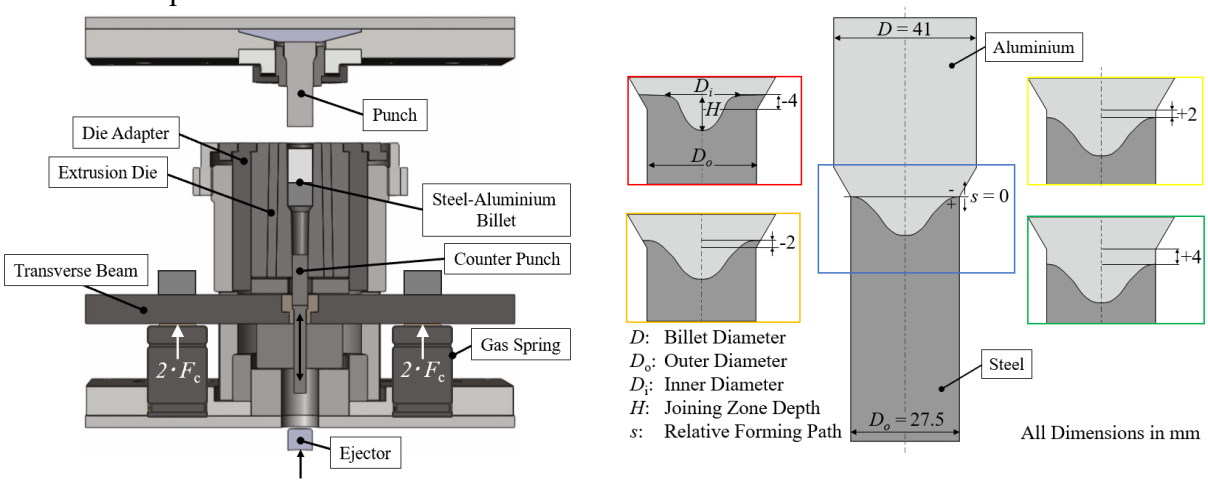
The temperature curves shown in Fig. 4 were determined during induction heating without subsequent forming using six thermocouples Type K. Induction heating takes place in segments I to III, where the power is continuously reduced in each stage to counteract overheating close to the surface. After a total of 28 s, the induction heating is finished and the sample is moved out of the coil by a pneumatic cylinder in segment IV so that an automated robot gripper can transfer the sample into the tool with a transfer time of approx. 5 s. By using the immersion cooling, significantly lower temperatures of 84°C instead of 237°C without cooling (Tc_6) are set in the aluminium part of the sample, while the steel temperatures at $t = 28$ s remain the same for both heating strategies reaching nearly 800°C (Tc_3). When comparing the material centres (Tc_3 and Tc_6), a temperature gradient of 694 K can be set with the help of cooling, while only 532 K are achieved without cooling. This corresponds to an increase of approx. 30.5%. An estimated yield stress of about 250 MPa for steel and about 140 MPa (uncooled) and 175 MPa (cooled) for the aluminium is set for strain rate of $\dot{\varphi} = 10$ 1/s and $\varphi = 0.4$.

Impact Extrusion

The forward rod extrusion of the specimens was carried out on a Lasco SPR 500 screw press and took place immediately after the transfer from the induction heating in the tooling system seen in Fig. 5a). To reduce tensile stresses inside the component, a counterpressure $p_{Counter}$ = 160 MPa was generated by four gas springs, which are connected to the counter punch via a transverse beam. The process is designed in such a way that the counterpressure acts on the component shortly before the joining zone passes the extrusion shoulder.

To observe the influence of the forming process on the geometric shape of the joining zone, the immersion depth of the punch was varied in a range of 8 mm with a step width of 2 mm. The relative forming path *s* (see Fig. 5 b)) describes the distance of the joining zone beyond the lower extrusion shoulder. In the case of a negative value for *s*, the joining zone has not passed the lowest point of the impact extrusion shoulder.



a) b)

Fig. 5. a) Tooling system for forward rod extrusion [19], b) Formation of the joining zone geometry after impact extrusion depending on the relative forming path s.

After forming, the samples were quenched in a water bath. To avoid thermal cracking, first the aluminium was quenched for 1 s, then the steel for 5 s and again the aluminium for 5 s, before the entire specimen was completely immersed for another 20 s. The samples were then cross-sectioned to measure the inner and outer diameter such as the depth of the joining zone to calculate the surface enlargement. The joining zone has a paraboloid geometry, which is why the modified surface area A_{JZ} was calculated approx. using the following equation:

$$A_{Jz} = \frac{\pi \cdot (\frac{D_i}{2})}{6 \cdot H^2} \left[\left(\left(\frac{D_i}{2}\right)^2 + 4 \cdot H \right)^{\frac{3}{2}} - \left(\frac{D_i}{2}\right)^3 \right] + \frac{\pi}{4}(D_o^2 - Di^2) \quad (1)$$

At a relative forming path *s* = -4 mm, the joining zone has not yet fully passed through the impact extrusion shoulder, which is why the paraboloid geometry is not found over the entire cross-section. Therefore, the unformed circular ring (D_o - D_i) was taken into account in the calculations. Samples with *s* = +4 were further prepared metallographically. Light microscopic and SEM images as well as EDX analyses were performed using a field emission scanning electron microscope Supra VP 55 to evaluate the cooling effect and the forming sequence on the joining zone geometry and quality as well as the emerging IMC.

Results and Discussion

The joining zone depth *H*, which contributes significantly to the surface enlargement, increases with higher relative forming paths *s* and reaches its maximum for *s* = +4 (see Fig. 6). In this case

a joining zone surface of $A_{JZ} = 1010.11$ mm^2 is obtained which corresponds to a surface enlargement of approx. 70% compared to the unaffected, flat joining zone after friction welding or with initially aluminium formed. The measured and calculated values for each variation are shown in Table 2. As the joining zone is passing through the extrusion shoulder, steel forms a funnel, dragging the materially bonded aluminium along with it. The material is drawn more strongly into the centre due to the locally varying forming speed and forms the funnel shape in the absence of subsequent material flow. With increased relative forming path *s*, the effect mentioned becomes stronger, which is why the shape of the joining zone between steel and aluminium is characterised by a steadily increasing joining zone depth *H*.

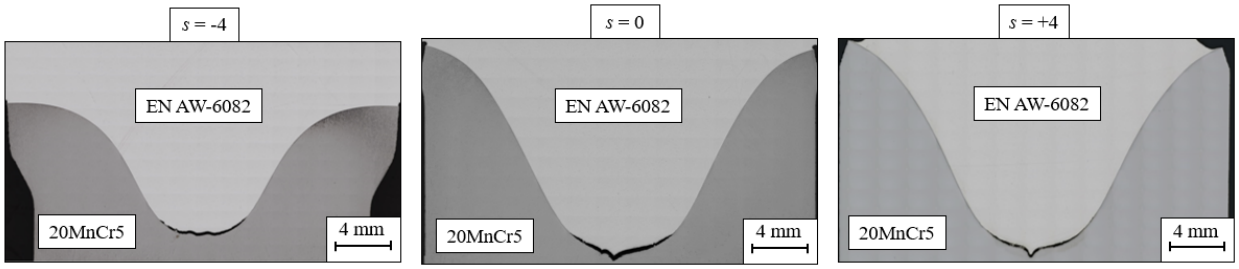


Fig. 6. Exemplary images of the joining zone formation for s = [-4, 0, +4].

Table 1. Comparison of the surface enlargement depending on relative forming path s.

Initially Formed Material	Relative Forming Path *s* [mm]	Inner Diameter D_i [mm]	Outer Diameter D_o [mm]	Joining Zone Depth *H* [mm]	Joining Zone Surface A_{JZ} [mm^2]	Surface Enlargement [%]
Aluminium	4	27.5	27.5	0	593.96	0
Steel	-4	21.8	27.5	9.5	803.44	35.2
Steel	-2	27.5	27.5	12.35	943.67	58.88
Steel	0	27.5	27.5	12.9	968.58	63.07
Steel	2	27.5	27.5	13.3	986.92	66.16
Steel	4	27.5	27.5	13.8	1010.11	70.06

The occurring defect in the centre of the specimen is caused by the funnel formation, which usually occurs in monolithic semi-finished products due to a lack of subsequent material flow at the end of the forming process [20]. A locally weak bond in the centre of the joined materials before forming is pre-existent, due to low relative friction speeds in the friction welding process. Combined with an increased forming speed in the centre and differing yield stresses, a detachment of the two materials is very likely. The defect can mostly be avoided if the extrusion takes place with high friction between the extrusion die and the specimen [21]. In this regard the use of a counterpressure can set the required stress state [11-13]. Since the gap was nevertheless observed during the tests carried out, it can be assumed that the set of a counterpressure $p_{Counter} = 160$ MPa is not sufficient to completely compensate the tensile stresses acting in the joining zone.

The greater temperature gradient caused by the immersion cooling (see Fig. 4) provides a better equalisation of the yield stresses, thus a lower deformation resistance ratio and therefore a less pronounced paraboloid shape. Furthermore, the constriction of the aluminium is largely prevented (see Fig. 7) so that, unlike the sample without cooling, no gap extends over the entire circumference of the component surface near the joining zone. Due to the improved material flow, the central defect is also slightly reduced from 132 µm to 53 µm, but cannot be completely prevented. The influence of the partial cooling is also reflected in the measured hardness (HV0.1),

which show an average increase of 12 HV from 61 HV without cooling to 73 HV with cooling for the aluminium. The hardnesses in the steel are subject to relatively large deviations, but also increased slightly on average by 8 HV from 283 HV to 291 HV.

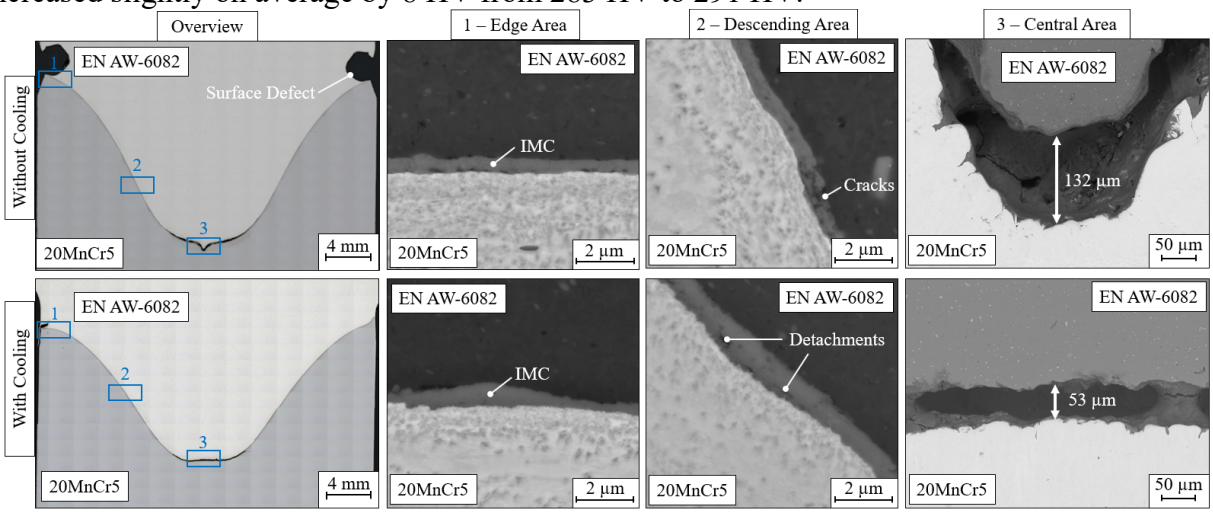

Fig. 7. Metallographic and SEM images of the joining zone (s = +4 mm) without and with cooling with a counter pressure of $p_{Counter}$ = 160 MPa.

Regardless of the used heating strategy, the formed IMCs have been influenced by the surface enlargement leading to a relatively homogenous structure. The thickness in the edge area as well as in the descending area is varying between 0.6 to 0.8µm. Near the central area, the brittle IMCs are destructed after forming due to the detachment between the two materials. The IMC thicknesses in the edge area are approx. in the same size range compared to the thicknesses in the central area, which is why no thinning of the IMC can be certainly observed due to the surface enlargement. However, since the IMC does not exceed the critical thickness of 1 µm [16] combined with the increase in surface area compared to a flat joining zone, a potential improvement of the bond strength can be assumed.

As expected, the chemical composition in the joining zone was not influenced by the cooling. An EDX line scan of the specimen without cooling at a forming path of s = +4 mm (see Fig. 8) is exemplary shown in Fig. 8. A diffusion and hence a deposition of manganese and silicon into the area of the joining zone with a concentration of up to 5 wt.% is seen, indicating the existing IMC.

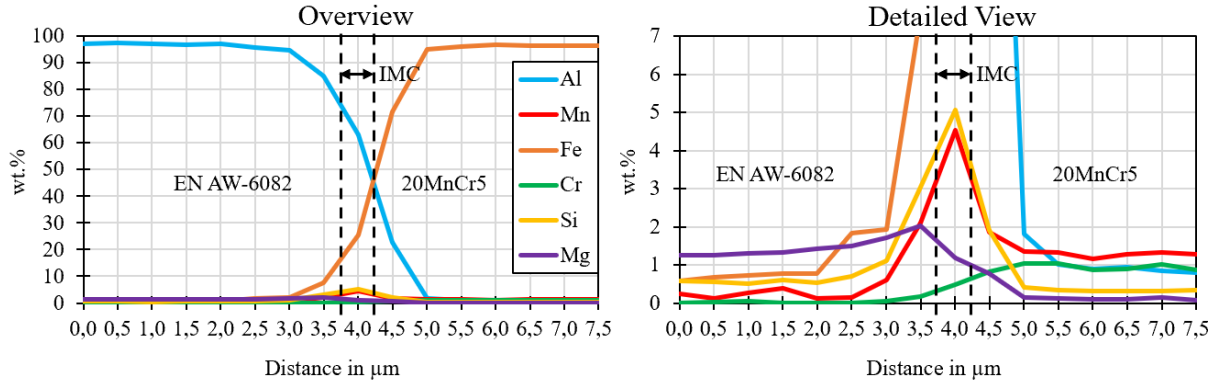

Fig. 8. EDX analysis of the descending area for a specimen without cooling (s = +4 mm).

Summary
In this study, a forward rod extrusion process was used which, based on preliminary work, focused on the forming sequence and the use of partial cooling for the aluminium side. The variation of the forming path showed a material flow-related increase of the surface enlargement of up to 70%. Furthermore, the complete passing of the joining zone through the impact extrusion shoulder resulted in defects near the surface as well as on the interior, which could be reduced with the help of the improved material flow through immersion cooling. A homogenous formation of the IMC is ensured in the enlarged areas. Partial detachments or cracking of the IMC was observed regardless of cooling in the areas with increased surface area, especially in the centre at the highest material flow rates. For future work, the counter pressure should be increased further in order to compensate the tensile stresses that occur for a defect-free bond. Furthermore, mechanical tests should be carried out to prove that the enlarged surface also improves the bond strength of the joining zone. To investigate the possible adjustable maximum temperature gradients, selecting other cooling strategies such as air-spray cooling should be considered.

Acknowledgments
The results presented in this paper were obtained within sub-project B03 of the Collaborative Research Centre 1153 “Process chain to produce hybrid high performance components with Tailored Forming” funded by the Deutsche Forschungsgemeinschaft (DFG, German Research Foundation) - SFB 1153 TP B03 - 252662854. The authors thank the DFG for the financial support of this project and also the Institute of Materials Science for the SEM/EDX investigations.

Keywords: Hot Rolling, Reinforcement Learning, Multi-Objective Optimization

Abstract. Rolling is a well-established forming process for producing finished or semi-finished products in various industries. Although highly automated, most rolling processes are designed manually by experts based on their knowledge, highly specialized heuristics and analytical process models or numerical simulations. This manual design approach does not lead to an optimization accounting for multiple objectives. Previous work [1] has shown the potential of coupling reinforcement learning (RL) with fast analytical rolling models (FRM) to optimize hot rolling processes. However, the designed pass schedules do not robustly reach the desired final height within typical industrial tolerances. Therefore, in this paper the existing approach of coupling RL with an FRM is extended by dynamically ranges for height reductions. This extension guarantees that the target height is always reached exactly. In addition to the height reduction, the RL algorithm can determine the inter-pass time, initial slab temperature and rolling velocity. For the optimization, an objective function, called reward function, considering all relevant optimization objectives such as the final grain size and energy consumption, was developed. An exemplary training was performed for a defined starting (140 mm) and final height (25 mm). The resulting, automatically designed pass schedules reach the target height and fulfill all defined optimization objective including the required average austenite grain size.

Introduction

Hot rolling of flat products is a widely-used metalworking process, in which the material is heated above its recrystallization temperature and then passed through an arrangement of rolls to reduce its thickness. It is typically used for processing cast slabs or ingots into heavy plates or sheets with the desired geometry and material properties for various industries such as the automotive and construction industry. In fact, a large proportion of all steel (> 90%) and aluminum (> 60%) products are rolled at some point during their manufacture, as Allwood et al. [2] pointed out.

With an annual global crude steel production of over 1,900 million tons in 2021 [3], it is clear that even small process improvements such as energy savings are of significant importance. It is therefore logical to further optimize the process parameters in hot rolling e.g. the height reduction, so that desired product properties, such as final geometry, grain size and corresponding mechanical properties, are achieved more efficiently thus minimizing the energy consumption.

The product properties are determined by the initial material state, material properties like flow stress, heat transfer, microstructure evolution as well as the process parameters of each pass. These include height reduction, rolling velocity and inter-pass time among others. The challenge lies in the fact that (hot) rolling consists of several subsequent and coupled passes with the process parameters summarized in one overarching pass schedule. These dependencies result in a change of properties during each pass, therefore indirectly influencing every subsequent pass.

Due to the complex interactions between the process parameters, the material properties as well as the processing constraints, the design and optimization of the pass schedule represents a complex multi-objective optimization problem. Despite great progress, detailed finite element

simulations as well as the use of classical optimization algorithms or specialized heuristics for process design are time consuming and hence not yet applicable for process optimization in the industrial context. Therefore, process design is often only based on experience of long-time rolling mill operators or fast process models. Previous work by Scheiderer et al. [1] showed that coupling RL with a FRM is very promising. RL is applied, since after a successful training process it is capable of solving given problems, e.g. to identify strategies in terms of a pass schedule, within seconds. During the training process, the learning part of the RL algorithm, which is called agent, learns through goal oriented interaction with a virtual process environment. Within the presented work, the required data for the RL-agent is provided by the FRM. However, the final height is not robustly reached within typical industrial tolerances.

To tackle this challenge, this paper presents a workflow to ensure that the final target height is always reached exactly within the tolerance. After a brief overview of the current pass schedule design approaches and the application of RL for process optimization, the coupled approach is shown and explained. The focus lies on the newly developed reward function and workflow for robust attainment of the target height. Finally, an exemplary training is presented and discussed.

Pass schedule Design and Optimization

Various approaches to design and optimize pass schedules exist, the first objective of which is always to guarantee the attainment of a target height. Known approaches to distribute the height reduction to several passes are, for example, to set the height reduction per pass to the maximum permitted by the rolling mill limitations [4] or to aim for a uniform distribution of the rolling forces between the individual passes [5]. These approaches are usually used to design a first version of a pass schedule, which is then further optimized.

As, Özgur et al. [6] pointed out in an extensive literature review, these pass schedules are mostly designed based on expert knowledge, analytical rolling models, finite element (FE) simulations and heuristics, and are therefore rarely optimized for several objectives simultaneously. These different approaches are often specialized for specific use cases, which makes a comparison or transferability almost impossible. A similar conclusion was reached by Pandey et al. [7] after their literature review demonstrating that, despite numerous methods, expertise is always needed.

In recent years, evolutionary algorithms have been increasingly used to design and optimize pass schedules, as shown by the work of Wu et al. [8] and Hernandez et al. [9]. However, these algorithms do not learn relationships between process parameters and target variables, thus a separate design process has to be performed for each pass schedule. With the usage of RL in contrast, knowledge can be (partially) transferred to other pass schedules.

Fast Rolling Models

Fast rolling models (FRM) are able to calculate rolling forces and microstructure development for complete rolling processes within a few seconds. For this purpose, they usually consist of simplified, analytical models using semi-empirical equations to describe the material behavior. Numerous fast rolling models with different emphases can be found in the literature.

Beynon and Sellars [10] present a rolling model called SLIMMER, which is able to describe the microstructure evolution and predict the rolling force and torque during hot rolling. Inspired by their work, Lohmar et al. [11] extended a similar model to include height resolution within the workpiece and considered the influence of shear during deformation. In addition to these classical approaches, data-driven methods have also been increasingly used in recent years to model the hot rolling process, for example by Shen et al. [12] to predict rolling forces.

Reinforcement Learning for Process Optimization

Reinforcement Learning (RL) is a branch of Machine Learning, which attempts to imitate natural learning behavior through reward and punishment. It consists of an iterative learning approach, in which it learns by mapping states to actions while trying to maximize a numerical reward [13].

In recent years, RL applications sprung up across the manufacturing field with exponential publication growth year by year as Li et al. [14] stated. The authors analyzed 264 different publications between 2013 and October 2022 and found, that optimizing energy consumption as well as costs and reducing reliance on expert knowledge as the main objectives of these applications. Esteso et al [15] came to similar conclusions and add that the great majority of RL applications in production technology utilize simplified (virtual) environments with discrete action spaces. Panzer and Bender [16] also conducted a literature review and conclude that in numerous applications RL outperforms previously used heuristics or algorithms. However, they are still not yet applied in real production.

There are already several successful applications of RL for the optimization of forming processes, such as in open die forging [17] and wire hot rolling [18]. Reinisch et al. [17] coupled a process model with a RL algorithm to design and optimize pass schedules for open-die forging in terms of final ingot geometry, press force and process duration. The designed pass schedules led to executable forging processes. Moreover, Gamal et al. [18] demonstrated that RL in combination with process data identifies model parameters and thus improve model predictions for bar and wire hot rolling processes. For hot rolling, Scheiderer et al [1] published a RL approach, which can design pass schedules considering several optimization objectives. The authors used a database of simulation data to train the RL algorithm. However, the target height could not be exactly achieved, which in any case is necessary for industrial application. Therefore, in this paper, based on this previous work, the coupling is extended to such an extent that the target height is always reached exactly. For this purpose, the previously statically defined limits of the height reduction are dynamically adjusted so that they prevent the target height from being undershot.

Advanced Coupling of RL with FRM

In this chapter, the advanced coupling between a FRM and a RL algorithm is presented. Fig. 1 schematically shows the structure of the coupled approach. The approach consists of an RL agent, representing the learning part, an environment, representing the problem and a set of selectable actions within defined ranges. At each discrete time step, the RL agent perceives the current state of the environment and performs actions, which result in changes of the environment. In this concrete use case, the RL agent chooses the process parameters of the next pass based on the current slab geometry and temperature. These process parameters lead to a change of the geometry and the temperature of the slab and therefore the state of the material. These changes are calculated by the FRM based on the chosen parameters, the previous material state and the material properties such as the flow stress. The RL agent designs the pass schedule pass by pass, thus feedback can be given to the agent directly after each pass

Based on the FRM results, a numerical reward is calculated evaluating the quality of the chosen process parameters (actions). It can be either positive or negative, representing a reward or a punishment, respectively. The reward as well as the current state are passed to the RL agent, which stores the information. Based on all stored information, neural networks aim to learn relationships between the previous states, the process parameters, the resulting new state and the reward.

The goal lies in identifying a sequence of process parameters (pass schedule), which result in a maximized reward. The described steps are repeated until the desired goal, here the target height, is reached. As soon as this is the case, the pass schedule design is completed, an iteration is finished and the material state is reset to the initial state. Afterwards, another iteration of the training process is performed. The training is carried out until the designed pass schedule converges. This means that the pass schedule does not really change from iteration to iteration.

Each further iteration provides the RL algorithm with new information and therefore helps improving the choice of process parameters in further iterations. To guarantee continuous improvement of the designed process, the chosen reward function is of essential importance. Here,

it e.g. tracks and rewards, whether the final grain size matches the desired one, or punishes the exceeding of the maximum rolling force of the rolling mill.

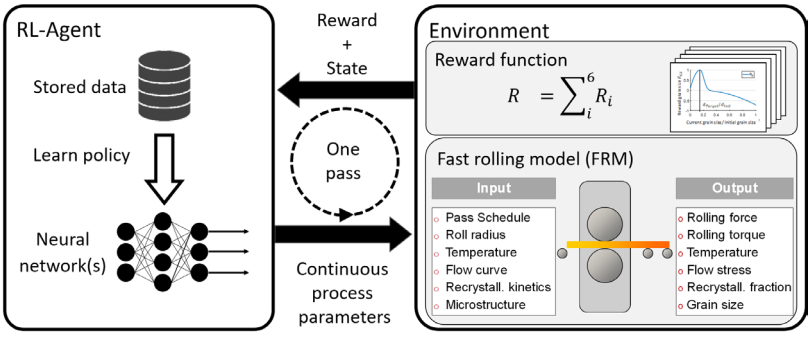

Fig. 1. Schematic depiction of the coupling of the RL algorithm with the FRM.

As previously mentioned, the pass schedule design is performed pass by pass. Hence, it follows that the reward is also calculated directly after each pass instead of only receiving feedback after a complete pass schedule. However, the RL algorithm can only process a single numerical value to evaluate all defined optimization objectives. Thus, each objective first has to be evaluated separately, before being summarized to one numerical value. Table **1** lists all considered optimization objectives.

Table 1. Overview of the optimization objectives.

Optimization objective	**Goals**
Grain size R_d	Final average austenite grain size after rolling
Force/torque R_F / R_T	No exceeding of the rolling mill limits (80% of max optimal)
Energy consumption R_E	Minimization of the energy consumption
Process time R_{time}	Minimization of the process duration
Height reduction R_{deltaH}	Minimization of total number of passes

In this paper, the reward R for each pass is composed as a weighted sum of six components R_i as shown in Eq. 1. The prioritization here lies in achieving a desired grain size as it corresponds to mechanical properties. Therefore, this reward component is provided with a higher weighting than the others. An evaluation of the height is not necessary as the target height is always achieved exactly by dynamic adjustment of the height reduction, which will be described later.

$$R = \sum_i^6 w_i \cdot R_i = 3 \cdot R_d + R_F + R_T + R_E + R_{time} + R_{deltaH} \quad (1)$$

For the definition of the individual reward components R_i, continuous functions were chosen, which scale between -1 and 1 to ensure no prioritization only by function design. To prevent the accumulation of positive rewards by simply adding a large number of passes, most reward components are defined negatively. Selected reward functions for individual objectives are described in more detail below.

During optimization, some goals are to be exactly reached ($R_d/R_F/R_T$), while others are to be minimized (R_E/R_{time}) or maximized (R_{deltaH}). Fig. **2** (left) shows the reward for the rolling force (R_F). The definition for the rolling torque (R_T) is equivalent to the one for the force. In both cases, it is important not to exceed the rolling mill limits while still using enough of the available supplies. Therefore, the reward increases up to an optimal working point (F_{opt}) sitting at 80% of the

maximum rolling mill force. This ensures that unintentional exceeding of the rolling stand limits is prevented even if process deviations or material fluctuations occur. If the defined operating point is exceeded, the reward decreases and reaches a penalty of -1 at the maximum rolling mill force.

Fig. 2 (right) shows the reward for the austenite grain size (R_d). The punishment increases the further the current grain size deviates from the desired target grain size (d_{Target}). Once the grain size lies within the desired tolerance, the reward (R_d) becomes positive.

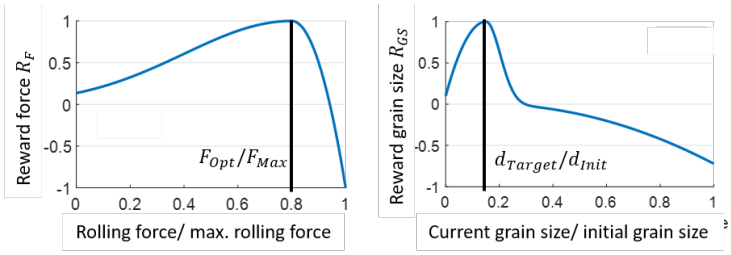

Fig. 2. Reward functions for rolling force (left) and grain size (right).

For components requiring the minimization or maximization of a given process parameter, parabolas as shown in Fig. 3 on the left for energy consumption (R_E) and on the right for height reduction (R_{deltaH}) are used. These reward components are only defined between 0 and -1 so that the agent is forced to minimize the punishment. The energy consumption is calculated considering the rolling torque, rolling speed, roll radius and the process duration for each pass.

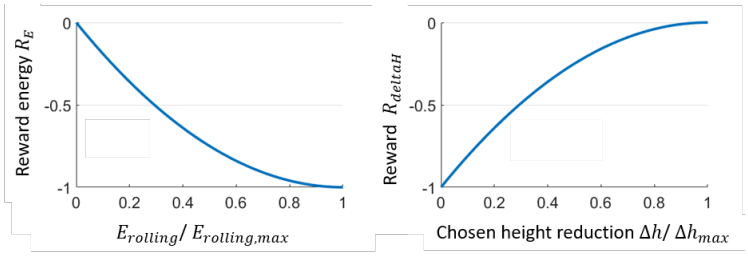

Fig. 3. Reward functions for energy consumption (left) and for height reduction (right).

In addition to the aspects described so far, the advanced coupled approach also has to ensure that the final height is exactly reached. Seeming to be particularly easy using human knowledge in process design, this has proven to be difficult for the RL algorithm in the past. In the work of Scheiderer et al. [1], the limits defined for the height reduction were the same absolute values for each pass. Therefore, the RL agent had to learn how to reach the target height, which did not always turn out to be successful. As soon as the maximum possible height reduction Δh was greater than the remaining difference between the initial height h_0 of the current pass and the target height h_{Target}, there was a risk that the pass schedule leads to heights below the target height. To prevent this, dynamic adjustments of the height reduction limits $[\Delta h_{min}, \Delta h_{max}]$ are implemented.

For the maximum permissible height reduction (Δh_{max}), two process-technological limits need to be respected. On the one hand, there is a maximum possible height reduction ensuring that no damage like cracking occurs. This limit ($\Delta h_{max,1}$) is material-dependent and typically lies at around 40 % of the initial height h_0 of the regarded pass. On the other hand, the bite condition during rolling has be taken into account. Depending on the friction coefficient μ and the roll radius r, it defines the maximum possible height reduction ($\Delta h_{max,2}$), for which the material is still drawn into the roll gap. However, since there are uncertainties regarding the friction coefficient, here, 85 % of the possible maximum height reduction is used. This ensures rollable pass. The

Materials Research Proceedings 28 (2023) 601-610 https://doi.org/10.21741/9781644902479-65

corresponding developed method is shown in Fig. 4. Based on the two calculated maximum possible height reductions ($\Delta h_{max,1}, \Delta h_{max,2}$), the smaller one is selected, so that both limitations are always fulfilled. In the next step, it is checked whether the chosen height reduction is larger than the remaining height difference between the current height and the target height h_{Target}. If so, the maximum permissible height reduction Δh_{max} is lowered to this difference.

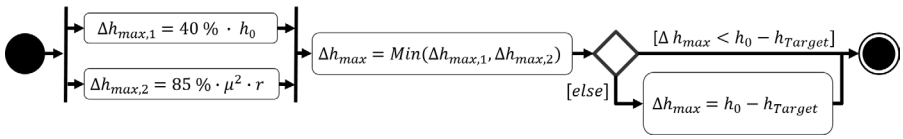

Fig. 4. Calculation of maximum height reduction Δh_{max} to guarantee reaching the desired final height.

Regarding the minimum height reduction (Δh_{min}), there are no fixed limits. Small height reductions are principally allowed, see Fig. 5. However, they usually lead to longer process times, which are punished by the reward function as shown in Eq. 1.

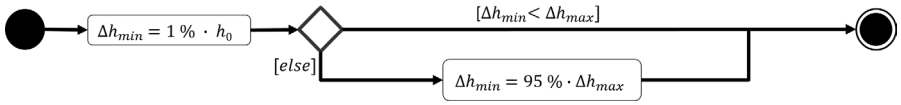

Fig. 5. Calculation of minimum height reduction Δh_{min} to guarantee reaching the desired final height.

Results: Training for Designing and Optimizing a Pass Schedule

The above described approach was used to design a pass schedule for reversing hot rolling of a S355 steel slab with an initial height of 140 mm to a target height of 25 mm on the universal rolling mill Bühler VRW-400 at the Institute of Metal Forming (IBF). Furthermore, the optimization aimed to reach a final grain size ($d_{Target} = 30\ \mu m$). The rolling mill limits were set to a force ($F_{max} = 4\ MN$) and torque ($F_{max} = 65\ kNm$), while energy consumption and process time were to be minimized. During the training, the RL agent was able to vary the process parameters within the limits shown in Table 2.

For the results shown in the following, an established RL algorithm, the Deep Deterministic Policy Gradient (DDPG) [19] was used. This algorithm uses two neural networks, allowing it to solve problems with continuous action spaces. One network estimates the cumulative long-term reward based on the current state and the chosen actions. The second network tries to learn a suitable strategy based on the reward estimation.

For the coupling with RL, an already existing fast rolling model is used, which was developed and validated at IBF by Lohmar et al [11]. It consists of several modules allowing the prediction of deformation, temperature and austenite grain size evolution as well as rolling forces and torques.

Table 2: Ranges of the RL agent's selectable process parameters.

Process parameter	**Limits**	
	Minimal	Maximum
Height reduction Δh	Δh_{min}	$\Delta h_{max}(\mu = 0.3, r = 205\ mm)$
Initial temperature	1000 [°C]	1200 [°C]
Inter-pass time	5 [s]	30 [s]
Rolling velocity	100 [mm/s]	500 [mm/s]

The presented training was carried out with 20,000 iterations, which corresponds to 20,000 calculated pass schedules. This equals about 24 hours of calculation time (CPU: Intel Xeon E3-1270). Fig. 6 shows the height evolution in black and the grain size evolution in red for the first and the final designed pass schedules. It is evident that the number of passes (from 18 to 8 passes) and the process time have been reduced and that the target grain size has been reached. Furthermore, both pass schedules reach the desired target height, regardless of the training progress. This is ensured by the dynamic adjustment described in Fig. 4 and Fig. 5.

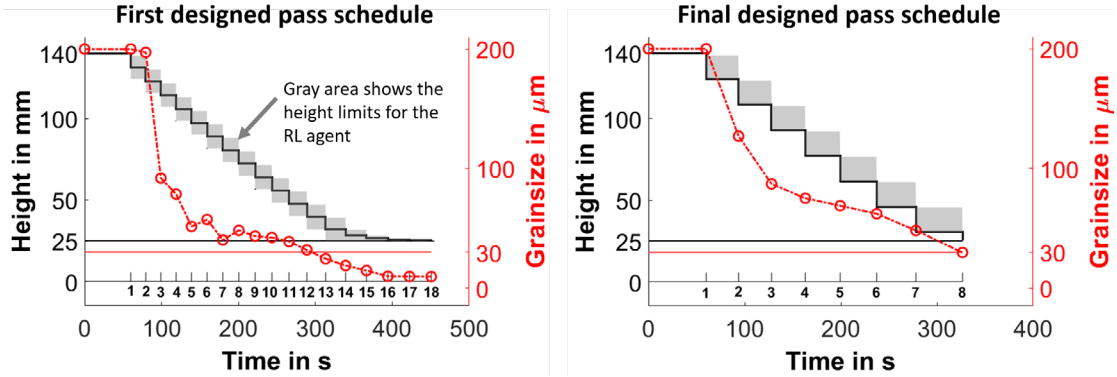

Fig. 6. The first (left) and the final (right) designed pass schedule after 20,000 iterations by the RL agent.

For comparison, Table 3 shows two pass schedules, one designed using static limits for Δh and one designed by the presented extended approach. In both cases, the same optimization objectives and boundary conditions were used. Both lead to similar results, e.g. final grain size.

Table 3. Comparison of the final designed pass schedule with static Δh limits and with the new dynamic approach.

Pass Number	**Height after each pass in [mm]**	
	Static Δh	Dynamic Δh
1	124.32	124.32
2	108.64	108.64
3	92.64	92.95
4	77.27	77.27
5	61.59	61.59
6	46.22	45.91
7	33.31	30.54
8	24.88	25.00

Although the difference between the two pass schedules appears to be negligible, it is of great importance since an undershooting of the final height is irreversible and leads to unsaleable products. The comparison demonstrates that the presented approach successfully supports the RL agent in identifying strategies, which lead to saleable products.

In addition to the resulting pass schedules, taking a closer look at the training progress is of interest, too. Therefore, the results achieved using the dynamic Δh are shown in more detail. Fig. **7** shows the evolution of the total reward R_{total} of the complete pass schedule in blue and the deviation ΔGS between the final average grain size and the target one in red during training. The evolution of the total reward over the iterations clearly shows that the reward increases the most within the first 1,000 iterations. Afterwards, it increases only slightly until it reaches a constant level at about 2,500 iterations.

A similar pattern can also be found for the deviation of the final grain size from the target one (ΔGS). The initial deviation of about 20 µm is significantly reduced in the first 1,000 iterations, so that the deviation at 2,500 iterations lies at only a few µm. Subsequently, the desired grain size is reached. The results show that the training is clearly converging towards a total reward of about -10, at which the target grain size is reached. Comparing the evolutions of the total reward and the deviation from the target grain size, it is noticeable that both correlate well, especially at the beginning and up to about 1,000 iterations. This strongly indicates that at the beginning the RL agent is trying to achieve the target grain size as soon as possible. This results from the prioritization of this component in the reward function. This indicates that weighting of individual components in the overarching reward function can be used to successfully focus on certain optimization objectives while still achieving all other desired objectives.

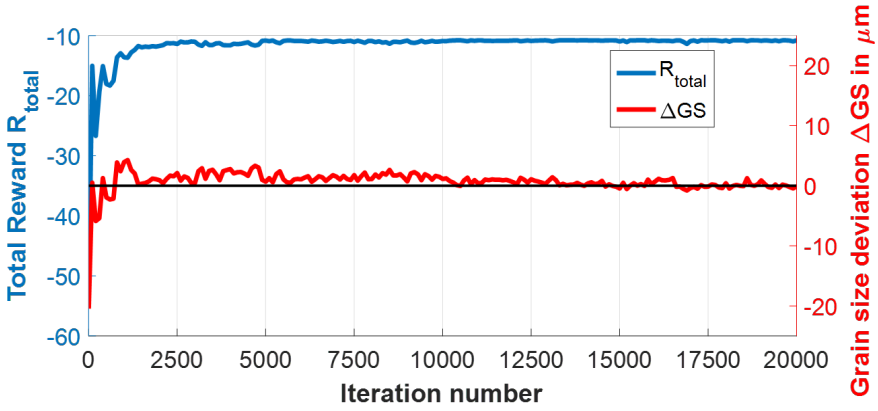

Fig. 7. Evolution of the total reward in blue and the deviation of the average grain size from the target grain size (30 µm) ΔGS in red.

Fig. 8 shows the evolution of the energy consumption as well as the total number of passes of the designed pass schedules during the training. It is noticeable that the energy consumption initially increases significantly, peaks at around 500 iterations at 0.14 GJ and then continuously decreases until it reaches a constant level at about 5,000 iterations with a value of 0.12 GJ.

Another example for the well-defined prioritization in the reward function is the evolution of the number of passes in the pass schedules laid out. The aim was to favor height reductions that are as large as possible so that the required number of passes is as low as possible. A small number of passes usually results in a shorter process time and thus higher efficiency. Here, the number of passes per pass schedule strives very quickly from 18 to the minimum possible number of eight.

In addition to the values shown here, the analysis of the resulting rolling forces and torques showed that the maximum rolling mill limitations were retained at all times during the training. Moreover, the final height is exactly reached by using the dynamic adjustment of the height

reduction presented in this work, it can be stated that rollable pass schedules have been laid out successfully after only a few thousand iterations. Moreover, the dynamic adjustment of the height reduction accelerated the training progress significantly compared to the previous work [1].

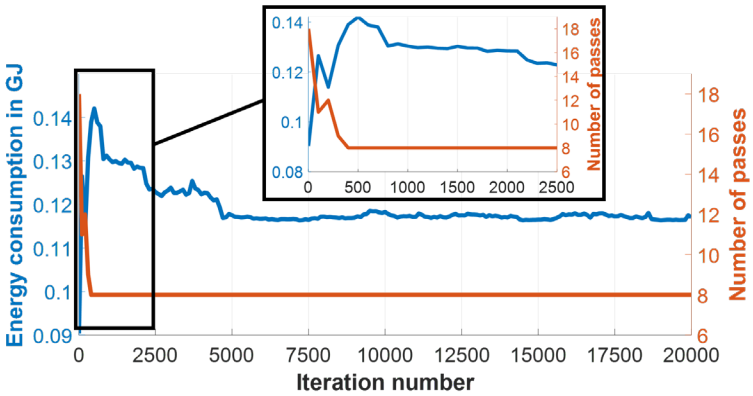

Fig. 8: Evolution of the energy consumption in blue and of the total number of passes in orange of the designed pass schedules during the training.

Summary

The results show that the coupling of RL with an FRM can successfully learn the complex interactions between process parameters, material behavior and the final properties such as the final austenite grain size. The approach does not require explicit knowledge or procedure and can automatically design pass schedules for multiple optimization objectives based on a reward function. The presented extension, the dynamic adjustment of the height reduction, ensures that the target height is always hit exactly. It guarantees automatically designed pass schedule that lead to saleable products. Furthermore, compared to the results of previous work, learning could rather be accelerated. Additionally, the further objectives, especially the target grain size, were successfully achieved. Following next, the designed pass schedules are to be experimentally validated, while the knowledge of the trained RL agents will be transferred to design further pass schedules with varying starting and final geometries.

Keywords: Stress Superposition, Trimming, Damage Reduction, Crack Formation

Abstract. Trimming processes are frequently used for the manufacturing of fastener heads and similar parts with high precision requirements for specific regions of the part. Compared to conventional cold forging processes, the desired geometry can be achieved with significantly lower forces. However, trimming of sharp-edged geometries often leads to a highly inhomogeneous material flow and stress state in the workpiece, resulting in crack formation at such edges. To address this shortcoming, superposition of compressive stresses can be used to reduce the damage in the trimming process significantly. In this paper, the beneficial effect of stress superposition on damage reduction in a trimming process of a splined part is presented. By means of a numerical investigation using the FE-software DEFORM 3D, the impact of compressive stress superposition on the damage respectively crack formation at the edges of a splined part was investigated. Afterwards, trimming dies were manufactured and experimental investigations with three different trimming die geometries and different preform geometries were conducted to manufacture the splined parts. The edges of the splined parts were then characterized with a digital microscope and compared to the numerical results.

Introduction and State of the Art

Cold forging is widely used due to its advantages regarding production of high-volume parts, the work hardening of the material due to the deformation and the possibility to obtain near net shape parts right after the forming process. Furthermore, high surface qualities and very low tolerances with regard to dimensional accuracy of the pressed components can be achieved [1]. Trimming processes are often used to trim scrap material from hot forged parts [2]. But trimming processes are also used e.g. for the manufacturing of complex, sharp-edged geometries with high accuracy requirements for which a conventional cold forging process would not lead to a sufficient filling of the die cavity [3]. One example of such a combined process is the production of fasteners. In particular, in the production of screws with hexagonal head and flange, the shape of the hexagonal head is trimmed while the trimmed material forms the flange in the simultaneous upsetting process. Afterwards, the flange is trimmed with a circular shaped tool. Hence, there are two different categories of trimming processes:

- Category A: Trimming processes in which the produced flange is relatively thin and gets sheared off directly at the initial trimming contour by the knock out pin while the punch is still in its end position (e.g. hexagonal screws without flange). [4]
- Category B: Trimming processes in which the produced flange is relatively thick and remains at the part (e.g. hexagonal screws with flange). Here, the flange is usually trimmed with a circular trimming punch in a following forming stage. [3]

Regarding trimming processes of category A, there are several scientific investigations. In [5], the trimming process of a fastener with a hexagonal head has been investigated numerically while the study was mainly focused on the tool load. It was found that the stopping distance has a major impact on the tool load but also affects the load of the knock out pin which is used to shear off the flange. In [6], a numerical investigation using 2D- and 3D-simulations was conducted to determine the impact of different trimming die geometries on the effective stress within the trimming die. Specifically, the corner geometry, land width, petal angle and rake angle were varied and beneficial values were obtained for these four parameters regarding screw sizes M6 and M20.

In [7], a trimming process of a fastener with a hexagonal head was investigated numerically using seven different damage models. Afterwards, the numerical results were compared to cracks that actually occurred on the sheared off chip of a real pressed part. Main objective of this study was the exact numerical modeling of the crack formation in the sheared off chip, whereby Cockcroft-Latham-Oh damage model was the most accurate model to reproduce those diagonal cracks numerically. Further investigations of the same authors show similar results [8].

In [9], the influence of different geometrical parameters on the target geometry of a fastener with a hexagonal head without flange was investigated. Three geometric phenomena were observed with respect to the target geometry – a roll-over at the top of the fastener head, an underfilling and a burr formation in the lower area of the head. The radius at the cutting edge was found to be the most significant parameter for these geometric deviations. A relatively new study from 2021 comprises an investigation on the die-service life of trimming dies for bolts with hexagonal head [10]. In this study, various combinations of geometric parameters of the trimming dies were investigated and the dies were used until failure due to, for example, broken cutting edges. Cutting edge radius and cutting width were found as the most significant parameters for die-service life.

Regarding trimming processes of category B and especially crack formation in such processes, the authors proposed the topic "Process limits in trimming of non-circular and asymmetrical geometries" as a study in the German Cold Forging Group (GCFG) in 2020 [3]. The aim of this study was a deeper knowledge of damage development during trimming of sharp-edged workpieces. For this purpose, a numerical parameter study was carried out based on a real part geometry of a hexagonal screw with flange. The impact of the workpiece preform geometry and tool geometry on the damage development in the workpiece was investigated. Normalized Cockcroft & Latham criterion was used for damage calculation. Among other things, an approach to superimpose compressive stresses was investigated. This approach showed promising numerical results in terms of damage reduction at the edges of the hexagonal screw. However, the results were not validated with an experimental investigation resulting in the initiation of this present study with the aim of proofing the beneficial effect of stress superposition on damage reduction in trimming processes.

Superposition of compressive stresses for an increased formability is also used in other applications, such as fine blanking [11]. In addition, there are also approaches to use stress superposition in lateral extrusion of brittle materials [12,13] and hollow lateral extrusion [14]. A more in-depth investigation of the connection between the stress state and the pore size in the microstructure as well as the resulting damage was carried out by [15]. Besides an improved formability, there are also investigations on the influence of stress superposition on residual stresses within the workpiece [16].

Material and Methods

The numerical investigations were performed with the FE-software DEFORM. Since the non-alloyed carbon steel EN 1.0214 is a common material for fasteners, this material was chosen for the numerical investigations. The used flow curves for the numerical investigation are depicted in

Materials Research Proceedings 28 (2023) 611-620 https://doi.org/10.21741/9781644902479-66

Fig. 1 and comprise data for two different strain rates (20 s^{-1} and 1 s^{-1}) and four different temperatures ranging from 20°C up to 300°C.

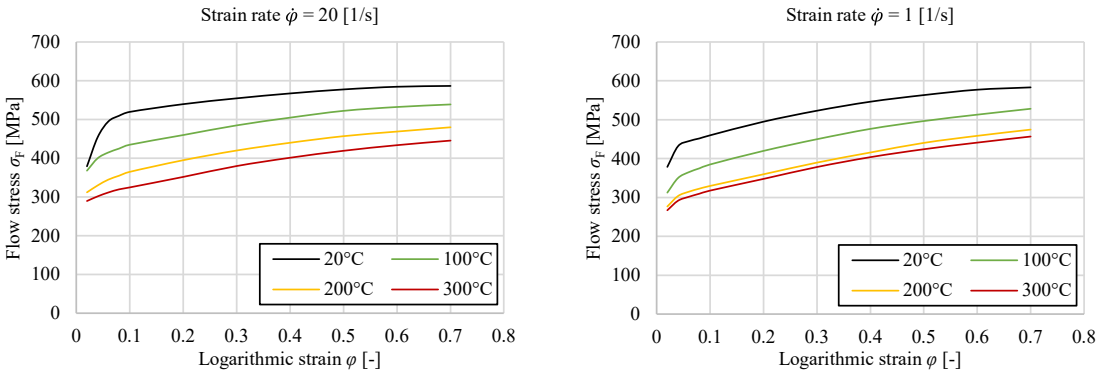

Fig. 1. Flow curves of the non-alloyed carbon steel EN 1.0214.

In order to proof the beneficial effect of stress superposition on damage reduction in trimming processes, a demonstrator geometry with a high susceptibility to crack formation during a conventional trimming process was chosen. In the previous GCFG-study, a screw with a trimmed hexagonal head was investigated (Fig. 2a) [3]. In coordination with the project partner, a gear-shaped geometry with a number of teeth of z_{spline} = 8 and a module of m_{spline} = 2 mm was selected for the present study as a demonstrator geometry (Fig. 2b). The large difference between the tip diameter and root diameter should most likely result in crack formation during conventional trimming. The shaft side of the demonstrator geometry was selected analogously to the hexagonal screw considered in the first study [3] which is based on a real process (Fig. 2c). In this way, it was possible to use the transfer system of the horizontal press without any modifications and the same process sequence. Just a modified trimming die had to be produced.

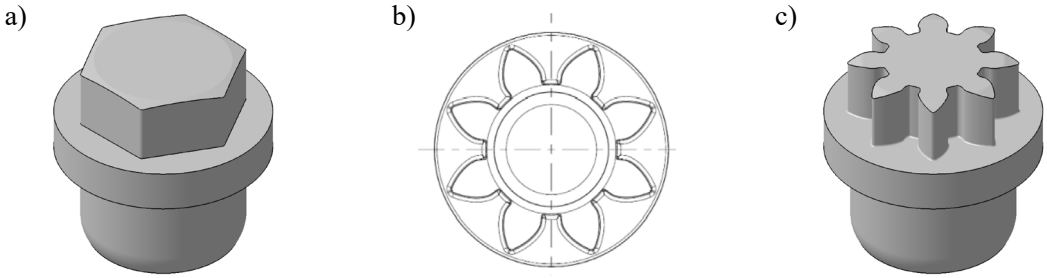

Fig. 2. a) Standard geometry with trimmed hexagonal shape [3], b) defined splined shape for the present study and c) modified geometry with trimmed splined shape.

For the numerical investigation, a multi-stage forming process has been developed in DEFORM comprising upsetting and heading as 2D-simulations, a 2D-3D-conversion and the trimming process as a 3D-simulation. The trimming process of the flange was not carried out, due to the fact that the damage at the edges can already be determined during the trimming process of the spline. Fig. 3 shows the developed multi-stage forming process for the numerical investigation in DEFORM. Since a high variety of different tool geometries was investigated, the workpiece was modelled as an ideal-plastic object whereas the tools were rigid objects. This approach has already been proven beneficial in the first study [3].

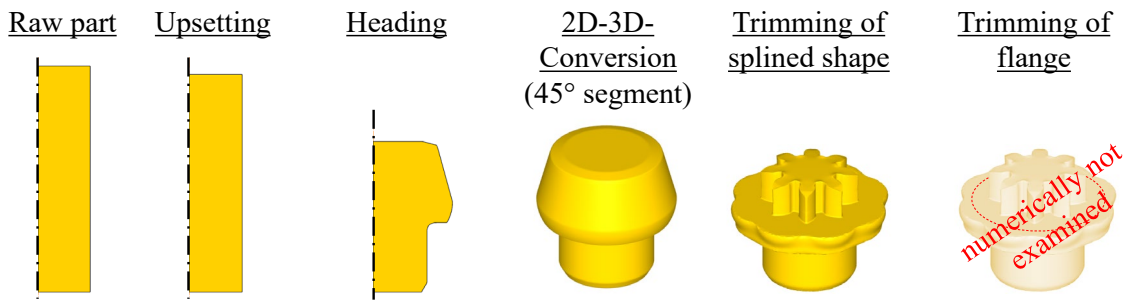

Fig. 3. Developed multi-stage forming process for the numerical investigation in DEFORM.

In the numerical investigation, shear friction model was used with a constant friction coefficient of $m = 0.1$. Furthermore, the velocity of the punch was set to 10 mm/s in each stage. For the upsetting and the heading process the number of elements for the FEM mesh was chosen to 2,500 elements with a minimum element edge length of 0.1 mm. Regarding the relatively simple geometries during upsetting and heading, this element edge length provides sufficient accuracy for the representation of the small radii. The raw part has a diameter of 19.7 mm and a length of 37.3 mm. After the upsetting process, the diameter is 20.75 mm and the length 33.62 mm. The initial preform angle of the conical shape in the heading stage is 16.5°. The preform angle was also varied to 25° since the tools were already available; a further increased value was not investigated based on the findings in [3] (the preform would need a very high radial dimension to meet the required height, and the amount of displaced material would increase disproportionately). The upsetting process is followed by an 2D-3D-conversion. Here, a 45° segment was investigated since this is the angle for simulate one complete tooth (Fig. 3 shows the 360° model for better overview). To decrease calculation time, also half of a tooth could be investigated. However, the relevant area of the tooth (the tooth tip) is directly in the symmetry plane which can influence the calculated workpiece properties. Therefore, one complete tooth was investigated. The hexagonal screw on which the demonstrator geometry is based on, has a wrench size of 19 mm to get an overall idea of the part size depicted in Fig. 2a. In the case of the demonstrator geometry of this study, the tip diameter is 21.6 mm and the root diameter is 12.6 mm.

The model of the 3D-simulation of the trimming process is shown in Fig. 4a. A 45° segment was investigated. This segment was modelled with a FEM mesh consisting of 180,000 elements. Mesh windows were used to obtain an accurate numerical result in the relevant area of the trimming zone. The smallest element size was 0.06 mm. Fig. 4b shows the stop-criterion of the process (flange height of 5.4 mm). The calculated workpiece geometry is depicted in Fig. 4c.

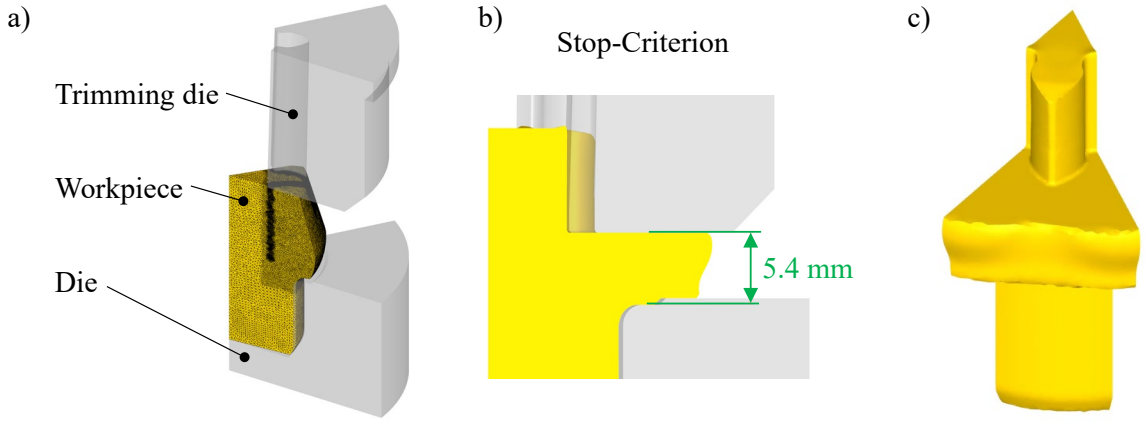

Fig. 4. a) Simulation setup, b) final height of the flange as a stop criterion and c) calculated workpiece geometry.

Materials Research Proceedings 28 (2023) 611-620 https://doi.org/10.21741/9781644902479-66

Regarding the stress superposition, five different trimming dies were used initially. Fig. 5 shows the dies considered for the numerical investigation. The reference die is designed like a conventional trimming die with a cutting edge radius of 0.25 mm. All other dies have the same cutting edge radius. Variant V1 features an indentation of 0.25 mm relative to the face of the die, which is applied close to the contour as an offset at a distance of 0.5 mm. Variant V1b is based on variant V1, but has an increased offset geometry distance of 1.0 mm (with regard to the tooth tip without the tooth root). Variant V2 features an annular indentation of 0.25 mm with a radial offset relative to the tip diameter of 0.5 mm. Variant V3 is designed to apply a compressive stress only in the local area of the tooth tip. For this purpose, the entire surrounding area is designed as a indentation. The offset of V3 was also selected to 0.5 mm, like V1 and V2.

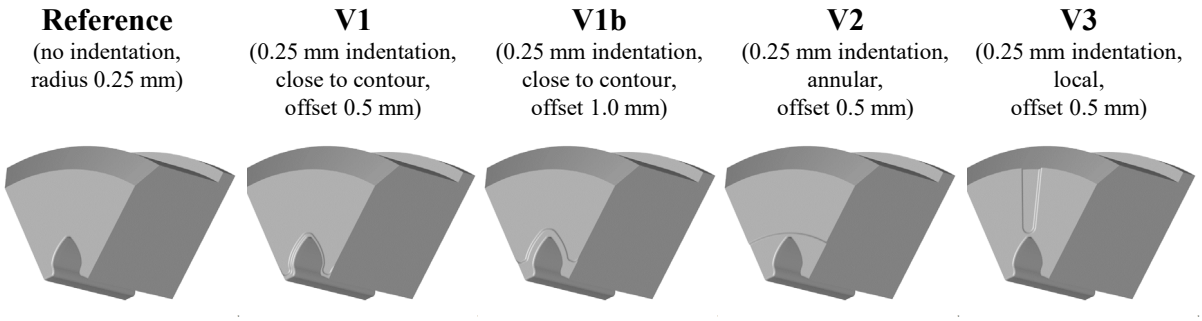

Fig. 5. Initially used trimming dies for the numerical investigation.

The experimental investigations were carried out on a mechanical press. In preparation, the series process for the production of a hexagonal screw with flange shown in Fig. 6 was equipped on the horizontal multi-stage press. Afterwards, the parts were pressed using the splined dies and the parts with cracks were analyzed using a Keyence digital microscope VHX-5000. Finally, the critical damage value was determined by comparing the numerically determined damage distribution with the measured crack height.

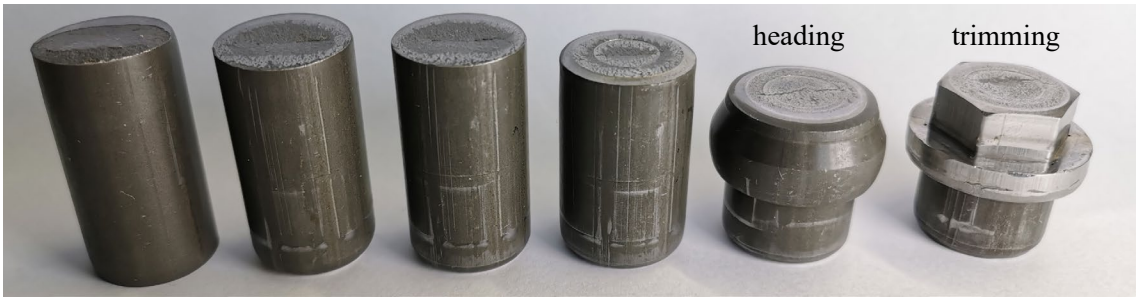

Fig. 6. Multi-stage process for production of a hexagonal screw with flange.

Results and Discussion

At first, the numerical results are evaluated. The geometry and the respective distribution of damage with Normalized Cockcroft & Latham damage model is shown in Fig. 7. The modified die geometry is well visible on the top side of the flanges. Regarding the determined damage values, also the maximum damage value for each variant is listed. As expected, the highest damage values occur at the tooth tip of the splined geometry. The reference die leads to the highest value of $D_{max,ref} = 5.41$. For all other variants the damage value is reduced due to the superposition of radial compressive stress. This can be explained by the additional redirection of the material flow at the transition of the indentation, which leads to an additional radial force. Owing to the highly inhomogeneous material flow caused by the large differences between tip and root diameter, the

modified variants have a different impact on the damage values. Variant V2 leads to the most homogeneous material flow due to the annular indentation and, as a result, provides the smallest damage value of $D_{max,V2} = 2.94$. With regard to the forces, there are only minor differences between all variants with 525 kN to 575 kN (Fig. 7). This can be explained with the only slightly varying volume differences of the indentations. Without an experimental test, the damage value only indicates the potential area of possible damage, but must always be validated with an experimental test. Therefore, it cannot be determined solely from the numerical results whether a crack will occur or not.

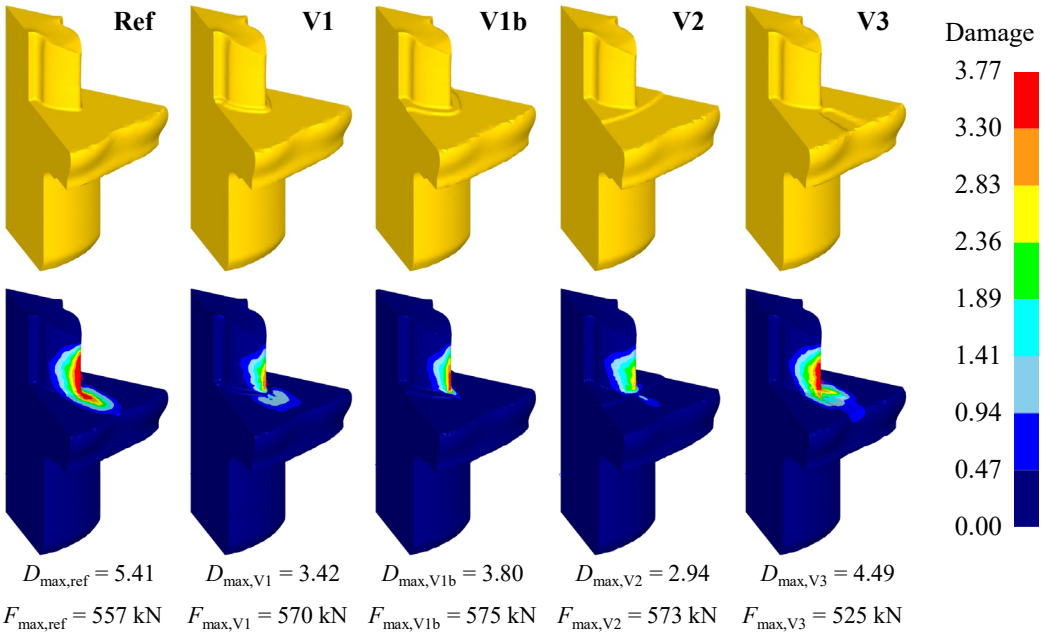

Fig. 7. Calculated geometries and respective distribution of damage with Normalized Cockcroft & Latham.

Due to the smallest numerically determined damage values, variant V2 was selected for the experimental investigations. The manufactured die with the splined contour replaced the hexagonal die in the process sequence depicted in Fig. 6. Initially, several parts were pressed with the conventional machine setting. Fig. 8 a shows the reference trimming die for the spline shaped parts. A pressed part is depicted in Fig. 8b. The crack formation at the sharp edges of the tooth tips is clearly visible. A detailed view of one tooth is shown in Fig. 8c. Thus, it can be concluded that the selected demonstrator geometry has a high vulnerability to crack formation with respect to conventional trimming processes.

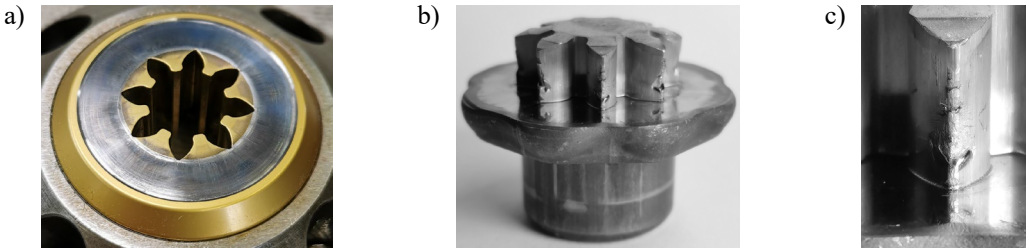

Fig. 8. a) Trimming die without indentation (reference), b) pressed part with cracks and c) detail of tooth tip.

Subsequently, the experimental investigation with the trimming die with an annular indentation of 0.25 mm was conducted. The pressed parts showed also cracks at the sharp edges of the tooth tips (Fig. 9b and Fig. 9c). At first, the initiation position of the cracks looked quite similar compared to the variant without compressive stress superposition. Therefore, also a comparison of Fig. 8c and Fig. 9c doesn't show much difference. But in fact the initiation position of the cracks was slightly lower which is made clear in Fig. 11 later.

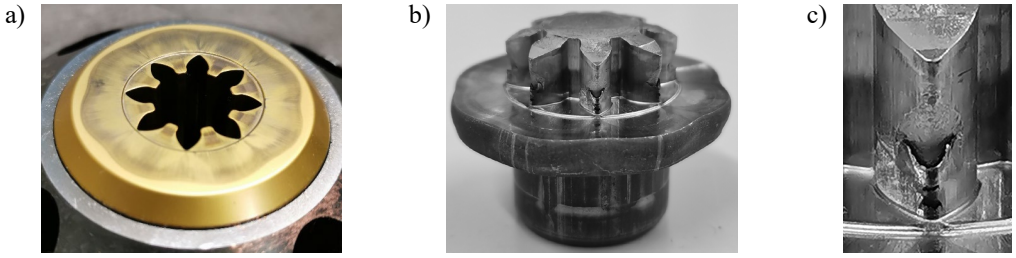

Fig. 9. a) Trimming die with annular indentation of 0.25 mm, b) pressed part with cracks and c) detail of tooth tip.

In a further investigation, the indentation was increased from 0.25 mm to 1.0 mm (Fig. 10a). As a result, there is a larger deflection of the material and, thus, higher induced compressive stresses occur. With this adjustment it was possible to press parts without any cracks. One exemplary part is shown in Fig. 10b with a detailed view in Fig. 10c.

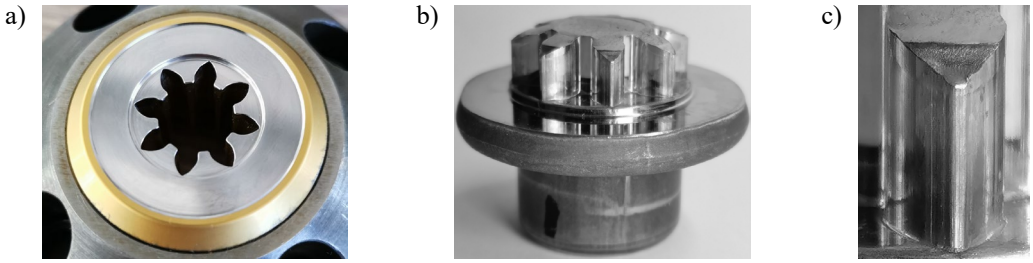

Fig. 10. a) Trimming die with annular indentation of 1.0 mm, b) pressed part without cracks and c) detail of tooth tip.

Besides those different die geometries, also the preform angle was varied in the experimental investigation using the trimming die with a 0.25 mm deep indentation. For comparison of the experimental results with the numerically determined damage values over 400 teeth were characterized using the Keyence digital microscope VHX-5000. In particular, the total trimming height h from the top edge to the flange, the trimming height s from the crack initiation to the flange and the difference between those two heights - the trimming height without crack a - were measured.

Fig. 11 shows the measured heights for characterization of crack initiation as well as the impact of the investigated variants with respect to the indentation and the preform angle on the trimming length without crack a. Furthermore, the number of measurements is indicated, since at some parts the very sharp edges were deformed due to the impact in the container after the forming process. Without a compressive stress superposition, an average trimming height without crack of $a = 1.02$ mm was determined. With a compressive stress superposition by the indentation of 0.25 mm, a 35 % higher value of $a = 1.38$ mm could be achieved for the same preform. The preform which was used initially in the numerical investigation comprising an angle of 16.5° has only a slight impact on the height a. Here, the average value is 1.33 mm. Regarding the variant with 1 mm indentation, no cracks occurred on any of the pressed parts. The height a therefore

always corresponded to the total trimming height h, with an average value of h = 5.22 mm. The maximum value of the total trimming height for one part with a very low end position of the trimming die was h = 5.80 mm.

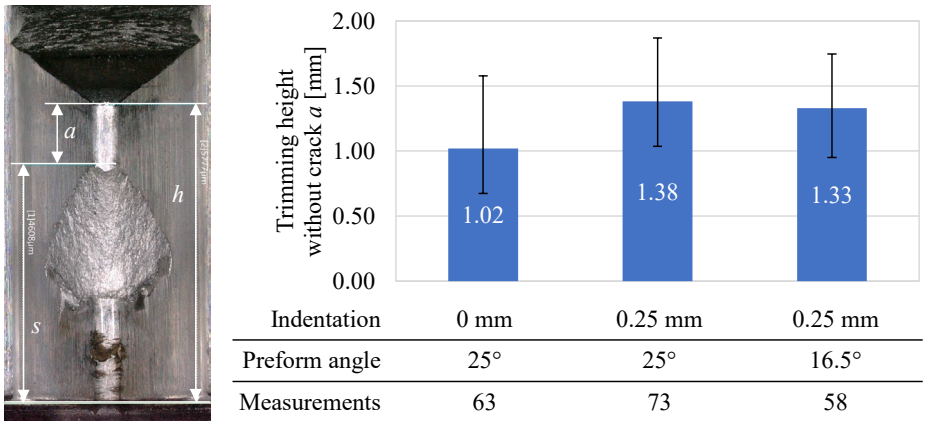

Fig. 11: Measured heights for characterization of crack initiation and impact of the investigated variants on the trimming length without crack a.

To compare the numerical and experimental results, the additional preform with an angle of 25° and the additional trimming die geometry with an indentation of 1 mm were first added in the numerical investigations and further simulations were carried out. Based on the average trimming height without crack *a*, the critical damage value was then identified for the reference die and the die with an indentation of 0.25 mm as well as for the preform angles 25° and 16.5°. Using this procedure, an average critical damage value of 0.93 was identified. The preform angle has no major impact and the penetration depth has no impact on the critical damage value. Fig. 12a shows the comparison of an edge of a pressed part (no indentation, preform angle 16.5°) and the numerically calculated damage distribution. The color scale is formatted in such a way that the critical damage value represents the transition from orange to red color (red circle).

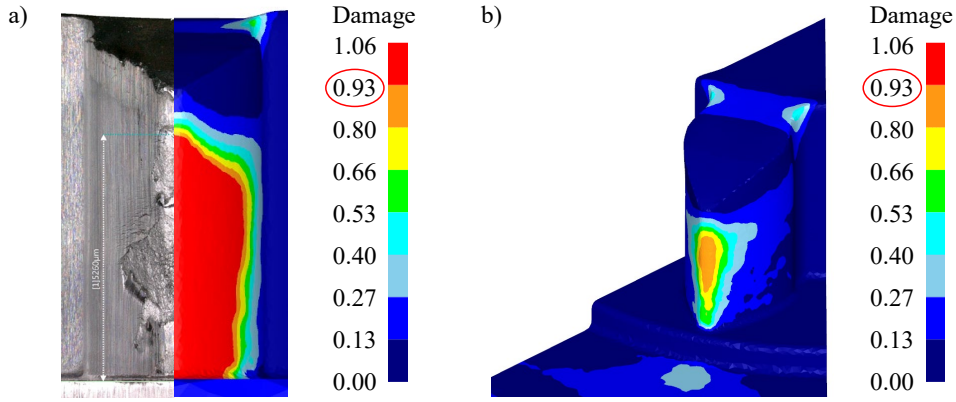

Fig. 1. a) Comparison of an edge of a pressed part (no indentation, preform angle 16.5°) and the numerically calculated damage distribution and b) calculated damage distribution of the variant with an indentation of 1 mm.

According to the damage distribution illustrated, the crack initiation height can be estimated quite accurate with ± 0.1 mm in height for all investigated variants. However, there is a difference in the shape of the cracks on the real part and the area with damage values higher than 0.93, which is probably due to the lack of element deletion. Using element deletion would in particular affect adjacent elements, which could lead to a more realistic representation of the shape of the crack.

The analysis of the variant with an indentation of 1 mm in Fig. 12b demonstrates, that the calculated damage values are lower than the critical damage value of 0.93. Since no cracks occurred during the experimental investigations with this trimming tool, it can be concluded that the numerical model can represent the crack initiation behavior realistically. In summary, compressive stress superposition can be used to improve trimming processes of parts which are vulnerable to crack formation.

Summary

In this contribution, a numerical study with a subsequent experimental investigation regarding superposition of compressive stresses in trimming processes of bulk forming parts has been conducted. At first, a gear-shaped demonstrator geometry which is vulnerable for crack formation during a conventional trimming process was defined. Afterwards, different trimming die geometries for stress superposition were investigated and their impact on the damage development in the workpiece was evaluated. Based on the numerical results, the trimming die which leads to the lowest damage values in the workpiece was selected and manufactured for the subsequent experimental investigation.

In the experimental investigations, different trimming die geometries and preform geometries were conducted to manufacture the splined parts. Besides the initially investigated trimming die geometries, also an additional geometry was investigated comprising an indentation of 1.0 mm for stress superposition. The edges of the splined parts were then characterized with the Keyence digital microscope VHX-5000 and compared to the numerical results for identification of the critical damage value. It was found that a minor compressive stress superposition (indentation of 0.25 mm) leads to slightly reduced damage values in the workpiece compared to a conventional die without compressive stress superposition. Using a further increased compressive stress superposition (indentation of 1 mm), it was even possible to press components without crack formation entirely.

In summary, it was shown that the superposition of compressive stresses is a useful method for improving trimming processes of parts that are vulnerable to crack formation. Since damage is very specific in terms of material and geometry, it is not possible to directly transfer the determined critical damage value to completely different geometries or materials. Experimental validation is always required to investigate on damage development. However, the developed simulation model can be used as a comprehensive basis for the investigation of similar splined geometries and other materials in the future. The method of compressive stress superposition in trimming processes can be transferred to other parts for which no trimming process could be applied so far, thus the existing process limits of trimming processes can be improved significantly.

Keywords: Cogging, Simulation, Recrystallisation, Stainless Steel, Ingot-To-Billet Conversion Process

Abstract. This study is focused on understanding the effects of key process parameters on the onset of recrystallisation of coarse, elongated, and dendritic grains of the as-cast microstructure during ingot-to-billet conversion, consisting of successive cogging, upsetting, and reheating operations, in type 316 austenitic stainless steel. The microstructural characteristics of the initial as-cast ingot (e.g., size, orientation and morphology of grains), and the complex thermo-mechanical path have significant impact on recrystallisation behaviours, which make the existing material models inefficient of precise microstructure prediction. These investigations aim at exploring the recrystallisation mechanisms and their dependency on the forging process parameters. Cogging trails were conducted on VIM-VAR stainless steel ingots and microstructural observations were made to identify the recrystallisation mechanisms. Finite element simulations coupled with constitutive material models were developed in parallel, to enable microstructurally informed prediction of the cogging process. Thus, static and discontinuous dynamic recrystallisations occur in succession after reaching a threshold level of deformation during cogging. Grain growth occurred in the statically recrystallised grains during reheating. The importance of the reheating and the associated static recrystallisation on the efficiency of the billet conversion process in terms of grain refinement is thus highlighted.

Introduction

The ingot-to-billet conversion process, consisting of hot forging operations of cogging and upsetting with intermediate reheating, is typically performed to generate a homogeneous and equiaxed grain microstructure from the initial as-cast's coarse, elongated, and dendritic structure. The different steps of the conversion route cause the occurrence of several metallurgical mechanisms, which lead to the evolution of microstructure. Continuous (CDRX) or Discontinuous (DDRX) dynamic recrystallisation are the main mechanisms of microstructure evolution, occurring during the hot forming operation. The plastic strain, strain rate and the temperature are the main thermomechanical parameters governing these mechanisms [1]. During intermediate reheating (i.e., between cogging/upsetting operations), static recrystallisation (SRX) can occur depending on the temperature and the accumulated strain energy in form of geometrically necessary dislocation density produced during the previous forming operations. Further, grain growth can also occur when the material is held at high temperatures for a long time, in particular, during heating and reheating processes.

Materials Research Proceedings 28 (2023) 621-628 https://doi.org/10.21741/9781644902479-67

The occurrence of these mechanisms are well-known in the case of austenitic stainless steels with an initial fine and equiaxed grain structure [1]. With the aim of optimising a forging route, the grain size can be predicted by Finite Element (FE) simulation integrating materials models, like the JMAK model [2], or full field models with scale transition [3].
However, the microstructural characteristics of the initial as-cast ingot have a significant impact on recrystallisation behaviours, which make the existing material models inefficient of predicting microstructure evolutions to a reasonable accuracy. For instance, the crystallographic texture resulting from the oriented solidification of the material during its casting, confers to the material an anisotropic plastic behaviour as described for type 718 nickel alloy by [4].

The present work aims at understanding the recrystallisation mechanisms in the as-cast microstructure occurring during ingot-to-billet conversion process of type 316 stainless steel. These involve investigating the effect of heating and thermomechanical processing on the evolution microstructure in the as-cast material with a coarse, elongated and dendritic grain microstructure. For this purpose, cogging trials were carried out following a typical industrial forging route, including intermediate heating. A FE simulation of the process was also conducted in parallel to estimate the evolution of stress, strain and temperature throughout the whole process. The experimental details are presented in a first part, and the second part is devoted to the numerical modelling of the cogging process. Finally, experimental and numerical results are presented and discussed.

Experiments

The initial ingot was a cylinder with a diameter of 190mm and a length of 600 mm (Fig. 1a). It was manufactured through a consecutive vacuum induction melting (VIM) and vacuum arc re-melting (VAR) processes. The as-cast macrostructure, similar to that reported by Park et al. for nickel superalloys [5], consisted of coarse dendritic grains elongated according to the solidification direction, oriented at ≈ 60° upwards with respect to the axis of the ingot (Fig. 1b), except in the centre, where the grains had their long axis parallel to that of the ingot.

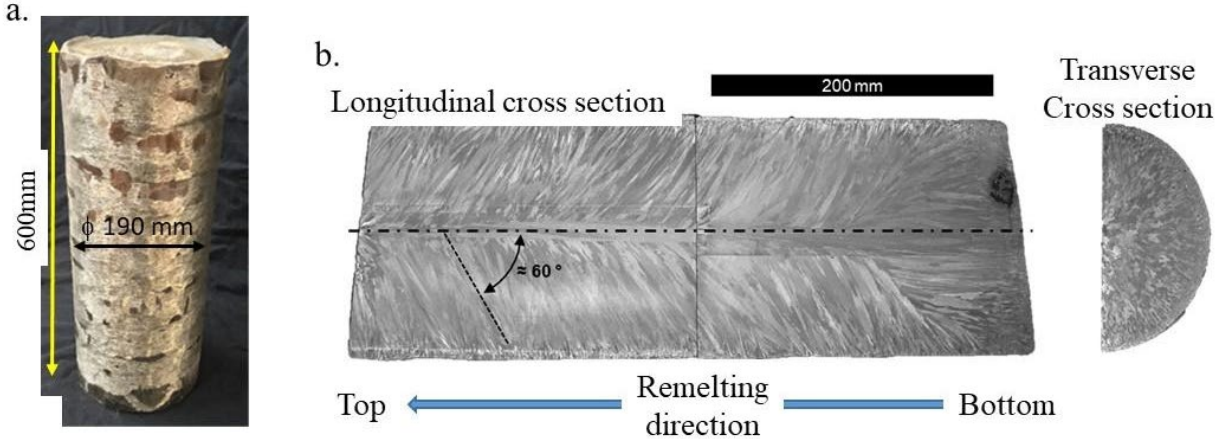

Fig. 1. Initial VIM/VAR melted type 316 austenitic stainless steel ingot, (a) a photograph of the ingot after being ground for the removal of surface scales, and (b) optical microscopy appearances of the longitudinal and transverse cross-sections of the ingot exhibiting the coarse, elongated, and dendritic grains, oriented at ≈ 60° to the axis of the billet.

The heating and cogging route is schematically depicted in Fig. 2. It consisted of three section-reduction stages of 20 %, 12 % and 12 % respectively, after an initial 12 h soaking at 1250°C, followed by two additional cogging stages of 20 % section-reduction after an intermediate 90 min reheating at 1250°C.

To investigate the effect of the different steps of the cogging route on the grain structure, and to highlight the occurrence of the different recrystallisation mechanisms, two ingots were forged. An ingot was subjected to the first three section-reduction stages before cooling to room temperature. The second was cogged according to the complete route presented in Fig 2, but the last two section-reduction stages were applied on its half-length only. Each section-reduction stage consisted of two successive cogging passes with an intermediate 90° rotation of the ingot (i.e., change of forging direction). Each cogging pass consisted of blows with an advancing feed of the ingot between two successive blows. The advancing feed of each stage and the target section dimensions are given in Table 1.

Table 1. Target section dimensions and feed of each stage (dimensions in mm).

Forging stage	1st	2nd	3rd	4th	5th
Target dimensions (mm²)	170 × 170	160 × 160	150 × 150	135 × 135	120 × 120
Feed (1st blow) (mm)	110	80	80	60	60
Feed (following blows) (mm)	60	30	30	30	30

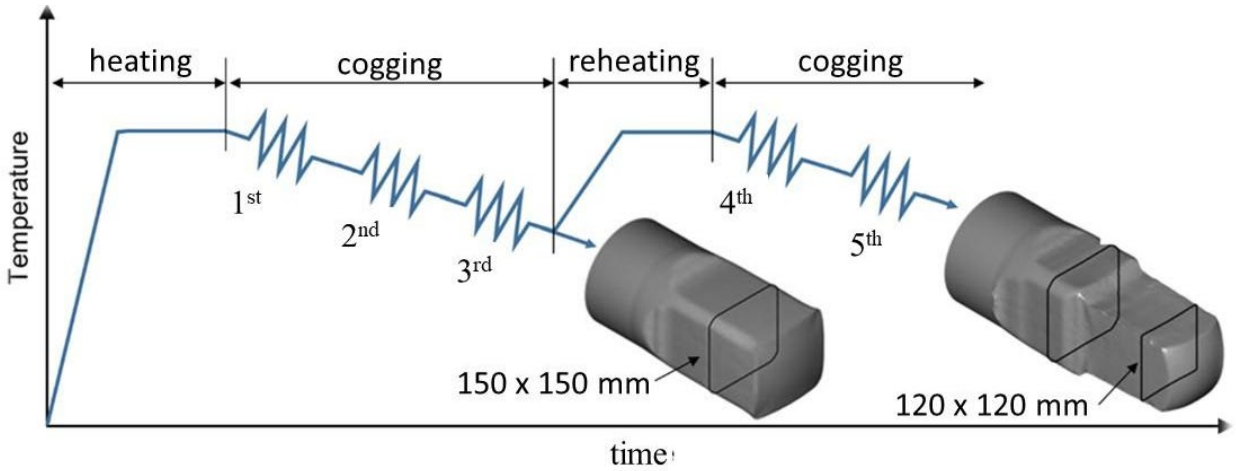

Fig. 2. Schematic illustration of the cogging route on the as-cast ingots.

The heating and reheating were performed in an electric furnace. The cogging operation were carried out using a LASCO® SPR-400 screw press. The ingots were initially coated with a refractory material to reduce oxidation during heat treatment and to limit heat losses during transfer from the furnace to the press. The ingots were handled by a six-axis robot equipped with a gripper (Fig. 3a and c), with unlockable compliances accommodating the axial and vertical deformation of the ingots during cogging blows. The anvils, whose main dimensions are given in Fig. 3b, were pre-heated to 450°C using embedded heating cartridges. Stoppers were placed between the upper and lower anvils to control the stroke.

After cogging, the ingots were optically scanned using a ATOS III Scan GOM® system. The ingots were then cut, ground and chemically etched to obtain optical macrographs from their longitudinal cross-sections. Smaller specimens were also machined out for further analyses at higher magnification by optical microscopy.

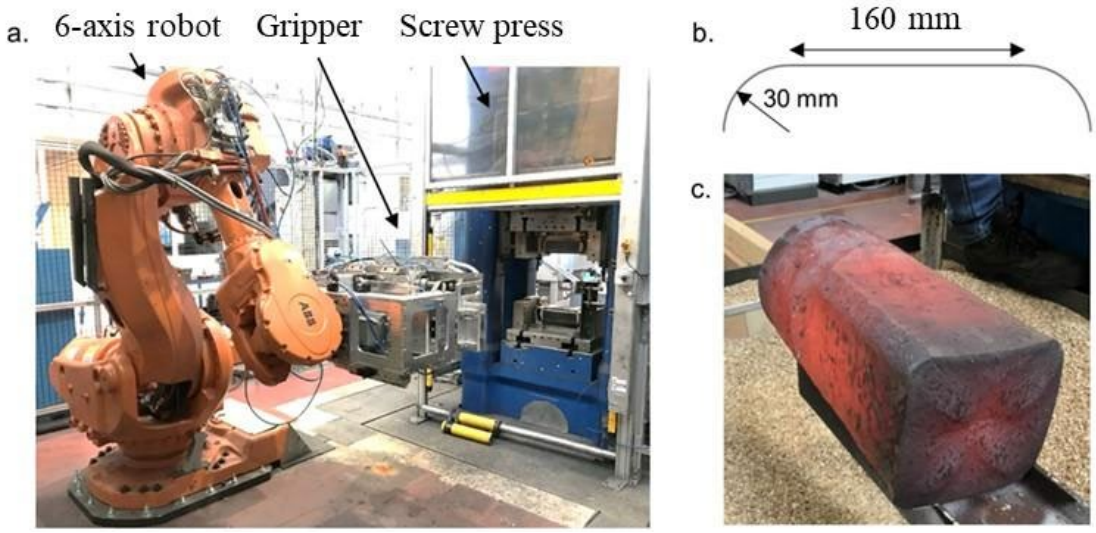

Fig. 3. (a) Experimental set-up, (b) the anvil profile, and (c) photographs of the ingot after the first three stages of the cogging operations.

Modelling and Simulation

The FE simulations were performed using the commercial Forge NxT 3.0® software to predict the evolution of temperature, plastic strain and strain rate within the ingot throughout the cogging route. A simplified Hensel-Spittel viscoplastic constitutive law was implemented into the FE model for the material's thermomechanical behaviour (Eq. 1). The material properties data for 316L were taken from the Forge® database.

$$\sigma = A \cdot e^{m_1 T} \cdot \varepsilon^{m_2} \cdot \dot{\varepsilon}^{m_3} \cdot e^{\frac{m_4}{\varepsilon}} \quad (1)$$

As shown by Paquette et al. [6], the anisotropy of the solidification induced textured microstructure was considered using the orthotropic Hill-48 criterion (Eq. 2). The constitutive law and the Hill criterion parameters are given in Table 2.

$$\sigma_0{}^2 = F \cdot (\sigma_{22} - \sigma_{33})^2 + G \cdot (\sigma_{11} - \sigma_{33})^2 + H \cdot (\sigma_{11} - \sigma_{22})^2 + 2L \cdot \sigma_{23}{}^2 + 2M \cdot \sigma_{13}{}^2 + 2N \cdot \sigma_{12}{}^2 \quad (2)$$

The Hill criterion was expressed in an anisotropic reference frame, assuming a grain orientation similar to that of the as-cast material (i.e., the solidification structure). In Eq. 2, the index 3 corresponds to the direction of solidification. The orientation of the anisotropic frame is symmetrically distributed around the axis of the ingot; hence the index 3 direction being orientated at 60° with respect to the axis of the ingot. The central zone of the ingot with the axially elongated grains was not taken into account.

Table 2. Hensel Spittel constitutive law parameters and orthotropic Hill-48 criterion parameters.

Hensel Spittel	A	m1	m2	m3	m4
	8905.34	-0.00383	0.01246	0.09912	-0.02413

Orthotropic Hill-48 criterion	F	G	H	L	M	N
	0.5	0.5	0.5	0.68	0.68	1.5

A Tresca limited Coulomb law ($\underline{m} = 0.4$, $\mu = 0.8$) was implemented to simulate the friction behaviour between the material and the anvil. The heat exchange rate between the ingot and the ambient medium was set to 10 $Wm^{-2}K^{-1}$, and to 10^4 $Wm^{-2}K^{-1}$ for the exchange with the anvils. The temperature of the anvil was set to 450 °C to make it similar to that of the experiments. According to the symmetries of the problem, the ingot was modelled by a quarter of the cylinder, with two planes of symmetry implemented (see Fig. 4). The ingot was meshed with tetrahedral elements with an average size of about 6.5 mm. The dies were considered as rigid bodies and their surfaces were meshed with triangular elements of 15 mm average size.

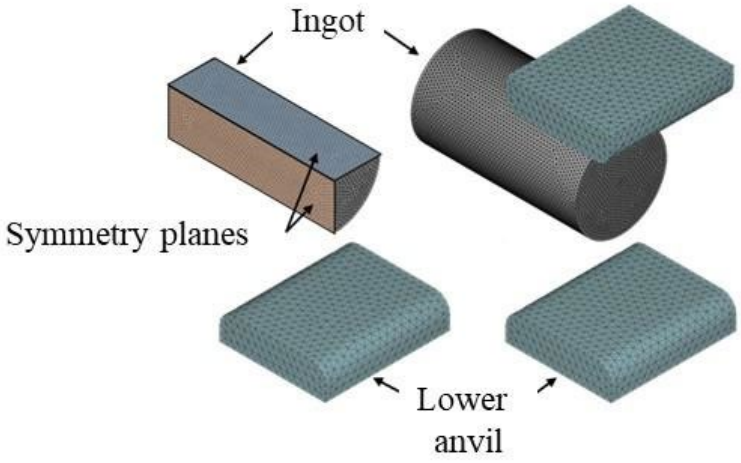

Fig. 4. Numerical model of the cogging operations.

A particular attention was paid to the temperature prediction, as it is one of the most influential thermomechanical parameters driving the recrystallisation mechanisms. The duration of each step of the cogging route, recorded during the trial, including the transfer from the furnace to the press, and the position of the ingot before each blow were therefore implemented in the simulation.

Results and Discussion

In Fig. 5, the 3D scan of the ingot after the first three stages of cogging and the simulated geometry obtained with both orthotropic and isotropic criteria are shown. It can be seen that the end of the ingot exhibited lobes along the diagonals. This feature was not captured by the FE simulation with the isotropic criterion implemented. On the other hand, the FE simulation with the anisotropic material model implemented allowed to predict the formation of these features, suggesting the important role of the anisotropy on the deformation behaviour of the as-cast material during the forging process. The geometrical discrepancy between the experimental and FE predicted geometries of the cogged ingot are highlighted by the circles in Fig. 5, and can partially be ascribed to the fact that the specific orientation of the grain at the centre of the ingot was not taken into account in the FE model.

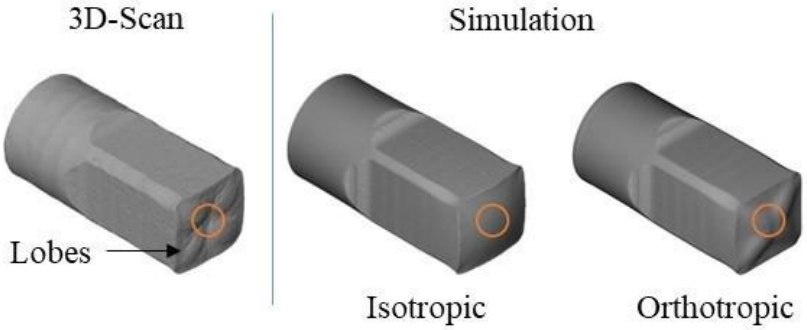

Fig. 5. Geometry of the ingot after the first three cogging stages; 3D scan after cogging trials, and FE simulated with isotropic and anisotropic material behaviours.

Fig. 6 presents macrographs of the two ingots. The macrograph of the first ingot (Fig. 6a) shows the macrostructure obtained at the end of the first three cogging stages, before the reheating. No obvious occurrence of recrystallisation can be seen from this macrograph.

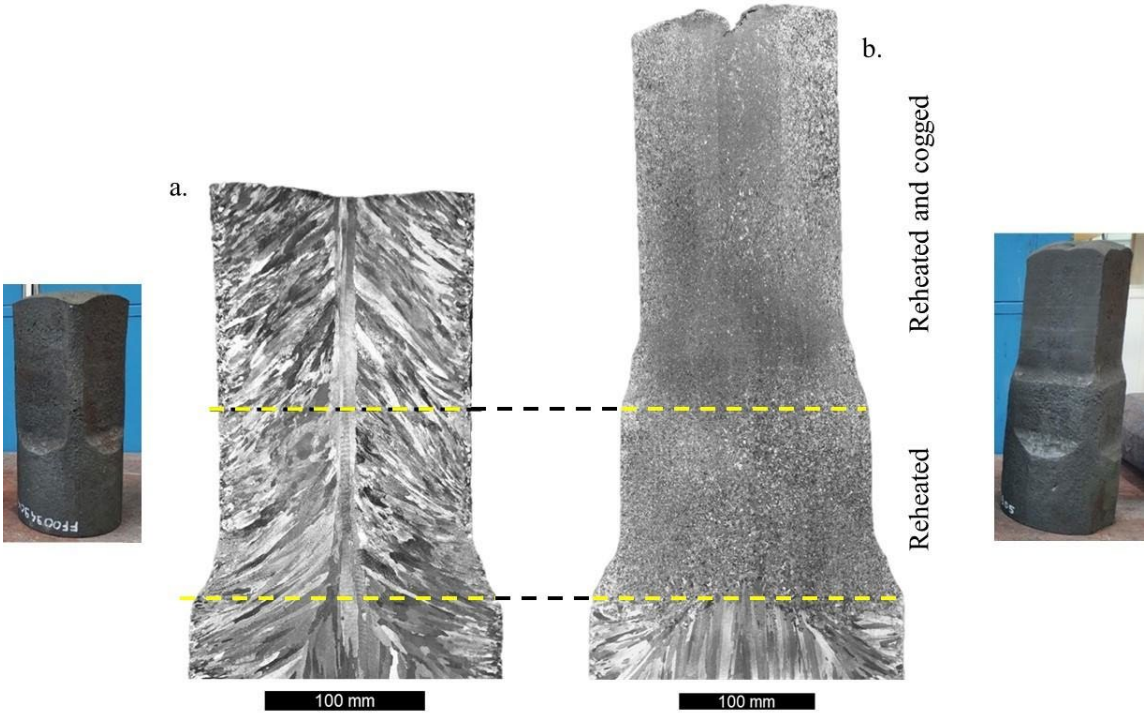

Fig. 6. Optical macrographs taken from the longitudinal cross-sections of the cogged ingots, (a) after the first three stages of cogging, and (b) following the complete cogging route plus reheating.

The macrograph of the second ingot can be split into two zones, (i) a reheated zone (RZ) which was re-heated after being cogged through the first three stages, and (ii) a reheated and cogged zone (RCZ) which was subjected to the complete cogging route. The onset of recrystallisation in both RZ and RCZ can clearly be seen in Fig. 6b. The difference in grain structure between the first ingot and the RZ is in the reheating, which has resulted in SRX of the material deformed during the first three cogging stages.

Analyses of higher magnification micrographs taken from different areas of these ingots were carried out to identify the recrystallisation mechanisms occurring during the cogging process (Fig. 7). Fig. 7a displays the microstructure in the cogged zone of the first ingot, where DDRX was observed at some boundaries of the parent microstructure. In the RZ of the second ingot, the recrystallised grains were large, but equiaxed. This confirms the occurrence of SRX, promoted by the deformation of the initial microstructure, induced by cogging. DDRX was very limited during the first cogging stages, and the plastic deformation was accommodated by strain hardening. SRX occurred during the reheating, and was followed by grain growth. In the RCZ, necklace type DDRX was observed. Such necklace-type DRX was previously reported in the literature for as-cast microstructures composed of large and elongated grains [6].

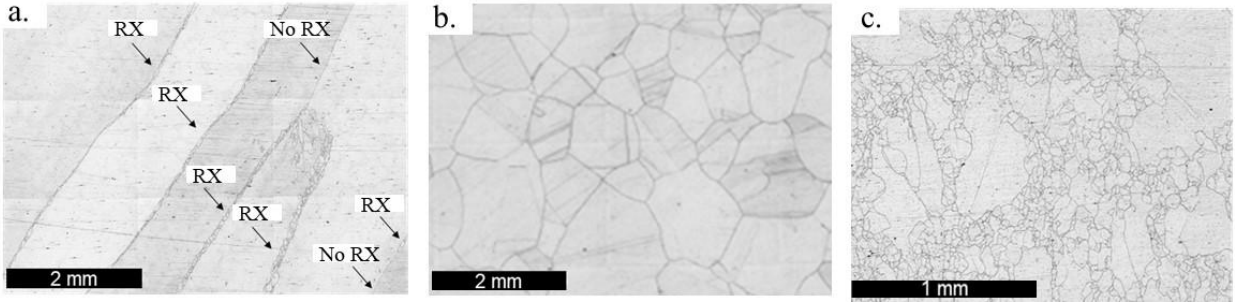

Fig. 7. Optical micrographs of the billets after cogging operations;(a) the cogged zone of the first ingot, (b) the reheated zone, and (c) the reheated and cogged zone of the second ingot.

Evolution of plastic strain and temperature during the first three cogging stages were estimated by FE simulation (Fig. 8). The maximum predicted strain was at the extremity of the ingot and was ascribed to the formation of the particular feature described in Fig. 5, as an edge effect. The final temperature at the core of the ingot was between 900 °C and 1000 °C, which are relatively low for DRX; and can explain the occurrence of strain hardening in the cogged zone of the first ingot.

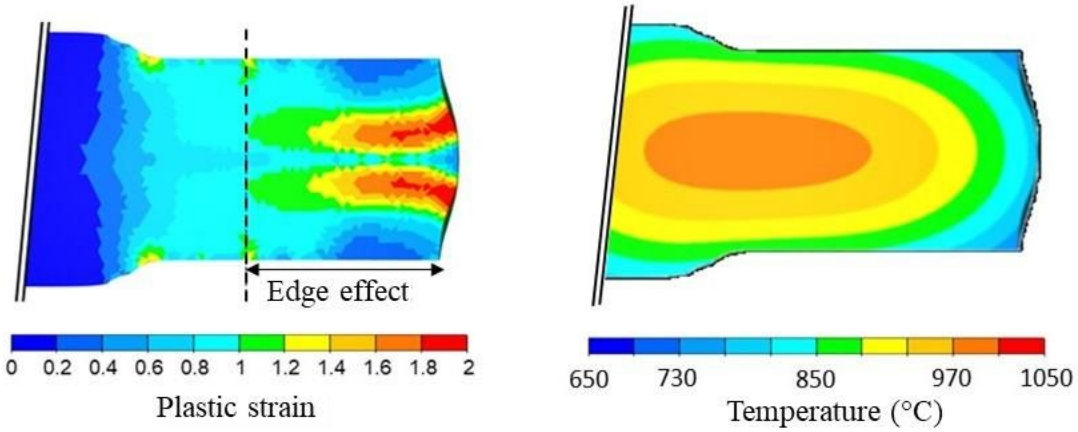

Fig. 8. Distributions of plastic strain and temperature predicted by FE simulations along the longitudinal cross-section of the ingot after the first three cogging stages.

Comparison of FE results and microstructures provided in Fig. 6 and Fig. 8, respectively, allowed to identify that SRX occurred during the reheating in the areas where the plastic strain obtained at the end of the first cogging stage was higher than the threshold value of ≈ 0.2.

The validity of the implemented anisotropic material model for equiaxed and recrystallised microstructure, such as that observed in the RZ, is questionable since the crystallographic texture of the microstructure issued from SRX was not characterised, and the parameters proposed by Paquette et al. [6] may not remain suitable. The last two cogging stages were therefore not simulated.

Summary

Cogging trials of VIM-VAR processed 316 type stainless steel ingots have been performed to investigate the recrystallisation mechanisms of an as-cast microstructure containing coarse, elongated, and dendritic grains. The cogging operations led to an insignificant amount of DDRX, localised to grain boundaries primarily. Otherwise, the cogging induced deformation led to strain

hardening during the initial stages of cogging, resulting in a significant level of static recrystallisation during the follow-up reheating. The latter led to new coarse, but equiaxed grains which then underwent DDRX during the following cogging stages (i.e., creating necklace structure). The efficiency of the SRX was a function of temperature gradient between the last cogging stage and the follow-up reheating. The large equiaxed grains after the reheating were most likely generated by normal grain growth, following the static recrystallisation. This must have been promoted by the higher temperature and the holding time of the reheating.

The strain hardening induced during the cogging process typically results from a competition between dislocations generation, their dynamic recovery, and the dynamic recrystallisation. The latter phenomena being favoured by a high temperature, as the lower the temperature at the end of the cogging stages the higher the strain hardening will become, and hence the more efficient the static recrystallisation during reheating. This study has shown the importance of temperature control and the role of static recrystallisation, as important parameters in optimising ingot-to-billet conversion processes.

Keywords: Radial-Axial Ring Rolling, Super Duplex Stainless Steel, VDOE, Cracks, Fishtail

Abstract. Welding neck flanges are commonly manufactured by radial-axial ring rolling (RARR). The service conditions of these elements are very demanding (mechanical loads and corrosive environments). For this reason, materials such as super duplex stainless steel (SDSS) are used, which could present workability problems under certain process conditions. In this work, a study of forming defects and failure occurrence in the RARR of SDSS flanges has been proposed. Firstly, a finite element model of the industrial RARR process was developed and validated. Then, a multivariate factorial analysis based on a virtual design of experiments was performed to identify the determinant parameters of the process. The diameter of the mandrel was identified as the most determinant parameter. An increase in diameter reduces the probability of developing underfilling defects and the development of cracks in the flange neck. The mandrel radial speed has no significant effect on the cracking of underfill defects while reducing the rotational speed of the king-roll could improve the uniformity of the deformation distribution in the flange section.

Introduction

The oil and gas industry demands extreme operating conditions, often combining high pressures with highly corrosive environments. In pipelines, flanges of 25 %Cr super duplex stainless steels (SDSSs) are generally used, as they require high strength and corrosion resistance [1]. The UNS S32760, which is considered an SDSS, meets these requirements thanks to the mixture of both austenite and ferrite which leads to a material with excellent mechanical properties and corrosion resistance. In addition, it typically contains 25% Cr and 7% Ni-doped with a small amount of N, (0.3%) providing improved corrosion properties, and allowing its use in the marine environment [2]. However, cracks could be generated in welding neck flanges made of SDSS during hot forming and thus, its workability at high temperatures could be limited under certain conditions [3].

Weld-neck flange rings of high diameter are manufactured on ring rolling machines, by enlarging the diameter of ring blanks. In this hot forming process, first, the blanks are heated to the forging temperature. Then, the RARR machine reduces the wall thickness using the king-roll and mandrel. In addition, two axial rolls act simultaneously to decrease the height of the blanks [4]. In this hot forming process, one of the most problematic issues is controlling fishtail and underfilling defects [5]. The fishtail could be defined as an undesirable plastic deformation at the ring's upper surface, which leads to a geometrical defect as there is a lack of material in that region. Giorleo et al. [6] investigated the influence of the mandrel idle speed on the fishtail, keeping the king-roll rotation speed constant. Nevertheless, they concluded that the effect of mandrel idle speed on fishtail was not significant. Zhou et al. [7] identified that a higher king-roll rotational speed increases fishtail, given that deformation is concentrated in the surface area of the ring in

the axial direction, as the diameter increase per revolution decreases. Allegri et al. [8] proposed a non-constant rotational speed of the main roller to keep the angular velocity of the ring constant. They conclude that maintaining a constant rotational speed in the ring could decrease fishtail dimension by 50%.

Regarding material damage and crack development, the ductility of SDSS decreases with lower temperature and higher strain rate, which facilitates the occurrence of plastic flow instabilities. The uneven uniformity of both strain and temperature in the ring section could lead to material failure [9]. Zhou et al. [10] highlighted the importance of uniform deformation and temperature distributions during RARR, given that they not only result in microstructure defects such as band structure and mixed crystals but also lead to internal cracks or even cause the interruption of the process. Meng et al. [11] analyzed the effect of geometries of king-roll and mandrel on material deformation uniformity. An increase in king-roll diameter was associated with better deformation uniformity, but caused workability problems due to the higher cooling rate, while mandrel geometry increase showed only positive effects on plastic deformation distribution.

In this work, a Virtual Design of Experiments (VDOE) has been proposed, using finite element method simulations of the RARR process to analyze the effect of selected process parameters on the development of cracks and forming defects on welding neck flanges made of S32760 SDSS.

Materials and Methods

Welding neck flanges made of S32760 SDSS were manufactured in an industrial RARR mill of the company ULMA Forging. Under investigated conditions, some of the flanges showed problems associated to crack development in the internal diameter (ID) surface of the neck region, and fishtail defects. Fig. 1 shows the FE model of the industrial RARR mill, and the cracks and fishtail defects identified in some RARR flanges.

Materials Research Proceedings 28 (2023) 629-637 https://doi.org/10.21741/9781644902479-68

The software Forge NxT was used to simulate the RARR process. The finite element (FE) model counted with king-roll, both conical upper and lower rolls, mandrel, and the ring, whose geometry was generated from the prior state of the ring before the RARR (see Fig. 1a). The lateral guiding rolls were not included as the FE model has implemented the self-centering of the flange. All geometries were set up as rigid objects, while the flange material behavior was set as viscoplastic according to

$$\sigma = 28332 \cdot e^{-0.0051T} \cdot \varepsilon^{-0.1} \cdot \dot{\varepsilon}^{0.112} \cdot e^{\frac{-0.035}{\varepsilon}} \quad (1)$$

where σ is the flow stress (MPa), T is the temperature of the material (ºC), ε is the strain (-), and $\dot{\varepsilon}$ stands for strain rate (s^{-1}). The values of the material constants were obtained from a set of compression tests performed by Kang et al. [12]. The contact conditions with the elements were modeled using Coulomb limited to Tresca friction model [13], with friction coefficients of $\mu = 0.4$ and $m = 0.8$. Heat exchange between the flange and tools was modeled with a contact conductance HTC = 10.000 W/m^{2}K and free convection with ambient media was assumed. The mesh of the ring was structured into 48 parts with an element size of 20 mm, refined to 10 mm in the neck of the flange. The mesh of tools had an element size of 20 mm. All the kinematics of the model were set to the values used in the experiments performed in the RARR mill. First, in order to validate the model, axial and normal forces were adjusted to the values recorded from the mill, and the ring growth speed vs diameter was reproduced by the simulation. The geometry of the manufactured flange and dimensional tolerances in hot conditions are compared to the values obtained in the simulation in Fig. 2.

	Measure (mm)	Tolerance (mm)	Deviation (mm)	Error (%)
D1	1385.5	±10	-3.5	0.3
d2	1032.7	+14/-13	+4.2	0.4
D3	1102	+18/-9	-5.7	0.5

h2	194.8	+16/-	+11.8	6.1

Fig. 2. Geometries of the flange in hot conditions compared to the simulated values.

The validated model was calculated using a king-roll rotational velocity of 25 rpm, a mandrel radial velocity of 3.03 mm/s, and a mandrel diameter of 170 mm. These were the selected variables to analyze their effect on the development of geometrical and crack defects. Then, a virtual design of experiments was carried out by simulating the RARR process. The conducted factorial analysis consisted of three levels and three factors. As a result, a total number of 27 simulations were carried out considering the conditions listed in Table 1.

Table 1. Factors and levels considered in the factorial analysis.

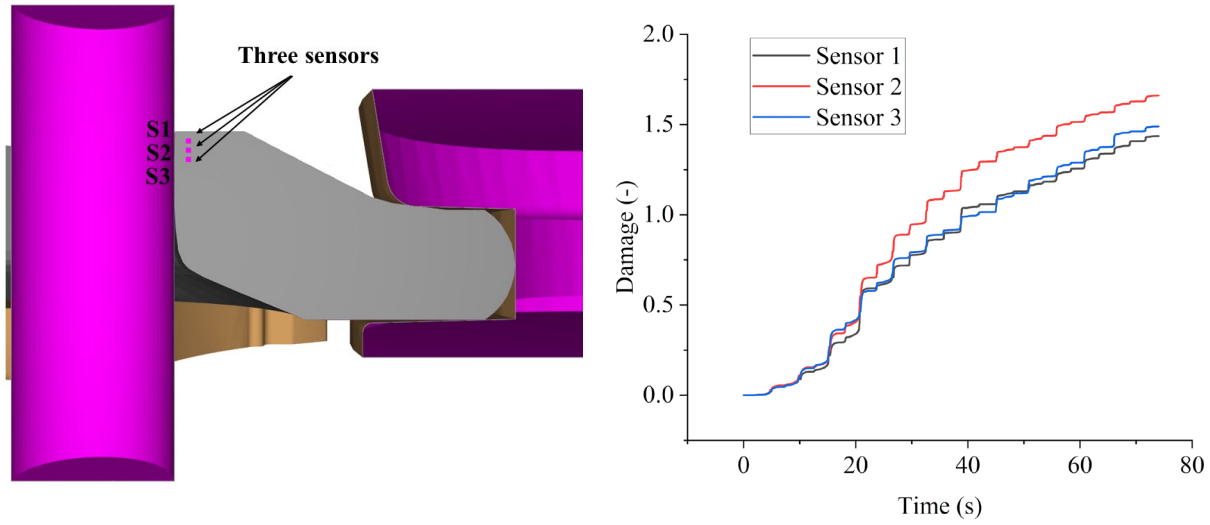
Factors	**Level 1**	**Level 2**	**Level 3**
King-roll angular velocity (KAV)	15 rpm	25 rpm	35 rpm
Mandrel radial velocity (MRV)	2.64 mm/s	3.03 mm/s	3.57 mm/s
Mandrel diameter (MD)	120 mm	170 mm	220 mm

The response variables selected to analyze the effect of the factors listed in Table 1 were the material ductile damage, fishtail defect, and uniformity of both strain and temperature in the flange section.

Damage. The simulation of damage in the RARR process has been considered by implementing the Latham&Cockroft ductile damage model. The damage in the material *D* is estimated according to

$$D = \int_{\varepsilon_0}^{\varepsilon_f} \frac{\sigma_1}{\sigma_{eq}} d\varepsilon \tag{2}$$

where σ_1 is the first principal stress, σ_{eq} Von Mises equivalent stress, ε_0 and ε_f the initial and final deformation, respectively. In order to compute the accumulated damage in each simulation, three sensors have been set in the neck of the flange to estimate the maximum damage value at the end of the RARR process, as illustrated in Fig. 3.



(a) **(b)**

Fig. 3. Sensors to compute the ductile damage on the neck of the flange during RARR (a) Initial position and (b) evolution of damage computation KAV = 15 rpm, MRV=2.64 mm/s and MD = 170 mm.

Fishtail. The fishtail defect can be appreciated in Fig. 1c. In order to measure and quantify the severity of this defect, the depth of the depression in the flange surface region has been measured in the simulation.

Uniformity of Plastic Strain (*SDP*) and Temperature (*SDT*). The uniformity of plastic strain and temperature in the section were analyzed through the calculation of the standard deviation according to

$$SDP = \sqrt{\sum_{i=1}^{N} (\varepsilon_i - \varepsilon_a)^2 / N}. \tag{3}$$

$$SDT = \sqrt{\sum_{i=1}^{N} (T_i - T_a)^2 / N} \quad (4)$$

Where N is the total number of analyzed points (12 in the neck of the flange), ε_i and T_i are the strain and temperature at a point, and ε_a and T_a stand for the average values of strain and temperature in the region analyzed. The position of these 12 sensors in the neck of the flange is provided in Fig. 4.

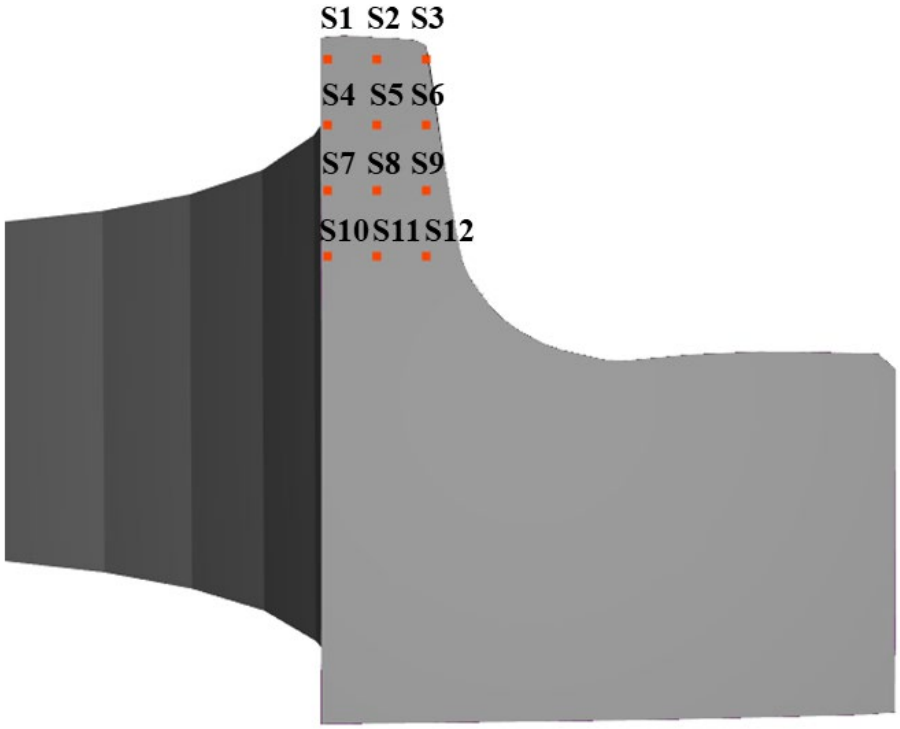


Fig. 4. Position of the 12 sensors in the neck of the flange to measure the uniformity of strain and temperature in the region where cracks are developed.

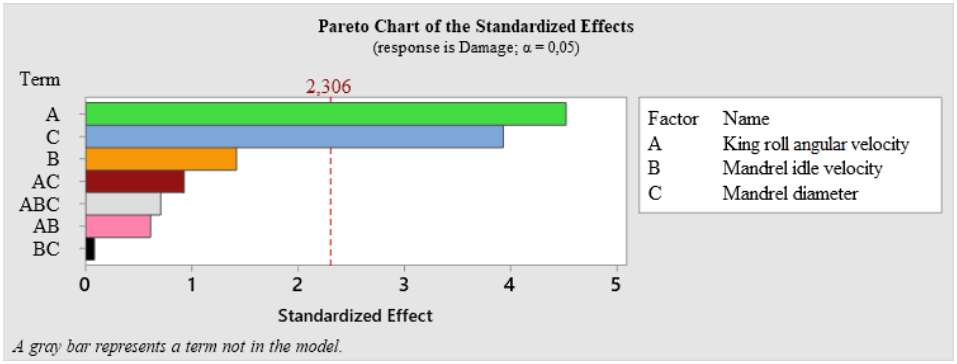
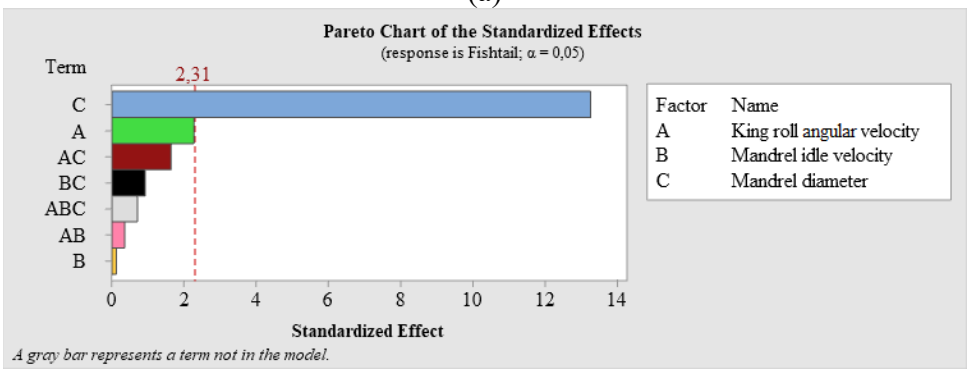
Results and Discussion

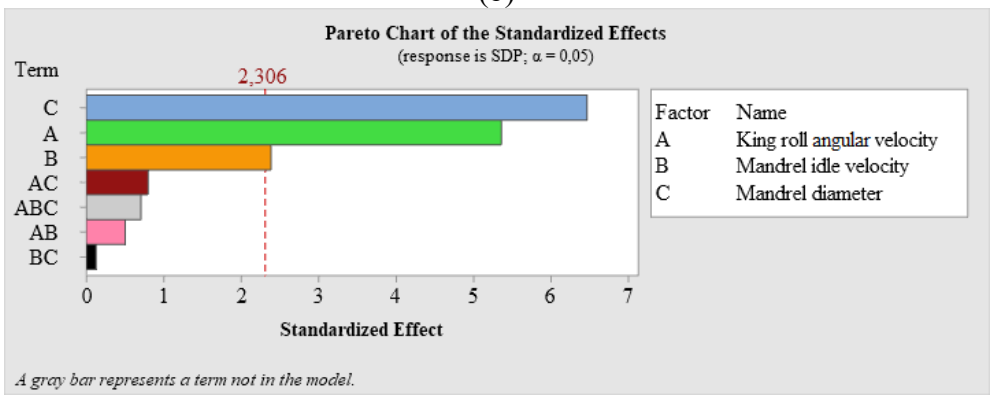
The results of the multivariate factorial analysis are provided. The Pareto chart with the standardized effects of each of the factors on the analyzed response variables is depicted in Fig. 5. In each of the charts, the factors are ordered from the highest to lowest standardized effect value.



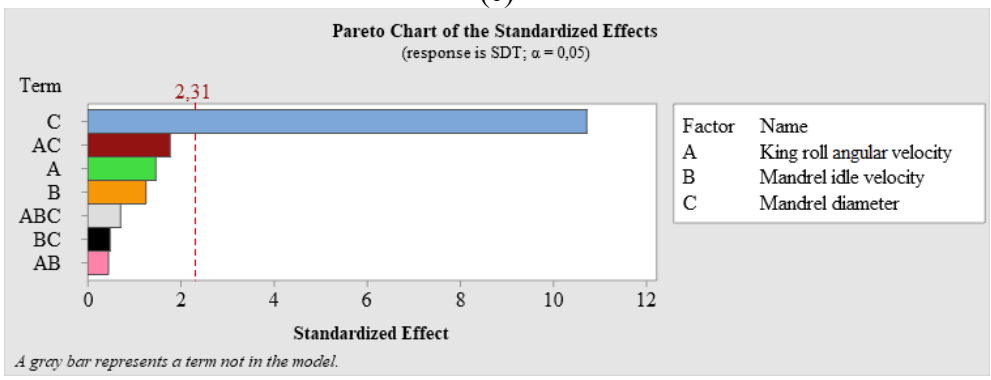
(a)



(b)



(c)



(d)

Fig. 5. Pareto chart of standardized effects of factors on (a) Damage, (b) Fishtail defect, (c) SDP, and (d) SDT.

The results shown in Fig. 5 put into evidence which factors contribute more to the variability in the response variables. Lenth's method was used to check which effects are significant (red dotted line). It is an objective method to test the effects of unreplicated factorial designs [14]. According to the results, KAV velocity shows a significant effect on Damage and uniformity of deformation. The MRV only provides a significant effect on the uniformity of deformation, but lower compared to the rest of the considered factors. Finally, the MD is the factor that shows a clear significant effect on all the considered response variables, namely, damage, fishtail, and uniformity in both, temperature and strain in the flange section. One interesting aspect to discuss is the interaction between the king-roll rotational speed and mandrel radial velocity, which has not shown any significant effect on the analyzed variables. In addition, the statistical significance of the model coefficients was determined by the P value. The P value less than 0.05 (95% confidence level) indicates that the model terms are significant [15]. After the revision of the results, it was confirmed the significance of the effects identified in the Pareto. Furthermore, the analysis of residuals confirmed that they were randomly distributed and had near-constant variance. Then, the main effects of the factors that showed significance in the previous analysis are presented in Fig. 6. No interaction between the analyzed factors has been identified.

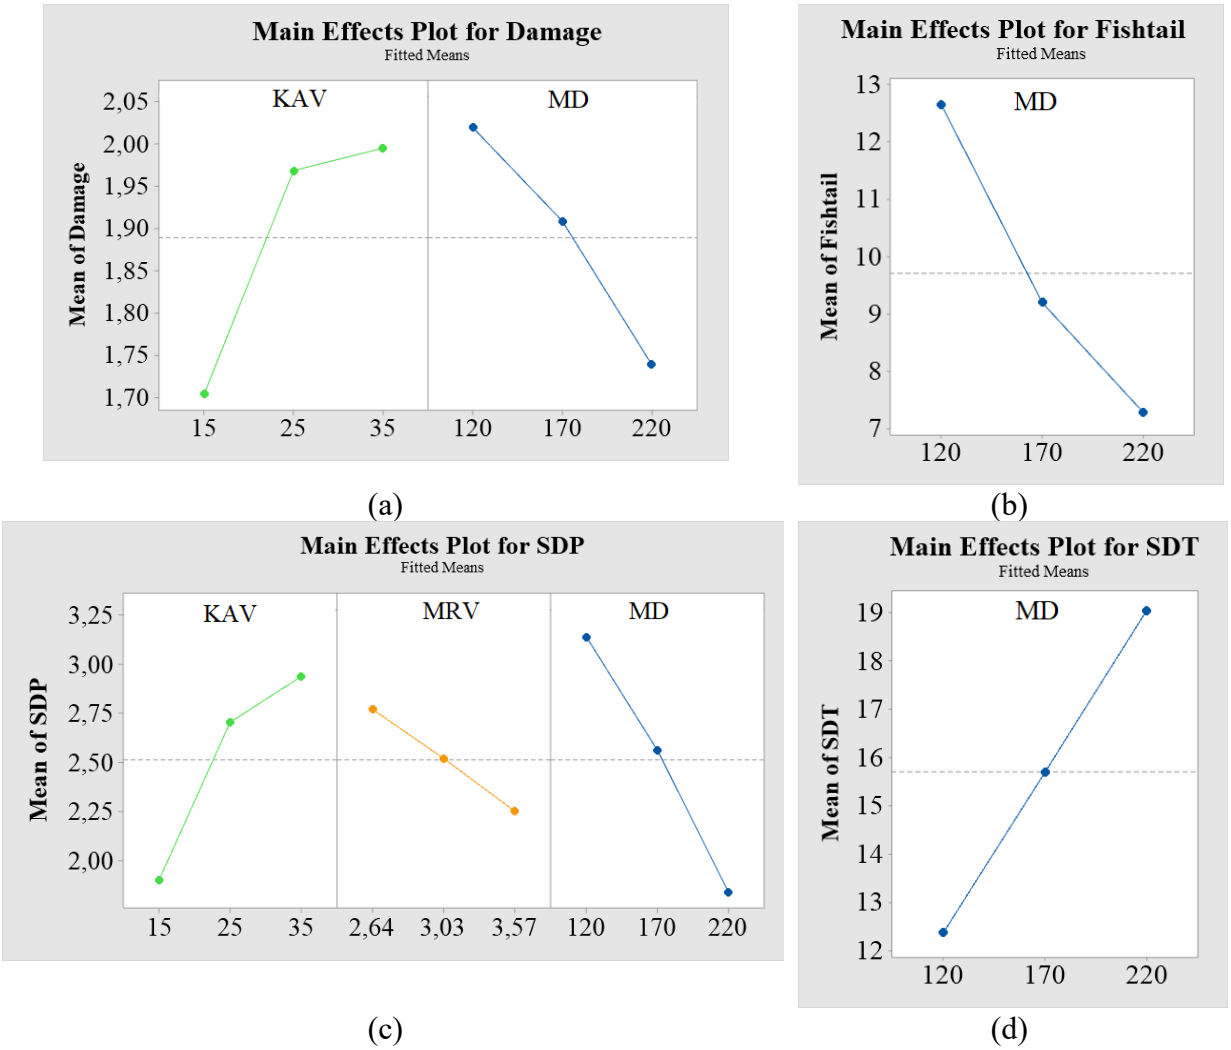


Fig. 6. Main effects of factors on (a) Damage, (b) Fishtail defect, (c) SDP, and (d) SDT.

According to the results of Fig. 6, the reduction in ductile damage in the neck of the flange could be achieved by reducing the KAV or increasing the MD. Regarding the fishtail defect, the MD shows a strong effect, reducing the fishtail the higher the MD. The uniformity of temperature in the neck of the flange depends on the effect of the MD, showing a higher deviation the higher the diameter of this element. In the case of uniformity of plastic strain, a decrease of KAV increases the uniformity, while an increase of the MRV or MD is associated with better uniformity of plastic deformation in the analyzed region of the flange.

From the analysis of the main effects, it is concluded that reducing the KAV presents a positive effect not only on the ductile damage but also on the fishtail defect and uniformity of plastic strain in the neck of the flange. However, the dimensions of the king-roll and flange should be considered given that material flow in the section of the flange depends on the combined effect of flange rotation, and mandrel and axial rolls displacement. A similar material flow could be obtained with higher KAV if the diameter of the king-roll or flange is reduced.

In the case of the MD, it is important to highlight that shows a significant effect on all the analyzed variables. However, the effect of the diameter of this tool on SDSS damage during the process or fishtail defect is not clear in the literature. A higher diameter is associated with lower values of fishtail, lower values of ductile damage, and better uniformity of plastic strain. The only drawback is a lower uniformity of temperature in the neck of the flange, which is expected given that the contact region with the ID of the flange is increased and there is a higher thermal exchange with the mandrel. A further thermo-mechanical study could provide insightful information about the impact of mandrel diameter on the stress state in the section of the flange and the material flow.

Summary

A study of forming defects and failure occurrence in the RARR of SDSS flanges has been proposed. First, a FE model of the RARR industrial process has been developed and validated. Then, some determinant process parameters, such as KAV, MRV, and MD, have been modified and simulated. The effect of modifying these process parameters on the development of cracks and fishtail defects has been assessed by means of a multivariate factorial analysis. From this study, the flowing conclusions have been drawn:

- The increase in mandrel diameter reduces underfilling defects and also the development of failures due to ductile damage in the ID of the flange neck. Nevertheless, it leads to an increase in forces in the early stages of the process. In addition, the higher contact area with the mandrel leads to a low temperature in the flange ID during the process, which could favor the precipitation of intermetallic phases that reduce SDSSs hot workability.
- The reduction of king-roll angular velocity hinders the development of cracks in the ID of the flange neck and improves the strain distribution on the flange section.
- The mandrel radial velocity doesn't show a significant effect on the development of cracks or fishtail defects. It only shows a slight effect on the strain distribution of the flange section, leading to better uniformity at higher values.

Keywords: Tube Rolling, Hot Forming, FEM Simulation

Abstract. In this paper seamless tubes hot manufacturing calibration rolling is studied by means of a finite element model, to improve product quality and process performance. Based on real data provided by an industrial partner, Tubos Reunidos Group, a finite element model of the process has been created and validated for the thermo-mechanical analysis of the process. The model has been used for the study of the wall thickness evolution and peripherical distribution during process, the eccentricity and the polygonization effects. Results show that the tube velocity in the process is one of the factors affecting wall thickness eccentricity, due to mass flow conservation. Regarding polygonization and eccentricity effect it has been found that both effects increase in the rolling stands with higher reduction ratio, and are corrected afterwards. These effects are mainly due to the ovality of the rolls. However, the effect the different sliding velocity along roll perimeter has implications in the local deformation of the material in contact with the roll, causing local compressive stress areas in addition to the predominant tension areas.

Introduction

The manufacturing of seamless pipes is a complex process in which high temperature, strain rates and forces are involved to achieve a high-quality product. Seamless pipes are used in severe environments applications, such us, refineries, transport of fluids under high pressures, oil drilling operations, etc. Usually, seamless tubes offer higher resistance and mechanical properties than welded pipes [1].

The manufacturing process of seamless tubes consists of three steps, piercing, elongation in mandrel mill and final rolling calibration. The three steps have influence on the quality and accuracy of the final product; however, in the last step the geometrical accuracy is given to product.

The efforts for improving the quality of the tubular products obtained with this process have been extended from the beginning of the process itself, as it can be seen in the research work of Vargas et al. [2]. However, the studies involving numerical models are more recent, mainly from the present century. In 2003, Bayoumi [3] developed a steady-state analytical model of the roll-pass geometry, which studied the effects of roll gap opening and the inter-stand velocity increase ratio in process parameters such as wall thickness, inter-stand tensions, roll load and rolling. The results showed that the interstand velocity increase ratio increased the inter-stand tension while the roll load remains almost unchanged. Carvalho et al. [4] modeled the process for the manufacture of seamless tubes both numerically and via hot torsion testing and predictions of final average ferrite grain sizes were given, with larger predictions for ferrite grains sizes, which were attributed to the assumptions made during the study.

The analytical models gave an interesting insight for the process; however, they were limited in terms of the accuracy of the results and the number of variables analyzed. Therefore, most of the recent works use the Finite Element Method, FEM, to simulate the process with a higher

accuracy and broader studies. The calculation power increase of computers and the improvements of the commercial software, has boosted the complexity of calculations and the results obtained.

The high accuracy demanded by final pipe users respond to the need to thinner but homogenous walls, free form residual stresses and superficial defects. Dimensioning of the tubes is based on the thinnest and, consequently, weakest section. Thus geometrical non-homogeneities such us eccentricity and polygonization lead to an increase in weight of material [5]. Accordingly, important research efforts have been dedicated to improve the geometrical accuracy of the final product. In fact, these effects are not exclusive of this rolling mill, since they can be generated even in piercing phase [6], and elongation in mandrel mill [7].

During the rolling of the tube its diameter is reduced progressively, higher reductions are performed in the initial boxes while lighter reduction occur at the end. In the rolling stands with greater reductions, the rolls have an elliptical shape to prevent material from jamming, which leads to polygonization of the tube. A study devoted to reduce polygonization [8] concluded that interstand tension and the correct selection of initial diameter are key factor for reducing this effect. Jiang et al. [9] developed a high precision FE model for predicting the defect of inner polygon. The model allowed the identification of the peak stress at the roll root contact area while the stress of the roll gap contact area was smaller, leading to a distribution of six stress peaks. These works pointed out the difficulties faced to obtain a proper and accurate Finite Element Model: material behavior constitutive model, contact and friction boundary conditions, and heat transfer.

Another aspect of interest is related to the tube eccentricity. Jiang et al. [10,11], designed a set of eccentric rolls which induced a moment on the tube causing it to rotate around its axis while it advances through the mill. In [10] the tube rotation method is presented for a single pass of the tube rolling process and analyzed by means of FEM, showing an improvement in the evenness of thickness distribution. Afterwards, in [11] the theory of the rotation is analyzed along with a FEM that is validated with experimental results. The rolling forces, torque, energy consumption are evaluated, from a process point of view, and the thickness, temperature and stress of the tube are studied from a product point of view. This technology is applied to thick steel tubes in a recent contributions of the authors [12].

In this paper a FEM model of the hot tube Sizing Mill, SM, of AISI 1016 has been developed based and validated with industrial data with the aim of fully understand the factors affecting the final geometry of the tube at the end of the process: wall thickness, eccentricity, and polygonization. Thanks to the model the reasoning for their occurrence, and alternatives to reduce its relevance have been obtained. The model has been also modified to evaluate the effect of typical alterations occurring in plant in the real process: pre-existing eccentricity, tube temperature heterogeneity, or roll misalignment.

Experimental Setup

In this study the calibration rolling of AISI 1016 steel is studied. Material composition % in wt. is presented in Table 1.

Table 1. Chemical composition of the AISI 1016 steel.

C	Si	Mn	Ni	P	S	Cr	Mo	Al	Cu
0.12 - 0.17	max 0.3	0.3 - 0.6	max 0.25	max 0.035	max 0.035	max 0.2	max 0.05	max 0.01	max 0.3

The calibration consists of seven driven stands of three rolls each, as it can be seen in Fig. 1, which are equally distributed to reduce the tube diameter from 200.50 mm to 180.80 mm. The disposition of the rolls in each box is rotated 60º from one box to another, giving as result that the groove of the rolls in the preceding box is the border of the rolls in the next, as shown in Fig. 1.

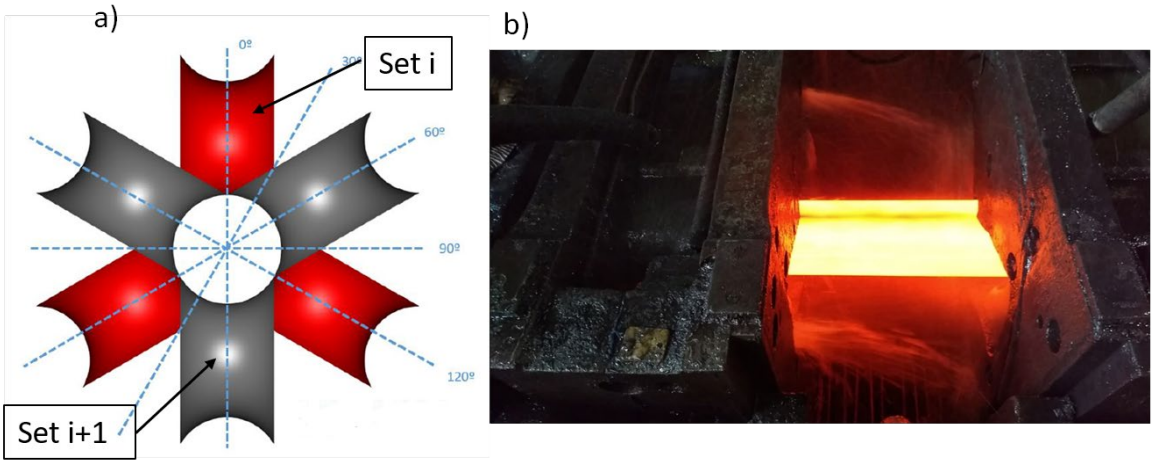

Fig. 1.a) Disposition of the rolls in the driven mill stand of two subsequent sets, where the rotation can be seen. B) Experimental image of the rolled tube passing between two driven stands.

Before entering rolling stands the material is reheated in a gas furnace to a temperature of 1020ºC. Then the material is pushed into the SM and is driven by the rolls thanks to friction. According to the measurements recorded by Tubos Reunidos Group on shop the advanced mean velocity of the tube is 1018.9 mm/s. Fig. 1 b) shows the tube passing between two boxes. By contrast, the tangential velocity of the rolls varies along the mill from 876.5 mm/s in the first stand to 1124 mm/s in the last two stands. Accordingly, for the analysis of the process it is important to notice that the usual contact between the roll and the tube is sliding contact.

During the rolling of the tube the mean power consumed by the electric motors was 24 kW, and the mean temperature of the billet between stands was 980.43ºC. After the process the final length of the tube was measured. Additionally, a tube was stopped in the middle of the process to measure its wall thickness between driven stands. For the thickness measurements, ten values have been acquired circumferentially equally distributed along tube perimeter using infrared IMS system. Results are used in section 4 for comparing experimental with numerical results.

Numerical Model

In this section the numerical model developed for the simulation of the SM is presented. The geometries of the different elements involving the mill were designed according to data provided by Tubos Reunidos Group separately using SolidWorks software and assembled together before being exported to Forge NxT®.

The model, Fig. 2, consists of seven rolling stands with 3 rolls in each stand, the tube or billet, a guide to lead the tube into the SM and a pusher used to feed the tube into the mill. For simplicity of the simulation, all tools were selected as non-deformable (rigid) objects with thermal properties and the billet (tube) was set as a deformable object with thermal properties. The tools where meshed with 2D triangular elements, while the billet was meshed with 3D tetrahedral P1+ linear elements with a bubble node, size factor of 0.7, volumic size factor of 2.2 and mesh size of 4 mm to achieve at least 3 elements on the tube initial thickness. The Hensel-Spittel constitutive law is chosen to model AISI 1016 behavior at different temperatures, strain, and strain rates. The materials coefficient were provided by the software and validated with the industrial partner [13]. The coefficients used are shown in Table 2.

Table 2. Hansel-Spittel coefficients for AISI 1016.

Coefficient	Value
A1	752.5394
m1	-0.00219
m2	-0.1523
m3	0.13792
m4	-0.0486

According to experimental data the initial temperature of the billet was set to 1020ºC, and that of the rolls to 50ºC. Heat transfer coefficient were set according to [14]. Regarding friction, based on [15] the viscoplastic or Norton law was selected for the contact between the rolls and the tube with a coefficient of 0.33, adjusted by curve fitting comparing experimental and numerical results, mainly velocity and power consumption.

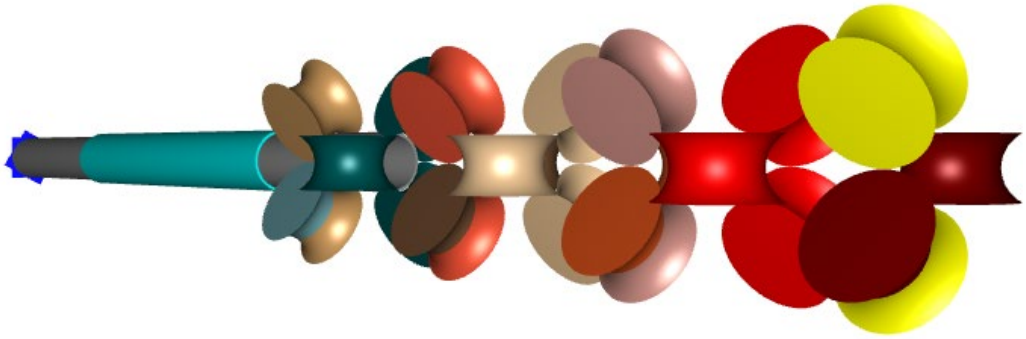

Fig. 2. Geometrical disposition of the model with the tube and the 7 driven stand rolls.

Results and Discussion

The results of the model are presented in this section along with the discussion of the main aspects obtained from the simulation.

For the validation of the numerical model the obtained results of power consumption, tube velocity evolution, temperature and tube thickness evolution and length increase are compared to experimental results. On the one hand the mean power obtained from the simulation is 28 kW, which is 16.7% higher than the experimental measurement, a result accurate enough result given the dispersion of experimental measurements done on-shop.

Billet velocity increases along the process from 968 to 1049 mm/s which agrees with the experimental measurements described in previous section.

The temperature evolution of the billet during the milling process is fairly constant both numerical and experimentally, being the difference of 4% between the experimental mean value (980.38ºC) and the numerical one (1016.51ºC).

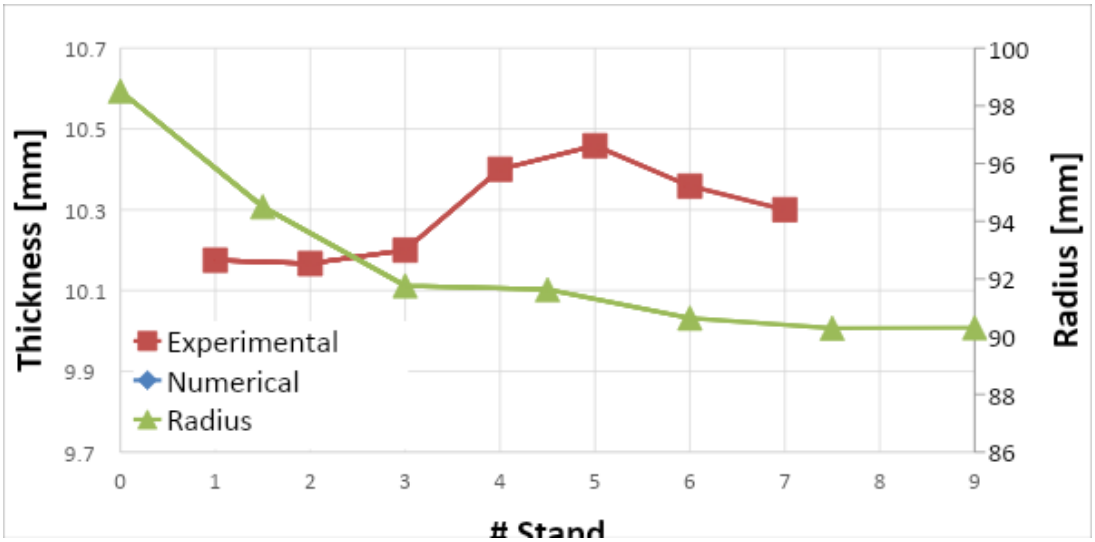

Fig. 3. Mean thickness evolution measured after each rolling stand. Experimental vs. Numerical.

Finally, the geometrical accuracy of the model is analyzed comparing the mean thickness evolution after each rolling stand. In Fig. 3 it can be seen that the agreement is good with a maximum deviation below 6%. Once the validity of the model has been justified, the model is used to study in detail eccentricity and polygonization effects during the process.

First the wall thickness increase is discussed. As in any plastic forming process, the volumetric flow rate must be kept constant during the rolling, (assuming that the density is constant). Accordingly, the diameter reduction must be accompanied with a length or/and thickness increase. In order to avoid the effect of thickness increase during the process, it would be necessary to adjust the billet velocity to keep the cross-section area constant while the diameter is reduced, for that the material velocity should be updated

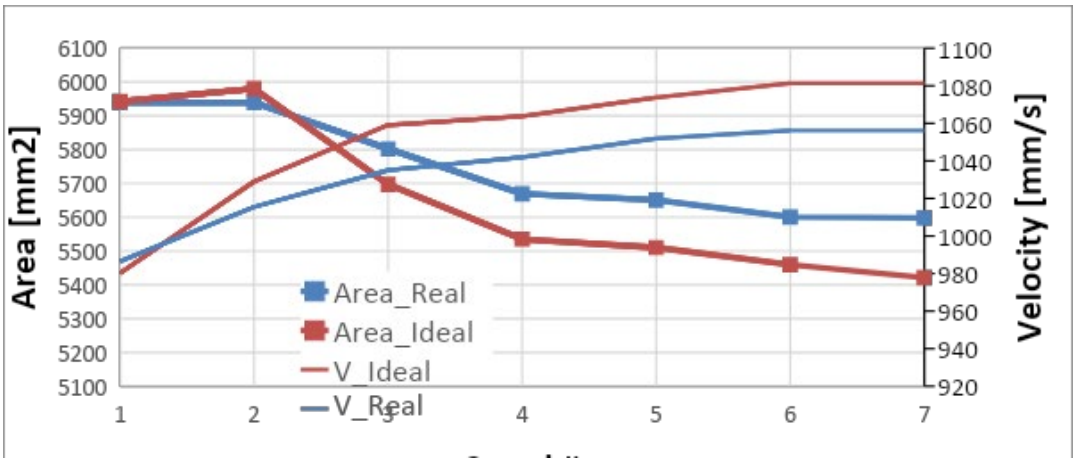

Fig. 4. Evolution of cross section area and tube velocity along the process. Real values are obtained from the model, and ideal values have been calculated to keep tube thickness constant.

From the model the real area after each rolling stand and the real velocity have acquired and they have been compared to the ideal area that would maintain the wall thickness constant, giving as a result the ideal velocity in each stand, that is, the velocity of the material that would make the wall thickness constant, results are shown in Fig. 4.

Results show that the velocity of the tube in the real process is lower than the ideal one, up to a 3% in the last stand. This analysis has not been found in literature, and it must be pointed out that the implementation of this solution in the industrial process would improve the quality of the product but a proper assessment of rolls velocity must be done to match the material flow given the effects of friction and sliding.

Fig. 5 shows the wall thickness evolution at different angles (0º, 30º, 60º, 90º, and 120º) (see Fig. 1)as well as the eccentricity evolution measured after each rolling step. Two interesting conclusions can be obtained from this graph.

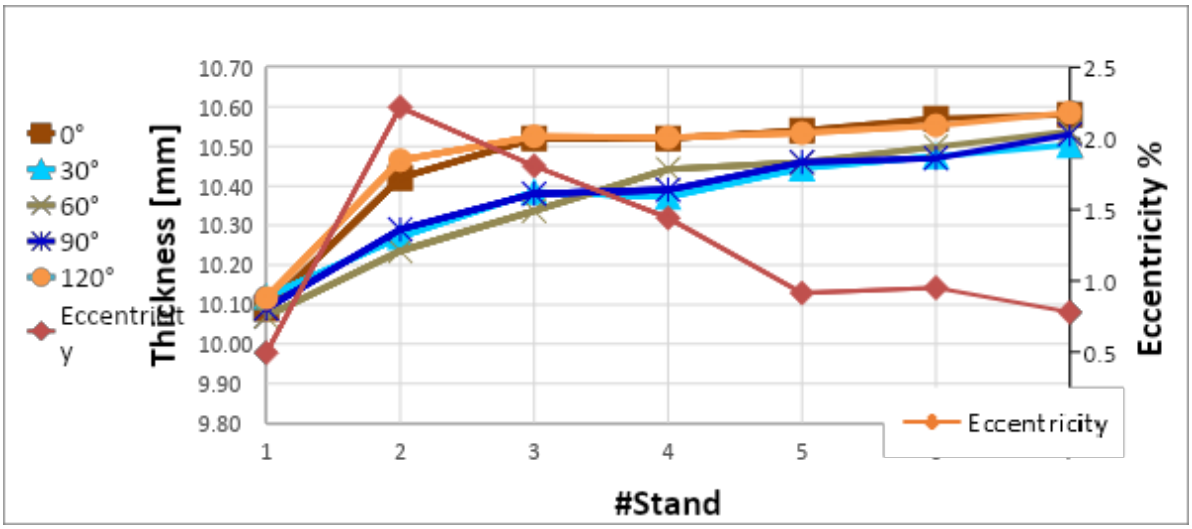

Fig. 5. Wall thickness evolution at different angles (0º, 30º, 60º, 90º, and 120º) and eccentricity evolution measured after each rolling stand.

On the one hand, it can be seen that the thickness evolution can be divided into 3 groups: group 1 involving 0º and 120º, group 2 with 30º and 90º, and 60º. The behavior of group 1 correspond to the planes that face the groove of the roll in the second stand, thus they experiment an important thickness increase. Group 2, instead, face the border of the roll at the second stand, leading to a smaller thickness increase. Finally, the plane at 60º is in the middle of the roll between the groove and the border. Looking at the eccentricity evolution it can be seen that it is at the stage of maximum difference between group 1 and group 2, that is in the second roll, that the eccentricity is higher. Then, as long as the lines trend to merge the eccentricity is reduced.

Thus, a clear relationship between the thickness evolution at circumferentially and the eccentricity is set. This difference is caused by the roll perimeter design, which is not circular but elliptical. It is also important to notice, that the biggest increase in eccentricity is generated in the rolls with the higher diameter reduction which are stands two and three, as shown in Fig. 3.

In order to fully understand the phenomena occurring at the contact between the rolls and the tube the sliding velocity and the longitudinal stresses of the tube are analyzed hereafter. Fig. 6 a) shows the relative velocity in the tube axial direction between the roll and the tube in the stand 3. There it can be seen that in the groove of the roll the material is moving faster than the roll, while in the corners of the roll it is the opposite: the tangential velocity of the roll is higher than the velocity of the tube. Fig. 6 b) shows the displacement of the material passing through the roll, where it is appreciated how the material is pushed forward in the area of the corner of the rolls, and it is retained in the groove of the roll, causing an undulated shape. This effect, which is due to the different diameter of the roll along its perimeter is enhanced by the roller's ovality. Moreover, it creates a stress-strain distribution which is depicted in Fig. 7 a) strain, and b) stress.

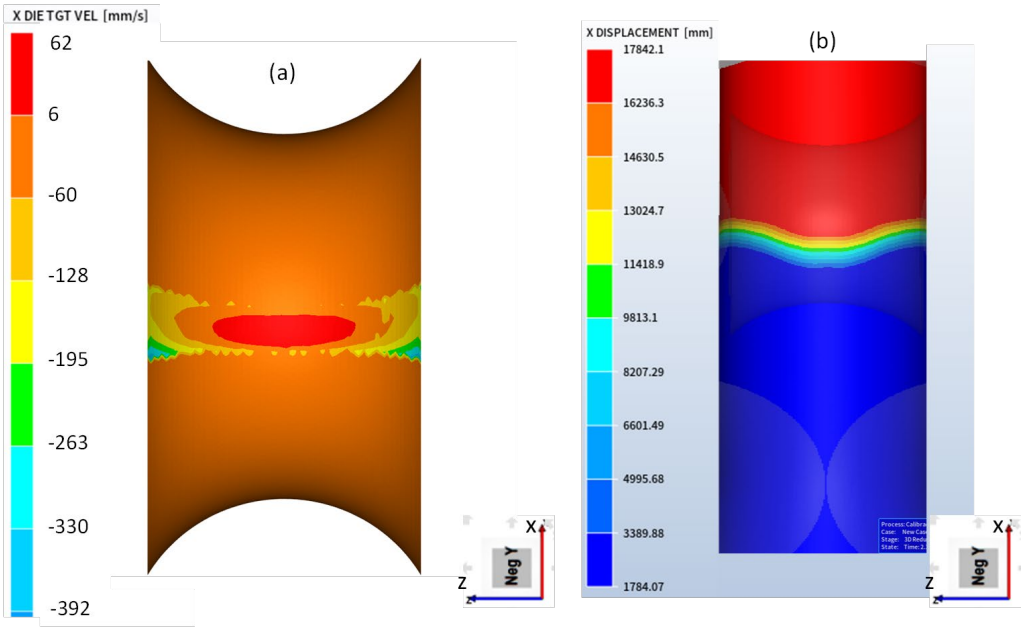

Fig. 6. a) Relative velocity between the roll and the tube in stand two. b) Tube material displacement at the pass of stand 3.

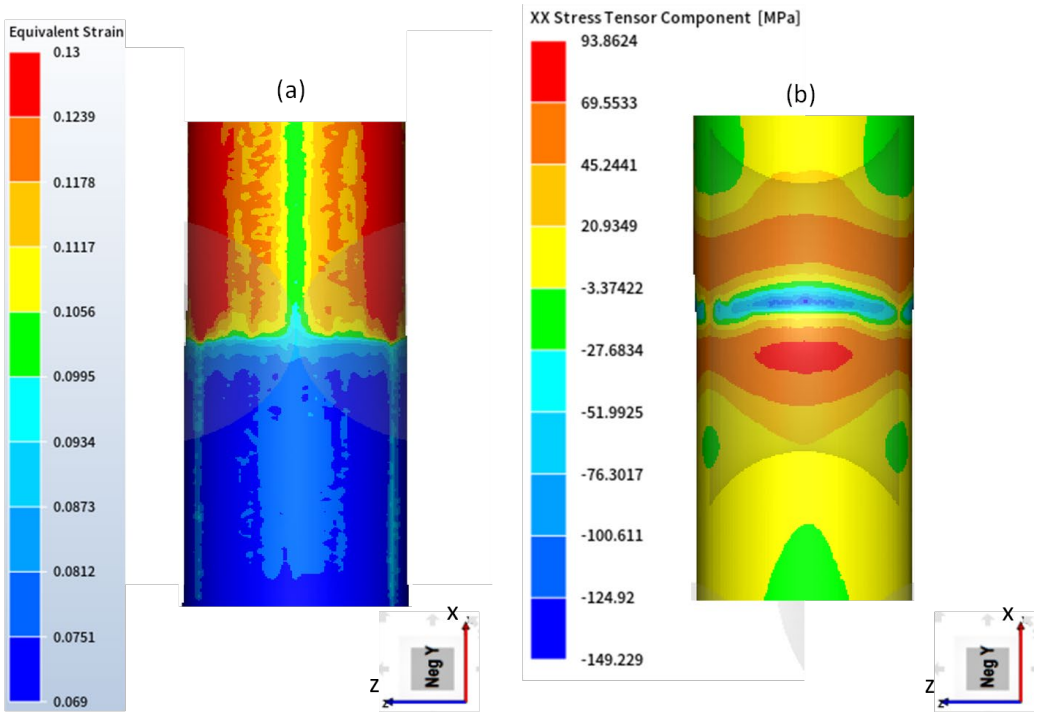

Fig. 7. a) Equivalent strain of tube material when passing through stand 3. b) Axial stress of the tube material in the surroundings of stand 3.

In Fig. 7 b) it can be seen that most of the tube is under tension stress (positive), which agrees with literature. However, in the contact region between the roll and the tube important compressive stresses are generated which are higher in the groove section and almost 0 in the corners of the roll. This finding has not been reported previously and is one of the reasons for the generation of eccentricity effect. The equivalent strain shown Fig. 7 a) confirms the difference in behavior between the central region in contact with the groove and the regions in contact with the border of

the roll. As above mentioned, the growing diameter of the roll along its wildness is responsible for this effect, and the ovality of roll's perimeter enhances the consequences.

Finally, the polygonization effect is addressed. It is related to the ovality of the rolls, which is high in the initial stands and reduced in the last ones. The evolution of this effect is shown in Fig. 8.

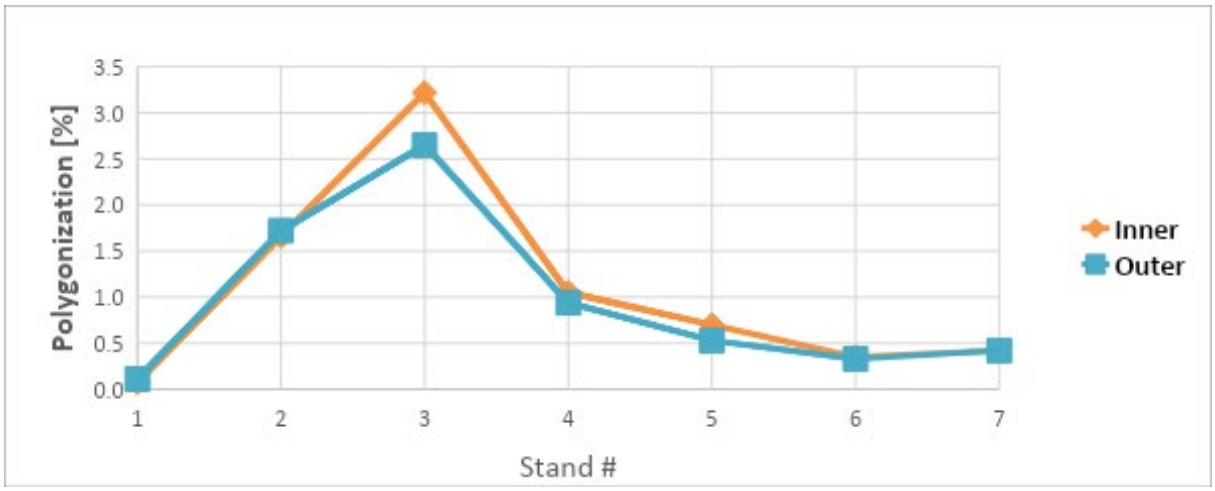

Fig. 8. Evolution of polygonization effect along the SM.

This effect increases from 0 at the beginning of the process to a maximum of 3.2% in stand number 3, where the maximum diameter reduction is done. Afterwards, the polygonization is reduced up below 0.5% at the end of the SM. This phenomenon is due to the ovality of the rolls, which flatten the tube passing over the groove of the roll. Since the ovality of the rolls decreases along the stands so does the ovality.

Finally, the radial deviation from the theoretical circular profile has been calculated in the cross section of the tube after each stand. Results are depicted in Fig. 9, the evolution of the radial deviation follows a sinusoidal trend with 3 positive peaks and 3 negative peaks, which represent the polygonization effect. These peaks are clearly relevant after stands 2 and 3, those with higher reduction and ovality, and consequently the higher polygonization of the tube in those positions. Then, in subsequent stands those peaks are flattened. This way it is illustrated how the tube profile is expanded in the corner of the roll ((positive and negative peaks) and flattened in the groove of the subsequent roll, due to the 60º rotated configuration is rotated 60º of the mill. This flattening effect of the rotated stands reduces progressively the big deviation created in stands 2 and 3, but the geometry is not fully corrected after stand 7.

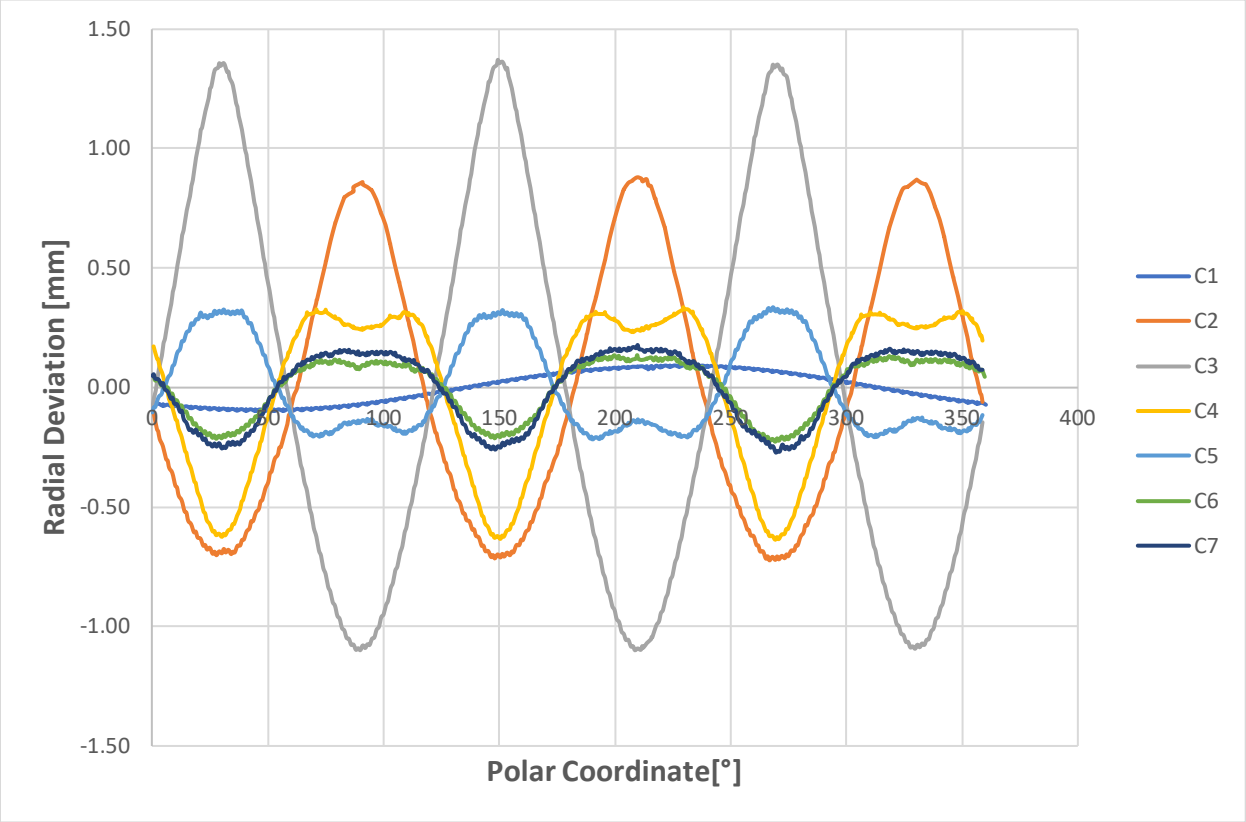

Fig. 9. Radial deviation of the tube along the periphery of the tube in each stand.

This polygonization is an undesired effect for tube produces and is due to the ovality of the roll's profile. Perfect circular rolls would strongly reduce this phenomenon; however, those type of roll profile could present limitations for material flow during rolling, according to actual experience.

Summary

In this paper the calibration rolling of seamless AISI 1016 tubes is deeply analyzed by means of a FEM validated thanks to experimental data provided by an industrial partner, Tubos Reunidos Group. From the work developed the following conclusions can be drawn:

- The effect of thickness increase is analyzed based on material flow. Results show that increasing tube velocity will help reducing this effect.
- The effects of eccentricity and ovality have been deeply assessed. Both effects increase between stands 2 and 3, and decrease progressively in the subsequent stands. The ovality of the rolls has been found to be the cause of both effects since it distorts the circularity of the tube.
- Process parameters such as relative velocity, material displacement, equivalent strain and axial tension are evaluated in the contact between the rolls and the material showing that the difference of tangential speeds along rolls perimeters leads to non-homogenous stress-strain states on tube material.

Keywords: Target Function, Sensitivity Study, Optimization Methods, Dynamic Behavior Model, Screw Press

Abstract. Dynamic models using masses, dampers and springs have been developed to represent the behavior of energy piloted machines. These models were proven to estimate more accurately the required amount of energy to forge a part. But how to identify the parameters of the model to accurately represent the behavior of a specific machine? In this study, the case of a strike without billet on a screw press is investigated, different target functions are tested to identify the model parameters and a sensitivity study of the optimization is performed. Results are encouraging.

Introduction

For forging processes using energy limited machines, such as hammers or screw presses, it is difficult to accurately predict the amount of energy that the billet actually absorbs as plastic deformation. This is due to energy losses caused by the dynamic behavior of the machines. That is why some dynamic models of forging machines were developed: first, models with masses and springs for gravity drop hammer [1,2] and then models with dampers in parallel with springs [3, 4]. For these models, the parameters were theoretically identified based on machine specifications. But nowadays, with the development of high-speed cameras, stereo vision systems and sensors, further experimental investigations are possible on forging hammers. For example, impact velocity was measured on a counter blow hammer and thus kinetic energy was deduced to determine blow efficiency [5,6]. Moreover, Yoneyama [7] was able to monitor the load, the pressure, the friction and the contact temperature while upsetting steel billets on a gravity drop hammer. Different sensors technologies to monitor ram displacement and load were also compared in the case of a screw press [8]. And finally, a dynamic model consisting in a spring-mass-damper model, was experimentally determined for a forging hammer [9]. To identify the parameters of such an experimentally based model, numerical optimization methods are required. And to guaranty the unicity, the accuracy and the reliability of the identified parameters, the target function has to be well defined [10] and a sensitivity study can be performed.

In this study, the method developed in a previous work to determine a dynamic model based on experiments [9] will be applied on a screw press. Once the model determined, a parametric identification will be run with different targets functions and results will be analyzed. Based on the analysis, a target function is chosen and a sensitivity study is conducted to ensure a proper model determination.

The Production System and its Dynamic Model

The focus is set on the screw press of the Vulcain Platform in Metz (Fig. 1.a). It is a direct drive screw press SPR 400 from Lasco, with a maximal energy of 28.9kJ for a maximal speed of 680 mm/s. A specific toolholder is mounted on the press, that allows the monitoring of the forging load, thanks to a load sensor embedded in the lower die, and the monitoring of the ram

displacement, thanks to three laser sensors attached to the lower die, in addition to the magnetic encoder of the press [11].

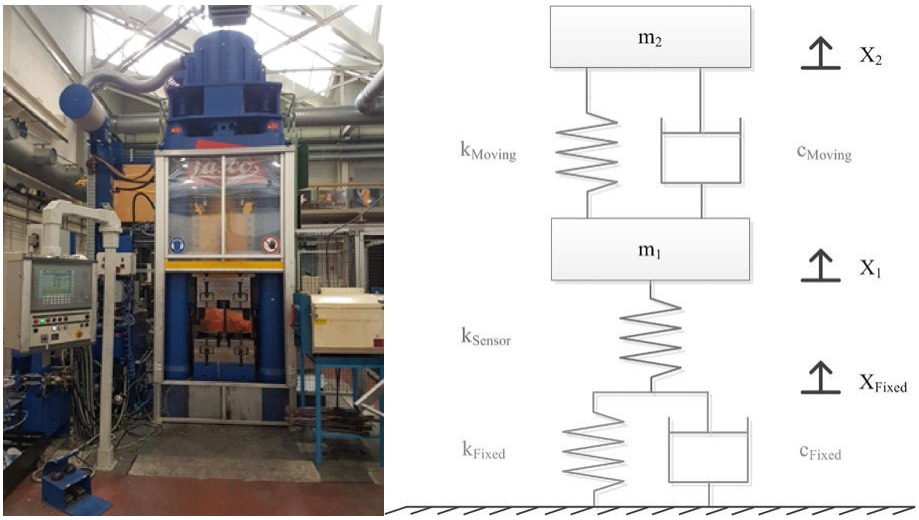

Fig. 1. a) the screw press b) the model of the screw press and its tool during a bare strike without billet.

An experimental campaign was launched to determine the dynamic model called the BIM model [9] of the screw press. Knowing the initial conditions and recording the load in function of the time for bare strikes (without billet), the model can be determined according to the method described in [9]. A Fast Fourier Transform (FFT) is performed on the load signal recorded during the strike (Fig. 2). As the impact duration is very short, it is not possible to have an analysis with a lot of frequency levels. Even though, two peaks are identified, thus a model with two degrees of freedom will be able to describe the dynamic behavior of the screw press (Fig. 1.b). The initial impact speed is known to be 365 mm/s. The load sensor is considered in the model thanks to the k_{sensor} spring and its value is set to $3.3997.10^{10}$ N/m as given by the supplier.

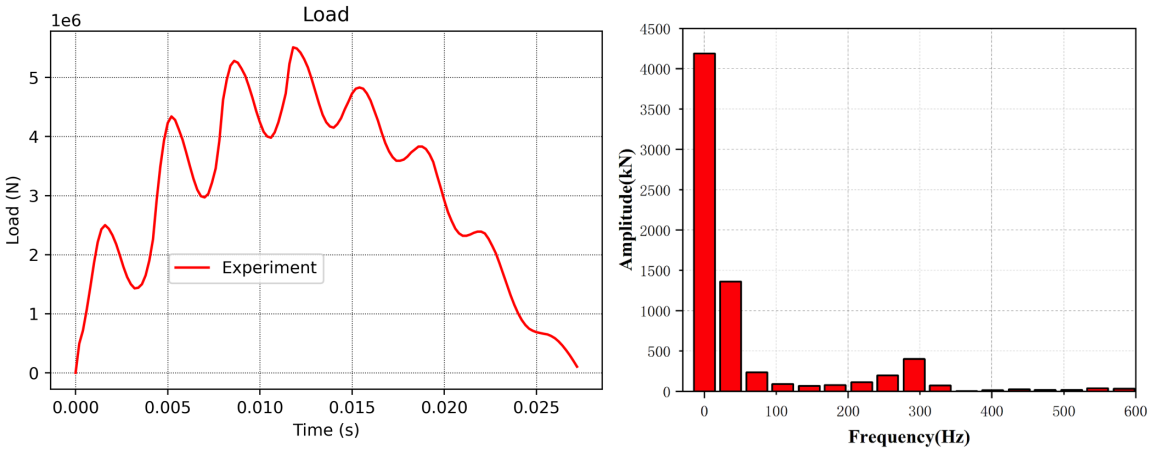

Fig. 2. a) the load signal measured by the sensor embedded in the lower die b) the FFT of the load.

Parametric Identification

Once the model defined, the parameters (m_1, m_2, k_{fixed}, k_{moving}, c_{fixed}, c_{moving}) have to be identified thanks to optimization algorithms. The optimizations were programed using Python. First, a target function was defined with a least square method only applied on the load in function of the time,

but in most of the cases the second vibration mode was lost. So, the FFT was also included in the target function. To ensure a good identification, three different target functions were analyzed using least squares (1) or gradient descent algorithms (2)(3) [10]:

$$CF1\ (load, FFT) = f \cdot \sum_{i=1}^{n} \frac{\left(load_i^{exp} - load_i^{sim}\right)^2}{\|load^{exp}\|^2} + (1-f) \cdot \sum_{1=1}^{m} \frac{\left(FFT_i^{exp} - FFT_i^{sim}\right)^2}{\|FFT^{exp}\|^2} \quad (1)$$

$$CF2\ (load, FFT) = f \cdot \sqrt{\sum_{i=1}^{n} \frac{\left(load_i^{exp} - load_i^{sim}\right)^2}{\|load^{exp}\|^2}} + (1-f) \cdot \sqrt{\sum_{1=1}^{m} \frac{\left(FFT_i^{exp} - FFT_i^{sim}\right)^2}{\|FFT^{exp}\|^2}} \quad (2)$$

$$CF3\ (load, FFT) = f \cdot \sqrt{\frac{1}{n}\sum_{i=1}^{n} \frac{\left(load_i^{exp} - load_i^{sim}\right)^2}{\|load^{exp}\|^2}} + (1-f) \cdot \sqrt{\frac{1}{m}\sum_{1=1}^{m} \frac{\left(FFT_i^{exp} - FFT_i^{sim}\right)^2}{\|FFT^{exp}\|^2}} \quad (3)$$

With $load^{exp}$ the load recorded by the sensor embedded in the lower die and FFT^{exp} the FFT deduced from that load signal.
And $load^{sim}$ the load obtained with the model and FFT^{sim} the FFT deduced from the modeled load.
With f a balance weight for the load and the spectrum, f was chosen equal to 0.5.

Results and Discussion

The load in function of the time, as well as the FFT, were plotted for the three different target functions and are compared to the experimental results (Fig. 3). For each function, the target value is also indicated. The three load curves obtained are significantly different, whereas the three FFT are very similar with the one coming from the experiments. Regarding the load curves, dephasing is observed in all curves as well as differences of amplitudes. As CF1 and CF2 have very closed definition (CF2 has just a square root more), results were expected to be similar, but this is not the case. The load curve for CF2 is singular compared to the ones for CF1 and CF3. For the experimental load curve, the load increase with important variations until reaching a peak, and after the load peak, the load decreases with smaller and smoother variations. CF1 and CF3 are following this trend, but this is not the case for CF2. This may be explained by the fact that the target functions may have found different local minimums.

Based on these results, the target function CF3 is chosen to perform a sensitivity analysis because it shows the best fit with the lowest target value.

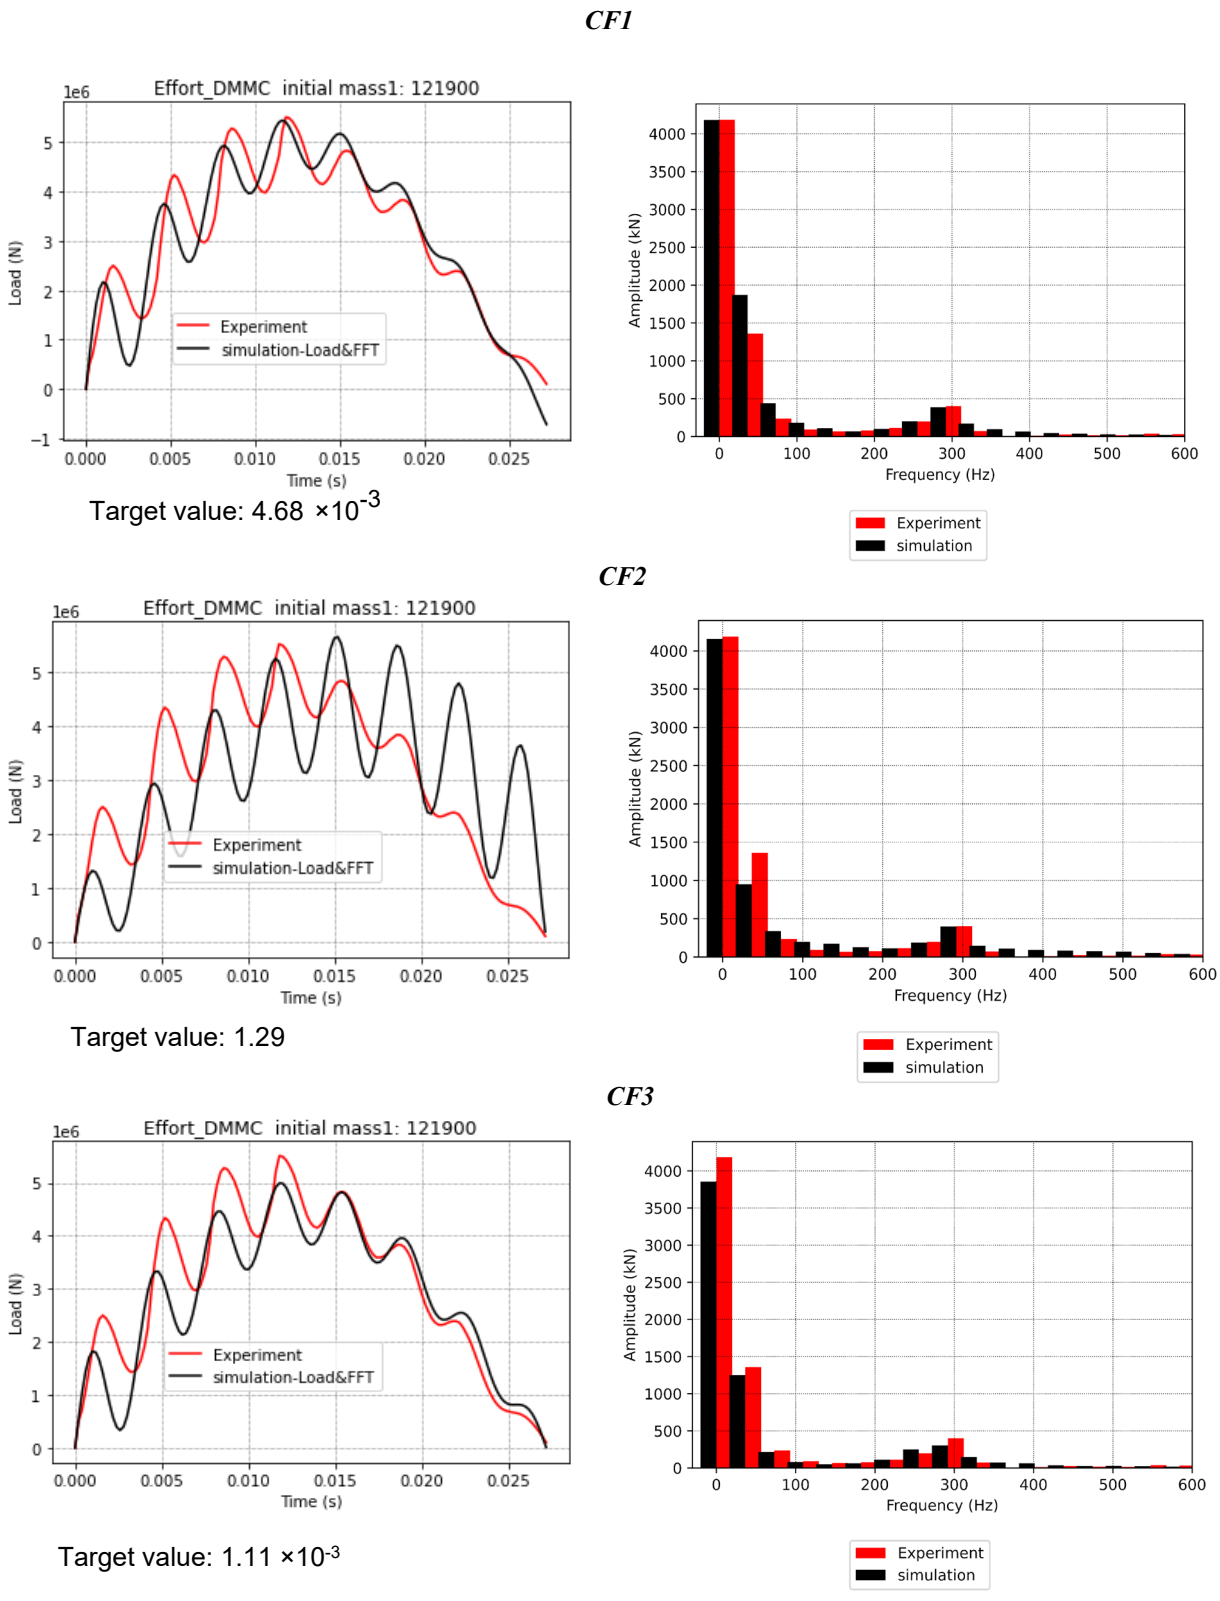

Fig. 3. a) comparison of experimental and simulated load signal for the 3 different target functions b) comparison of FFT on the experimental and simulated load signals for the 3 different target functions.

Sensitivity Analysis

To ensure the convergence of the algorithm to a minimum, a criterion on the target function variation is used and called *TolFun*. The minimization is stopped if, at the increment *i+1*, the equation is satisfied:

$$\frac{\left|CF3\ (load,FFT)_i - CF3\ (load,FFT)_{i+1}\right|}{\left|CF3\ (load,FFT)_i\right|} < TolFun \quad (4)$$

TolFun is obtained with a convergence study: the optimization is run with smaller and smaller values of *TolFun* and the identified parameters and target values of each *TolFun* values are compared (Table **1**). When the variation of these parameters is less than 1%, the *TolFun* value is considered to be adequate. There is no significant improvement of the target function or variation of identified parameters for *TolFun* values lower than 0.1. thus, *TolFun* will be set to 0.1.

Table 1. Target values and parameters values for different convergence criteria.

Convergence criterion	Fonction coût	m (kg)	c (N.s/m)	k (N/m)
1	1.5×10^{15}	3207	730117	2.07×10^{9}
1e-1	$\mathbf{1.1\times10^{-3}}$	**3192**	**360000**	$\mathbf{9.94\times10^{9}}$
1e-2	1.1×10^{-3}	3192	360000	9.94×10^{9}
1e-3	1.1×10^{-3}	3192	360000	9.94×10^{9}
1e-4	1.1×10^{-3}	3192	360000	9.94×10^{9}
1e-5	1.1×10^{-3}	3192	360000	9.94×10^{9}
1e-6	1.1×10^{-3}	3192	360000	9.94×10^{9}

Satisfying the equation (4) is not sufficient to ensure the convergence to a global minimum. The initial set of parameters can also have an impact on the solution find by the algorithm. The initial parameters are defined thanks to suppliers' documentations, when possible and a sensitivity study of the optimization on the initial parameters is conducted. For that, 50 new sets of initial parameters are generated by creating a +/- 10% perturbation according to a uniform law on the reference parameters. 46 optimizations are converging to the same target value with the same identified parameters, thus a global solution seems to be reached.

Then a sensitivity study of the optimization on the initial speed conditions is realized. 50 optimizations were run with 50 different values for the initial speed v_1 and v_2: the 50 different speed values were generated by creating a +/- 5% perturbation according to a uniform law on the reference speed values. Results are plotted (Fig. 4): 37 optimizations were converging to the same target value with 37 same sets of parameters identified.

The impact of the speed on the simulated load at k_{sensor} is also of interest. Thus, optimizations were run with +/-10% uncertainty error for the press input speed and the impact on the load was plotted (Fig. 5). Uncertainty error on the determination of the speed only affects the magnitude of the load with a relative deviation of 3.8%.

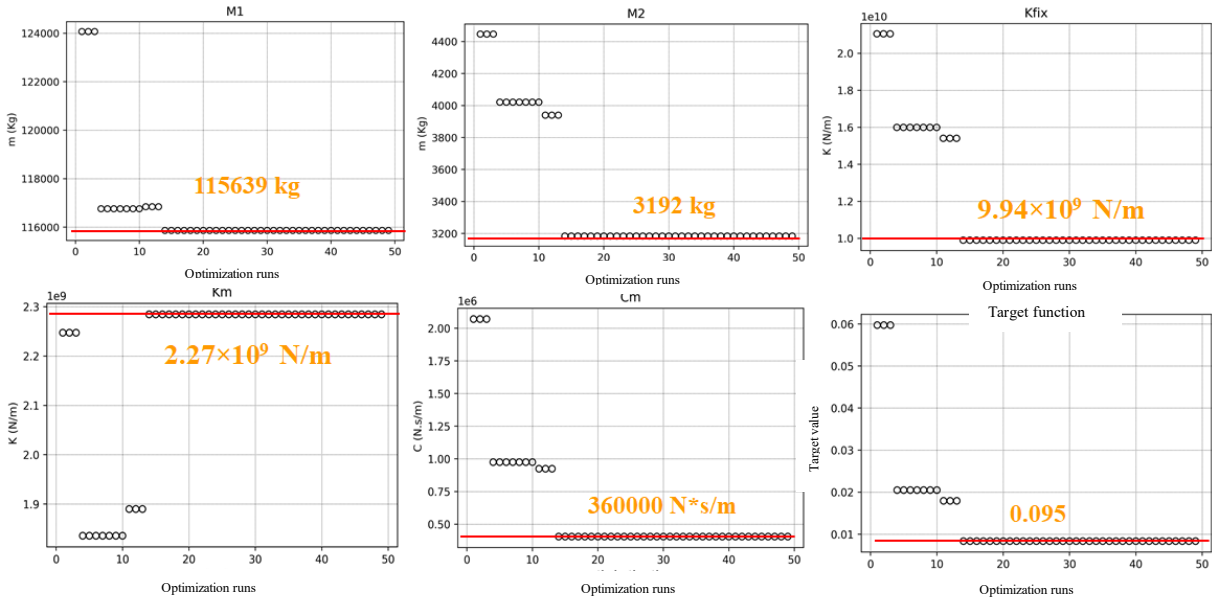

Fig. 4. Identified parameters values (m_1, m_2, K_{fixed}, K_{moving}, C_{moving}) and the target value for the 50 optimization runs with 5% uncertainties on the initial speed conditions.

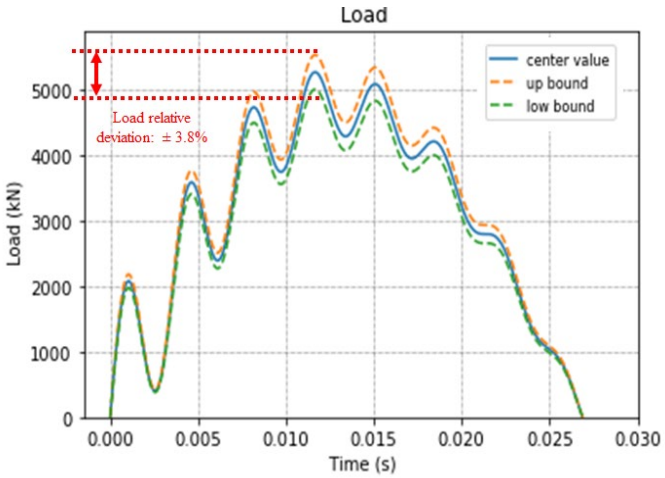

Fig. 5. Simulated load signal for the +/- 10% uncertainties on the initial speed conditions.

Finally, the impact of the parameters identification on the load simulated is also considered. For that, 10% uncertainty error was set for the identified parameters and the load response is plotted (Fig. 6). Uncertainty errors on the identified parameters induce a relative deviation of the load of 1.5% and affect both the load and the vibration mode.

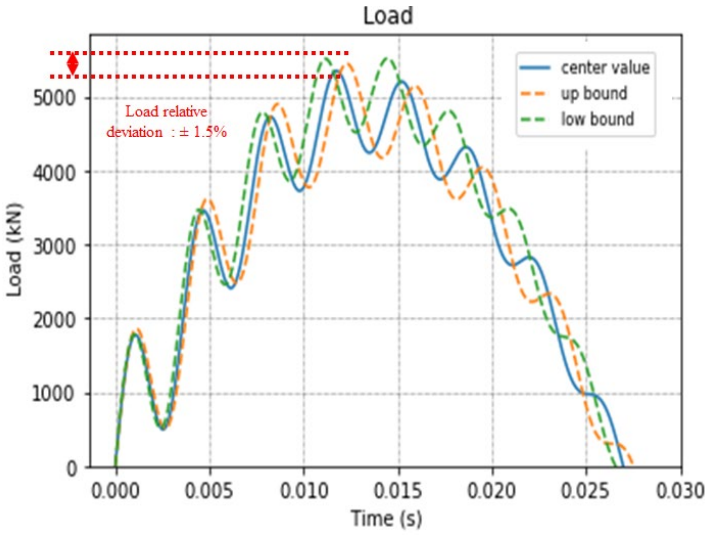

Fig. 6. Simulated load signal for the +/- 10 % uncertainties on the set of identified parameters.

Discussion

Concerning the parametrical identification, three different target functions were already tested and the one that seemed to be the best in terms of target values and load signal fitting was chosen. Despite these different tests, even more target functions could have been tested as well and the target function chosen could be different. The study can also be enlarged by testing different optimization algorithms to ensure that the global minimum is found. For instance, the target function integrates the load in function of the time and the FFT of that signal, but maybe the target function still can be improved by adding the ram displacement into consideration. Thus, the coefficient *f* of the target function could be revised, to give a different weight to each term.

Then, with the target function that was chosen, a sensitivity study of the algorithm on the initial set of parameters was conducted. The results converge; thus, it seems to indicate that a global minimum has been found. To ensure that fact, the study could be enlarged with a bigger perturbation on the initial set of parameters and with a higher number of optimizations.

The impact of the initial speed conditions on the parameters identified and the load simulated was considered. Concerning the parametric identification, results are converging, more than half of the sets of parameters identified are the same. Thus, the optimization is not significantly sensible to uncertainties on the ram speed. And the impact on the load simulated is lower than 4%, so it is negligible.

For the uncertainties on the identification of the set of parameters, it has an impact on the load's amplitude variation and on its dephasing. A relative deviation of 1.5% on the load amplitude was observed, thus remaining very low.

Summary

In this preliminary work on the parametric identification of a dynamic behavior model of a forging machine, one target function was chosen and a sensitivity study on the optimization was conducted. For the uncertainties ranges investigated, results are encouraging as they show a low sensitivity of the algorithm to perturbations on the initial conditions and on the initial set of parameters. But the study should be continued by testing other algorithms and larger ranges of uncertainties to ensure an accurate identification.

Furthermore, here the parametric identification is performed on a model of a press and its tools obtained thanks to bare strike, without billet. Thus, it could be interesting to validate the identified parameters on a case of a model integrating a blow on a billet.

Besides, the model presented here is valid for an entire production system including the press and its tools, but as several different tools can be installed on the same machine, it would be wise to dissociate the tools from the machine in such a dynamic model. And this would necessitate some changes in the target function's definition.

Abstract. In the context of the current study, an analytical method is developed to determine the deformation field of the workpiece under the forming roller for an unconventional incremental radial disk rolling (IRDR) process. As the industrial forming machine is in the development phase, the machine and process design requires a preliminary assessment tool that is sensitive to process parameters and roller geometry. Establishing a parametric relationship between process parameters and induced deformation field enables designers to determine the parameters needed to obtain the target geometry and microstructure as well as the forming machine requirements. Instantaneous roller-workpiece interface, i.e. contact zone, and cross-sections that plastic flow occurs in between are calculated. The contact zone is spatially discretized to two-dimensional surface elements. The principle of volume conservation during plastic deformation is utilized to obtain velocity fields in three dimensions. Strain rate distributions are calculated by taking the gradient of the velocity fields in respective directions. Average values of strain at each cross-section are the accumulated plastic strain that is created by the multiple circumferential passes of the roller and computed numerically, accounting for different strain rates and contact times at each pass. Obtained contact zone geometries, deformation fields, and the effect of different process parameters are discussed. Results show that deformation occurs mainly in the circumferential direction and the tangential velocity of the roller in the circumferential direction has a more pronounced effect on the deformation than the radial advance of the roller per revolution.

Introduction

Having a firm grip on the deformation of the material is essential in a forming operation. Controlling the deformation allows for avoiding possible failures, defects, and undesired inhomogeneities and estimating other crucial forming phenomena such as residual stresses, springback, buckling, pile-up at the onset of forming zone, and diametral growth for cylindrical and disk-shaped products [1,2]. Also, the deformation has a significant effect on the microstructural evolution during the process which affects the mechanical performance of the final product [3]. Microstructural effects are important especially for the hot forming operations due to the recrystallization and grain growth which are usually dictated by narrow temperature, deformation, and time limitations [4]. Therefore, obtaining the desired microstructure depends on the degree of control the process designer can exert on the deformation of the material.

In the literature, mathematical models are often used to assess the deformation of the material in forming operations [5]. One of these methods is the upper-bound method which utilizes an energy functional that has to be minimized to obtain the correct kinematically admissible velocity

field. Kinematic admissibility was derived from the incompressible volume principle [6]. Rolling applications combined the analytical methods with the finite element method for plane-strain rolling [7]. Analytical methods are used to provide the material property update to the finite element model [8]. The volumetric restrictions and plastic flow velocity field are often determined by different approaches based on the upper-bound method such as arc tangent velocity field and cosine velocity field methods [9,10]. The analytical methods are employed to optimize the process parameters of wire flat rolling [11]. The aim was mainly the determination of required rolling force and torque [12]. In extrusion problems, velocity fields had to be substantially modified according to the die geometry [13].

The incremental radial disk rolling (IRDR) process employs two forming rollers which are positioned reciprocally and pulled radially outward. Rollers form the rotating workpiece disk to a higher diameter and a lower thickness. One of the differences between conventional rolling processes and IRDR process is that the axis of roller rotation is either parallel to the axis of the roller feed (radial) or located on the radial-axial(thickness) plane for IRDR while the axis of roller rotation and axis of roller feed are generally perpendicular to each other in conventional rolling [14]. Another difference is that a relatively smaller portion of the workpiece material is subjected to plastic deformation at any instant during the IRDR process. Compared to conventional rolling processes, tube spinning is more similar to IRDR. Apart from the final workpiece shape, the difference distinguishing IRDR from tube spinning is that circumference of the roller path increases and the curvature of the material under the contact zone decreases as the roller moves away from the centre of the disk throughout the IRDR process. Therefore, ensuring the plastic flow stability and homogenous deformation during the IRDR process is much more difficult [15].

Previous studies investigated relatively simpler deformation states of conventional rolling processes. Developed models considered much simpler tool designs and contact zones as the current process requires a complex tool geometry. Also, deformation fields for the current rolling machine have never been researched before. This study focuses on developing parametrical velocity field, strain, and strain rate expressions accounting for any tool geometry, workpiece geometry, and process parameter set. The study aims to provide a preliminary assessment tool for the optimization of the process and the roller geometry for the IRDR process. An analytical method is developed and utilized to determine strain and strain rate distribution in the workpiece material under the forming roller. The forming machine is still in the development phase and optimization of the process requires the evaluation of an extensive number of combinations of process and roller parameters. Even though approaches involving the finite element method are useful, their computational cost is extremely high compared to the current method. Therefore, far fewer finite element method (FEM) simulations are needed in cooperation with the current method. A validation study of the current method with experiments and FEM is in progress. Also in future works, the deformation fields found by the current method will be employed to determine roller geometry and process parameter ranges satisfying the requirements derived from time, force, microstructure, and processing map limitations.

Theory

Roller geometry depends on four independent parameters: roller nose radius (R_n), roller radius (R_r), roller attack angle (α), and roller height (Δt) which is equal to the thickness reduction in this study. Roller geometry also includes smooth angle, smooth nose radius, length of the upper levelling, upper levelling draft angle and length of the lower levelling but they are not included in the calculations due to the limitations of the analytical method. Previous studies showed that the length of the upper levelling and the upper levelling draft angle parameters affect the material pile-up at the onset of feed direction and other parameters control mainly the springback and final surface quality [16]. These subjects are not in the context of the current study and can be neglected in the calculations. The general layout of the moving parts of the machine and the roller geometry

is shown in Fig. 1. Workpiece is attached to the mill which provides the rotational drive to the workpiece.

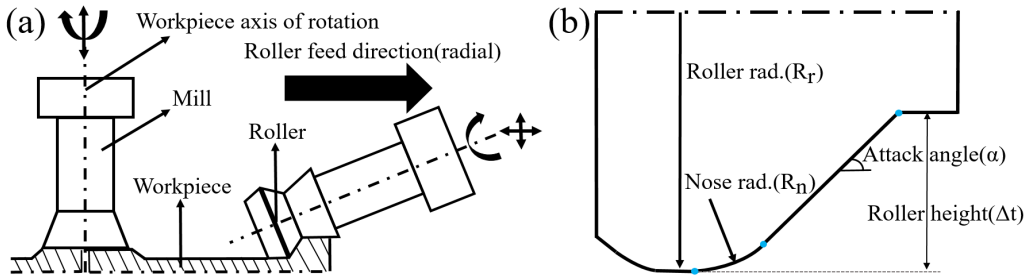

Fig. 1. (a)Layout and motion of roller, mill and workpiece, (b) roller geometry.

The roller is pulled radially outward as the workpiece turns and the roller idles around its axis of rotation. The roller bites the material and the contact zone develops. The area and shape of the contact zone depend on roller geometry, radial feed (f) and radial feed per revolution (pitch, p). Thickness reduction is assumed to be equal to roller height (Δt) to reduce the number of independent variables. The width of the contact zone is assumed to be parallel to the circumferential direction and the system is defined in the Cartesian coordinate system since the width of the contact zone is usually very short compared to the circumference of a near-circular roller path. The origin is defined at a location radially inward by pitch amount with respect to the bottom of the roller nose. The trials with CAD models showed that the contact zone can be represented by a region within seven points, four of which lie on the radial-axial(thickness) plane that the width(b) is zero. Eqs. 1 and 2 provide parametric expressions for radial and axial(thickness) distances between points.

$$L_1 = R_n \sin\alpha, \qquad L_2 = \frac{\Delta t - R_n(1 - \cos\alpha)}{\tan\alpha}, \qquad t_1 = R_n(1 - \cos\alpha), \qquad t_2 = \Delta t - R_n(1 - \cos\alpha) \tag{1}$$

$$t^* = R_r - R_n(1 - \cos\alpha) - \sqrt{\left(R_r - R_n(1 - \cos\alpha)\right)^2 - b_{mid}^2} \tag{2}$$

Broadwise locations of points P_5, P_6 and P_7 are expressed as b_{up}, b_{mid} and b_{low}, respectively. Fig. 2 illustrates point locations which are calculated with found distances. The three-dimensional geometry of the contact zone is obtained parametrically by utilizing cubic area interpolation between these points.

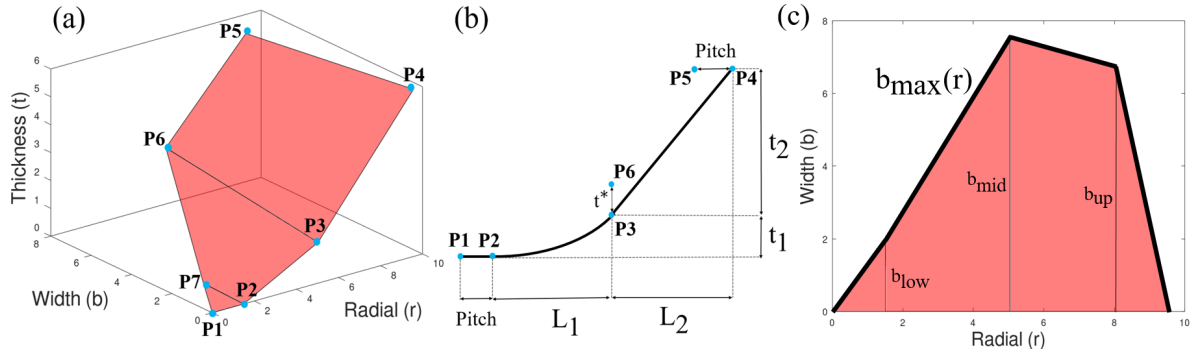

Fig. 2. (a)Points defining the contact zone, (b)Positions of points in radial(r)-axial(t) plane, (c)Maximum width as a function of radial location.

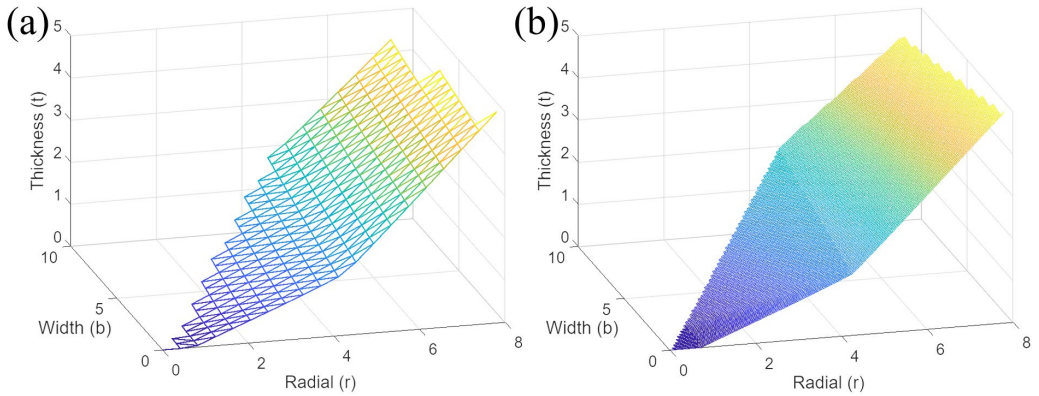

Fig. 3. Discretization of the contact zone with (a)450 and (b)13000 elements.

Interpolated area is spatially discretized into triangular surface elements using Delaunay Triangulation [17]. The centroidal location of each element is calculated and the developed analytical model is implemented on these centroids. Fig. 3 compares contact zones obtained by different mesh densities. The contact zone employing finer mesh which has 13000 surface elements, accurately captured the curvature of the nose region as well as the flatness of the lower levelling region below the nose. Also, the model with finer mesh achieved a more precise contact zone boundary representation.

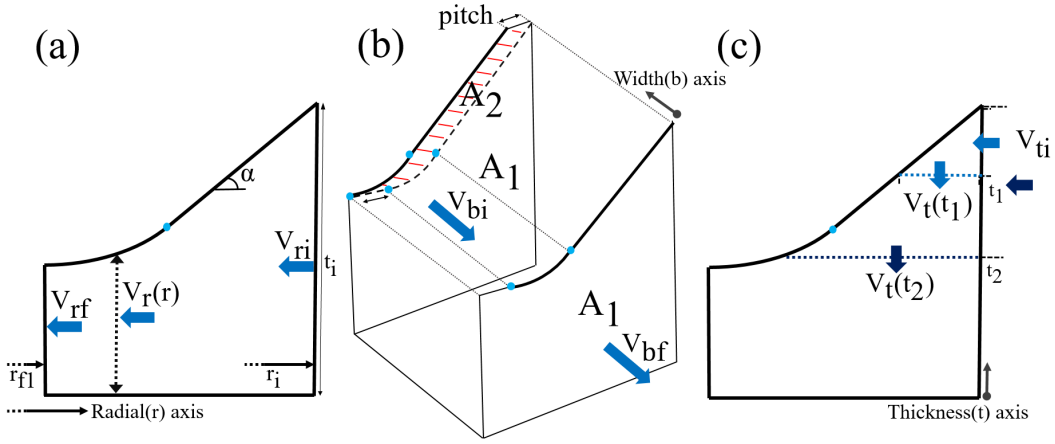

Fig. 4. Plastic flow directions and cross-sections in (a)radial, (b)width and (c)thickness axes.

Derivation of Velocity Field.

The material is assumed to undergo no elastic strain relaxation between circumferential passes since the induced plastic strain is expected to be much higher than the elastic strain. Strain rate calculations start with the derivation of analytic expressions for plastic flow velocities in three axes. Fig. 4 illustrates flow velocities and cross-sections that the flow travels in corresponding directions. Calculations rely on the assumption that plastic deformation induces no volume change. Flow in each direction is assumed to be independent of each other. The tangential velocity of the roller in the circumferential direction is much higher than that in the radial direction for process parameters tested in this study. Therefore the contribution of plastic flow in different directions to each other is negligible. This assumption should be improved in the future. Firstly, initial volumetric flow rates are calculated. Then, cross-sections normal to the flow are parametrically expressed for any location. The plastic velocity that the material has to have while travelling through a defined cross-section is obtained by employing the volume conservation principle. The velocity found is the average velocity of the material flowing below the corresponding point of the roller as the cross-section is dictated by the contact zone and the radial location of the roller, in

Materials Research Proceedings 28 (2023) 657-666 https://doi.org/10.21741/9781644902479-71

addition to process parameters. Finally, strain rate expressions are obtained by taking the gradient of the velocity field along the corresponding direction.

The radial plastic velocity field is illustrated in Fig. 4(a). For calculations, the radial axis is separated into two regions, the inclined region and nose region, divided by the upper end of the roller nose whose radial location (r^*) is formulated in Eq. 3 where r_i is the initial radius. For all calculations, subscript i and the term "initial" denote the initial properties just before entering the contact zone. Radial location of the bottom end of the nose (r_{f1}) is also given in Eq. 3.

$$r^* = r_i - \frac{\Delta t - R_n(1 - \cos\alpha)}{\tan\alpha} \quad \text{and} \quad r_{fl} = r^* - R_n \sin\alpha \tag{3}$$

Only the variation of thickness with radius is different for these two regions. Volume conservation in radial direction and radial flow velocity as a function of radius are expressed in Eq. 4 where feed (f) is the initial radial velocity and t_i is the initial thickness.

$$V_r(r)t(r)\, 2\pi\, r = f\, t_i\, 2\pi\, r_i \;\rightarrow\; V_r(r) = \frac{f\, r_i\, t_i}{r\, t(r)} \tag{4}$$

Variations of thickness with radial location and consequent radial flow velocities are formulated in Eqs. 5 and 6.

$$t(r) = t_i + \frac{r - r_i}{\tan\alpha} \quad \rightarrow \quad V_r(r) = \frac{f\, r_i\, t_i\, \tan\alpha}{r\,(t_i\, \tan\alpha + r - r_i)} \qquad \text{for} \quad r^* < r < r_i \tag{5}$$

$$t(r) = t_f + R_n - \sqrt{R_n^2 - (r - r_{fl})^2} \;\rightarrow\; V_r(r) = \frac{f\, r_i\, t_i}{r\,(t_f + R_n - \sqrt{R_n^2 - (r - r_{fl})^2})} \quad \text{for} \quad r_{fl} < r < r^* \tag{6}$$

Circumferential plastic flow is shown in Fig. 4(b). Material starts to flow under the roller when it encounters the furthest point of the contact zone in the width axis: b_{mid} which is broadwise location of P_6 shown in Fig. 2(a). The initial cross-section that plastic flow velocity passes has an area of A_1+A_2. As the flow continues under the contact zone, the cross-sectional area is assumed to be linearly decreased to A_1. A_2 is the projectional area of the contact zone on the radial-axial plane and equal to pitch times Δt. The expression found for A_1 is given in Eq. 7.

$$A_1 = t_f\,(R_n \sin\alpha + p) + \frac{t_i^2 - (t_f + R_n\,(1 - \cos\alpha))^2}{2\tan\alpha} + R_n^2\,(\sin\alpha\left(1 - \frac{\cos\alpha}{2}\right) - \frac{\alpha(\text{rad})}{2}) \tag{7}$$

Volume conservation in the width axis and resulting relation for circumferential velocity field expression are presented in Eqs. 8 and 9 where V_{bi} is the known initial tangential velocity in the circumferential direction. Variation of the cross-sectional area with broadwise location is obtained by the use of assumed linear area decrease between $b = b_{mid}$ *and* $b = 0$.

$$V_b(b)A(b) = V_{bi}\,(A_1 + A_2) \;\rightarrow\; V_b(b) = V_{bi}\,\frac{(A_1 + A_2)}{A(b)} \tag{8}$$

$$A(b) = A_1 + A_2\,\frac{b}{b_{mid}} \;\rightarrow\; V_b(b) = V_{bi}\, b_{mid}\,\frac{A_1 + A_2}{A_1\, b_{mid} + A_2\, b} \tag{9}$$

In radial and circumferential velocity field calculations, initial cross-sections were assumed to be constant and all cross-sections were parallel to each other. In contrast, for the axial velocity field, the initial cross-section has normal in the radial direction and it is assumed to be a function of thickness. Because, the material enters the contact zone in the radial direction and is pressed downward in the axial axis at any point on the roller, as demonstrated in Fig. 4(c). The expression for axial plastic velocity is formulized in Eq. 10.

$$V_t(t)\,(r_i - r)\,2\pi\,\frac{r_i + r}{2} = f\,(t_i - t)\,2\pi\, r_i \;\rightarrow\; V_t(t) = 2f\, r_i\,\frac{(t_i - t)}{(r_i - r)(r_i + r)} \tag{10}$$

Axial flow velocity as a function of axial location is presented in Eq. 11.

$$r = r_i - (t_i - t)\tan\alpha \;\rightarrow\; V_t(t) = \frac{2f\,r_i}{\tan\alpha\left(2\,r_i - (t_i - t)\tan\alpha\right)} \tag{11}$$

Strain Rate Distribution.

Strain rates are calculated by taking the gradient of the velocity field in respective directions. Eqs. 12 and 13 provide the radial strain rate expression which is the gradient of Eqs. 5 and 6 in the radial direction.

$$\dot{\varepsilon}_r = \frac{dV_r}{dr} = f\,r_i\,t_i\,\tan\alpha\,\frac{-t_i\,\tan\alpha - 2r + r_i}{r^2(t_i\,\tan\alpha + r - r_i)^2} \quad \text{for} \quad r^* < r < r_i \tag{12}$$

$$\dot{\varepsilon}_r = \frac{dV_r}{dr} = f\,r_i\,t_i\,\frac{-\sqrt{R_n^2 - (r - r_{fl})^2}\,(t_f + R_n) + R_n^2 - (r - r_{fl})^2 - r\,(r - r_{fl})}{r^2\sqrt{R_n^2 - (r - r_{fl})^2}\left(t_f + R_n - \sqrt{R_n^2 - (r - r_{fl})^2}\right)^2} \quad \text{for} \quad r_{fl} < r < r^* \tag{13}$$

Circumferential and axial strain rate relations are shown in Eqs. 14 and 15 which are gradients of velocity fields in circumferential (b) and axial (t) directions, see Eqs. 9 and 11, respectively.

$$\dot{\varepsilon}_b = \frac{dV_b}{db} = -V_{bi}\,b_{mid}\,\frac{A_2\,(A_1 + A_2)}{(A_1\,b_{mid} + A_2\,b)^2} \tag{14}$$

$$\dot{\varepsilon}_t = \frac{dV_t}{dt} = -\frac{2f\,r_i}{(2\,r_i - (t_i - t)\tan\alpha)^2} \tag{15}$$

Strain Distribution.

Strain at each element is considered as the cumulative plastic strain induced by circumferential passes of the roller. At each circumferential pass, the material is subjected to varying strain rates under the contact zone in three directions. As the strain rate distributions are found, strain increments ($\Delta\varepsilon_j$) at each pass and the sum of the strain increments (ε_j, accumulated strain) can be calculated according to Eq. 16 for each element. In the strain equation, j is the direction of the strain and strain rate, e is the domain of locations that the element presented at previous passes and Δt(e) is the duration of contact time for each location. b_{max} values are calculated by interpolation between b_{up}, b_{mid} and b_{low} at known previous radial locations as shown in Fig. 2(c).

$$\varepsilon_j = \sum_e \Delta\varepsilon_j\,(e) = \sum_e \Delta t(e)\,\dot{\varepsilon}_j(e) \quad \text{where} \quad \Delta t(e) = \frac{b_{max}(e)}{V_{bi}} \tag{16}$$

Results

The workpiece material and the process temperature does not affect the results of this study. Also, even though the developed method is capable of accounting for varying initial radii, all calculations in this study are done for only one value of initial radius which is 120 mm. It is found that the contact zone changes as the roller moves in the radial axis for low radii. As the roller further moves away from the centre, the contact zones at different radial locations become very similar. The employed initial radius is chosen to be obeying the second trend. Also, a mesh dependency study is carried out but it is not presented here to restrict the extent of the paper. Results for only the finer mesh are evaluated. Firstly, the effect of roller geometry on the contact zone is investigated. Four roller geometry (RG) parameter sets are created and tabulated in Table 1. Obtained contact zones are shown in Fig. 5. To preserve comparability, each contact zone was formed by the same process parameter set which is 0.3 mm/s feed rate(f) and 25 RPM spindle rate. A higher roller radius leads to a wider contact zone, comparing RG1 and RG2. Contact zones of RG1 and RG3

show the effects of nose radius and roller height. The inclined region constitutes a much higher portion of the contact zone than the nose region for the roller with a lower R_n and higher Δt. Also, increased roller height elongated the contact zone in the radial direction. Examining the contact zone of RG4, a low attack angle also causes a significant increase in the radial length of the contact zone.

Table 1. Dimensions of 4 different roller geometries (RG).

	Roller Radius, R_r [mm]	Nose Radius, R_n [mm]	Attack Angle, α [°]	Roller height, Δt [mm]
RG1	35	5	45	5
RG2	70	5	45	5
RG3	35	2.5	45	7.5
RG4	70	2.5	30	7.5

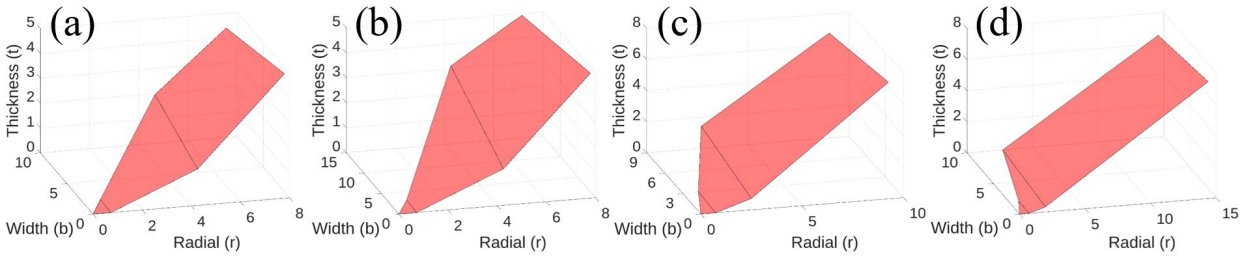

Fig. 5. Contact zones of (a) RG1, (b) RG2, (c) RG3 and (d) RG4 for w=25 RPM, f=0.3 mm/s.

For investigations on deformation distribution, only one roller geometry which is RG1, is employed so that the effect of process parameters could be examined clearly. The effect of roller geometry on the deformation will be studied in the future. Fig. 6 shows directional and the von Mises equivalent strain rate distributions. The radial strain rate ($\dot{\varepsilon}_r$) is equal to zero at the beginning of the radial axis for a pitch amount of length since that region is flat and induces no radial deformation. Then, the magnitude of the $\dot{\varepsilon}_r$ increases with r because the round profile of the nose region leads to higher cross-sectional area differences between different radial locations on the nose region. On the inclined region, the magnitude of $\dot{\varepsilon}_r$ linearly decreases with r due to the increasing thickness of the workpiece.

Circumferential strain rate ($\dot{\varepsilon}_b$) values are similar along the width axis. Magnitude of $\dot{\varepsilon}_b$ is much higher than strain rates in other directions which shows that material flows mainly in the width axis. Axial strain rate ($\dot{\varepsilon}_t$) is very small and almost constant along the contact zone. Along the radial axis on the b=0 plane, the equivalent von Mises strain rate is around 1.3 for the given process and roller parameters.

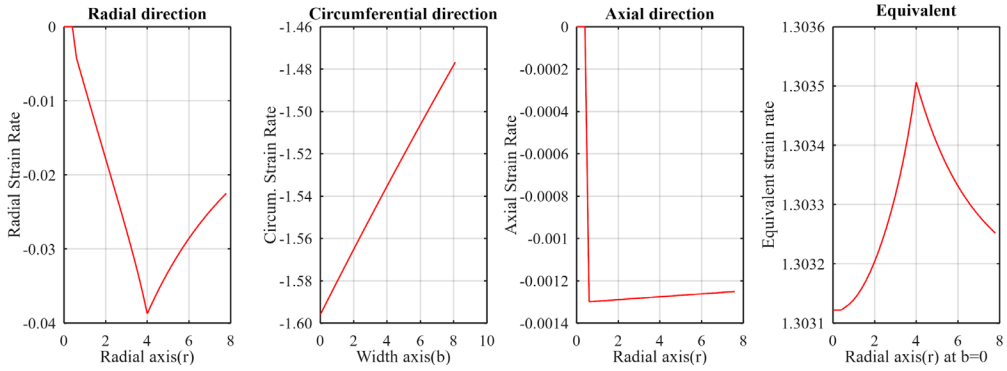

Fig. 6. Radial, circumferential, axial, and von Mises equivalent strain rate distributions for w=25 RPM, f=0.3 mm/s, $t_i = 15$ mm and roller geometry of RG1.

Materials Research Proceedings 28 (2023) 657-666 https://doi.org/10.21741/9781644902479-71

Variations of mean von Mises equivalent strain rate and strain with process parameters are shown in Fig. 7. In each plot, the effect of only one process parameter is tested and other parameters are kept constant. As shown previously, equivalent strain rate distribution is very uniform along the contact zone thus the mean value can represent the deformation behaviour accurately. For strain distribution, however, the mean value provides only a general perspective since strain value increases accumulatively as the circumferential passes form the material.

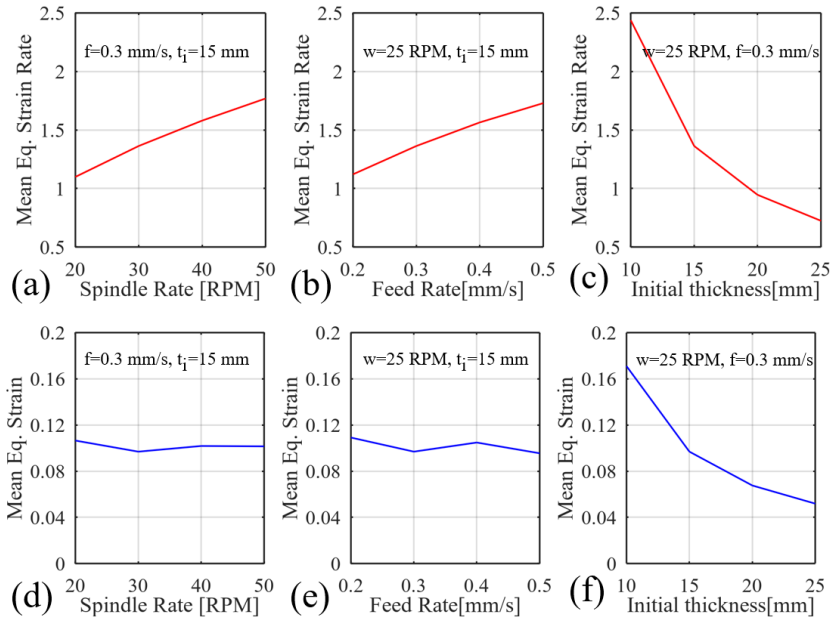

Fig. 7. Mean equivalent strain rate and strain for RG1 roller geometry and varying (a,d) spindle rates, (b,e) feed rates, (c,f) initial thicknesses.

Fig. 7(a) indicates an increase in spindle rate results in a higher mean equivalent strain rate while Fig. 7(d) clearly shows that obtained mean equivalent strains are similar. Positive proportionality between spindle rate and strain rate is due to the higher tangential velocity in the circumferential direction for increasing spindle rate. Even though an increased spindle rate leads to a smaller radial bite which is called pitch, the effect of tangential velocity appears to be higher and overcomes the negative effect of pitch decrease. As the tangential velocity increases, contact time per pass decreases. Consequently, similar mean equivalent strain values are obtained.

A very similar trend is observed for feed rate as shown in Fig. 7(b,e). The equivalent strain rate increases with increasing feed rate but the equivalent strain remains almost constant. As the feed rate is increased while the spindle rate is kept constant, the pitch increases and the tangential velocity does not change. Therefore, a higher equivalent strain rate is obtained for a higher feed rate. Thus the total number of circumferential passes is lower for higher pitch and cumulative strain is similar for different feed rate values. Having similar mean equivalent strain values for different sets of feed rate and spindle rate confirms that the calculated velocity fields are accurate.

Mean strain rate and strain are more sensitive to initial thickness than other parameters as shown in Fig. 7(c,f) For the constant thickness reduction, the proportional decrease in the cross-sectional area during forming is much higher for low initial thicknesses. For different initial thicknesses, the pitch is kept constant and the bite area is not modified. However, the ratio of the bite area to the rest of the circumferential cross-section decreases with increasing initial thickness, and consequently, the strain rate also decreases. For constant feed rate and spindle rate, the total number of passes and contact time per pass do not change. Thus, mean strain rate and strain follow the same trend.

Summary
An analytical method is developed to predict deformation fields for an incremental disk rolling process. Effects of process parameters and roller geometry on the contact zone and plastic deformation fields are examined.

Roller radius is proved to have a considerable effect on the circumferential width of the contact zone which is important for the circumferential plastic deformation. Radial deformation and radial length of the contact zone are mainly controlled by the roller height and the attack angle. Also, nose radius has an important effect on the radial plastic flow since the highest radial strain rate is calculated at the nose-inclined region interface.

The equivalent strain rate is proved to increase with increasing spindle rate due to the higher tangential velocity despite the shorter pitch. It shows that the tangential velocity is more influential on the deformation than the pitch. It can be said that the deformation can be controlled by adjusting the spindle rate without having to modify process time as the process time is controlled by only the feed rate. Increasing the feed rate also causes a higher strain rate but the underlying cause is the higher pitch which enables shorter process time. Therefore a compromise can be established between strain rate and process time by optimizing the process parameters provided that their effects are well understood as aimed by the current study. Strain rate affects recrystallization, failures, forces and related machine requirements as the process time affects grain growth, tool life and related machine requirements. This analytic method plays a key role in machine development as it provides insight into the connection between machine design, process parameters and induced deformation.

Keywords: Hot Process, Recrystallization, FEM, JMAK

Abstract. In the aerospace industry, the turbine disk plays a crucial role. Controlling the average grain size during the hot forming of nickel-based superalloys such as Inconel 718 is critical for turbine disk production. Recrystallization is primarily responsible for evolution of microstructure during a hot forming process. In the current study, Finite Element Method (FEM) is employed to assess grain size evolution during an incremental disk rolling process. FEM simulations are used to obtain temperature, strain and strain rate distributions. Then, utilizing these deformation distributions, recrystallization and consequent average grain size distributions are calculated using Johnson-Mehl-Avrami-Kolmogorov (JMAK) equations. Simulations are conducted for different spindle rates of the workpiece. This process is sensitive to the temperature and meta-dynamic recrystallization. Results show that temperature increases with the spindle rate due to the inelastic heat generation. Also a higher grain size variation through thickness is obtained for the simulation with lower spindle rate since meta-dynamic recrystallization fraction is higher.

Introduction

A wide range of alloys have good mechanical properties at room temperature, however, only a few alloys can be used at elevated temperatures. The primary category of these alloys is Nickel-based superalloys. These properties are governed mostly by the microstructure [1]. The key to achieving good and uniform characteristics during the manufacturing process is being able to control the grain size. Most frequently used approach is to simulate the process using FEM. This provides an understanding of microstructure evolution of the material during the process and reduces the number of trials required for process development. The reason is that temperature, strain, and strain rate distributions are significant parameters affecting the grain size [2]. JMAK equations can calculate recrystallization fractions with these values [3].

At elevated temperatures, three different forms of recrystallization can occur. These are static, dynamic, and meta-dynamic [4]. Static recrystallization may occur if there is cold work in the material before heating. When the material is subjected to hot deformation, dynamic recrystallization takes place. A more accurate description of the occurrence of dynamic recrystallization is strain rate being greater than zero. Meta-Dynamic recrystallization is similar to static recrystallization, but it only occurs if the dynamic recrystallization fraction(X_{DRX}) is lower than 1 during the hot deformation process. Fig. 1 depicts the summary of the recrystallization phenomenon.

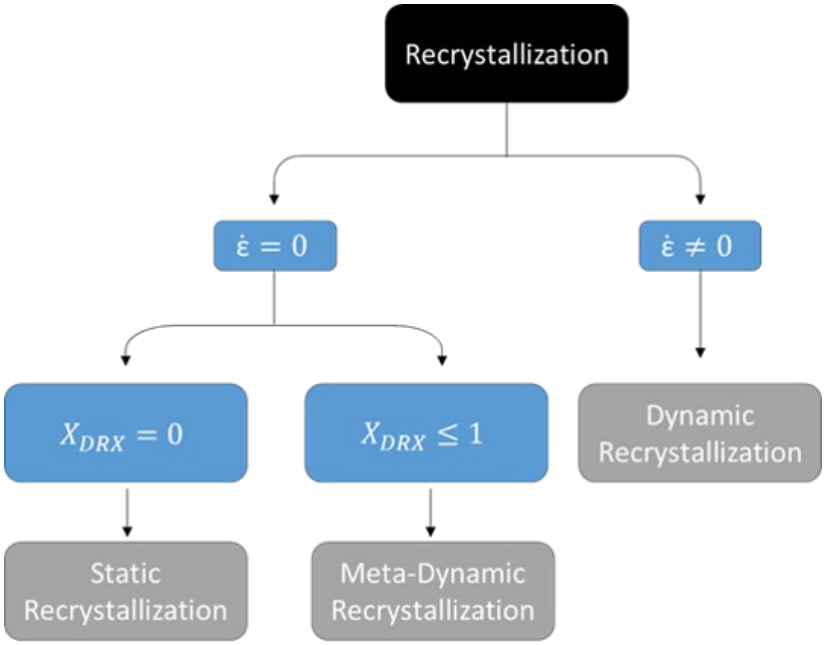

Fig. 1. Summary of Recrystallization.

All these calculations are covered by JMAK equations [3]. However, the majority of equations are empirical. Experiments have to be conducted to determine the material coefficients. To predict material parameters for recrystallization and grain growth, single and double compression tests have to be applied. Provided that the initial grain diameter is known, the single compression test is applied with different sets of constant strain rate and constant temperature. With these experimental results, dynamic recrystallization parameters can be obtained with the curve fitting method. To predict meta-dynamic recrystallization and grain growth parameters, a double compression test has to be applied with different combinations of strain rate, temperature, and waiting time between loadings [2]. These equations can be employed once the relationship between properties has been determined.

Dynamic recrystallization equations:

$$X_{DRX} = 1 - exp\left(A_1 \times \frac{\varepsilon(t) - A_3 \times {\varepsilon_c}^{A_2}}{\varepsilon_{0.5} - A_4 \times \varepsilon_c}\right) \quad (1)$$

$$\varepsilon_c = A_{crit} \times B_1 \times {d_0}^{B_2} \times \dot{\varepsilon}^{B_3} \times Z^{B_4} \times exp\left(\frac{Q_{B_5}}{R \times T}\right) \quad (2)$$

$$\varepsilon_{0.5} = C_1 \times {d_0}^{C_2} \times \dot{\varepsilon}^{C_3} \times Z^{C_4} \times exp\left(\frac{Q_{C_5}}{R \times T}\right) \quad (3)$$

$$D_{DRX\ Nuclei} = D_1 \times {d_0}^{D_2} \times \dot{\varepsilon}^{D_3} \times Z^{D_4} \times exp\left(\frac{Q_{D_5}}{R \times T}\right) \quad (4)$$

Meta-Dynamic recrystallization equation:

$$X_{MDRX} = 1 - exp\left(E_1 \times \left(\frac{t}{t_{0.5}}\right)^{E_2}\right) \quad (5)$$

$$t_{0.5} = F_1 \times \varepsilon^{F_2} \times {d_0}^{F_3} \times \dot{\varepsilon}^{F_4} \times Z^{F_5} \times exp\left(\frac{Q_{F_6}}{R \times T}\right) \quad (6)$$

$$D_{MDRX\ Nuclei} = G_1 \times {d_0}^{G_2} \times \dot{\varepsilon}^{G_3} \times Z^{G_4} \times exp\left(\frac{Q_{G_5}}{R \times T}\right) \quad (7)$$

Grain growth:

$${d_{grain\ growth}}^{H_1} = {d_0}^{H_2} + H_3 \times exp\ exp\left(\frac{Q}{R \times T}\right) \times t \quad (8)$$

Table 1. Parameters list.

Material coefficients	A_1-A_4	Dynamic recrystallization fraction
	B_1-B_5	Critical strain
	C_1-C_5	Half recrystallized volume fraction strain
	D_1-D_5	The average grain diameter of dynamically recrystallized fraction
	E_1-E_2	Meta-dynamic recrystallization fraction
	F_1-F_6	Half recrystallized volume fraction time
	G_1-G_5	The average grain diameter of meta-dynamic recrystallized fraction
	H_1-H_3	Grain growth
d_0		The initial average grain diameter
$\dot{\varepsilon}$		Strain rate
ε		Strain
Q		Activation Energy
R		Gas constant
T		Temperature
Z		Zener-Hollomon parameter
X_{DRX}		The fraction of dynamic recrystallization
$D_{DRX\ Nuclei}$		The average diameter of dynamic recrystallization
X_{MDRX}		The fraction of meta-dynamic recrystallization
$D_{MDRX\ Nuclei}$		The average diameter of meta-dynamic recrystallization
$d_{grain\ growth}$		The average grain diameter of grain growth

Recrystallization is governed by strain, strain rate, and temperature, as demonstrated by the preceding equations and Fig. 1. These equations are only applicable to isothermal conditions with a constant strain rate. However, the deformation in the hot incremental disk rolling process is not completely isothermal and the strain rate is not constant or uniform. Both strain rate and temperature are a function of time. To include that effect, these equations need to be updated with their differential form with respect to time [5]. However, assuming isothermal and constant strain rate condition is not a completely wrong assumption when the spindle rate is optimized accordingly as demonstrated in this study.

Modelling Approach

As the workpiece spins, four rollers deform the workpiece radially outward. As the thickness of the workpiece decreases, the outer diameter of the workpiece increases. Forge NxT commercial finite element software using implicit time integration scheme is used for the process simulations. These simulations consist of thermo-mechanical calculations. The Johnson-Cook plasticity material model is used to simulate the flow of bulk material in order to examine the history of temperature, strain, and strain rates. Ideally, process would be simulated as it is; however, this is not feasible due to large computational time. Instead, an angular segment of the disk is modelled

with boundary conditions applied at each side of the disk. These boundary conditions could be applied as cyclic symmetry boundary condition. However, this option is not available in the software at the moment. Instead, boundary conditions are applied as two planes which are adiabatic and allow for sliding of the nodes along the plane, but do not allow for node separation. Due to the numerical integration of the variables, the time step of the simulation has to be small for microstructure evaluation. To overcome this problem and reduce computational time, a comparison between angular segments of varying size and a full disk model was performed. This study showed that 1/8 angular segment of the disk produces similar results with full model. Results of the convergence study are not included here for brevity. As demonstrated in Fig. 2, the horizontal plane of the disk exhibits mirror symmetry. Thus, only top half of the disk can be used with symmetry boundary condition at the horizontal plane. The two boundary conditions applied through the planes do not fully reflect the nature of the process. Therefore, to minimize their effect on the results, only results for the middle of the angular segment are taken into consideration, as shown in Fig. 3 [6]. Rollers are assumed to be frictionless and do not rotate around their axes, the assumption being that the effect of friction can be neglected. Effect of friction and roller rotation will be examined separately in future studies. The temperature of the process atmosphere is controlled by a furnace. Heat transfer due to conduction between the rolles and the workpiece, radiation and convection with the environment are all included together. Value taken is: 50W/m^{2}K which is the average of the value widely available in the literature. The metallurgical part of the calculations is uncoupled with a thermo-mechanic solver. Outputs of the thermo-mechanical model are used to calculate the recrystallization and growth mechanism. Mechanical and thermal parameters of Inconel 718 are taken from JMatPro material property simulation software and the JMAK equations parameters are taken from Forge NxT Software.

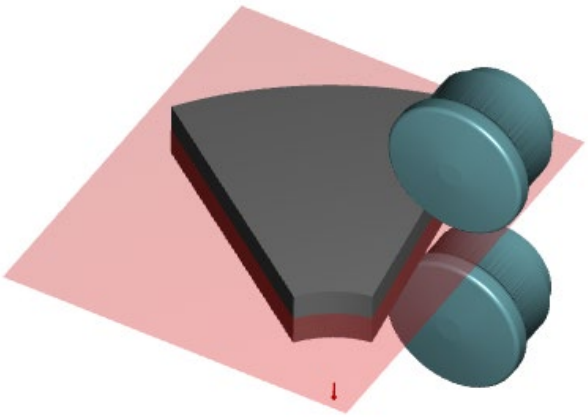

Fig. 2. The simulation model of an incremental disk rolling.

Results and Discussion

This section simulates and compares the effect of three distinct spindle rates (RPM of the workpiece). Fig. 3 illustrates the portion of the simulated part that is shown in the subsequent figures.

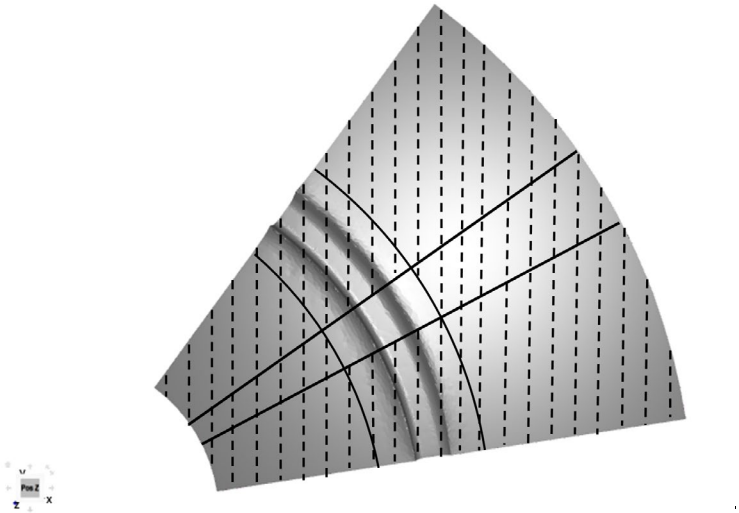

Fig. 3. Comparable area of the simulation model.

The results of simulations with three different spindle rates are evaluated. Temperature, equivalent strain, dynamic recrystallization, meta-dynamic crystallization, and average ASTM grain diameter are compared. The spindle rate has a significant effect on the temperature. The inelastic heat generation increases as the deformation rate increases. Temperature change is not found to be important unless it exceeds the range of the JMAK equation parameter. Despite grain growth being unaffected at the time scale of the first pass, it will be modified during the rest of the process. The other issue is that the temperature exceeds 1030°C for the fastest spindle rate case, as seen in Fig. 4(c). This temperature level is close to the upper limit of the JMAK equation parameter range for Inconel 718. These limits come from the processing map of Inconel 718. 1030°C is the most efficient temperature for the dynamic recrystallization range for forged Inconel 718 [7]. It was shown that the material starts to behave differently above this temperature [3]. The equivalent strain is also strongly affected by the spindle rate as it is an expected result due to the nature of the rolling process as shown the Fig. 5. Results show that equivalent strain values are very high even after the first pass for the high spindle rate case. The reason for having different equivalent strain values for the same thickness reduction is that the plastic flow in the circumferential direction increases when the spindle rate is increased. For high spindle rates, elements become elongated not only in the radial direction but also in the circumferential direction.

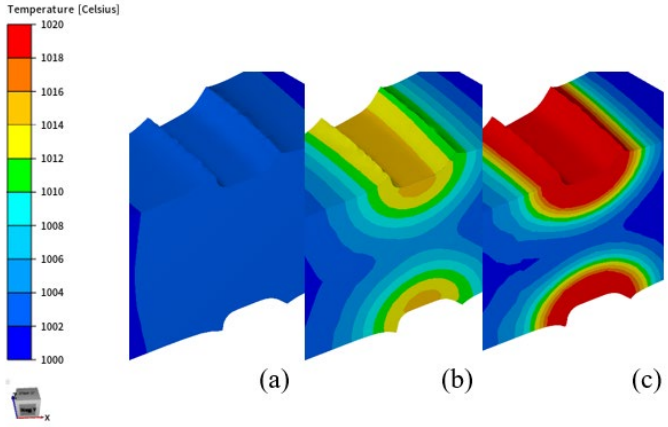

Fig. 4. (a) The lowest spindle rate, (b) medium spindle rate, (c) fastest spindle rate result of temperature distribution during the process.

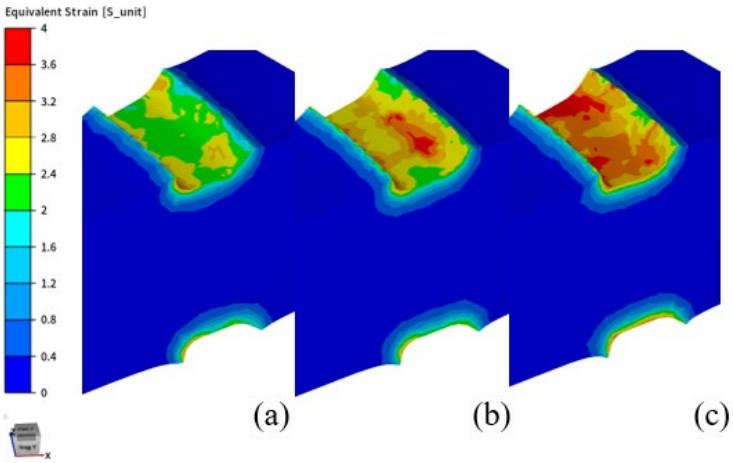

Fig. 5. (a) The lowest spindle rate, (b) medium spindle rate, (c) fastest spindle rate result of Equivalent strain distribution during the process.

Dynamic recrystallization occurs due to the deformation. Temperature, strain, and strain rate change over time. Therefore every parameter in Eq. 1 is affected even though the dynamic recrystallization equation contains no time parameter. The area of dynamic recrystallization fraction is almost constant throughout the first pass for different temperature and equivalent strain values, as shown in Fig. 6. When the deformation rate increase with the spindle rate, the critical strain (ε_c) value and half recrystallization fraction strain ($\varepsilon_{0.5}$) value increase. So the affected dynamic recrystallization zone stays the same.

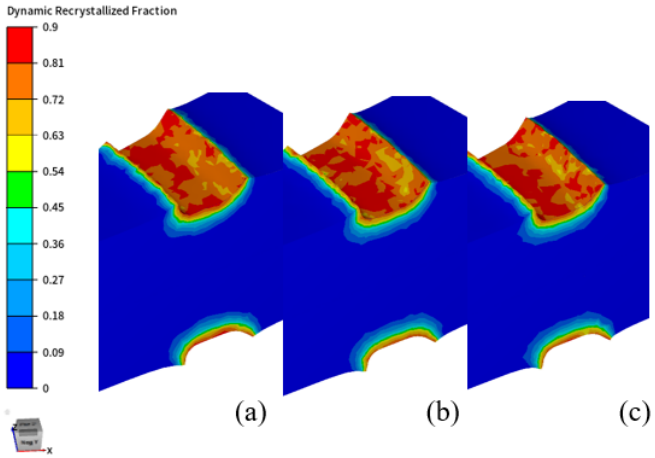

Fig. 6. (a) The lowest spindle rate, (b) medium spindle rate, (c) fastest spindle rate result of dynamic recrystallization distribution during the process.

The area of meta-dynamic recrystallization is affected by the spindle rate since changing the spindle rate modifies the time interval between two subsequent passes. The primary variable in meta-dynamic recrystallization is the time. When the spindle rate is low, meta-dynamic recrystallization can take place over a longer period of time, as shown in Fig. 7.

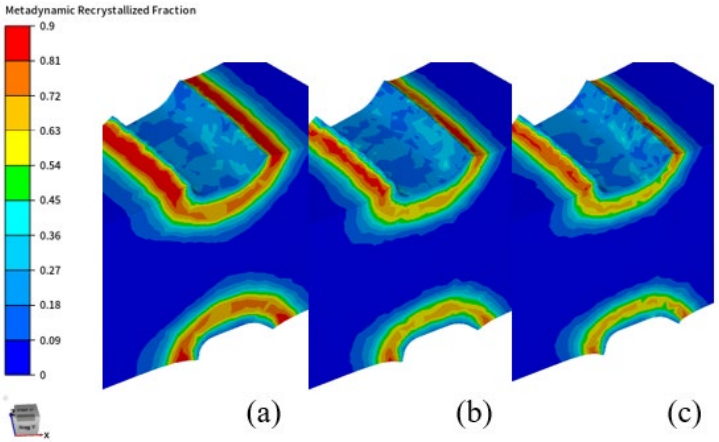

Fig. 7. (a) The lowest spindle rate, (b) medium spindle rate, (c) fastest spindle rate result of meta-dynamic recrystallization distribution during the process.

Fig. 8 illustrates the variation of the average grain diameter with the spindle rate. Recrystallization plays a substantial role in grain size reduction. Although the overall recrystallization zone is similar in all three simulations, the time between subsequent passes is high for low spindle rate. Therefore lower spindle rate leads to a higher variation of ASTM grain size through the thickness due to the meta-dynamic recrystallization.

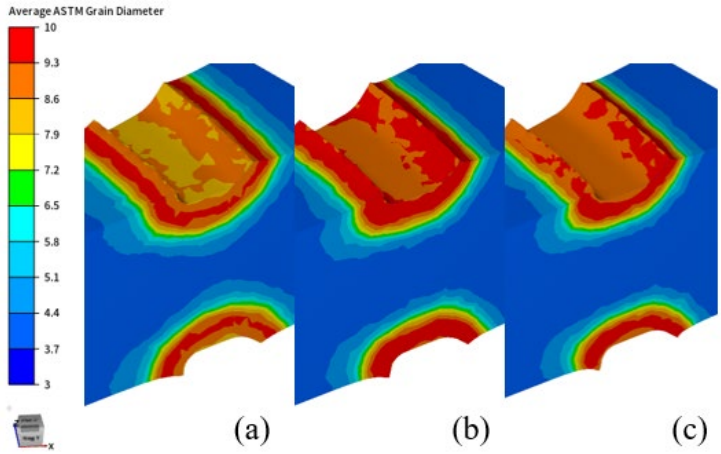

Fig. 8. (a) The lowest spindle rate, (b) medium spindle rate, (c) fastest spindle rate result of average ASTM grain diameter distribution during the process.

Summary

These results demonstrate the significance of the spindle rate as a process parameter in hot incremental disk rolling. The temperature increases dramatically at high spindle rates due to inelastic heat generation. The stability of the JMAK equations depends on the temperature. At the slowest spindle rate, temperature change is negligible. When the spindle rate increases, elongation in the circumferential direction becomes considerable. Effects of equivalent strain and temperature cannot be observed in the first circumferential pass for dynamic recrystallization. On the other hand, the area of meta-dynamic recrystallization is influenced by the spindle rate. The time between subsequent passes decreases when the spindle rate is increased. Therefore, the meta-dynamic recrystallization fraction decreases as the spindle rate increases. Forming with a lower spindle rate leads to a higher variation of ASTM grain size through the thickness. There was no linear dependence found between average ASTM grain size and spindle rate. The optimum spindle

rate is between the lowest and the medium spindle rate. The limiting factors of spindle rate range are temperature change which is important for JMAK equation stability and meta-dynamic recrystallization fraction which changes the variation ASTM grain size through the thickness.

Keywords: Hammer Forging, Hot Forging, Ti-6Al-4V, Thermomechanical Testing, Intermediate Rate Testing, Adiabatic Heating, Microstructure, Mechanical Properties

Abstract. Ti-6Al-4V is a widely employed material in the aerospace, power generation and bioengineering industries due to its low density, excellent corrosion resistance and outstanding mechanical properties. Hammer forging is one of the most utilized manufacturing processes to produce high-performance titanium components and it is known that the process parameters highly affect the microstructure, and thus, the mechanical properties of the manufactured parts. Ti-6Al-4V alloy has a temperature dependent dual structure and forging below or above the β-transus transition temperature (≈980ºC) highly influences the resultant microstructure. Due to the significant adiabatic heating in high-speed hammer forging processes the β-transus temperature can be exceeded during the process. Therefore, it is of vital importance to study the phase transformation limits and the resultant effects on the mechanical properties to establish the optimum processing window for the hammer forging of Ti-6Al-4V. In this work, the Direct-Impact Drop Hammer (DIDH), a purpose-built laboratory hammer with a maximum blow speed of 5 m/s is employed to perform intermediate strain rate (≈200 s^{-1}) uniaxial compression tests of Ti-6Al-4V at 900ºC, 940ºC, 980ºC, 1000ºC and 1020ºC. The flow behaviour of this titanium alloy is experimentally characterized under a wide range of hammer forging conditions, and the microstructure of the tested samples is analysed to study the influence of the adiabatic heating on the phase transformation of Ti-6Al-4V.

Introduction

Ti-6Al-4V has become one of the most employed titanium alloys in the aerospace and the biomedical sectors due to its outstanding mechanical properties and relatively low density. The high cost of this alloy is justified in demanding applications as it offers superior performance and good corrosion resistance even under extreme environments [1]. Ti-6Al-4V is a dual α-β structure titanium alloy, and a variety of resulting microstructures can be obtained depending on the processing route and posterior heat treatment employed to obtain the components [2,3]. The final microstructure highly influences the mechanical properties of the manufactured part; therefore, it is of vital importance to analyse the influence of temperature on the phase transformation of this titanium alloy to correctly define the process parameters

Hammer forging is one of the most employed manufacturing processes for Ti-6Al-4V components, as it is versatile and very cost-effective for large series production [4]. The forging temperature range for this titanium allow is however, narrow, and in general two forging strategies are differentiated in function of the processing temperature [1]. On the one hand,

α-β forging, when forging is carried out below the β-transus temperature (≈980ºC); and on the other hand, β forging, if the forging temperature is above β-transus [5]. Due to the high adiabatic heating found in hammer forging attributed to the high strain rates reached in the process (≈200 s^{-1}), the temperature in some zones of the forged component can exceed the β-transus critical temperature [6]. This can result in undesired resulting microstructures, and hence, poor mechanical properties in the manufactured part.

Therefore, the narrow processing temperature range of Ti-6Al-4V and the complexity of hammer forging itself, makes essential the use of finite element (FE) numerical simulations to explore diverse forging strategies and determine optimised process parameters [4]. It is well-known however that the correctness of the simulation results is directly linked to the accuracy of input parameters and boundary conditions. The correct definition of the material behaviour under the process conditions is one of the most important input parameters, and experimental testing is generally needed for that purpose. Experimental data is employed to calibrate the material models that numerically represent critical aspects, such as the flow behaviour and the microstructural evolution of the material in function of the processing strategy.

Experimental material characterization at the intermediate strain rate range found typically in hammer forging processes (10^2-10^3 s^{-1}) is however challenging, and consequently, the flow behavior and phase transformation of Ti-6Al-4V under these conditions is rarely reported in the literature. The use of universal testing machines equipped with conventional load cells becomes extremely challenging for testing at this strain rate range since they often have a limited stroke velocity. If such velocity is not an issue, then inertia effects and wave propagation become more relevant making the load measurements more troublesome [7]. The most used equipment for dynamic testing is the well-known Split Hopkinson Pressure Bar (SHPB) system, but it also has certain limitations when it comes to testing at these strain rates [7]. As an alternative to the SHPB systems for intermediate strain rate testing, we developed an in-house designed and constructed laboratory facility: the Direct-Impact Drop Hammer (DIDH). In this work, this purpose built machine was employed for the experimental characterisation of Ti-6Al-4V under hammer forging conditions.

The Direct-Impact Drop Hammer (DIDH)

Considering the difficulties to perform intermediate strain rate tests employing universal hydraulic commercial testing devices and SHPB systems, an automatized in-house Automatic ThermoMechanical Tester (ATMT) was designed and constructed. This testing machine is capable of reproducing a wide range of hot and cold industrial metal forming conditions, from low strain rates (<1 s^{-1}) up to intermediate strain rates (>100 s^{-1}). This novel apparatus (Fig. 1a) was designed to be able to test diverse forming strategies, including intermediate heating cycles combined with different loading rate scenarios. The ATMT is composed of four main sections: a heating furnace (max. 1350ºC), an isothermal hydraulic press for low strain rate tests (<1 s^{-1} and max. 1350ºC), a cooling system, and the main novelty, the Direct-Impact Drop Hammer for intermediate strain rate testing. To reduce human errors as much as possible and increase the repeatability of the tests, the apparatus is fully automatized and the sample manipulation is carried out by an electro-pneumatic arm that is integrated in the machine.

Focusing on the DIDH, its mechanical module is comprised of a 92 kg hammer that is pushed by a high-pressure pneumatic cylinder propelling it towards the anvil, the fixed part of the system. The hammer can be set-up at different heights, which allows for impact velocities to range from 2.5 to 5 m/s and a maximum applicable deformation energy of 1.15 kJ. Regarding data acquisition, the anvil is instrumented with a piezoelectric force sensor allowing for direct force measurements. The kinematics of the tests are recorded with a high-speed camera (Fig. 1b) and post-processed by Digital Image Correlation (DIC). The suitability of the DIDH for the mechanical characterisation within this strain rate regime was successfully demonstrated [8]. Interestingly, this device

incorporates an optimized cooling system which is capable of quenching the tested sample in less than 1 s after the high-speed test takes place. This is of particular interest for the microstructural evolution characterisation of materials combining both high temperatures and intermediate strain rate tests.

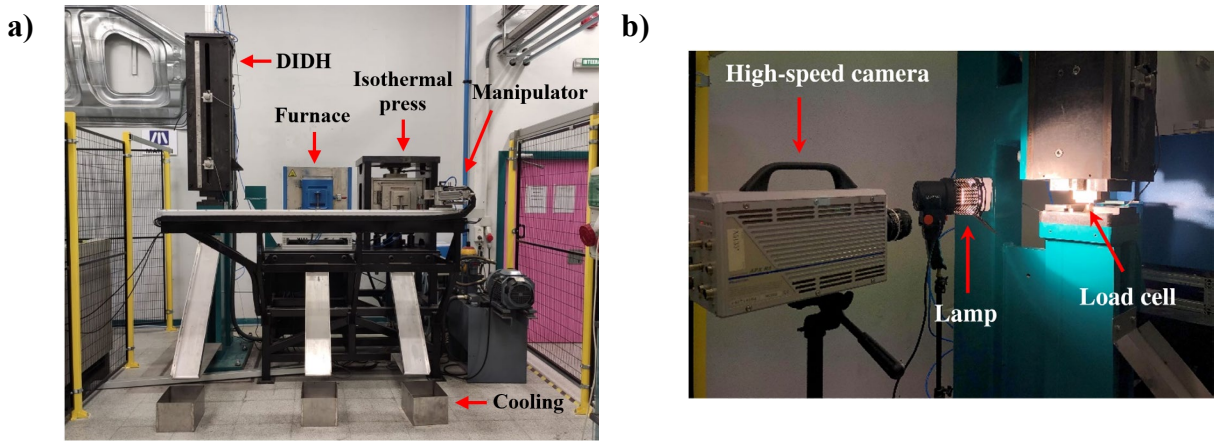

Fig. 1. a) The Automatic ThermoMechanical Tester (ATMT) and b) the data acquisition setup in the DIDH.

Experimental Procedure

In this work, the new DIDH was employed to characterise the flow behaviour of Ti-6Al-4V alloy under hammer forging conditions. Uniaxial compression tests were performed at 900 ºC, 940ºC, 980ºC, 1000ºC and 1020ºC using Ø16x24 mm cylindrical samples and they were air cooled after the compression. A deformation speed of 5 m/s was employed in all the cases, which means that a deformation energy of 1.15 kJ was applied to the samples. These were painted with the CONDAERO 313 glass coating to protect the surface from oxidation and reduce the friction between the sample and the tools.

To monitor the hammer kinematics, a Photron Fastcam-APX RS250K high-speed camera with appropriate illumination lamps was utilised. It was set up to record at 15,000 fps with a resolution of 256 x 512 px^2. The specimen length history $l[t]$ was obtained by DIC analysis from the displacement history of the hammer, which was calculated by post-processing the high speed camera images with the GOM Correlate software [9]. To obtain the force histories $F[t]$, a Kistler 9106A piezoelectric force sensor mounted directly on the anvil was employed in combination with a Tektronix TSD 2004B oscilloscope with an acquisition frequency of 300 kHz. As the displacement of the DIDH tests was recorded with a lower acquisition frequency, the displacement histories were linearly interpolated for the load cell time base.

The axial true stress (σ), true strain (ε) and true strain rate ($\dot{\varepsilon}$) were calculated by $\sigma = F[t]/A[t]$, $\varepsilon = \ln(h[t]/h_0)$, and $\dot{\varepsilon} = v[t]/h[t]$, respectively, where $F[t]$ is the force measured by the piezoelectric $\dot{\varepsilon}$rce sensor, h_0 is the initial sample height, $h[t]$ and $A[t]$ are the instantaneous height and cross-section area of the sample, respectively, and $v[t]$ is the instantaneous tool velocity, assuming [0] = 0 s^{-1}.

Results and Discussion

The same blow speed (5 m/s), and hence, the same deformation energy (1.15 kJ) was employed in all the tests, therefore, as the strength of the Ti-6Al-4V decreases with increasing the forming temperature, higher deformations were obtained at higher temperatures (
Fig. **2**). Final true strains of 0.63, 0.77, 1.01, 1.12 and 1.15 were reached in the tests performed at 900ºC, 940ºC 980ºC, 1000ºC and 1020ºC, respectively. Three repetitions were performed per condition showing very little deviation between them, with a mean stress deviation of 1.29 % in the worst case. This is mainly because the tests are performed automatically in the DIDH.

Fig. 2. Initial sample and samples tested in the DIDH at 900ºC, 940ºC, 980ºC, 1000ºC and 1020ºC (from left to right).

A friction factor (*m*) of 0.3 was estimated by inverse simulation taking into account the barrelling of the tested samples (Fig. 2). FORGE® simulation software was employed for that purpose. The estimated friction factor is in accordance with the friction reported by Zhu et al. [10] for Ti-6Al-4V alloy forgings using glass lubricant.

Force-displacement curves of the intermediate strain rate tests performed in the DIDH at 900ºC, 940 ºC, 980ºC, 1000ºC and 1020ºC are presented in Fig. 3. The high-speed blow of the DIDH lead to some oscillations in the force readings particularly at the beginning of the curves. However, these fade out to certain extent as tests progress leaving the piezoelectric load cell noise as the only source of the oscillations, and the material behavior is clearly identified.

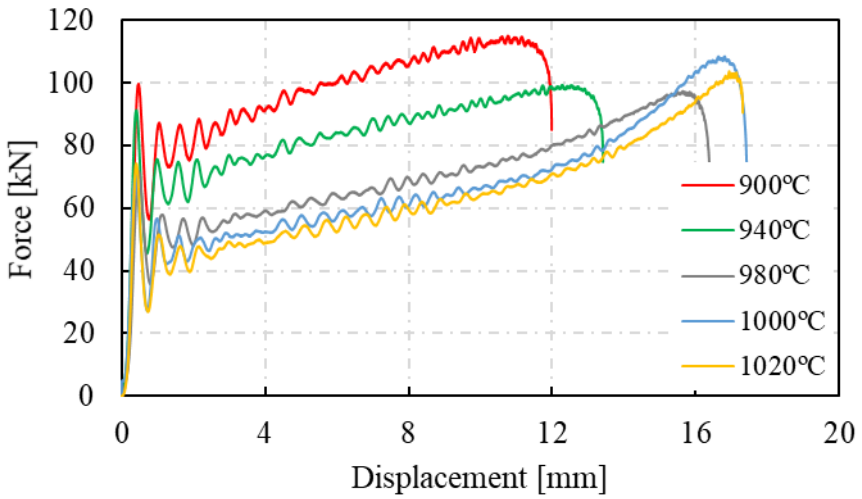

Fig. 3. Force-displacement curves of tests performed in the DIDH with a blow speed of 5 m/s at 900ºC, 940ºC, 980ºC, 1000ºC and 1020ºC.

The true stress-strain curves are shown in Fig. 4. A clear and coherent temperature dependency is observed in the results, with lower forces at higher temperatures. The softening observed in the curves can be attributed to the considerable adiabatic heating and low heat dissipation times found at these strain rates. No analytical adiabatic heating correction was applied to the flow curves

presented in Fig. 4. The true strain rate evolution is also presented in Fig. 5, in which the intermediate strain rates reached in the tests demonstrate that the DIDH is capable of testing at strain rates comparable to those found in industrial hammer forging operations. This results are of significant industrial and scientific relevance as few laboratory thermomechanical testers allow testing at both intermediate strain rates and high temperatures. Therefore, the study of the flow behavior of Ti-6Al-4V under hammer forging conditions is hardly reported in the literature.

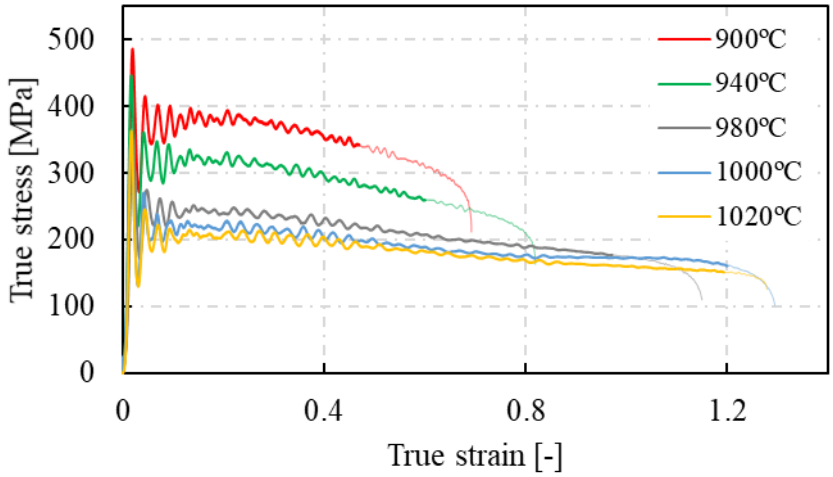

Fig. 4. True stress-true strain curves of Ti-6Al-4V tested in the DIDH at intermediate strain rates (≈200 s^{-1}).

A non-constant strain rate evolution is observed in Fig. 5, which occurs due to the nature of the DIDH tests. The hammer velocity starts decreasing once it gets into contact with the sample until it completely stops. Anyhow, due to the optimised sample dimension a relatively constant strain rate evolution is attained up to high strain levels, especially at higher temperatures. As a reference, thicker solid line are depicted in Fig. 4 and Fig. 5 until the strain rate dropped below 80 % of the initial strain rate value.

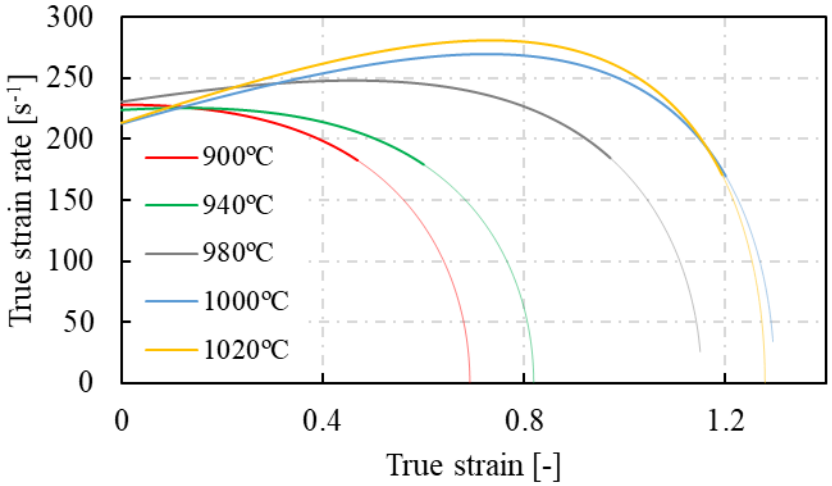

Fig. 5. True strain rate evolution of the DIDH tests at intermediate strain rates.

The effect of this strain rate drop in the flow curves is irrelevant, as the initial and the final strain rates are in the same order of magnitude. Mean strain rates attained up to this point for the

tests at 900ºC, 940ºC, 980ºC, 1000ºC and 1020ºC are 215 s^{-1}, 215 s^{-1}, 235 s^{-1}, 245 s^{-1} and 250 s^{-1}, respectively. At higher strain levels beyond the 80 % strain rate drop, the strain rate decreases considerably and the rate effect becomes more significant in the flow curves, with a sharp drop at the end of the curves (Fig. 5).

The strain rate dependency of Ti-6Al-4V is clearly observed in the comparison between the low strain rate (<10 s^{-1}) flow curves at 900ºC presented by Porntadawit et al. [11] and the intermediate strain rate (215 s^{-1}) flow curve obtained from the test in the DIDH at the same temperature (Fig. 6). A classical strain rate dependency is shown, with higher flow stresses at higher strain rates.

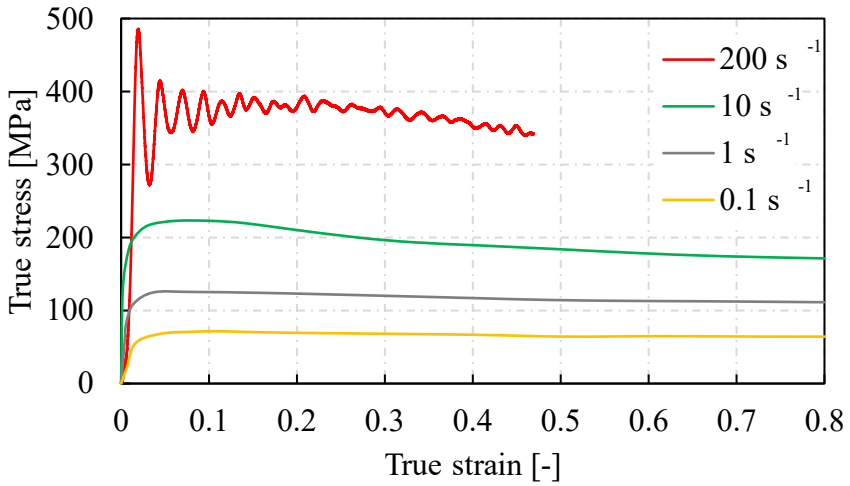

Fig. 6. Comparison between low strain rate (0.1 s^{-1}, 1 s^{-1} and 10 s^{-1}) flow curves of Ti-6Al-4V at 900 ºC extracted from [11] and the intermediate strain rate flow curve obtained from the DIDH test at the same temperature.

Once the tests were performed, the tested samples were cut from the cross-section to analyse the resulting microstructure (Fig. 7). Samples were prepared for microstructural analysis by conventional sanding and polishing procedures and they were etched with Kroll's reagent.

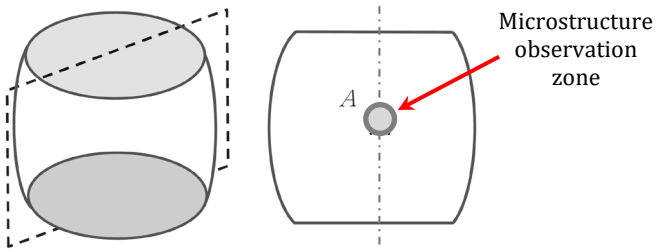

Fig. 7. Cutting plane of the tested samples to analyse the resulting microstructure.

Fig. 8 shows the micrographs of the samples tested in the DIDH at intermediate strain rates (≈200 s^{-1}) at temperatures of 900ºC, 940ºC, 980ºC, 1000ºC and 1020ºC. A clear bimodal microstructure composed of equiaxed α phase and lamellar α-β is found at the tests performed at 900ºC and 940ºC, with lower equiaxed α fractions with higher temperatures. Samples tested at 980ºC and 1000ºC, close to the β-transus transition temperature, show even lower equiaxed α fractions, and the sample tested at 1020ºC show a clear β microstructure.

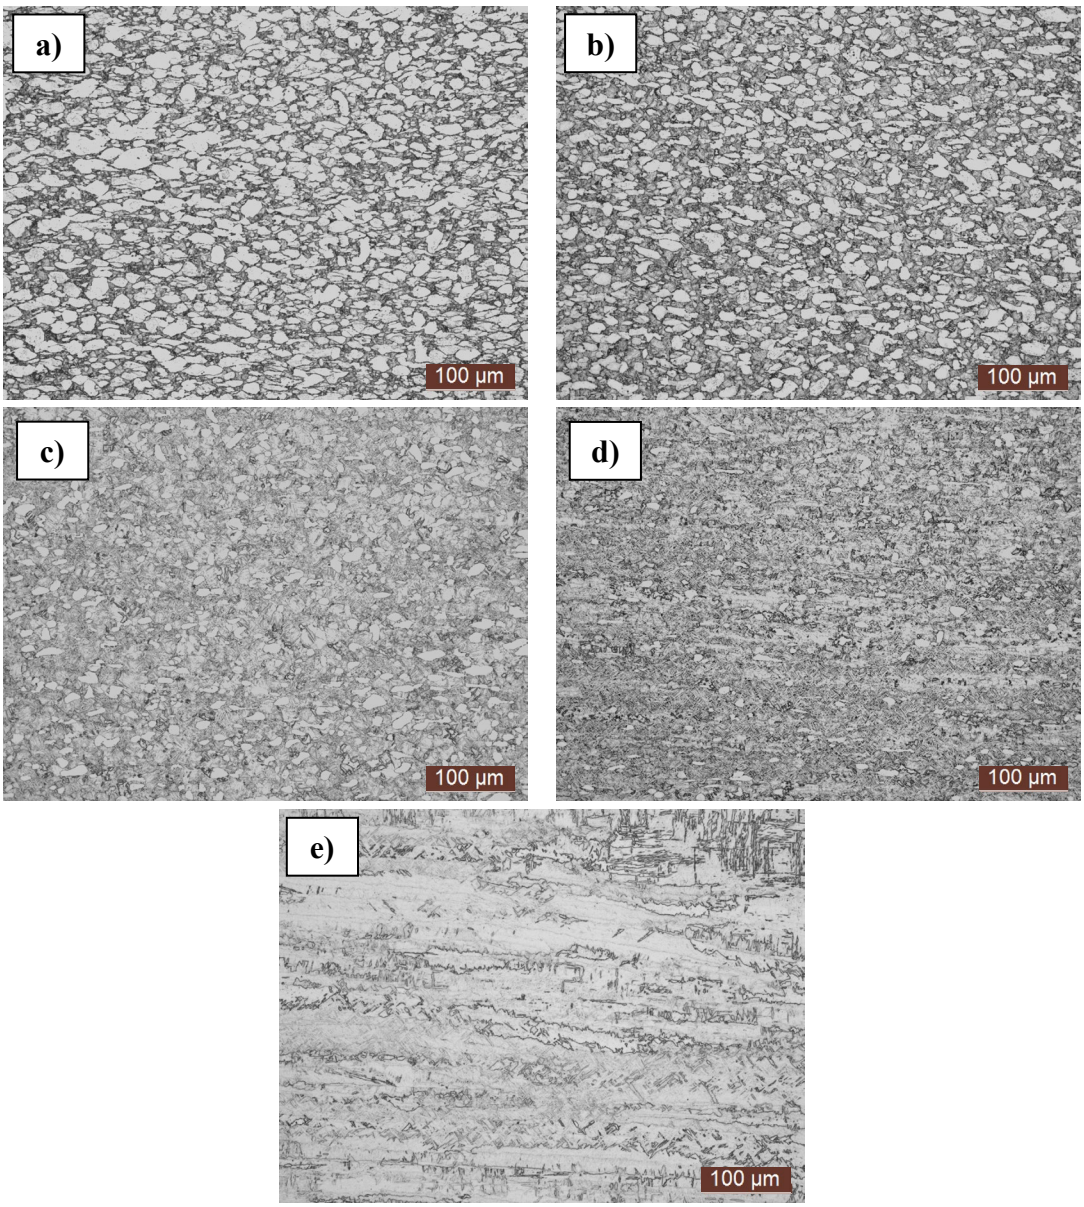

Fig. 8. Micrographs of the samples tested in the DIDH at intermediate strain rates at a) 900ºC, b) 940ºC, c) 980ºC, d) 1000ºC and e) 1020ºC.

Summary

The following conclusions were extracted from the present work:

- The purpose-built laboratory hammer, the Direct-Impact Drop Hammer (DIDH), is a suitable thermomechanical tester for testing under both intermediate strain rates and high temperatures. As the tests are performed automatically, the results show a great repeatability.
- The flow behaviour of Ti-6Al-4V was successfully characterised under a wide variety of hammer forging conditions. A clear temperature dependency was observed in the tests perform from 900ºC to 980ºC. This dependency decreased significantly in the tests performed from 980ºC to 1020ºC, close and beyond the β-transus transition temperature.
- A clear bimodal microstructure was found in the tests performed below the β-transus temperature, at 900ºC and 940ºC, with a lower equiaxed α phase fraction at higher temperatures. Even lower α fractions were observed at the tests performed at 980ºC and

1000ºC, close to the β-transus temperature, and only β-phase microstructure was observed in the tests performed at 1020ºC.

Abstract. This paper analyses the potential of standard mean-field models available in commercial FE software Deform®, Forge® and QForm® for a microstructural prediction during multistage forging process of Inconel 718 at conditions close to industrial ones. The special set of experimental trials including heating, forging, reheating and final forging were conducted on 5 MN hydraulic press with detailed measurements of temperature distributions, timings and forging parameters. The microstructure distribution was investigated after each stage of the process (optical and EBSD) and compared with the predictions obtained in three softwares. Standard and optional capabilities as well as limitations and challenges of the models were investigated, and some improvement ideas were proposed.

Introduction

Microstructural modelling, as well as appropriate calibration and application of available mean-field microstructure evolution models for industrial hot forging processes, remains a bottleneck [1,2]. It is getting even more complex when these models are applied for the real-life technological processes where material goes through number of forging and reheating stages. The goal of such complicated route is to get a final part with a required microstructure. Due to a large number of technological parameters involved in this process, troubleshooting and optimisation of the manufacturing route requires the capability of microstructure evolution models to predict final microstructure with some acceptable accuracy.

All the most popular commercial FE metal forming softwares, like Deform®, Forge® and QForm® have some in-built capabilities for microstructural modelling. The study presented in this paper carried out using Inconel 718 alloy. For this and similar to it nickel-based superalloys dominating mechanisms during hot forging, which are intended to be simulated, are Dynamic (DRX), Meta-Dynamic (MDRX) and Static (SRX) recrystallisation along with the static Grain Growth (GG). There also few other microstructural mechanisms which are not directly modelled in available in-built models, but which should however be kept in mind as they can affect the results: Recovery (RC), Twinning (TW) and Continues Recrystallisation (CRX). The question of their consideration will be briefly touched in the Results and Discussion section.

The microstructural models in-built into the three above mentioned metal forming softwares for DRX, MDRX, SRX and GG have quite similar mathematical structure (with minor variations in shape and coding realisation) and individual material library of default parameters. Three recrystallisation models belong to the so-called JMAK-type class of the models [3] and the grain-growth model is described with the classical model of P.A. Beck [4].

The limitations of the JMAK-type models are well known and analysed in many papers [1, 5-7]. They are not well fitted for the processes with the sharp changes in temperatures and strain rates. The set of material parameters is normally suitable for a fixed range of temperatures and

strain rates which they are optimised for, etc. However, these models are the simplest, intuitively "physically" clear and available as in-built models in the commercial FE softwares.

The main goal of this benchmarking study was to work out some practical conclusions regarding application of standard models. The set of tests consisting of heating, forging, reheating and second blow forging was specially designed for this purpose. Accurate direct measurements of all possible process parameters was done for the fine tuning of FE models providing robust prediction of the thermo-mechanical histories of all points of the performs. All the data gathered was further used as input for the microstructural modelling. Separate analysis of microstructure at every stage provided an ability to decouple the models of recrystallisation and give additional information on the reason of the "wrong" behavior of the models.

The special attention was addressed to investigation of the areas of the forged billets where microstructure prediction was not accurate. The reasons of inaccurate prediction were analysed to suggest possible improvements of the models.

Methodology

Forging trials.

Two-blows forging route with reheating between the blows was employed to obtain experimental data for benchmarking microstructure evolution models (see Fig. 1). The standard double truncated cone (DTC) geometry with 50.8 mm initial height was used for the forging. The billets were machined from IN718 material with standard chemical composition. Forging trials of IN718 DTC geometry were carried out at the sub-solvus temperature of 990°C on 5 MN hydraulic press. The dies of the press were heated up to 600°C. The billets were reheated in the furnace back to 990°C between the blows. Taking into account non-isothermal conditions of the forging, relatively bulky billets, as well as multi-stage forging route, these trials mimic a real industrial forging conditions for this alloy. To track the microstructure evolution at the various stages of the forging route, three DTC-s were forged using following routes:

- DTC#1: 1st blow air cooling (AC)
- DTC#2: 1st blow reheating in furnace back to 990°C AC
- DTC#3: 1st blow reheating 2nd blow AC (full route)

A number of real-time process parameters was recorded during the forging trials. Such press readings as velocity of top ram, force and displacement were recorded as a function of a time. Along with that, temperature in 3 reference points was measured for each processed billet during all the forging route including initial heating and final air cooling. For this purpose 3 thermocouples were embedded into the each proceed billet: one thermocouple for the centre of the billet and two thermocouples were embedded on the 5mm distance from the top and bottom surface of the billet in the same way as it was shown in [2, 8]. The example of obtained thermocouples readings is shown in Fig. 2. The trial of each billet was video-recorded to define the exact time of each operation of the processing route. The shape of final geometry of forged parts was analysed using a 3D blue light-based metrology scanning system (by GOM ATOS TripleScan III).

Digital twin of the experiment. Digital twins of thermo-mechanical processing were created for each processed billet. By the term "digital twin" here is implied validated FE simulations which reproduce particular forging conditions, heating and cooling profiles, timings of operations, as well as peculiarities of metal flow for each forged billet. The FE models were created using several commercially available FE packages: DEFORM, QFORM and FORGE. Each of these software developers has its own mean-field microstructure evolution model for IN718 material, which was benchmarked in this work.

This phase of study is critically important because microstructure evolution models employ macroscopic process parameters, namely strain, temperature and strain rate obtained from FE

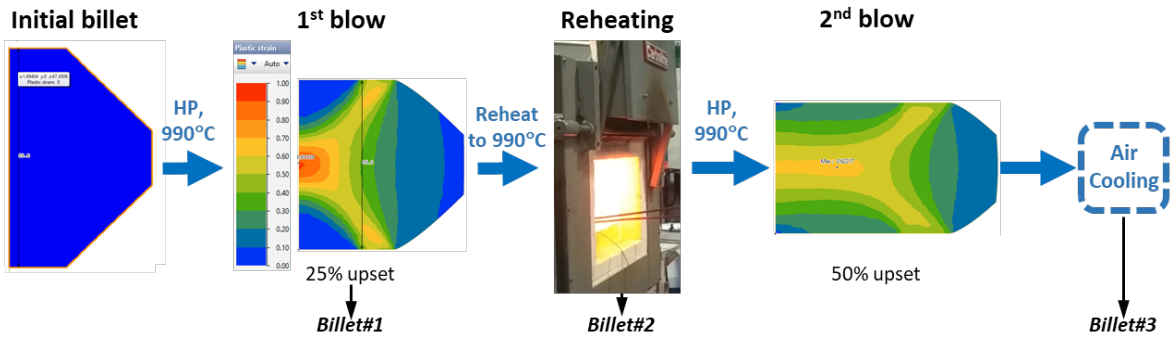

Fig. 1. Forging route used for two-blow forging trials of IN718 on hydraulic press.

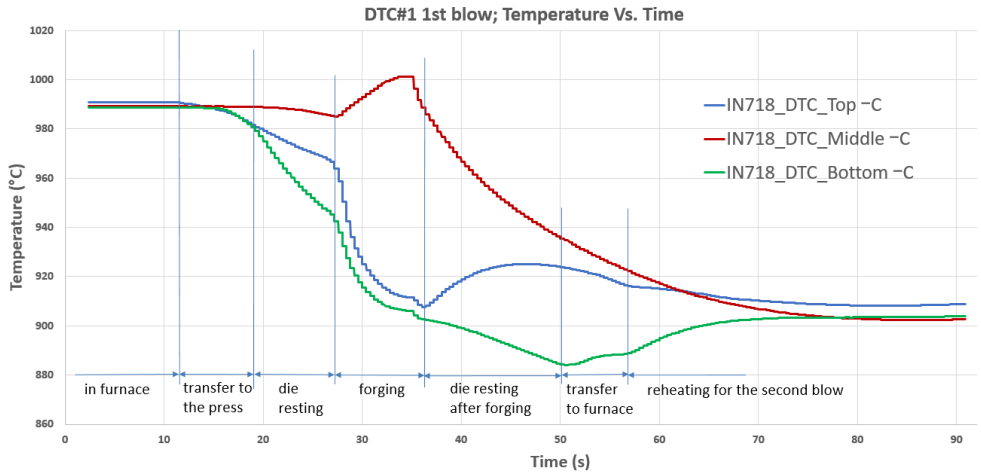

Fig. 2. Thermocouples readings for the DTC#2 (just the 1st blow and transfer back to furnace).

simulations. The settings in the FE models were adjusted in a way to reflect actual forging conditions. The calibration procedure consisted of following steps:

- Defining exact time of each operation using video-recordings and thermocouples' readings. The full list of simulated operations was: pre-heating, transfer to furnace, die resting before the 1st blow, 1st blow forging, die resting after the 1st blow, transfer back to the furnace, re-heating, transfer for the 2nd blow, die resting, 2nd blow forging, die resting, transfer for air cooling, air cooling.
- Adjusting heat-exchange coefficients in simulations in a way to repeat experimentally obtained profiles of temperature in reference points.
- Friction conditions were validated by superimposing images from GOM scan and those obtained in the simulations.
- Validating metal flow in the simulations using available experimental data. The final shapes and positions of the holes drilled for the thermocouples were used to validate the metal flow and strain values locally in the vicinity of the billets' dead-zones and central locations. Also force readings from the press were used to check the force prediction in simulations.

More detailed description of the procedure of creating digital twins is shown in earlier studies [2, 8].

The main calibration criteria for the simulations were temperature and strain fields, which have had to be similar to those obtained in the experiment and to be equal between FE simulations created in various FE packages. Fig. 3 demonstrates the comparison between the temperature fields and strain fields in all utilised FE packages for the billet after the first blow (Fig. 3*a*) and the second blow (Fig. 3*b*).

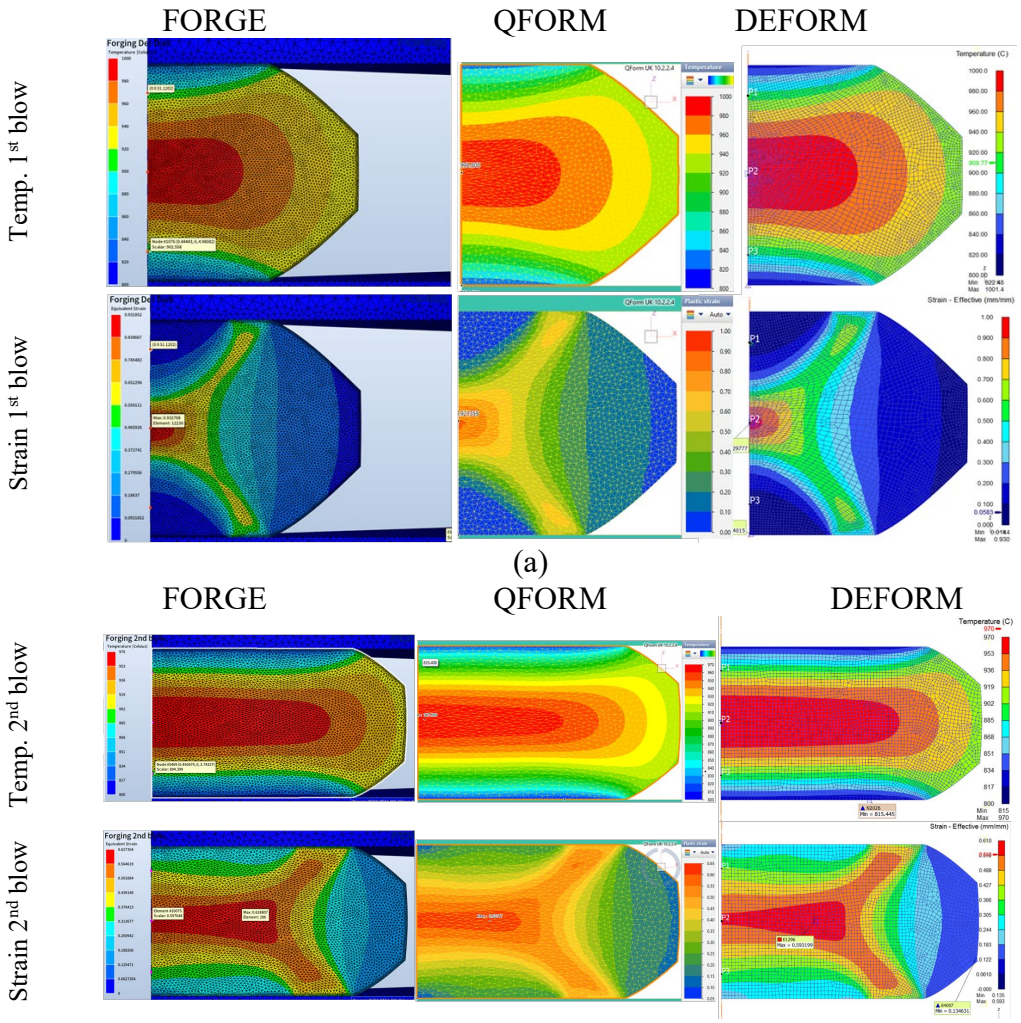

Fig. 3. Comparison between the temperature fields and strain fields in all utilised FE packages: (a) temperature and strain fields straight after the first blow; (b) temperature and strain fields straight after the second blow.

Methodology of microstructure study.

Processed double truncated cones were cut in half and prepared for optic microscopy and EBSD analysis. The boundaries of recristallised area in the billet's cross-sections were defined using optical microscopy with the accuracy 5%. EBSD maps were obtained in reference points of each forged billet, namely central area and area where recrystallisation was initiated.

Benchmarked mean-field microstructure evolution models.

Standard mean-field models available in commercial FEA software Deform®, Forge® and QForm® were used for microstructural prediction during multistage forging process. All the models were used "as is" with the default set of parameters for IN718 available in the material libraries of each software. For the detailed description of the models and values of the model parameters please refer to description of the models [9-11]. The initial grain size of the material was set to 17μm and temperature limit of 950°C was used for the initiation of microstructure evolution in all the models. All the microstructure evolution mechanisms available in the models were set as active: DRX, MDRX, SRX and static GG. It was also assumed that material was fully recovered (no retained strain) after the re-heating operation before the second blow.

Results and Discussion

The outputs of microstructure evolution models for total recrystallized volume fraction are compared with the experimental observations in Table 1 (for the scale from 0% to 100%) and Table 2 (for the scale from 0% to 5%). The scale used in Table 2 allows to compare the boundaries of the recrystallised area more precisely. Note that total RX volume fraction presented in the tables below shown as a summary of contribution from all three various types of recrystallisation: DRX, MDRX and SRX. According to [12, 13] all three mechanisms were in play during the selected processing route.

As it follows from the Table 1 and Table 2, none of the standard JMAK-type models embedded in the commercially available FEA software and used with the default settings have demonstrated accurate predictions. Though the boundaries of recrystallised area for DTC#1 was predicted by FORGE and QFORM models quite well (see the first row of Table 2), the volume fraction of the recrystallised material was predicted wrongly. It is assumed that this type of models should predict microstructure evolution for one single forging operation correctly on the condition that model is calibrated in proper way. Such a big disagreement with the experiment indicates that default settings of the models are not suitable for this case and model should be re-calibrated. In this particular case, large value of total RX vol% predicted by models is caused by overestimated MDRX vol%, while prediction of DRX is much closer to the experimental value of 26%.

Table 1. Comparison of microstructure evolution models outputs for RX vol% versus experiment in scale 0 to 100%.

Route	Total RX volume fraction in scale 0 to 100%			
	Experiment	DEFORM	FORGE	QFORM
DTC#1: 1st blow + AC				DTC#2: 1st blow + reheating + AC				DTC#3: 1st blow + reheating + 2nd blow + AC				
Table 2. Comparison of microstructure evolution models outputs for RX vol% versus experiment in scale 0 to 5%.

Route	Total RX volume fraction in scale 0 to 5% (for indicating onset of RX)			
	Experiment	DEFORM	FORGE	QFORM
DTC#1: 1st blow + AC				DTC#2: 1st blow + reheating + AC				DTC#3: 1st blow + reheating + 2nd blow + AC				
For the more complex processing routes used for DTC#2 and DTC#3 the prediction of the models became worse. For these more complicated cases the problem of transferring material and its properties between in-line manufacturing operations prevails.

It is important to note that all used standard JMAK-type models were de-coupled models. This fact limits their application for multiple-blows simulations as changes in the microstructural state are not connected with the model of the material (i.e. flow stress data) directly. To compensate this essential drawbacks and transfer key material parameters between the operations, the software developers use number of assumptions and patches [5]. However, even in their current de-coupled form these models can be improved significantly to make their prediction more accurate. Several reasons causing wrong predictions, as well as suggestions regarding model improvements are given below.

Temperature limits for activation various microstructure evolution mechanisms.

The value of temperature limit is important as it largely defines (together with accumulated plastic strain) recrystallised area and RX volume fraction. JMAK-type models implemented into FE softwares have single temperature limit for all microstructure evolution mechanisms and do not allow to set various temperature limit for DRX, SRX and MDRX separately. Probably it is not correct approach, because according to the experimental observations grain growth activation requires higher temperature threshold than nucleation process. Ideally temperature limits should

be set separately for each microstructure evolution mechanism as a function of temperature and some internal state variables which characterise microstructure state, e.g. dislocation density, grain size, etc. Also, it could be beneficial do not use "hard cut-off" by temperature with some particular temperature value, but have temperature limit as function of some process parameters instead, e.g. strain and strain rate. It will better fit "physics" of the recrystallisation, as bigger strain and strain rate results in bigger internal energy and, correspondently, requires lower temperature limit for the activation of RX mechanism.

The way of representing multiple rounds of recrystallisation by the model.

As it can be seen from the third row of Table 1 and Table 2, the prediction for the RX vol% after the second blow looking strange. The reason is that in all the benchmarked models the RX vol% during the second blow is overlapped with the RX vol% fields remained after the first blow. There is an assumption in the models that if RX vol% getting close to 100% during the recrystallisation, then all recrystallised fractions are reset back to 0% considering a fully non-recrystallised new microstructure obtained. This solution is inconvenient for representation of multiple rounds of RX, because it is not possible to distinguish between the fully recrystallised material during the previous operations and material which was never recrystallised, for example, dead-zones. It is also hard to distinguish RX during the second blow and compare it with experimentally defined RX-ed area after the second blow. It would be beneficial to reconsider the way of representation of RX vol% in such a way to make the previous rounds of recrystallisation visible to the user.

Transferring non-uniform microstructure to the re-heating operation.

As can be seen from Fig. 4 (a, b, c) DTC#1 has various types of non-uniform microstructure after the first blow. The microstructures differ by grain size, grain shapes and dislocation densities. These three types of microstructure later re-heated in the furnace for the second blow. During the re-heating SRX occurs. It is assumed that SRX will have different kinetics for all these 3 cases. The problem is that SRX models in their current form cannot take into account such peculiarities of microstructure. Current equations for SRX volume fraction and grain size have average grain size parameter in some power (material constant) [3-5], but it cannot be used to describe bimodal microstructure or partially recrystallised microstructure adequately. The possible solution of this problem within current architecture of the SRX model is utilising both average recrystallised and non-recrystallised grain sizes in the SRX model equations. Such modifications of the model was already tested by developers of FORGE FEA software [5].

Transferring accumulated plastic strain and microstructure to the second blow.

This problem is partially overlapped with the previous one as microstructures after the reheating operation can be also quite different, see Fig. (d, e, f), so it is assumed that it should influence kinetics of DRX during the second blow. This part of the problem could be partially sorted out in the similar manner as suggested above.

The second part of the problem is figuring out what ratio of the accumulated plastic strain should go for the second blow after the re-heating operation. Obviously material which was not SRX-ed in full and have remained strain will be DRX-ed in different way and its rheology also will be different. There is a patch to solve this problem in the FE softwares, namely, "retaining strain" which is calculated as inverse ratio to "RX total vol%":

$$\varepsilon_i = (1 - X_{rex})\varepsilon_{i-1} \quad (1)$$

Alternatively "retaining strain" can be calculated as a function of parameters which define recovery, e.g. time and temperature. This way is better as it covers the cases when SRX did not happen, but deformed grains were recovered during the re-heating operation.

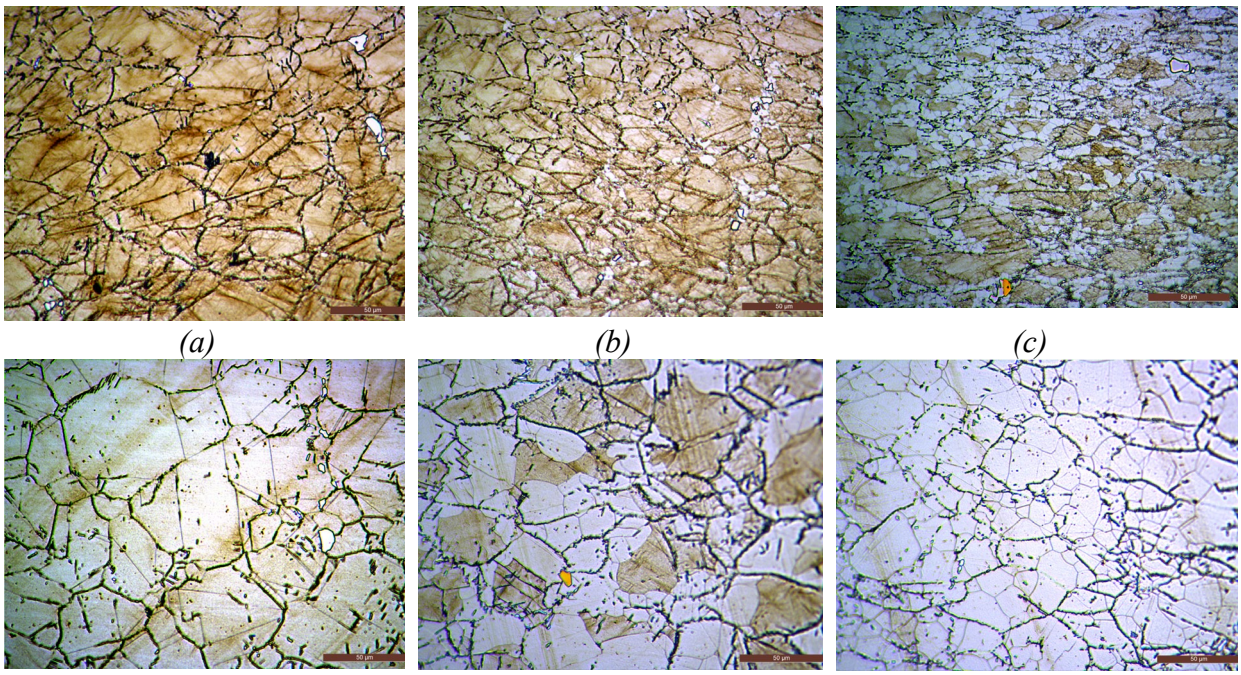

Fig. 4. Optic microscopy images obtained at some reference points of the processed billets: (a) DTC#1: non-recrystallised location with heavily-deformed initial grains; (b) DTC#1: necklace microstructure - location where DRX initiated; (c) DTC#1: heavily DRX-ed location in the centre of the billet; (d) DTC#2: location at the vicinity of bottom dead-zone where SRX was not started; (e) DTC#2: partially SRX-ed location; (f) DTC#2: fully SRX-ed location in the centre of the billet.

However, due to de-coupled nature of the investigated models, Eq. 1 influences only the critical strain needed for the following round of RX, but it is not coupled with the model of the material, i.e. flow stress data, so the metal flow on the second blow does not take into account changes in microstructure. The only solution here is employing coupled model where some microstructure parameters are coupled with the material model and flow stress data is recalculated on each step of simulation taking into account microstructure changes. To this end microstructure evolution model should be re-written in incremental form.

Taking into account contribution of other mechanisms of microstructure evolution.

Apart from DRX, MDRX, SRX and static GG described in the investigated models, there are also some microstructure evolution mechanisms which were not taken into account. Among them are recovery (RC), twinning (TW) and continues dynamic recrystallisation (CDRX). All listed mechanisms were also in play during the thermo-mechanical processing used for this study and they influenced average grain size of non-recrystallised grains as well as level of internal energy locked in the material. These mechanisms cannot be taken into account within the decoupled approach and can be described only by coupled models.

To sum up, there are number of ways for improving standard JMAK-type models in their current de-coupled state without changing their mathematical formulation. In brief, the proposed improvements include: setting temperature limits for each microstructure evolution mechanism; calculating retained strain (strain transferred to the next blow); better way of representing multiple rounds of RX; taking into account both average recrystallised and non-recrystallised grain sizes.

Each FEA package tested in this study has strong points in its own mean-field model which are useful for microstructure prediction during multi-pass forging processes. For instance, DEFORM Avrami model has inbuilt capability to use multiple sets of model parameters for various

temperatures and strain rates, which potentially allows to cover wide range of process parameters; it also uses retaining strain concept which allows to some extent compensate drawbacks of the de-coupled model. FORGE JMAK-model has possibility to use tabulated parameters, also software developers suggested the way of modelling heterogeneous microstructures during multi-pass processes [5]. QFORM JMAK-model also has inbuilt equation for calculating retaining strain and option for cyclic recrystallisation inbuilt in GUI, also due to convenient Lua programming the model can be easily modified by user. All these features listed above give user good possibilities to adjust the model in each software for the particular multi-stage forging processes.

Mean-field models in itself operate with some representative volume of the material and averaged characteristics of the process. This approach can work well if the representative volume is uniform. However, the problems arise when material is non-uniform, for instance in the case of partially recrystallised microstructure, or in the case when there are grains with big difference in properties in the same representative volume. Although it is challenging, these more complicated cases could also be described by mean-field approach providing that some new alternative equivalent parameters introduced into the model for representing current state of the microstructure.

Full-field modelling at the meso-scale level, e.g. by using DIGIMU (Transvalor) software, could be useful tool for getting better understanding of microstructure evolution in the cases when prediction of mean-filed models is not accurate, e.g. microstructures with non-uniform distribution of grains by size; or with non-uniform distribution of dislocation density (stored energy) among the grains. It can help to find out what new equivalent parameters could be introduced into the mean-field models to get robust prediction for these cases. Such alternative equivalent parameters potentially could be equivalent dislocation density, equivalent work of plastic deformation, equivalent grain sizes, aspect ratio of grains, etc.

Summary

1) All JMAK-type models considered in the paper have a big potential for predicting microstructure evolution during multiple-blow forging process. The peculiarities of this processes should be taken into account and models should be adjusted to it correspondingly. Developers of FEA packages improving their models continuously and microstructure evolution models embedded into DEFORME, FORGE and QFORM in their current state have plenty of opportunities for the adjustments and improving their predictions.
2) For the cases of bimodal microstructure or necklace microstructure where average grain size cannot represent the microstructure correctly, outputs of the model should be considered critically. For instance, to estimate the scatter in the results, upper and lower-bound methods can be used with two various average grain sizes.
3) Mean-field models should be calibrated for the particular (narrow) range of process parameters (strain rate and temperature range) as they cannot predict microstructure evolution within the wide range of process parameters correctly. In addition to this, model of the material, i.e. flow stress data, should be calibrated for the particular range of process parameters as well.
4) Coupled mean-field models are required for predicting microstructure evolution during multistage thermo-mechanical processing in more accurate way. It is implied that such type of models should have in the model of the material some parameter which characterises current state of the microstructure, for instance, dislocation density or work of plastic deformation. Full-field modelling using DIGIMU Transvalor software can be effective tool for getting better understanding of active microstructure evolution mechanisms in play and identification of parameters for coupled mean-field models.

Keywords: Air Bending, Steel, Digital Image Correlation, Strain Distribution, Total Strain, Bend Shape

Abstract. Air bending is a commonly used method for sheet-metal forming. However, several challenges exist around the bending behavior of materials with poor global formability, that are difficult to study using conventional bending test methods, and thus may not be fully understood. In this study, nine thermomechanically rolled steel grades with various strengths and ductility properties are bent using three different punch radii. The strain distributions on the outer surface are measured using Digital Image Correlation (DIC). The relationships between the strain distribution, peak strain, and total strain (area under the strain distribution curve) are determined. The total strain is observed to be independent from the peak strain and the shape of the strain distribution. The total strain is found to depend on the bend angle and sheet thickness. An analytical formula for approximating the total strain is derived. Potential for further approximations of the total strain, strain distribution and bend shape are discussed.

Introduction

Air bending is a commonly used forming method for sheet metals due to its flexibility, cost-effectiveness, and speed. A large range of bend angles can be achieved without tool changes just by controlling the punch displacement. The radius of the bent sheet is usually controlled by changing the punch radius. However, the shape of the bend is also dependent on the material properties. The distribution of strain and curvature on the outside bend surface can vary significantly depending on the work-hardening properties of the material. When bending materials with poor global formability (i.e., low work-hardening and uniform elongation), the inside radius of the bent sheet may decrease far below the punch radius, leading to high local strains and bend shapes that may be difficult to predict [1]. Various terms have been used referring to this phenomenon in previous studies: multi-breakage, gap formation, punch-sheet separation, punch detachment, punch-sheet-liftoff, loss of contact with the punch/sheet etc. [2-8]. The phenomenon has been known for a long time. However, research on the root of the phenomenon, i.e., the causes and effects of the strain distribution development in air bending, has been relatively scarce. Strain distributions in air bending have been studied by several authors [1,9-14], but not for a large selection of materials and punch radii, that would allow thorough analysis of the effects of certain tool parameters and material properties. Research in this area is therefore necessary.

In this paper, nine steel grades are bent in a 3-point bending setup using three different punch radii. The development of the strain distribution on the outer curvature is measured from each test using a Lavision Digital Image Correlation (DIC) system. The aim of the paper is to study the relationships between the strain distributions, peak strains, and total strains (area under the strain distribution curve).

Experimental Procedure

Nine thermomechanically rolled steel grades are tested in this study. Table 1 provides the sheet thicknesses, tensile properties of the investigated materials, along with the typical minimum bend radii for corresponding grades, provided by a steel manufacturer. The tensile data was measured from ISO 6892 compliant tests, using dog-bone specimens with straight sections of 6 × 8 × 45 mm^3, and strain rates of 0.0025 1/s (to yield point) and 0.008 1/s (after yield point). Both longitudinal and transverse directions were tested, relative to the material's rolling direction. In terms of the direction of the major strains relative to the rolling direction, the longitudinal (0°) tensile test corresponds to the transverse (TD) bend test and the transverse (90°) tensile test corresponds to the longitudinal (RD) bend test.

Table 1. Sheet thicknesses (t) and mechanical properties of the tested materials. The yield strength (R_e), ultimate tensile strength (R_m), uniform elongation (A_g) and total elongation with 40 mm gage length (A_{40}) were measured from the performed tensile tests. The minimum bend radii to 90° bend angle (R_{min}) were provided by a steel manufacturer for corresponding grades.

Material	t [mm]	R_e [MPa]	R_m [MPa]	A_g [%]	A_{40} [%]	R_{min} (to 90°)
St355 (0°/90°)	5.94	438/480	496/502	16.4/15.4	32.7/31.2	0.3 t
St500 (0°/90°)	5.92	585/628	653/669	11.7/10.4	26.9/25.4	0.8 t
St700 (0°/90°)	6.04	785/818	864/907	6.0/4.5	18.2/15.2	1 t
St900_1 (0°/90°)	5.99	974/1024	1042/1142	3.2/2.2	13.4/8.2	3 t
St900_2 (0°/90°)	5.93	1034/1067	1130/1151	3.9/3.1	13.9/11.4	3.5 t
St1100_1 (0°/90°)	6.01	1132/1127	1161/1172	4.7/4.7	15.4/13.8	3.5 t
St1100_2 (0°/90°)	5.93	1098/1111	1253/1271	2.9/2.4	12.1/10.8	3 t / 4 t
St1500 (0°/90°)	5.68	1537/1500	1761/1780	3.4/3.1	10.6/9.4	6 t
St1700 (0°/90°)	6.09	1740/1680	1958/1975	2.7/2.7	9.6/9.0	6 t

The bending tests are conducted in both longitudinal (RD) and transverse (TD) orientations. In this paper, the longitudinal bend orientation (RD) refers to the bend axis being parallel to the rolling direction, and the transverse orientation (TD) refers to the bend axis being perpendicular to the rolling direction. The bend specimens were cut from the 6 mm thick sheets into rectangular strips with a width of 80 mm. The specimen width is small enough to prevent exceeding the force limit of the used Zwick 100 kN universal tensile test machine, while still ensuring plane strain conditions at the center of the bend.

The specimens were bent in room temperature using purpose-built bending tools, shown in Fig. 1a. Using the tensile test machine for the bend tests allows accurate measurements of the bending force and punch displacement. The punch displacement is then used for calculating the bend angle according to ISO 7438 [15]. The measured vertical force is used to adjust the punch displacement and bend angle calculations for the vertical elasticity of the setup (51.9 kN/mm).

The shape of the die (lower bend tool) is illustrated in Fig. 1b. The openings allow an unobstructed line-of-sight between the DIC cameras and the measured specimen surface. The die width, i.e., the distance between the centers of the two shoulders, is also adjustable with this tool. The shoulders rotate freely in their sockets. To minimize the effect of friction even further, a PTFE lubricant spray is applied to the shoulders before each test.

Fig. 2 shows a schematic representation of the bending geometry used in this paper. Three bending tool setups are used in this study, in order to achieve a large variety of strain distributions, and to observe their effects on the behavior of the materials. The parameters for each setup are presented in Table 2. In each setup, the specimens were bent until they either fractured or reached the bend angle of α_{end}. Two repeat tests were conducted for each combination of tool setup, material, and bend orientation. Therefore, a total number of 108 tests are included in this study.

A DIC system, Strainmaster by Lavision, was used in this study for measuring the deformations on the outer bend surface. The system was equipped with two monochrome CCD cameras with a resolution of 2456 × 2058 pixels. The captured images were processed in the DaVis 8.4 software, which uses an iterative least squares matching (LSM) algorithm for displacement and strain calculation. The DIC recording and processing parameters are presented in Table 3. After calculating the strain maps from each image of each test, the values of the major strain were extracted from three sections positioned at the center of the bend, as illustrated in Fig. 1c. The average of the peak values of the three sections were also calculated at each point in time, as well as the average total strain (Riemann sums) of the three sections.

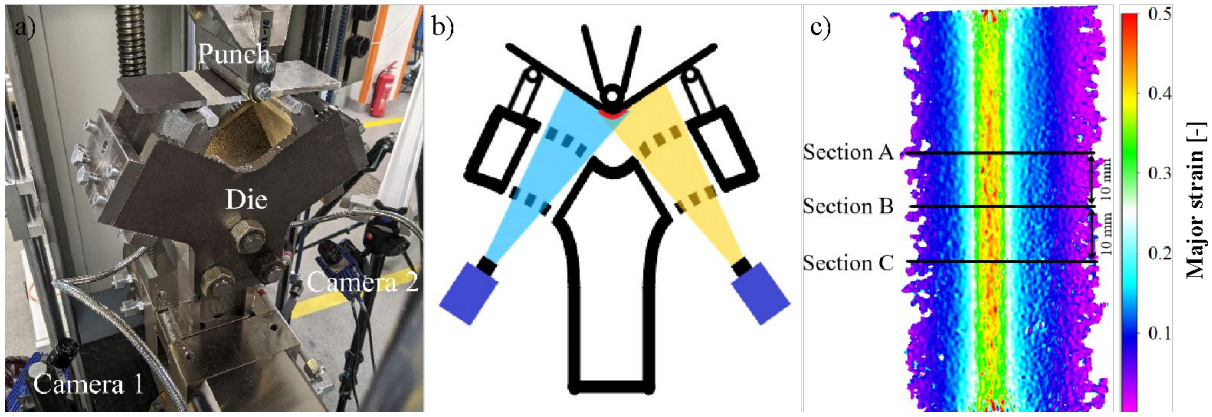

Fig. 1. a) The bending test setup, b) positioning of the DIC cameras, and c) sections A – C on a strain map of the St1100_1 (RD) at 90° bend angle, using a punch radius R_p = 2 t.

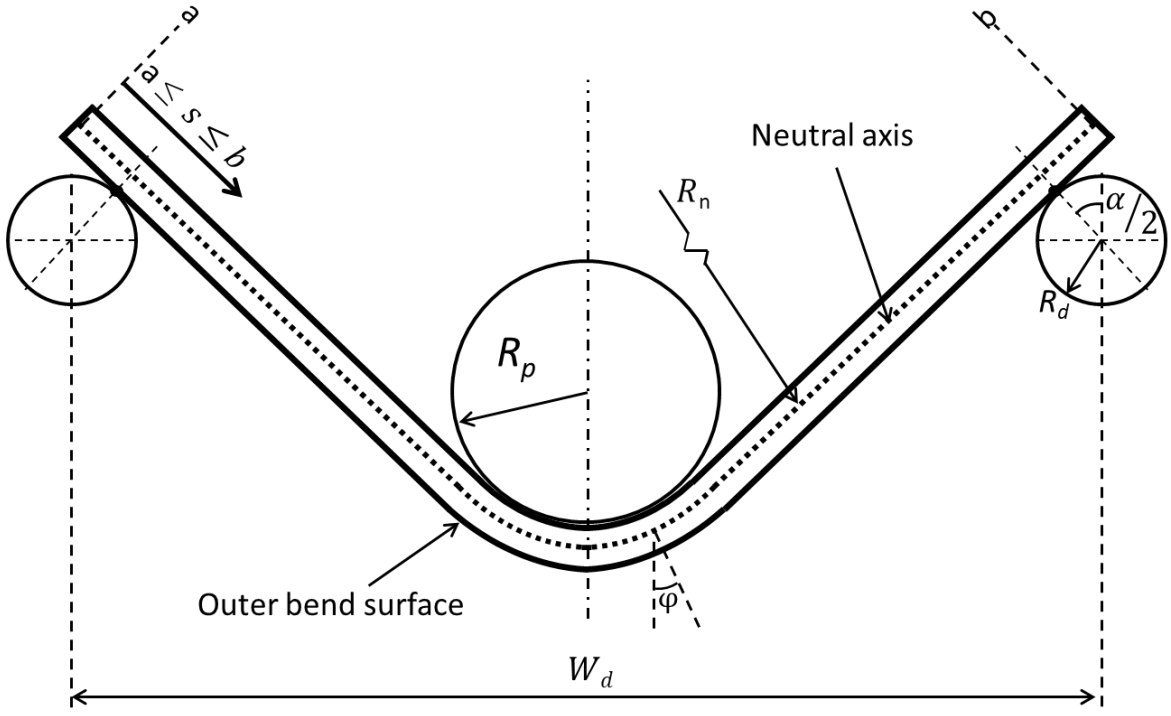

Fig. 2. The bending tool geometry and parameters involved in the analytical solution for the total strain $A_{\varepsilon b}$.

Table 2. Bending tool setup parameters: Punch radius (R_p), die width (W_d), radius of the die shoulders (R_d), vertical speed of the punch (V_p) and the final bend angle before unloading (α_{end}).

Tool setup	R_p	W_d [mm]	R_d [mm]	V_p [mm/s]	α_{end} [°]
1	4 mm ≈ 0.66 t	90	6	1	120
2	12 mm ≈ 2 t	90	6	1	100
3	24 mm ≈ 4 t	110	6	1	110

Table 3. Recording and processing parameters for the DIC system.

DIC system	Lavision Strainmaster (Stereo DIC)
Sensor and digitization	2456 × 2058, 12-bit
Lens, imaging distance	35 mm C-mount, 0.37 – 0.57 m
Imaging rate	2 Hz
Subset size	15x15 pixels
Step size	5 pixels
Strain window, smoothing method	5x5 data points, 2nd order polynomial fit
Virtual strain gage size	35 pixels
Image scale	21 – 30 pixels/mm
St.dev of principle strain	450 - 1700 microstrain
Interpolation, shape function, algorithms	6th order spline interpolation; affine shape function; LSM (iterative least squares matching) algorithm based on optical flow estimation

Before each test, a black-and-white speckle pattern was spray painted on the specimen surfaces to improve the DIC measurement reliability and to minimize glare. To minimize the effect of paint peeling on the measurements, the surfaces were cleaned with ethanol before painting and the tests were conducted as soon as possible after painting to prevent the paint from becoming excessively dry and brittle.

Results and Discussion

Fig. 3 shows the strain distributions of St700 in the RD direction measured at 30°, 60° and 90° bend angles and with three different punch radii. Fig. 3b illustrates the area under the strain distribution curve at 30°, i.e., the total strain $A_{\varepsilon b}$, as well as the peak strains ε_{b_max} at 30° and 90° angles. The distributions are similar for all three punches at 30° but as the bend angle increases, the effect of the punch radius on the strain distribution is clear. With the punch radius R_p = 0.66 t, the deformation increases mostly at the center, creating a narrow strain distribution with large peak strain at the center. In contrast, when using larger punches, as in Figs. 3b and 3c, the deformation is spread more evenly, creating a wider strain distribution with lower peak strains at the center. In fact, when using the largest punch (R_p = 4 t), the peak strain does not increase at all between 60° and 90° bend angles, as the deformation increases solely from the sides.

Fig. 4a presents the developments of the peak strain ε_{b_max} (average peak values of sections A, B and C) for St355 (TD) and St700 (RD) using three different punches. The peak strains develop almost identically in the first 15°, but after around 15 – 20° bend angle (0.05 – 0.10 peak strain) the effects of the punch radii and the material properties start to show. With the smallest punch radius (R_p = 0.66 t), the peak strain increases almost linearly between 30 – 90° bend angles for both materials, with only a slight stagnation in peak strain towards the end of the test. For R_p = 2 t, the stagnation of peak strain seems to start at around 30 – 40° bend angle, and for R_p = 4 t, around 15 – 20° bend angle.
