is applied to a vast dataset of measurements, the following relationship is obtained:

$$\begin{bmatrix} Y_1 \\ \vdots \\ Y_n \end{bmatrix} = \begin{bmatrix} 1 & x_1 & z_1 \\ \vdots & \vdots & \vdots \\ 1 & x_n & z_n \end{bmatrix} \begin{bmatrix} \beta_0 \\ \beta_1 \\ \beta_2 \end{bmatrix} \rightarrow \boldsymbol{f} = \boldsymbol{M}\ \boldsymbol{c} \tag{2}$$

Thus, the vector $\boldsymbol{c}$ of unknown parameters can be determined by

$$\boldsymbol{c} = (\boldsymbol{M^T M})^{-1} \boldsymbol{M^T f} \tag{4}$$

Mechanical power generation

The correlation analysis pointed out that the engine torque has a strong correlation with the throttle valve opening and (at weaker level) engine speed. Therefore, the torque for the Wankel engine of the propulsion system has been modelled as:

$$T_W(\tau, \omega) = a_1\left[1 + \gamma_1\left(\omega - \omega_{ref}\right)\right]\tau + a_2\left[1 + \gamma_2\left(\omega - \omega_{ref}\right)\right]\tau^2 \tag{5}$$

Materials Research Proceedings 69 (2026) 683-688 https://doi.org/10.21741/9781644904251-121

where T_W is the torque in Nm, τ is the throttle opening percentage (from 0 to 100); ω is the angular speed in rad/s, while a_k and γ_k are unknown model parameters (k=1,2).
By assuming a rigid transmission from the Wankel engine to the system output shaft, we have

$$\omega_a = \omega_b = \omega \tag{5}$$

and the momentum equation at the output shaft becomes:

$$J_o\dot{\omega} = T_W + T_L - B_f\omega \tag{6}$$

In Eq. (6), T_L is the external load, while J_o, the equivalent system inertia, and B_f , the viscous coefficient, are unknown model parameters. Substituting Eq. (4) in Eq. (6), we obtain:

$$J_o\dot{\omega} = a_1\left[1+\gamma_1\left(\omega-\omega_{ref}\right)\right]\tau + a_2\left[1+\gamma_2\left(\omega-\omega_{ref}\right)\right]\tau^2 + T_L - B_f\omega \tag{7}$$

Using Eq. (7), a two-step identification has been carried out:

1. in steady-state conditions, i.e. $\dot{\omega} \approx 0 \ \ and \ \ \left|\omega-\omega_{ref}\right| < 0.01$, for the identification of the parameters $B_f, \mathrm{a}_1, \mathrm{a}_2$.
2. in transient conditions near the nominal speed: $\dot{\omega} \neq 0 \ \ and \ \ \left|\omega-\omega_{ref}\right| < 0.1$, for the identification of the parameters J_o, γ_1, γ_2 identification.

Fuel flow consumption and intake manifold air pressure
Both fuel flow and manifold air pressure signals exhibited a strong correlation with throttle valve opening and engine angular speed was again found, so that the following models have been used:

$$\dot{m}_f(\tau,\omega) = \phi_0 + \phi_1\left[1+g_1\left(\omega-\omega_{ref}\right)\right]\tau + \phi_2\left[1+g_2\left(\omega-\omega_{ref}\right)\right]\tau^2 \tag{8}$$

$$P_m(\tau,\omega) = \psi_0 + \psi_1\left[1+k_1\left(\omega-\omega_{ref}\right)\right]\tau + \psi_2\left[1+k_2\left(\omega-\omega_{ref}\right)\right]\tau^2 \tag{9}$$

where $\dot{m}_f$ is the fuel flow in kg/s, P_m is the manifold pressure in Pa, while ϕ_0, ϕ_1, ϕ_2 and ψ_0, ψ_1, ψ_2 are unknown model parameters to be identified in steady-state conditions, while g_1, g_2 and k_1, k_2 in transient conditions.

Thermal transfer in the combustion chamber
The temperature dynamics in the combustion chamber has finally been modelled via an energy balance applied to the chamber control volume, Fig. 1.

$$I_t\dot{\theta}_e = \dot{m}_f LHV - T_w\omega + B_f\omega^2 - k_c(\theta_e-\theta_c) - \dot{m}_f c_v(1+\lambda)\theta_x \tag{10}$$

where θ_e , θ_c and θ_x are the engine chamber, the coolant and the exhaust gas temperatures in °K, LHV is the fuel lower heating value in J/kg, $\boldsymbol{c_v}$ is the specific heat at constant volume in J/kg°K, and λ is the air-to-fuel ratio, while I_t and k_c are unknown model parameters.

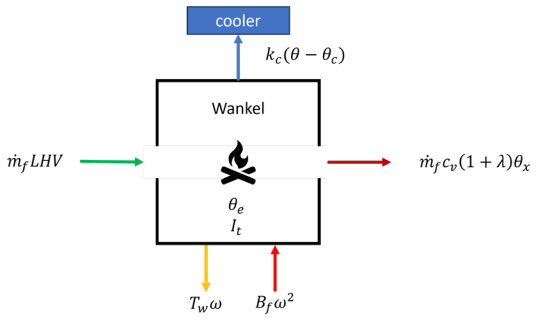

Figure 1 – Energy flows in the combustion chamber control volume.

Results and discussion

A comparison between simulation and experimental results are summarized from Fig. 2 to Fig. 4. When simulating the operation near the nominal speed, the model exhibits a strong matching with experiments (Figs. 2-3). As highlighted by Fig. 3, the model errors are small throughout the test in nominal operative condition. The detailed comparison in Fig. 4 permits to confirm the satisfactory accuracy of the developed model.

Keywords: Aircraft Electrification, Hybrid Propulsion, Power Management Systems, Reliability, Safety, Functional Hazard Analysis

Abstract. The development and the technological demonstration of Hybrid-Electric Propulsion Systems (HEPSs) represent fundamental steps towards more sustainable air transports, especially with reference to regional applications. Beyond performance aspects, the reliability and safety of the electrical power devices integrated in the HEPSs are still far to be substantiated, especially with reference to Li-Ion batteries and fuel cells. In addition, due to the presence of multiple power paths, a safety-critical element of all HEPSs is the power management system, defining the torque split among sources and monitoring the health-state of subsystems. This work presents the preliminary Functional Hazard Assessment of the power management system of a 2-MW HEPS with hydrogen fuel cells for regional aircrafts, developed within the context of the EU-funded AMBER project, launched in 2023 and part of the Clean Aviation program. The activity conducts to the identification of the most critical failure conditions of the HEPS power management system, which can bring up to hazardous consequences (depending on the mission phase), and to the proposal of possible enhancements of the system architecture aiming to mitigate or eliminate the failure effects.

Introduction

Environmental sustainability is nowadays one of the most crucial challenges of aviation industry, which is striving to validate technologies capable of reducing aircraft noise and Greenhouse Gas (GHG) emissions [1]. In this context, the development and the technological demonstration of Hybrid-Electric Propulsion Systems (HEPSs) represent fundamental steps towards more sustainable air transports, especially with reference to regional applications [2-7], To address such issue, the EU-funded AMBER project has been launched in 2023 as part of the Clean Aviation program [8], aiming to mature, integrate and validate a 2-MW HEPS powered by hydrogen fuel cells. The main goal of the AMBER project is to reduce the fuel burn and the GHG emissions by at least 30% at aircraft level, compared to 2020 state-of-art [9]. The HEPSs essentially try to combine and balance the advantages of electric propulsion in terms low noise emissions and high power efficiency with those of Internal Combustion Engines (ICEs) in terms of long flight endurance, high power density and proven reliability [10]. Actually, beyond performance aspects, the reliability and safety of electrical propulsion systems are still far to be substantiated, especially with reference to energy storage devices [11]. In HEPSs with hydrogen fuel cells, multiple power paths can be used for propulsion, so that a power management system is needed to define the torque split among sources, while monitoring the health-state of critical subsystems (e.g. Li-ion batteries and fuel cells) and estimating the pollutant emissions [12]. In the AMBER HEPS, this task is allocated to the so-called Supervisory and Hierarchical Control System (SHCS) and this work presents the Functional Hazard Assessment (FHA) [13, 14], referred to a preliminary architecture of the system, aiming to highlight its potentialities and limitations for the airworthiness certification [15-17].

The paper is articulated as follows: in the first section, a brief description of the AMBER HEPS and its main components is provided. In the second part, the methodology for the FHA development is briefly recalled, by defining the system functional requirements, the mission profile, the failure types and the related severities. In the third section, an excerpt of the HEPS SHCC FHA table is reported, by highlighting the most critical failure conditions and proposing possible enhancements in the system architecture.

Materials and Methods

System description

In the AMBER twin-engine aircraft, the HEPS is made of two assemblies, each one dedicated to one of the two engine. The main components of each HEPS assembly are, Figure 1:

- ICE, composed of Gas Turbine (GT) and related FADEC
- electric propulsion system, composed of
  - Electric Motor (EM) subsystem, including
    - a three-phase permanent magnets synchronous electric machine
    - Electronic Control Unit (EM ECU)
    - Electronic Power Unit (EM EPU)
    - Thermal Management System (EM TMS)
  - fuel cell subsystem, including
    - hydrogen tank
    - Fuel Cell (FC)
    - Master Electronic Control Unit (FC M-ECU)
    - secondary ECUs (Fuel Cell Control)
    - Thermal Management System (FC TMS)
  - battery subsystem, including
    - Battery Pack
    - Electronic Control Unit (BS ECU)
    - Thermal Management System (BS TMS)
- SHCS, composed of:
  - Supervisory and Hierarchical Controller (SHC)
  - Fault Detection, Isolation and Accommodation Control Unit (FDIA-CU)
  - Power Fault Compensation Control Unit (PFC-CU)
- Electric Power Distribution (EPD) module
- Propeller Actuators and Sensors (PAS) module
- clutch and gearbox connecting the ICE and EM output shafts to the propeller in parallel torque-summing configuration

Concerning the interfaces, each assembly receives commands from the Power Lever Angle (PLA) module (in the AMBER aircraft, it is the basic pilot interface with the HEPS to define, depending on the mission phase, the propulsion request) and exchanges data with avionics and the SHCS of the other HEPS assembly. In addition, the SHCS can communicate with the maintenance ECU, when connected.

Materials Research Proceedings 69 (2026) 689-694 https://doi.org/10.21741/9781644904251-122

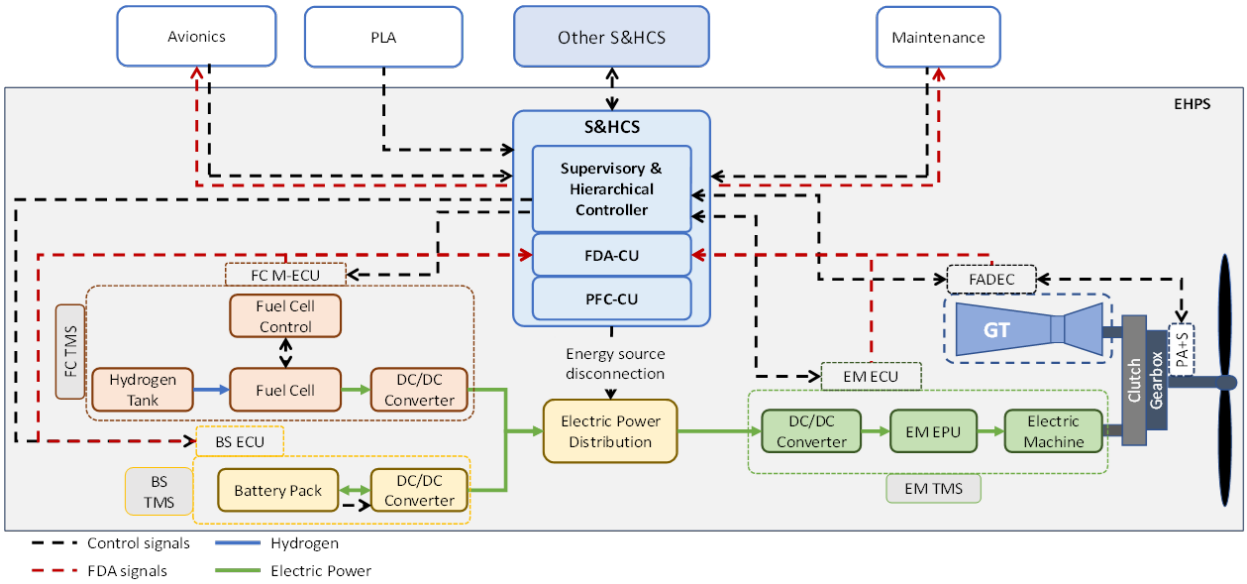

Figure 1. Architecture of one of the two HEPS assemblies of the AMBER regional aircraft.

Aircraft and HEPS mission profile

Due to the double power source, the HEPS mission profile has been constructed starting from the mission of a typical regional aircraft and defining the power demands limits on the two propulsion sources, up to identify the HEPS Operating Modes (OMs).

As pointed out in Table 1, the following OMs have been defined:

- *Check-in*, in which the SHCS validates the HEPS health-state and manages the power-up operation;
- *Eco*, in which the SHCS manages the power demands to minimize the noise and CO2 emissions of the HEPS, by limiting the GT power demand;
- *Boost*, in which the SHCS manages the power demands to maximize thrust while optimizing the HEPS efficiency;
- *Cruise*, in which the SHCS manages the power demands to maximize range or endurance, while optimizing the HEPS efficiency;
- *Hold*, in which the SHCS manages the power demands to maintain the thrust demand while cooling the electrical systems (the EM power demand is limited).

Table 1 - Mission phases (with related FHA ID), OMs and power demand limits.

Mission phase	FHA ID	OM	Power demand limits	
			GT	EM
Power-on	a	Check-in	Full	Full
Taxi-out	b	Eco	Limited	Full
Take-off	c	Boost	Full	Full

Taxi-in	j	Hold	Full	Limited
Power-off	k	Check-out	Full	Full

Materials Research Proceedings 69 (2026) 689-694 https://doi.org/10.21741/9781644904251-122

Functional requirements of the HEPS SHCS

The SHCS functional requirements have been identified starting from aircraft- and engine-level requirements, up to allocate the following first-level capabilities:

- communication with external systems (avionics, PLA, SHCS of the other HEPS assembly, maintenance ECU);
- communication with HEPS subsystems;
- diagnosis of HEPS major faults;
- management of the propulsion power.

Failure types and severity categories

To develop the FHA, generalized Failure Types (FT) have been addressed, i.e.:

- *total loss* (FT1), i.e. a complete inability of implementing the function under exam, for the whole duration of the examined mission phase;
- *incorrect operation* (FT2), including partial and/or intermittent loss of a function, i.e. the function can be achieved with limited effectiveness for the whole duration of the mission phase and/or it can be achieved only for a limited duration of the mission phase;
- *inadvertent activation* (FT3), applicable to functions the implementation of which requires the pilots' intervention, in case that it unintentionally occurs.

Concerning the severity classification of the failures, it has been defined by evaluating the failure effects on aircraft, flight crew and passengers as recommended by [17], as well as on the propulsion system [15].

Results and discussion

The FHA demonstrated that only total losses (FT1) can determine a large reduction of aircraft safety margin. In particular, hazardous consequences can derive from two failures (Table 2):

- the inability to shut down the HEPS in case of emergency, caused by a total loss of communication with avionics (SHCS.116.1), impeding the pilots to send commands to the HEPS SHCS, or a total loss of the SHCS power management functions, once a shut-down command is received (SHCS.416.1)
- the inability to perform FDIA via in-flight BIT against propeller overspeed (SHCS.321.1c-i), thrust deviation (SHCS.322.1c-i), power deviation (SHCS.323.1c-i), overheating (SHCS.324.1c-i) or anomalous vibrations (SHCS.325.1c-i), in case that the fault occurs

Concerning the major consequences, the FHA identified 31 failure conditions, which can be essentially grouped into the following categories (Table 2):

- failure leading to the shutdown of one of the two HEPS power lines when the full power is requested to both GT and EM, causing a one-side inopera-tive condition (e.g. SHCS.113.1c-d, SHCS.113.2c-d)
- failure leading to the incorrect power management of the HEPS power lines (e.g. SHCS.114.1f, SHCS.114.2f, SHCS.414.1f, SHCS.414.2f)
- the inability to restore the HEPS functionality after an inadvertant shutdown (e.g. SHCS.116.3c-i) or an erroneous mode selection (e.g. SHCS.113.3b, SHCS.114.3b-e, SHCS.115.3b-g)
- a total loss or incorrect operation of all the SHCS power management func-tions, except the emergency shutdown (e.g. SHCS.411.1a, SHCS.411.2a, SHCS.412.1b, SHCS.412.2b, etc.). It is worth noting that these failure condi-tions, in conjunction with loss of protection against thrust deviation can lead to significant thrust in the opposite direction (HAZ)

Table 2 - Severity classifications with related FHA ID.

Failure ID from FHA	Description (Capability to…)	Severity	MTBF [FH^{-1}]
SHCS.116.1	… communicate with avionics for selecting the HEPS OM: Check-out	HAZ	10^{-7}

Keywords: Hydrogen Enrichment, Plasma-Assisted Combustion, Lean Blowout, Flame Stability, Methane-Hydrogen Flames

Abstract. Hydrogen enrichment increases the reactivity of methane flames but can reduce stability under lean conditions, limiting operability. This work investigates the enhancement of lean blowout (LBO) limits in methane-hydrogen blends through plasma-assisted combustion in a swirl-stabilized combustor at fixed thermal power. Experiments were performed with fuel mixtures containing 0%, 30%, 40%, 60%, 80%, and 100% H_2 by volume. While higher hydrogen content enhances flame reactivity, it also progressively reduces stability under lean operation. The application of non-thermal plasma was found to significantly extend the LBO limits across all tested blends by $\Delta\phi_{LBO} \approx 0.04$, effectively stabilizing hydrogen-enriched flames. These results highlight the potential of plasma-assisted combustion to improve flame operability and enable low-emission performance in lean hydrogen-containing fuel mixtures.

Introduction

Hydrogen is increasingly recognized as a promising fuel due to its zero carbon emissions during combustion. Its use is rapidly expanding as a key strategy to reduce CO_2 output in both energy production and transportation [1]. Upon combustion, H_2 primarily forms water, making it an environmentally friendly alternative to fossil fuels. While the long-term objective is the transition to 100% green hydrogen, in the short term blending hydrogen with natural gas, mainly methane, offers a practical approach to partially lower CO_2 emissions in gas turbines and industrial burners. Modern combustion systems are designed for "fuel flexibility," i.e., the capability to safely operate with varying hydrogen content, accommodating fluctuations in renewable energy availability [2]. Hydrogen differs significantly from methane in its combustion characteristics, exhibiting a much higher laminar flame speed (SL = 2.5 m/s for H_2 vs. 0.3 m/s for CH_4) [3]. These features enhance reaction rates but can make flame stabilization more difficult, particularly under lean conditions. Furthermore, hydrogen flames achieve higher adiabatic temperatures, potentially increasing NO_x formation; however, lean premixed operation can limit thermal NO_x due to lower oxygen availability and shorter residence times.

Several studies have explored how hydrogen enrichment affects methane flames in swirl-stabilized and dual-fuel burners. Marragou et al. [4] investigated flame stabilization regimes and pollutant emissions in a CH_4/H_2 dual swirl low-NOx burner. Patel et al. [5] analyzed hydrogen's impact on swirling and non-swirling methane flames. Kwak et al. [6] and Li et al. [7] studied the forced response of H_2/CH_4 flames in dual-nozzle swirl-stabilized setups. An et al. [8] examined flame stabilization mechanisms and shape transitions in a 3D-printed H_2-enriched CH_4/air low-swirl burner. Guo et al. [9] focused on the effect of hydrogen on swirl/bluff-body lean premixed flames, considering mixtures with ZH_2 = 0%, 40%, and 80%. Collectively, these works show that while hydrogen increases flame reactivity, it can also enhance dynamic instabilities.

Despite these insights, the combined effects of hydrogen enrichment on flame behavior under partially premixed and swirl-stabilized conditions, particularly regarding flame stability and lean blowout (LBO), remain incompletely understood. Non-thermal plasma (NTP) systems such as dielectric barrier discharges (DBD) or nanosecond pulsed discharges operate at reduced electric fields of E/N = 100–300 Td and can promote oxidation reactions by directly generating O*, H*, and OH* radicals. Previous works [10-13] demonstrated that nanosecond discharges accelerate ignition kinetics and lower LBO thresholds. However, few studies have explored the combined effects of hydrogen enrichment and plasma activation in swirl-stabilized combustors. To address this gap, the present study examines methane flames with varying hydrogen content and evaluates how plasma-assisted combustion can improve LBO limits. Experiments were carried out with fuel blends containing 0%, 30%, 40%, 60%, 80%, and 100% H_2 by volume in a swirl-stabilized combustor. The focus is on understanding flame stabilization and operability under lean conditions, providing guidance for the development of hydrogen-enriched, low-emission combustion systems.

Experimental Setup

Flame stabilization at different levels of hydrogen enrichment was studied using an atmospheric-pressure swirl-stabilized burner. The setup consists of a central fuel injector mounted on a support nozzle and a quartz-windowed combustion chamber that allows for high-resolution optical access, as illustrated in Fig. 1.

Swirled flames were produced using an air-blast nozzle with an effective outlet area of 319 mm^2, representative of the geometric scale typical of aero-engine combustors, similar to the configuration reported by Kasabov et al. [14]. The nozzle includes two concentric air swirlers: Swirler 1 with a geometric swirl number of 0.76 and Swirler 2 with a swirl number of 0, followed by an air diffuser. Methane and hydrogen were injected axially through a central tube, while primary and secondary air streams were supplied through separate inlets located in the lower and upper sections of the nozzle holder.

The setup was enclosed in a Faraday cage to prevent interference from electromagnetic fields generated by the plasma discharge. The plasma actuator consists of a needle with a diameter of 1 mm and a length of 46 mm, positioned at the center of the nozzle with a blunt tip angle of 90°, serving as the high-voltage (HV) electrode. The nozzle itself acted as the grounded (GND) electrode. Experiments were performed at an inlet air temperature of 298 K. Fuel flow rates were adjusted for each case to maintain a constant thermal power of 4.6 kW. Fuel compositions ranged from pure methane to pure hydrogen, with intermediate blends containing 30%, 40%, 60%, and 80% hydrogen by volume. A summary of all operating conditions is provided in Table 1.

Materials Research Proceedings 69 (2026) 695-700 https://doi.org/10.21741/9781644904251-123

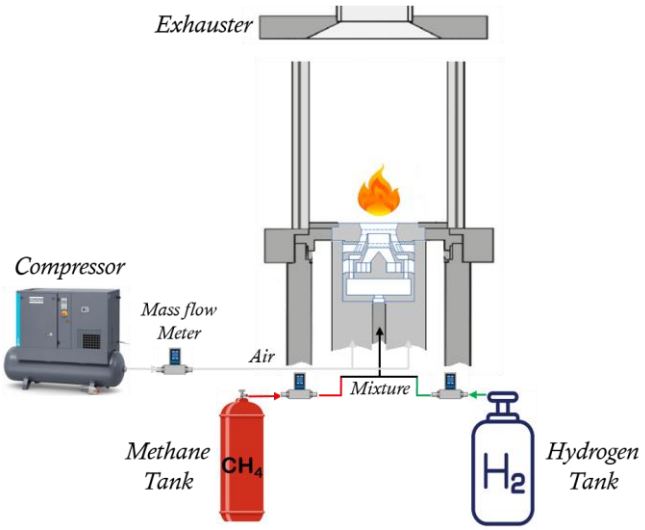

Fig. 1 Experimental Set-Up

Table 1 Experimental conditions

Case	H_2 volume [%]	Thermal Power [kW]	CH_4 [Nm^3/h]	H_2 [Nm^3/h]
1	0%	4.6	0.5	0
2	30%		0.44	0.2
3	40%		0.41	0.3
4	60%		0.35	0.5
5	80%		0.23	0.9
6	100%		0	1.6

Flame Characterization with H_2 Addition

The effect of hydrogen enrichment on flame structure was investigated by analyzing the spatial distribution of chemiluminescence intensity for different fuel mixtures. Fig. 2 shows representative flame images for three of the tested cases: pure methane (0% H_2), and blends with 30% and 40% hydrogen by volume. The images reveal a clear trend in flame morphology as the hydrogen content increases.

In the pure methane case (Test 1), the flame exhibits a moderately broad shape with less intense emission. Introducing 30% hydrogen (Test 2) results in a more compact and brighter flame, indicating higher reaction rates and increased flame stability. At 40% hydrogen (Test 3), the flame becomes even more intense and well-defined, suggesting that hydrogen enrichment enhances combustion reactivity and reduces geometric irregularities.

Materials Research Proceedings 69 (2026) 695-700 https://doi.org/10.21741/9781644904251-123

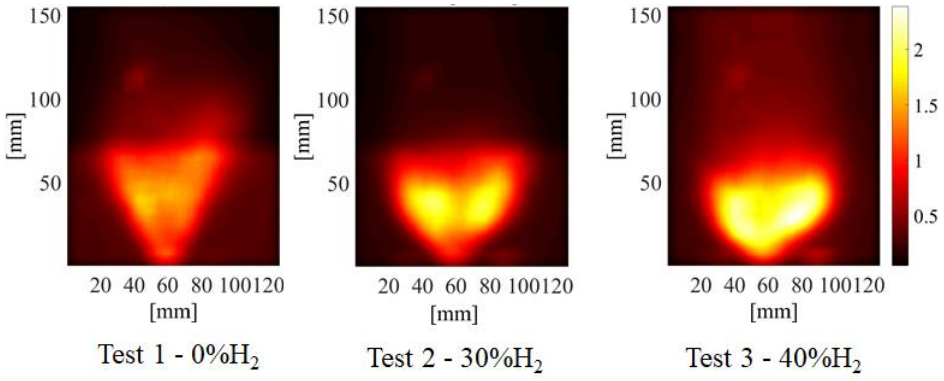

Fig. 2 Chemiluminescence imaging of broadband signals, reported as mean fields from pure methane to 40% hydrogen by volume.

Plasma-Assisted Combustion and LBO Improvement

For each hydrogen-containing fuel blend, combustion was investigated under the application of non-thermal plasma at different intensity levels, corresponding to 25%, 40%, 50%, and 75% of the generator's maximum amplitude. The electrical set-up consisted of HV sinusoidal amplifier, a current transformer, and a high voltage (HV) probe and an oscilloscope. The HV generator supplies the voltage in sinusoidal waveform *V(t)* at different amplitudes and a constant frequency of about 20 kHz.

The plasma application enhanced flame stability and extended lean blowout limits across all tested H_2/CH_4 mixtures, as shown in Fig. 3.

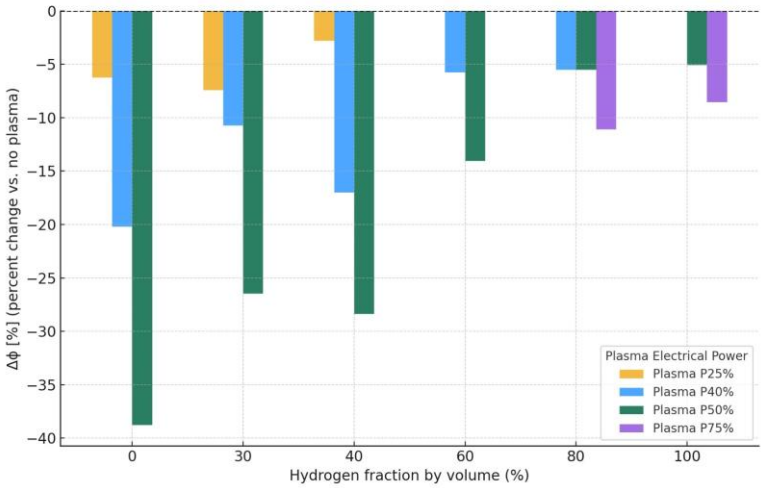

Fig. 3 Variation of LBO Equivalence Ratio with Plasma Activation

The effect of plasma on lean blowout was evaluated by measuring the percentage variation of the equivalence ratio ($\Delta\phi$) relative to the no-plasma case as a function of hydrogen fraction in the CH_4/H_2 mixture. Negative $\Delta\phi$ values indicate enhanced flame stability, allowing combustion at leaner conditions. All plasma-assisted conditions show negative $\Delta\phi$, confirming that the plasma stabilizes the flame. The stabilizing effect generally increases with plasma power, reaching a maximum around 50% of the generator amplitude (P50%), while higher power (P75%) produces a slightly smaller improvement, suggesting possible saturation or less efficient energy use. The effect is most pronounced at low to moderate H_2 fractions (0–40%), where plasma-generated radicals (H*, O*, OH*) significantly enhance reaction rates and flame stability. At high H_2 fractions (≥80%), the mixture is already highly reactive, and the additional contribution of plasma becomes less relevant. In summary, at 30–40% H_2, plasma power levels of 25–40% reduce the

LBO threshold by 10–20%, while higher power levels (50–75%) achieve reductions exceeding 30%. Overall, these results highlight the effectiveness of non-thermal plasma in extending lean blowout limits, particularly for moderately hydrogen-enriched methane flames.

Conclusions

This study demonstrates that hydrogen enrichment increases methane flame reactivity but reduces stability under lean conditions. Plasma-assisted combustion effectively extends lean blowout limits across all tested H_2/CH_4 blends, with the strongest stabilizing effect observed at low to moderate hydrogen fractions. Plasma-generated radicals accelerate reaction kinetics, improving flame stability and operability without requiring additional thermal power. These findings highlight the potential of non-thermal plasma as a tool to enhance combustion of hydrogen-enriched fuels and support the development of low-emission, lean-burning combustion systems.

Keywords: Water Electrolysis Propulsion (WEP), CubeSat, Micro Propulsion, Green Propellant, Proton Exchange Membrane (PEM) Electrolysis

Abstract This work presents the conceptual design and numerical modeling of a electrolysis based water propulsion system tailored for CubeSat applications. A Python based simulation framework models the complete electrolyze–store–burn cycle, integrating a Proton Exchange Membrane (PEM) electrolyzer, gas storage reservoirs, a catalytic ignition chamber, and an isentropic nozzle expansion stage. The system evaluated over an input power range of 3.95–9.7 W, with electrolyzer efficiencies ranging from 71% to 76%. At optimal conditions (P_c = 6 bar, T_c = 3300 K), the quasi-steady nozzle model predicts a theoretical specific impulse of 450.3 s. However, realistic pulsed operation includes startup and shutdown transients that reduce the effective specific impulse to 405 s approximately 10% performance penalty. Each operational cycle consumes around 1.25 g of water, producing sufficient thrust for CubeSat scale maneuvers. These performance metrics demonstrate alignment with small satellite propulsion requirements. The integrated model offers a foundational tool for linking electrochemical generation with thrust performance, supporting future development of green, multi-mode micro propulsion systems for agile CubeSat missions.

Introduction

The rapid growth of CubeSat missions has increased demand for compact, safe, and energy efficient propulsion systems. Traditional chemical and electric thrusters, designed for larger spacecraft, often exceed CubeSat limits in mass, complexity, and safety. This has led to a shift toward green propulsion technologies using nontoxic propellants. Water has recently become a strong candidate due to its availability, stability, and ease of handling. Electrolysis allows water to be split into hydrogen and oxygen, stored and combined to produce thrust an approach known as Water Electrolysis Propulsion (WEP).

Table 1: Summary of Representative Water Based Micro propulsion Studies.

Reference	Power[W]	Thrust+[N]	I_{sp} [s]	Propellant
Hwang et al. (2022) [1]	4.0 ~12	1.0	~430	H_2/O_2 (Electrolysis)
Porter et al. (PTD-1 / HYDROS-C) [2]	0.5 ~10	0.8	~300	Water (HYDROS-C)

Materials Research Proceedings 69 (2026) 701-706 https://doi.org/10.21741/9781644904251-124

summarizes key system performances, highlighting the balance between power, thrust, and efficiency.

System Architecture and Modeling

The proposed Electrolysis-based water propulsion system Propulsion (WEP) system is structured around four modular sub systems in Table 2, Each module is integrate into a Python based simulation pipeline that models the complete electrolyze–store–burn cycle, including mass and energy transfers. Key modeling assumptions include ideal gas behavior, quasi steady state operation, complete combustion, adiabatic nozzle expansion, and negligible heat losses.

Table 2: Subsystem Functions and Governing Equations in WEP Model

Subsystem	Inputs	Output and Equations
PEM Electrolyzer	Electrical power (P_{in}), current (I), current efficiency(η_c)	Hydrogen production rate: $\dot{n}H_2 = \eta_C \frac{1}{2F}$
		System efficiency: $\eta_{sys} = \frac{\dot{n}_{H_2} \cdot \mathrm{HHV}_2}{P_{in}}$
Gas Storage Unit	Molar flow rates ($\dot{n}H_2O_2$), Temperature(T)	Tank pressure: $P = \frac{nRT}{V}$ (Ideal Gas Law)
Catalytic Ignition Chamber	Tank pressure (P), temperature (T), catalyst mass (m_{cat})	Ignition delay:$\tau_{ign} = \frac{m_{cat}}{Ae^{-Ea/(RT)C_r}}$
		Combustion chamber pressure (P_c), temperature (T_c)
Nozzle Expansion	P_C, T_c, heat capacity ratio (γ), throat area (A_t)	Choked mass flow rate: $\dot{m} = \frac{P_C A_t}{\sqrt{Tc}} \sqrt{\frac{\gamma}{R}} \left(\frac{2}{r+1}\right)^{\frac{r+1}{2(r-1)}}$

PEM Electrolyzer Operation and Propellant Generation: The PEM electrolyzer splits water into hydrogen and oxygen in a 2:1 stoichiometric ratio of $2H_2O \rightarrow 2H_2 + O_2$.Hydrogen production follows Faraday's law, scaling linearly with stack current. The system efficiency, based on the Higher Heating Value (HHV) of hydrogen, improves from 71% to 76% across an input power range of 3.96–9.70 W. At 9.7 W over 45 minutes, the system consumes 1.255 g of water, producing 140.4 mg of H_2 and 1.114 g of O_2, stored at 5.67 bar. The specific impulse defined as:

$$I_{sp} = \frac{V_e}{g_0} \quad (1)$$

where V_e is the exhaust velocity, derived from nozzle thermodynamics. Total thrust is:

$$F = mV^{\cdot} + (pe - pa)Ae \quad (2)$$

with the pressure term clamped to ensure physical consistency during low-pressure operation.

Transient Efficiency and Impulse Modeling. While steady-state predictions suggest $i_{sp} = 450.3s$, practical pulsed operation yields $I_{sp,eff} = 450.3s$ due to transient effects. The thrust follows a trapezoidal profile comprising: (i) ignition delay τ_{ign} = 61.7 ms (at ϕ = 0.5), (ii) steady combustion plateau, and (iii) tail-off $\tau_{tailoff} \approx$ 138 ms. Impulse per pulse is approximated by integrating thrust over time:

Materials Research Proceedings 69 (2026) 701-706 https://doi.org/10.21741/9781644904251-124

$$I_{bit} = \int_0^{t_{burn}} F(t)dt \quad (3)$$

assuming a trapezoidal thrust profile with a linear ramp up(startup), steady plateau and linear decay(shutdown) then the impulse per pulse will be:

$$I_{bit} = \frac{1}{2}F \cdot \tau_{ign} + \mathrm{F} \cdot \left(t_{burn} - \tau_{ign} - \tau_{tailoff}\right) + \frac{1}{2}F \cdot \tau_{tailoff} \quad (4)$$

Transient efficiency is defined as:

$$\eta_{transient} = \frac{\tau_{ign}+\tau_{tailoff}}{2t_{burn}} \quad (5)$$

reaching ~ 98% at t_{burn} = 5 s and dropping to ~ 67% for short 0.3 s pulses. The ignition delay varies quadratically with equivalence ratio:

$$\tau_{ign}(\phi) = k_{scale}\,(-0.4394\phi^2 + 0.9357\phi + 0.4087) \quad (6)$$

Electrolysis to Thrust Performance: To quantify system level performance, a detailed parametric analysis was conducted across input power levels, focusing on a 45-minute accumulation window. Once the tank pressure reaches the design threshold of 6 bar, combustion is initiated in a catalyst assisted ignition chamber. Solenoid valves deliver 50ms gas pulses, triggering ignition with a 61.7ms delay. The resulting combustion raises the chamber temperature to approximately 3300 K, producing a choked mass flow of 205.08 mg/s. This generates 0.815 N of thrust and achieves a specific impulse of 405.3 s during a 1 second burn. These values are validated against Cantera and Rocket CEA simulations, showing agreement of and I_{sp}values within 2% of predicted results in Fig. 5.

Table 3: Thruster Performance vs. Electrolyzer Power (45 min accumulation)

Power [W]	p_{H2} [bar]	p_{O2} [bar]	$P_{c,eff}$ [bar]	Thrust [N]	I_{sp} [s]
3.96	2.16	2.16	2.46	0.372	166.3
5.87	3.29	3.29	4.72	0.713	318.9
7.78	4.46	4.46	6.00	0.815	405.3
9.70	5.67	5.67	6.00	0.815	405.3

Fig. 1,2, illustrates the relationship between effective chamber pressure $P_{c,\mathrm{eff}}$ and electrolyzer power under a fixed 45-minute accumulation period. At lower input power, less propellant is produced, resulting in lower tank and chamber pressures. As power increases, accumulated volumes of H_2 and O_2 rise, increasing chamber pressure. The pressure reaches the 6 bar design limit at approximately 7.15 W, beyond which it saturates due to nozzle constraints.

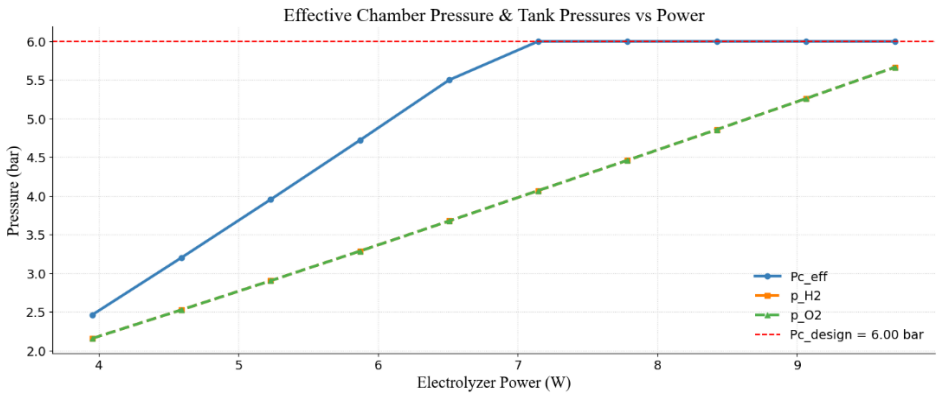

Figure 1: Effective chamber pressure Pc,eff vs. input power (45 min accumulation). Chamber pressure increases with power, saturating at 6 bar.

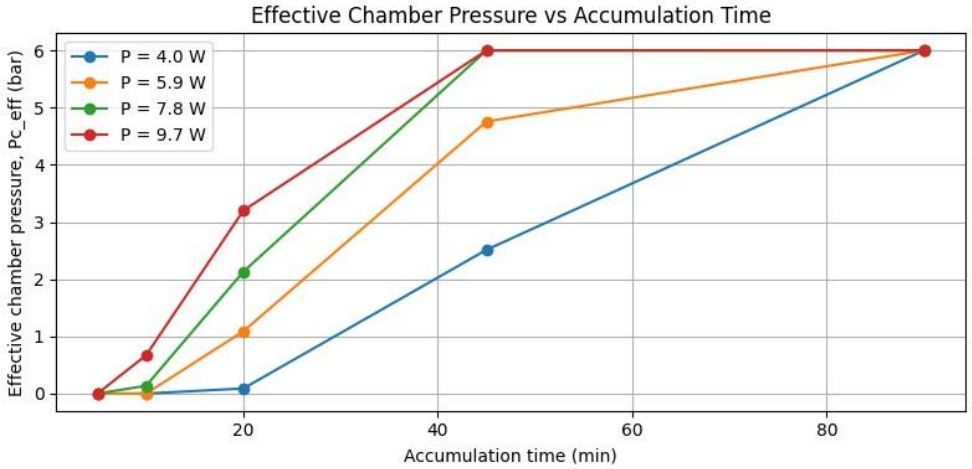

Figure 2: Tank and chamber pressures vs. input power. All pressures increase with power due to higher propellant generation.

This saturation behavior is further confirmed by the thrust and specific impulse trends shown in Table 3 and Fig. 4. Once P_c reaches the maximum limit, further increases in power do not yield higher thrust, indicating diminishing returns beyond 7.5 W.

A performance trade-off analysis shows that at 4 W, full pressurization takes up to 90 minutes. In contrast, systems operating between 7.8–9.7 W achieve optimal performance within 40–45 minutes—well within a typical CubeSat daylight orbit. This enables synchronization between solar charging and thrust execution, supporting flexible and energy efficient mission planning.

Materials Research Proceedings 69 (2026) 701-706 https://doi.org/10.21741/9781644904251-124

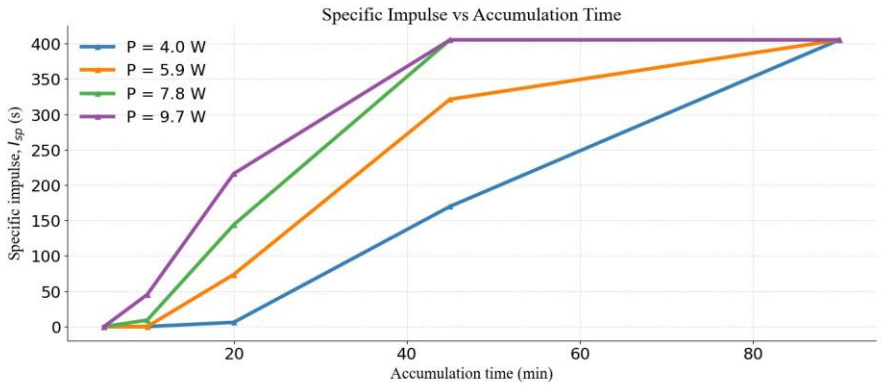

Figure 3: Specific Impulse vs. Accumulation time.

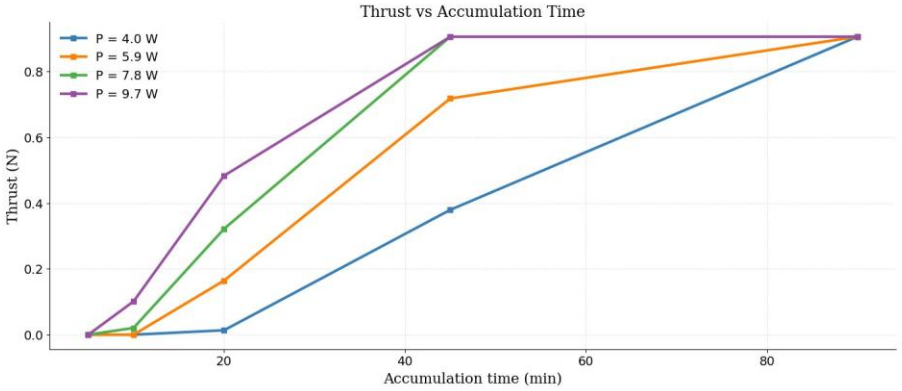

Figure 4: Thrust vs. Accumulation time.

Validation using Cantera and Rocket CEA:

The model was validated against Cantera (GRI-Mech 3.0) and Rocket CEA. At $P_c = 6$ bar and $\phi = 1.0$, the simulation predicted $T_c \approx 3300$ K and $I_{sp} \approx 405$ s, while Cantera predicts $T_c \approx 3320$ K and $I_{sp} \approx 410$ s, Rocket CEA yielded $T_c \approx 5359$ K and $I_{sp} \approx 351$ s. These deviations stemmed from differences in enthalpy and mixture assumptions. After adjusting combustion enthalpy and setting $\phi \approx 1.0$, the results aligned with actual T_c and I_{sp} values within 2% of Cantera values, confirming accurate integration of electrolysis, combustion, and nozzle flow in the simulation.

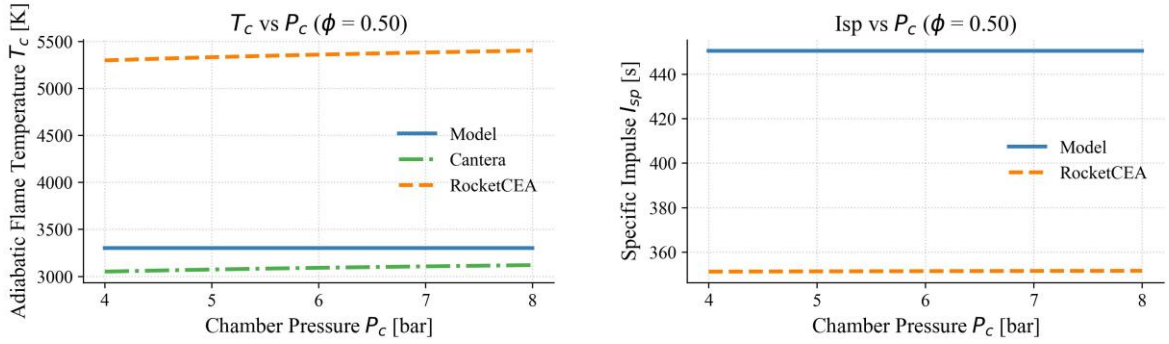

Figure 5: Comparison of I_{sp} and T_c vs. P_c for the model, Cantera, and Rocket CEA.

Conclusion and Future Work

This study presented the modeling and validation of a Water Electrolysis Propulsion (WEP) system for CubeSat scale applications. The integrated simulation—combining PEM electrolysis, gas storage, catalytic ignition, and nozzle flow—achieved 0.8 N thrust, 405 s specific impulse, and up to 76% efficiency at 10 W input, aligning with CubeSat mission requirements. Validation against Cantera and Rocket CEA showed less than 2% deviation with the actual adjusted final $T_c$and I_{sp}values, confirming model accuracy. A key outcome was the identification of a 6-bar chamber pressure cap, highlighting a performance saturation point critical for power and energy planning. Future efforts will include experimental hardware validation, regenerative fuel cell integration for water recycling, and exploration of plasma assisted ignition. Hybridization with vaporizing liquid micro thrusters (VLMs) also proposed to support dual mode, green micro propulsion for next-generation CubeSats.

Keywords: UAM, UAVs, Propeller, Non-Uniform Inflow, Aerodynamics

Abstract. Urban Air Mobility (UAM) is highly dependent on Unmanned Aerial Vehicles (UAVs) operating in complex urban environments, where propellers often encounter non-uniform inflows. These conditions can deteriorate the performance and stability of the vehicle, making standard uniform-inflow assumptions unrealistic and even dangerous for the prediction of the performance of UAVs. It is therefore of paramount importance to develop the capability to accurately reproduce in a repeatable manner such complex inflow conditions. This paper presents an experimental investigation of a propeller wake under controlled, non-uniform sheared inflow. Using Particle Image Velocimetry (PIV), the wake of a D=0.3 m propeller was characterized when operating in forward flight conditions. A modular fan array generated both uniform baselines and four linear shear rates. The results show that the sheared inflow creates an asymmetric wake with reduced vorticity magnitude and a radial streamtube expansion. Furthermore, Turbulent Kinetic Energy (TKE), highly localized in uniform flow, becomes significantly more diffused under sheared conditions, indicating altered turbulent mixing. These findings highlight the critical impact of the inflow conditions on the on the wake development.

Introduction

The viability of Urban Air Mobility (UAM) requires a step forward in the deployment of Unmanned Aerial Vehicles (UAVs), especially when operating in complex urban environments. Applications such as logistics and surveillance require low-altitude flight, where UAV propellers inevitably encounter non-uniform inflows, owing to the presence of unstructured environments, buildings and street canyons. These conditions significantly deviate from the ideal, uniform flow assumptions typically employed especially at a preliminary design stage. Operating in such perturbed aerodynamic environments can deteriorate propeller efficiency, induce unsteady loads, and compromise flight stability. Consequently, standard performance models, which assume uniform inflow, are often unrealistic. This discrepancy can lead to the underestimation of energy consumption and control effort required for stable flight, particularly in challenging scenarios like urban delivery, where adverse atmospheric disturbances are common [1].

Despite the clear operational need, many assessments of UAV propulsion systems and aerodynamics still rely on simplified inflow assumptions, potentially leading to overestimation of performance and reliability. Although the detrimental impact of non-uniform inflows is well-recognized, dedicated studies in the literature remain limited, particularly on the experimental side. Much of the available research relies on numerical simulations (CFD) to investigate the aerodynamic performance and forces on propellers subjected to wind fields [2]. Experimental work, in turn, has provided comprehensive force and flow-field datasets for propellers in steady non-axial (yawed) inflow conditions [4]. However, more complex simulations and experimental studies highlight that accurately modeling gust effects is crucial for predicting power consumption, as simplified aerodynamic models fail to capture performance degradation under high gust

intensity [3]. Furthermore, accurately and repeatably simulating complex spat-temporal disturbances, such as the sheared inflows investigated in this work, remains a significant challenge for conventional wind tunnel facilities [3]. To address this gap, the present study takes a first step by experimentally characterizing the wake flow field of a propeller operating under controlled sheared inflow conditions.

Experimental setup

Experiments were performed in the indoor flight arena at Politecnico di Torino. The facility is equipped with a WindShaper modular fan array [5], which comprises an 8 × 6 matrix of modules with individually controllable fans. This setup creates a 2 m × 1.5 m active test section, enabling the generation of both uniform and precisely controlled non-uniform inflow profiles.

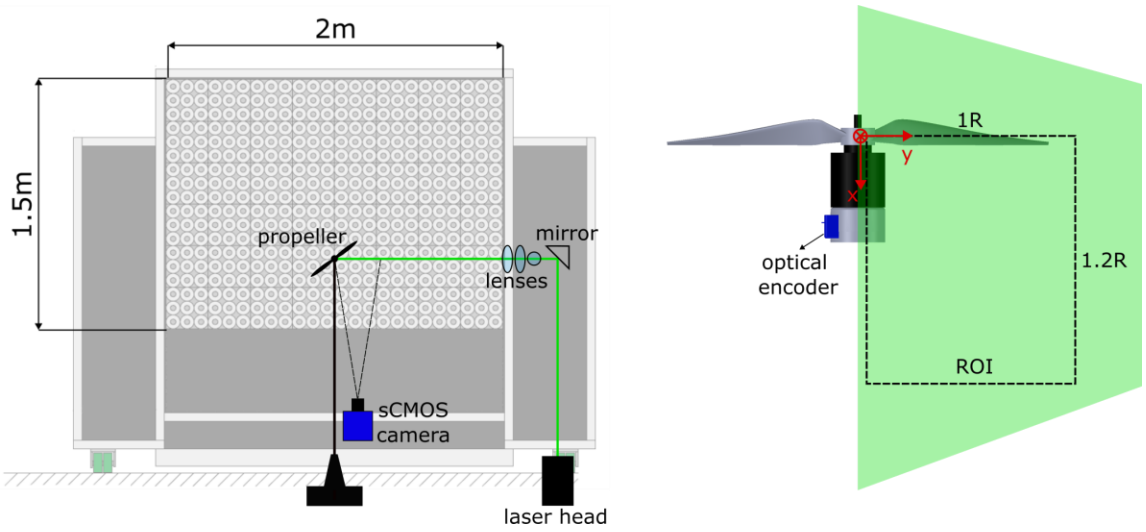

Figure 1: Schematic of the experimental setup.

The propeller used in the experiments was 3D-printed in resin with a diameter of D = 2R = 0.3 m, following the geometry from [6]. It was actuated by a brushless motor and an Electronic Speed Controller (ESC), controlled via an Arduino UNO board. An optical rotary encoder monitored the propeller's rotational speed, which was held constant at 2000 rpm for all tests. The propeller was positioned 1 m downstream from the fan array, with its rotation plane parallel to the fan wall to simulate forward flight. Particle Image Velocimetry (PIV) was employed to characterize the propeller's wake field; a schematic of the setup is shown in Figure 1. The flow was seeded with 1 µm diameter droplets generated by a Laskin nozzle. The region of interest was illuminated by a dual-pulse Nd:YAG laser (200 mJ/pulse) operating at 15 Hz. The laser beam was shaped into a 1 mm thick sheet, and the time separation between pulses was set to Δt =140 µs. PIV images were acquired using a 5.5 MP sCMOS camera (2560 × 2160 pixels) equipped with a 60 mm focal length lens set to $f_{\#}$=11. The imaged area covered approximately 1 R (radial, y) by 1.2 R (streamwise, x) downstream of the propeller, yielding a digital resolution of 13.5 px/mm. For each test case, 2200 image pairs were acquired. Raw images were pre-processed by subtracting the historical minimum to each acquired image in the dataset. Vector fields were computed using the PaIRS software [7] via a multi-step cross-correlation algorithm, using a final interrogation window of 32 × 32 pixels with 75% overlap. This resulted in a final vector spacing of 0.59 mm.

The experimental campaign focused on two primary inflow scenarios: uniform and non-uniform (shear flow). For the uniform inflow case, the advance ratio, defined as $J = U/(nD)$ was systematically varied over the range $0.2 \leq J \leq 0.7$. For the non-uniform cases, the WindShaper generated linear shear flow profiles across the propeller disk (in the y-direction). In these

Materials Research Proceedings 69 (2026) 707-712 https://doi.org/10.21741/9781644904251-125

configurations, the advance ratio, calculated using the velocity at the propeller hub ($y/R = 0$), was varied within the range $0.4 \leq J \leq 0.6$. Four distinct shear intensities were investigated, defined by the tip-to-tip velocity difference (ΔV_k) across the propeller: 1, 1.5, 2, and 3 m/s. These cases are hereafter denoted as SR_1 through SR_4, respectively.

Results

The analysis begins with the uniform inflow conditions, which serve as a baseline for the subsequent sheared cases. Figure 2 illustrates the normalized time-averaged flow fields of the streamwise component of the velocity, for three representative advance ratio $\boldsymbol{J} = 0.4$, 0.5 and 0.6. These baseline cases depict the classic propeller slipstream structure, where the influence of $\boldsymbol{J}$ on the flow acceleration behind the rotor and the subsequent wake development is clearly visible. In particular, as the advance ratio increases, we notice a lower slipstream contraction, as expected.

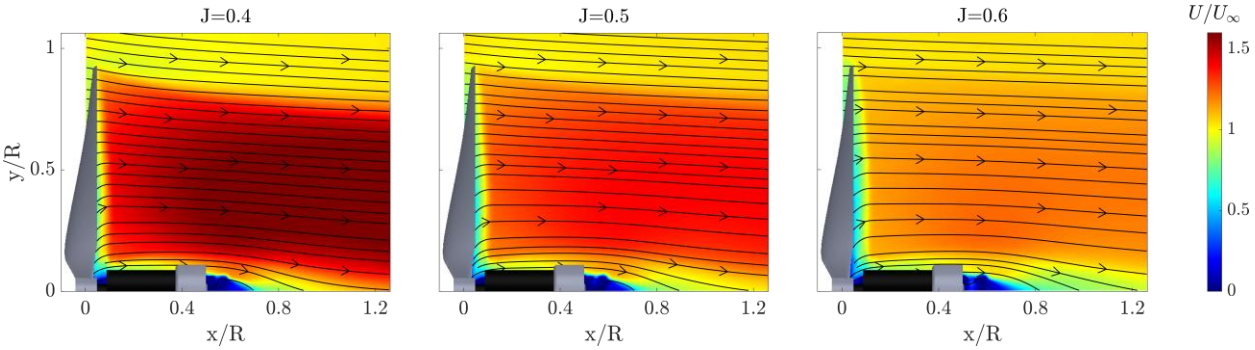

Figure 2: Time-averaged flow fields of the normalized streamwise velocity component. Cases of uniform inflow at J= 0.4, 0.5 and 0.6.

When introducing a sheared inflow, clear modifications in the wake topology are observed. This effect is highlighted in Figure 3, which displays the normalized out-of-plane vorticity (Ω_z) contours for the $J = 0.4$ case. The figure contrasts the baseline uniform inflow (a) against the four increasing shear rates, SR_1 to SR_4 (b-e). Two primary observations emerge. First, a progressive reduction in the overall vorticity magnitude is observed as the inflow shear rate increases. This distortion is an inevitable consequence of the inflow condition: a sheared flow imposes a non-uniform velocity U across the propeller disk. This, in turn, locally modifies the advance J and thus the aerodynamic loading on different sections of the blade, leading to an asymmetric and deformed wake structure.

Materials Research Proceedings 69 (2026) 707-712 https://doi.org/10.21741/9781644904251-125

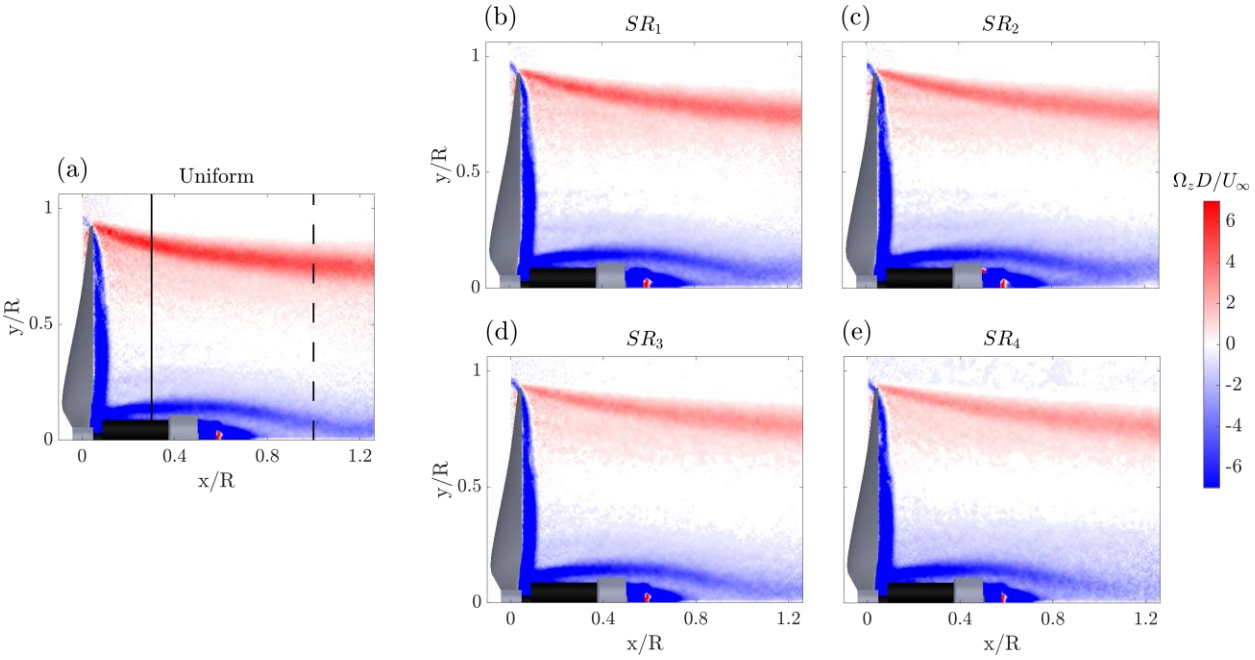

Figure 3: Time-averaged flow fields of the normalized out-of-plane vorticity $\boldsymbol{\Omega_z}$. Cases at $\boldsymbol{J = 0.4}$. (a) Uniform inflow. (b-e) Increasing sheared inflow from $\boldsymbol{SR_1}$ to $\boldsymbol{SR_4}$. The vertical solid ($\boldsymbol{x/R = 0.3}$) and dashed ($\boldsymbol{x/R = 1}$) lines in (a) indicate the reference stations selected for subsequent analysis.

To provide a more quantitative observation, Figure 4 shows the radial profiles of the normalized vorticity at the two reference stations identified by the two black lines in Figure 3(a). The results are presented for two advance ratios, $\boldsymbol{J} = 0.4$ and $\boldsymbol{J} = 0.6$. Within each plot, the solid lines refer to the station closer to the blades ($\boldsymbol{x/R} = 0.3$), while the dashed lines represent the station further downstream ($\boldsymbol{x/R} = 1$). The different colors distinguish the uniform inflow case from the four sheared conditions ($\boldsymbol{SR_1 - SR_4}$). Analyzing the near-wake station at $\boldsymbol{x/R} = 0.3$, two distinct peaks of opposite sign are evident. The negative peak at lower $\boldsymbol{y/R}$ corresponds to the mean trace of the hub vortices, which roll up near the motor, while the positive peak at higher$\boldsymbol{y/R}$ marks the mean trace of the tip vortices detaching from the blade tips and evolving along the wake. Focusing on this positive peak, it is clear that as the inflow shear rate increases, its intensity progressively decreases. Moreover, the location of the peak shifts at higher radial positions ($\boldsymbol{y/R}$), indicating an expansion of the streamtube in the analyzed region. By comparing the two plots, it is also evident that this combined effect (reduction in intensity and outward shift) is more pronounced at the lower advance ratio.

To further investigate the wake's turbulent characteristics, the velocity field is decomposed into its mean (U) and fluctuating (u') components using Reynolds decomposition. From the fluctuating parts, the Turbulent Kinetic Energy is computed as $TKE = {}^{1}/_{2}\left(\overline{u'^2} + \overline{v'^2}\right)$, considering only the measured components of the velocity fluctuations.

Materials Research Proceedings 69 (2026) 707-712 https://doi.org/10.21741/9781644904251-125

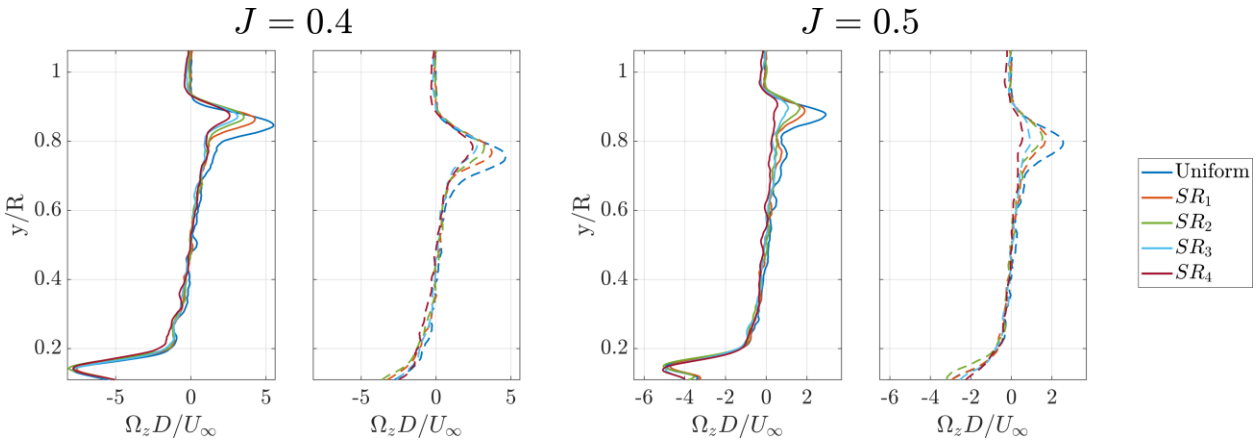

Figure 4: Radial profiles of normalized out-of-plane vorticity ($\boldsymbol{\Omega_z}$) for $\boldsymbol{J = 0.4}$ (left) and $\boldsymbol{J = 0.5}$ (right). Solid lines correspond to the near-wake station ($\boldsymbol{x/R = 0.3}$) and dashed lines to the far-wake station ($\boldsymbol{x/R = 1}$).

Figure 5 shows the radial profiles of the TKE at the same downstream stations ($x/R = 0.3$ and $x/R = 1$) and for the same advance ratios ($J = 0.4$ and $J = 0.5$) analyzed for the vorticity. A clear distinction emerges between the inflow conditions. For the uniform inflow cases, the TKE is highly concentrated, showing a sharp peak co-located with the mean tip vortex trace. This indicates that turbulence generation is primarily localized in that region. Conversely, in the presence of sheared inflow, the TKE is more diffused and spread out across the entire radial extent of the wake and is less localized in the tip region, suggesting that the incoming shear promotes a more widespread turbulence production and mixing.

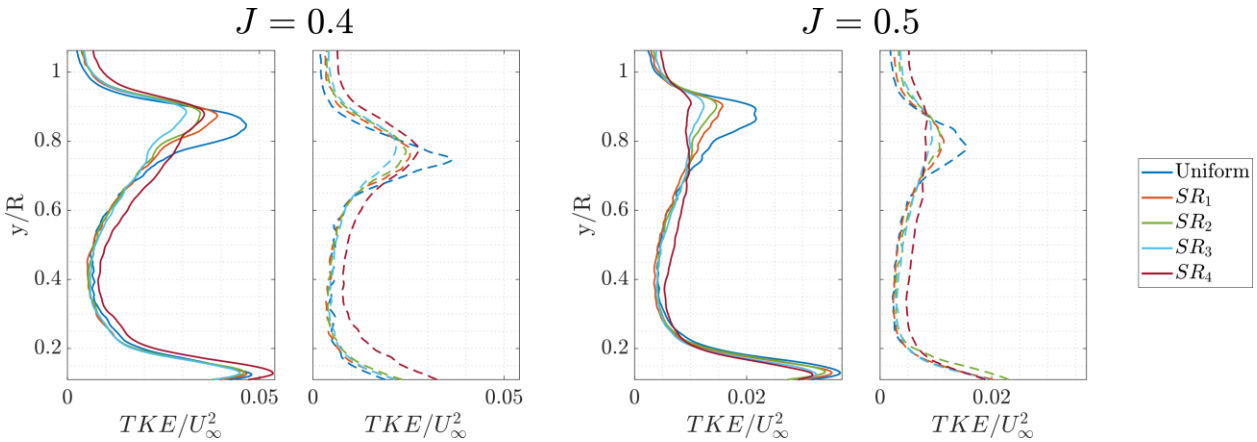

Figure 5: Radial profiles of normalized TKE for $\boldsymbol{J = 0.4}$ (left) and $\boldsymbol{J = 0.5}$ (right). Solid lines correspond to the near-wake station ($\boldsymbol{x/R = 0.3}$) and dashed lines to the far-wake station ($\boldsymbol{x/R = 1}$).

Summary and outlooks

This study presented an experimental PIV analysis of a propeller wake under both uniform and controlled sheared inflow conditions. The uniform inflow cases served as a baseline, exhibiting the expected slipstream contraction which diminished with increasing advance ratio $\boldsymbol{J}$. The introduction of a linear sheared inflow was shown to fundamentally alter the wake topology. The local changing of the operating conditions creates an asymmetric development of the wake, characterized by a reduction in the mean tip vortex vorticity and a radial expansion of the streamtube in the region under investigation. These effects are more pronounced at lower advance

ratios. Furthermore, the turbulence characteristics were significantly modified: while the TKE is highly localized in the tip vortex core for uniform flow, it becomes broadly diffused across the wake under shear, indicating enhanced turbulent mixing.

These results confirm that even in the simplest conditions of a linearly sheared inflow, the wake evolution is clearly affected, highlighting the limitations of uniform-inflow assumptions for UAM applications.

Keywords: Hydrogen Tanks, Sustainable Mobility, Aircraft Design, Composite Structure, Thermal Insulation

Abstract. Storage of liquid hydrogen in new generation aircraft is deemed crucial yet complex due to the cryogenic conditions involved. As a consequence, a multifunctional structure needs to be detailed design to meet the means of compliance for this kind of system. This paper showcases the pressure vessel design to equip a hydrogen fueled regional aircraft. The storing system is designed in detail considering different solutions. First a simplified model is used to study the trends of specific figure of merits while changing the stored mass. This shows the feasibility of the design when limited time duration is considered. Then, a high fidelity thermostructural analysis is carried out to verify local stresses and temperature of the system. Although, the capability of the pre-designed tank to withstand the operative conditions can be verified, the interlaminar stresses due to the multi-layered nature of the mechanical system become very high and need to be accommodated by a specific retaining system.

Introduction

On the way to sustainable mobility, aircraft design is experiencing a paradigm shift in the way propulsive technologies and architectures are conceived. Specifically, the new generation of aircraft requires electric powertrain to achieve net zero carbon emissions by 2050 [1]. In this context, green hydrogen is considered the energy carrier of the future as it can be conveyed to be burnt by turbofan or distributed to generate electricity to feed electric engines. However, despite the advancements in this sense, there is still a strong gap in the development of auxiliary systems which needs to be redesigned according to the new requirements.

One of the major concerns is the storing and deployment of fuel because the cryogenic temperatures play a critical role. Different possibilities in storing hydrogen are available, mostly including crystal confinement, compression and liquefaction. Among them, compressed and liquid forms can be carried on board. However, the former requires higher volumes, becoming unfeasible for flight. Instead higher energy density can be achieved in liquid form, making it attractive where weight limitations apply. However, hydrogen needs to be cooled down to extremely low temperatures until it becomes a liquid, opening a very challenge situation. As a matter of facts, improved storage methods are essential to realize the full potential of hydrogen as the new energy carrier in aviation [2]. In addition, to design appropriately hydrogen tanks, preliminary design of aircraft and its architecture need to be addressed. Afterward, the design of the tank can be performed with different degrees of fidelity [3].

There are several solutions to address these challenges, which have different strengths and drawbacks. Among these, the current paper presents the design of a multifunctional pressure vessel made of different structural and insulation layers coupled together with different solutions. Firstly, 50 passengers aircraft is preliminary conceived, returning that 492 kg of hydrogen is necessary to fulfill the considered flight mission [4]. The design carried out is then used to obtain a baseline

tank model, whose geometrical and material properties can be varied to obtain the optimal configuration

Materials and Methods

The tank concept to store liquid hydrogen is reported in Figure 1. The multifunctional composite structure consists of four main layers aiming to deal with thermal exchange (insulation layers) and load bearing (structural layers). The inner tank (1) is made of carbon fiber reinforced polymer (CFRP) is the first structural layer and contain the liquid hydrogen. An open cell insulation layer (2) made of fiber reinforce aerogel is then used as first heat flux barrier. A second CFRP layer is used to withstand loads, specifically connected. Even though the material is the same, different layup and thickness is considered for the skirt (3) and the dome (4), as different stress levels arise due to the pressure loads. A closed cell insulation layer (5) made of PolyMethylMethAcrylate foam PMMA is finally wrapped to balance the external temperature. To keep simple the analysis, the tank shape factor is kept fixed in the geometrical configuration, with the same radius for cylindrical and spherical parts and the length of the tank is equal to three times the radius of the cylinder.

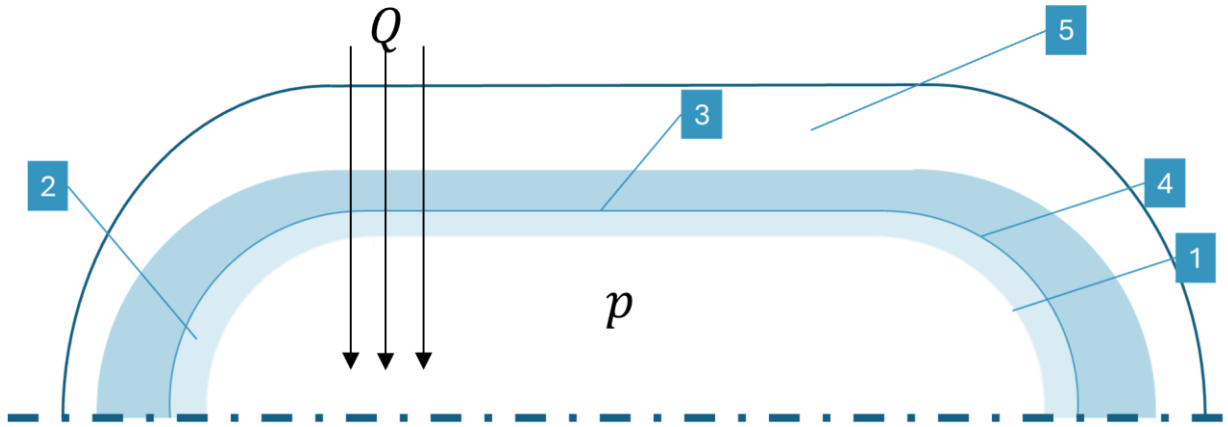

Figure 1. Preliminary LH2 Tank Configuration used for sizing.

Structural Analysis

To design the structural layers the ANSI/AIAA S-081B 2018 Standard for Space Systems Composite Overwrapped Pressure Vessels is considered to define the means of compliance. As to the static conditions, only pressure and thermal loads are accounted in this study. The Maximum Expected Operating Pressure (MEOP) is set equal to 6.5 bar with a stress safety factor equal to 2.0. The operation temperature is set as initial guess to be 218oK at layer 3-4 (flight temperature) and 90oK at layer 2. The design of the structural layers is carried out considering the temperature gradient and sizing the thickness to withstand either pressure or buckling. A carbon epoxy lamina is considered and stacked by filament winding as $[\pm 45,\pm 5,90]_s$, $[\pm 5, \pm 45, 90_3]_s$ or $[\pm 5, \pm 45, 90_2]_s$ according to the specific load. The resulting equivalent material properties are used to size the layer. The minimum thickness is obtained considering buckling due to temperature gradient

$$\sigma_{cr} = \frac{E}{3(1-\nu^2)}\left(\frac{t}{R}\right) \quad (1)$$

and limit stress along radial and longitudinal directions due to the pressure:

$$\sigma_r = \frac{pr}{2t}; \quad \sigma_l = \frac{pr}{t}; \quad (2)$$

Materials Research Proceedings 69 (2026) 713-717 https://doi.org/10.21741/9781644904251-126

Thermal Analysis

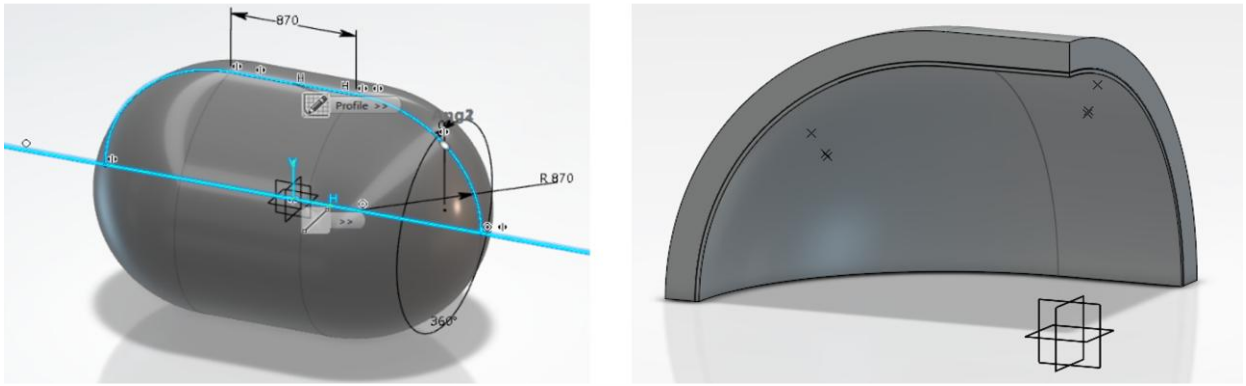
To size the insulation layers classical heat transfer mechanisms (conduction, convection, and radiation) are considered starting from the thicknesses sized through the structural configuration for the composite layers, which can be considered thermalized due to the temperatures involved. In particular, the tank system heat flux is set equal to the latent heat of vaporization of liquid hydrogen (Q = 447.60 kJ/kg), the evaporation rate is set equal to 8 kg/h, the temperature between the first insulation layer and the outer tank is set equal to 90 K, no structures acting as thermal bridges (piping, support systems, etc.) are considered. Starting from these assumptions, a first 2D modeling of the tank is made by considering its section only and omitting convective heat transfer with the external environment:

$$q = \frac{k\Delta T}{(s)}; \tag{3}$$

where k represents the thermal conductivity of the material, and (s) denotes the thickness of the layer under consideration. Afterwards a 3D Modeling is carried out heat flux was divided by the overall surface area of the structure, and the heat flux of the skirt and the dome are analyzed individually. At this stage, convective heat transfer with the external environment is also evaluated.

Thermostructural Analysis

A sequentially coupled thermostructural analysis is carried out in 3D Experience software. Only a section of the structure is considered, having in mind the simmetry of the problem, as depicted in Figure 2. The thermal analysis determine the thermal response by analyzing variables such as the temperature gradient and heat flow through time and space. The structural analysis takes the temperature map and determine the structural response by analyzing the imposed loads and temperatures.



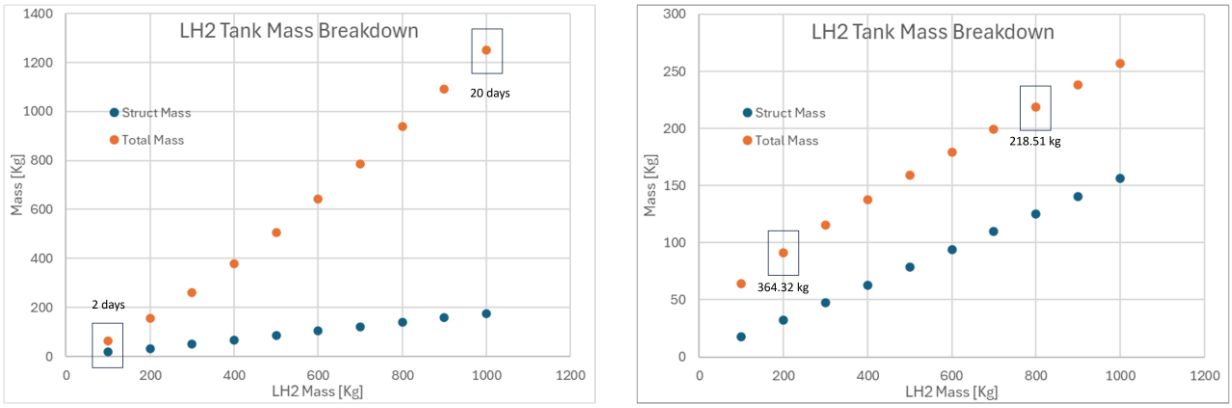


Figure 2. Virtual prototyping of the tank (left) and reduced model due to the symmetry of the problem (right).

Preliminary Sizing

The preliminary sizing carried out through the analytical framework returns a model used for the weight assessment of the whole system including thermal management and load bearing components (see Figure 3). Despite it returns qualitative results, the preliminary sizing shows shows relevant trends when increasing hydrogen volume. In particular, considering constant evaporation time rather than constant evaporation rate returns a feasible mass, which does not diverge while increasing hydrogen mass. In addition, it is important to maximize the volume and the ratio between volume and length (i.e.: using minimum number of tanks possible) to reduce weight and overall volume needed. Having in mind 800 Kg of hydrogen would require 218.51 Kg for a single tank configuration or 364.32 Kg for a 4 tank configuration.

Materials Research Proceedings 69 (2026) 713-717 https://doi.org/10.21741/9781644904251-126

(a) (b)

Figure 3. Mass breakdown of the tank obtained varying the liquid hydrogen mass under constant evaporation rate (a) and constant evaporation time (b).

High Fidelity Simulation

The high-fidelity analysis explored various design alternatives to optimize performance while connecting different layers at the interface. The thermal analysis confirmed the model's validity, showing that the temperature gradient and heat fluxes align with expectations and that the selected materials effectively maintain cryogenic conditions. Instead, structural results are affected by the interlaminar shear stresses and deformations arising between insulation and structural layers. The high deformation of the insulation materials, whose effect is neglected in the preliminary sizing, increases loads returing severe stresses at the structural layers, particularly at the outer dome. Thickening the structural layers reduced maximum stresses by 58.5%, ensuring they remained below the compression allowables for CFRP, but increased weight (142 kg to 287 kg). Despite the weight can be reduced resorting to stiffeners instead of increased thickness, the shear interlaminar stresses still remain high, resulting in unfeasible connection between structural and insulation layers, which requires for structural supports between inner and outer tank.

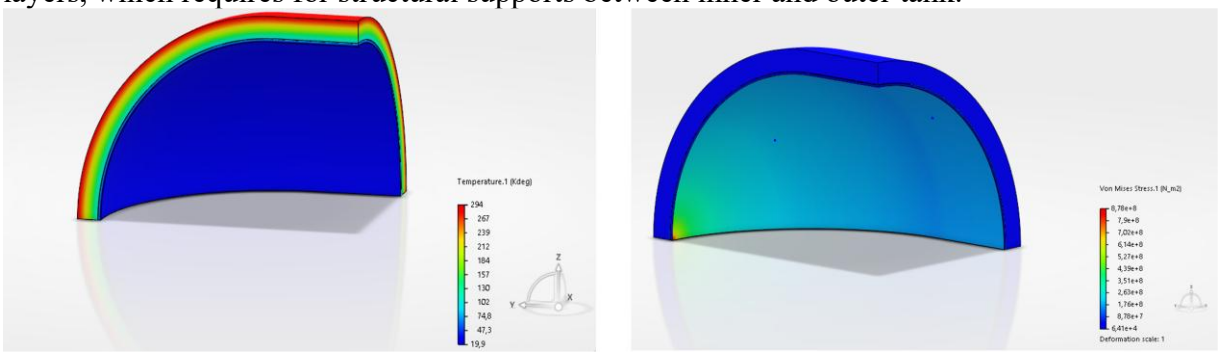

Figure 4. Temperature (left) and stress (right) distribution all over the tank due to hydrogen storage.

Conclusions

This paper showcases the pressure vessel design to equip a hydrogen fueled regional aircraft. Starting from a multi-disciplinary analysis and optimization of the air vehicle according the top level aircraft requirements, the hydrogen storing system is designed in detail considering different solutions. A further analysis shows the necessity to account the weight of the system versus its volume/surface ratio as a key parameter for preliminary design of such systems. In addition, the ratio between the actual volume of the tank and the volume of the hydrogen can give an overview of the system efficiency once the hydrogen rate is set to have a specific hydrogen duration. As a final study, a high fidelity multidisciplinary analysis is carried out to verify local stresses and

temperature of the system to validate the capability of the tank to withstand the operative conditions. Specifically, this last investigation shows the critical role of interlaminar stresses due to the multi-layered nature of the mechanical system.

Configuration Analysis and Impeller Design for an Oxidizer Pump in Small Liquid Rocket Engines

Miłosz KOZYCZ[1]

[1]University of Science and Technology in Wrocław, Wrocław, Poland

miloszkozycz@gmail.com

Keywords: Oxidizer Pump, Liquid Propulsion, Sounding Rockets, Turbomachinery, CFD

Abstract. This article presents the design of an oxidizer pump impeller for experimental sounding rockets, based on the NOVA engine developed by the Scientific Student Association PWr in Space. The proposed methodology is applicable to other liquid-propelled engines in the 3–15 kN thrust range. The working fluid is nitrous oxide (N_2O), whose thermodynamic properties pose specific design challenges discussed in the paper. The model can also be adapted for other oxidizers, such as liquid oxygen (LOX). The paper begins with a comparison of engine cycles based on system mass and complexity, followed by an analytical impeller design approach grounded in established literature. Numerical validation was conducted using ANSYS Fluent and the BEM supercomputer at Wrocław University of Science and Technology. The study investigates optimal operating conditions, including pump operating parameters, selection of working fluid properties, and evaluation of pump-fed system influence on the total propulsion unit mass. An analytical procedure for impeller geometry design is proposed based on technical references. After defining the preliminary impeller geometry, further analysis focused on optimising selected parameters such as hydraulic efficiency, pressure head, and cavitation risk. The combination of analytical and CFD methods provides a foundation for the development of efficient oxidizer pump impellers. The findings are particularly relevant for small-scale, low-cost propulsion systems, where N_2O is often overlooked in favour of LOX.

Introduction

Pumps are rarely used in experimental sounding rockets, as their apogees are often limited to 10 km. However, for rockets targeting higher altitudes, where engines must deliver over 60,000 Ns of total impulse, their use becomes justified (see Section: System Configuration).

The pump was designed for the NOVA engine — a bipropellant liquid rocket engine developed in 2025 by the Student Scientific Association PWr in Space. The first version delivered 3.5,kN thrust and a specific impulse of approximately 16 000 Ns, using nitrous oxide and ethanol as propellants.

A new conceptual version of NOVA, intended for missions exceeding 20 km, required increased thrust and specific impulse. Design assumptions for the updated engine include estimated thrust of 5 kN, with N_2O mass flow rate of 2 kg/s and ethanol flow rate of 0.5 kg/s.

This paper presents the design process of an oxidizer pump impeller for NOVA, serving as a reference for small-thrust liquid engines in sounding rockets. It focuses on two main aspects: pump cycle configuration (as the rationale for pump use), and the impeller hydraulic design process, considered the most critical pump subsystem element. Structural design and material strength analysis are beyond the scope of this work.

System configuration

In rocket propulsion systems, several cycles involve pumps. Some of them are too complex to be considered at the initial stage of the project. After preliminary analysis, the following cycles were

Content from this work may be used under the terms of the Creative Commons Attribution 3.0 license. Any further distribution of this work must maintain attribution to the author(s) and the title of the work, journal citation and DOI. Published under license by Materials Research Forum LLC.

Materials Research Proceedings 69 (2026) 718-723 https://doi.org/10.21741/9781644904251-127

selected: pressure-fed (nitrogen as pressurant), oxidizer and fuel pump, and oxidizer pump with fuel pressurized by nitrogen.

In pump-based cycles, the pump was treated as an independent component; the type of pump power supply was not analysed here. According to [2], several engine work cycles can be identified. A comparison between turbine- and motor-driven pumps, as well as turbine based engine cycles, is beyond the scope of this paper. To simplify the analysis, the pump is assumed to be driven by an electric motor. The combined mass of the pump and motor was estimated at 12 kg for inertia calculations.

To estimate cycle efficiency, basic calculations were performed for pump parameters and propulsion subsystem mass. A simplified analytical model was prepared to justify the use of a pump for the oxidizer (and possibly also for the fuel). The model includes the mass of propellants, pressurant (nitrogen), pressure vessels, and tank structural components. Wall thicknesses were calculated according to [7].

Figure 1 compares system mass across three configurations: pressure-fed, oxidizer pump only, and both pumps.

The results clearly show that at higher total impulse, pump-fed cycles become more favourable. Therefore, since the second version of NOVA engine is intended for higher impulse missions, the pressure-fed configuration will not be further considered.

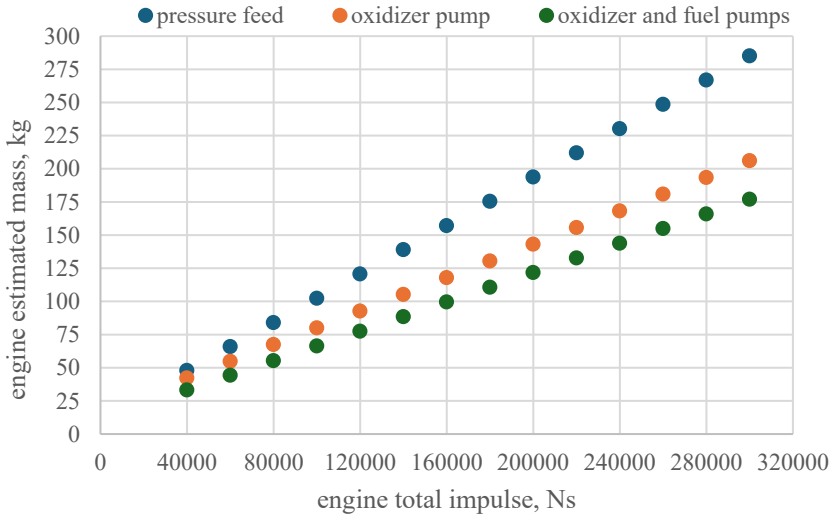

Figure 1: Estimated mass of propulsion system for three considered engine cycle configurations

The specific speed of pump n_q was calculated from formula 1

$$n_q = \frac{n \cdot \sqrt{\frac{Q}{k}}}{\left(\frac{H}{i}\right)^{\frac{3}{4}}} \tag{1}$$

Where: n_q-specific speed of pump, , n-rotation speed, Q-volumetric flow rate, H-total pressure head, k-number of channels, i-number of stages.

According to [5], the recommended range of specific speed values for centrifugal pumps with single-curved blades is between 15 and 30. Therefore, different pump configurations were compared based on their specific speed values. The considered options included single-stage and multi-stage pumps for both oxidizer and fuel, as well as the use of a pressurant gas for the fuel system. Ultimately, due to its lower complexity, a single-stage pump was selected as the most suitable option for the oxidizer. In contrast, designing a single-stage fuel pump is challenging due to the low flow rates involved, which typically necessitates a multi-stage configuration. This article

Materials Research Proceedings 69 (2026) 718-723 https://doi.org/10.21741/9781644904251-127

focuses primarily on the design of the impeller for the oxidizer pump; therefore, further analysis of the fuel pump is not included. However, for small-scale rocket engines, both multi-stage fuel pumps and pressurized fuel systems are viable options. If the manufacturing cost and complexity of a multi-stage pump are acceptable, it offers a more favourable solution from a mass balance perspective. For the oxidizer pump, the operating parameters were assumed, and the corresponding specific speed was calculated, from formula (1) for parameters listed below:

$$n = 35000\ RPM, Q = 0.0019\frac{m^3}{s}, i = 1, k = 1, H = 331m$$

As a result of iterative calculations, final value of specific speed, calculated from listed parameters is: $n_q = 19.43$.

Design methodology for an Impeller

Impeller geometry was based mostly on analytical code according [3] and [4].

Table 1presents the dimensions of the impeller, where: d_s – shaft diameter, d_{in} – inlet diameter. Other parameters follow the nomenclature presented in [3] and [4].

Table 1: Impeller dimensions

$d_s,[mm]$	$d_{in},[mm]$	$d_h,[mm]$	$d_1,[mm]$	$d_2,[mm]$	$b_1,[mm]$	$b_2,[mm]$
8	26.4	15	22	48	6	2

The blade was designed according to the point method [4].

The impeller geometry, represented as a 3D model, is shown in Figure 2.

The impeller geometry, represented as a 3D model and schema of meridional section of an impeller with marked the most significant dimensions are shown in Figure 2.

Numerical Calculation of Impeller Parameters

To verify velocity ranges and determine impeller performance, CFD simulations were conducted using Ansys Fluent 2023 R1. The Realizable *k-ε* turbulence model was applied, and the impeller region was modeled using the Moving Reference Frame (MRF) approach as the cell zone condition.

Boundary conditions were defined as follows: pressure inlet (Dirichlet) and mass flow rate outlet (Neumann). The Coupled algorithm was used as the solution method.

The simulations were carried out for four rotational speeds: 25,000; 30,000; 35,000; and 40,000 RPM. For each case, the pressure head H and hydraulic efficiency η_h were calculated.

The results of these calculations are presented in Table 2.

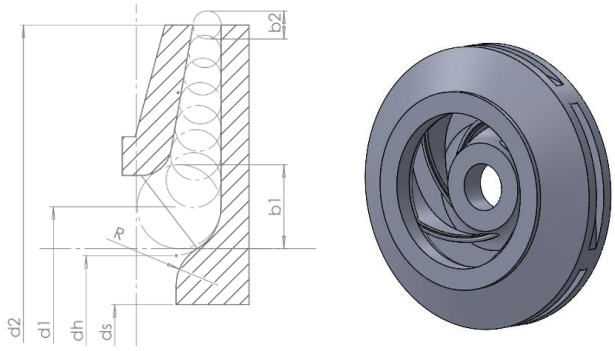

Figure 2: geometry of impeller, meridional section schema and 3D model

Materials Research Proceedings 69 (2026) 718-723 https://doi.org/10.21741/9781644904251-127

Table 2: Impeller parameters for different rotation speed

n	H	η_h
$[RMP]$	$[m]$	-
25000	167	0.82
30000	277	0.82
35000	422	0.82
40000	581	0.80

The highest hydraulic efficiency was observed at 35,000 and 40,000 RPM. However, 35,000 RPM was selected as the target rotational speed due to its proximity to the assumed pressure head value of $H_t = 331$ m.

Impeller parametric optimization

The current iteration of the impeller geometry revealed several areas with potential for improvement. The optimisation process focused on three main objectives: minimising regions susceptible to cavitation (defined as areas where the static pressure drops below the boiling pressure of nitrous oxide), enhancing hydraulic efficiency, and ensuring the required pressure head is achieved. The optimisation was conducted as a three-factor experimental design, with the selected variables being the inlet blade angle β_1, outlet blade angle β_2, and inlet region fillet radius R.

In order to reduce the number of geometry models, the range of selected factors was limited. As a result, the experimental plan was based on 18 different impeller geometries, divided into groups. The values of the considered factors are presented in Table 3. Each geometry was subjected to both qualitative and quantitative analysis. The qualitative analysis focused on identifying regions with potential cavitation risk, while the quantitative analysis included evaluation of impeller hydraulic efficiency and pressure head.

CFD results for impeller models.

Cavitation may occur in regions where the static pressure falls below the boiling pressure of nitrous oxide at the given temperature. The static pressure distributions for the selected impeller iterations are presented in Figure 3, showing the best-performing geometry in terms of cavitation risk from each group (iterations 1, 4, 8, 11, 14, and 16).

The results indicate that the impellers from group 5 (in particular, impeller 14) exhibit the smallest cavitation-prone areas on the blade surface. Conversely, the worst performance in this regard was observed for impellers from group 3 (impellers 8 and 11), which show significantly larger regions where cavitation may occur.

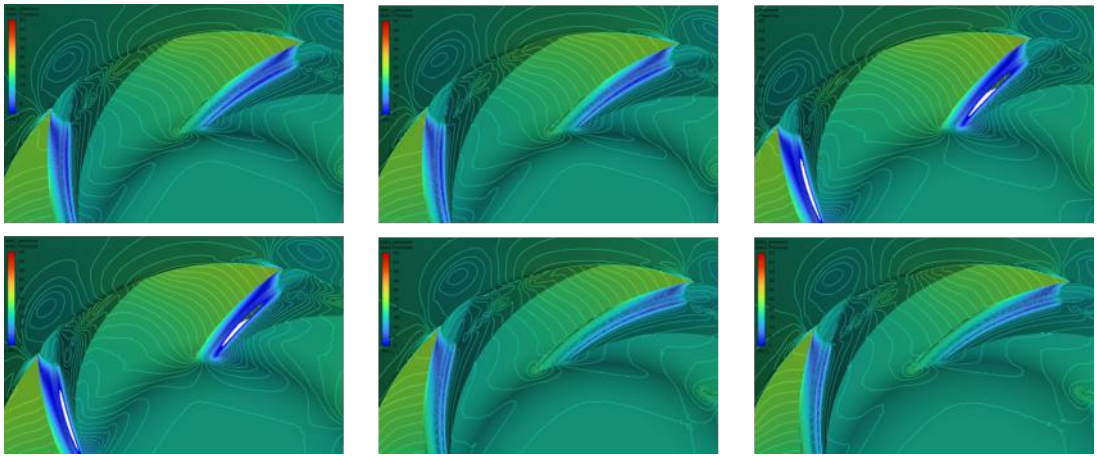

Figure 3: Static pressure on impeller blade for best cases in each group

Materials Research Proceedings 69 (2026) 718-723 https://doi.org/10.21741/9781644904251-127

The values of pressure head, mechanical efficiency, and hydraulic efficiency for all geometry iterations are presented in Table 3. From the perspective of pressure head, the best-performing impellers are iterations 2 and 3. In terms of efficiency, impellers 2 and 3 also achieve the highest values, although impellers from groups 5 and 6 demonstrate comparable performance.

Conclusions

From the quantitative perspective, the best-performing impellers are iterations 2 and 3. However, impellers from groups 5 and 6 show comparable results. Considering that, from the qualitative perspective, impellers from group 5 exhibit the lowest cavitation risk, they should be considered the most suitable option for the current configuration.

Further research will focus on validating the impeller geometry using a two-phase flow model and experimental verification. In the long term, the impeller is planned to be implemented in the pump of the second iteration of the NOVA engine, intended for higher-apogee flights.

Table 3: Impeller geometry variants with CFD results: hydraulic efficiency, pressure head and minimal static pressure

Iteration number	β_1, [°]	β_2, [°]	R, [mm]	Iteration group	η_h [mm]	H, [m]	p_{min}, [bar]

Keywords: Turbomachinery, Multi-Objective Optimization, Kolmogorov-Arnold Networks

Abstract. This work presents an AI-driven framework for the inverse and constrained design of turbine blade sections, aimed at accelerating early-stage aerodynamic optimization. The methodology integrates automated database generation, surrogate modeling, and constrained multi-objective optimization within a unified process. A large set of high-Reynolds-number 2D uncooled blades is automatically generated and simulated through an in-house workflow, providing physically consistent data for model training. Kolmogorov–Arnold Networks are employed as surrogate models to establish a direct mapping between the aerodynamic duty parameters and the corresponding blade geometries and performance indicators. The surrogates are tuned through the Optuna optimization framework to ensure accuracy and robustness over the design space. Once trained, the models are coupled with a constrained optimization environment to identify the Pareto front between kinetic-energy losses and aero- dynamic loading while satisfying geometric feasibility requirements. The resulting framework enables rapid and physically informed exploration of turbine design alternatives without iterative CFD computations, offering a general and reproducible methodology for data-driven aerodynamic design.

Introduction

Conventional turbomachinery design follows an iterative, CFD-centered loop in which blades are iteratively modified and simulated. Although effective, this workflow is slow and computationally expensive, and success depends heavily on designer intuition. Early concepts often neglect physics that dominate performance, such as tip leakage, secondary and 3D flow structures, boundary layer development, and shock/boundary layer interaction, requiring expensive redesigns even in preliminary phases. Reliable early prediction of aerodynamic quantities and flow features is therefore essential to explore the design space broadly, preserve physical realism, and assess concepts before high-fidelity campaigns. Recent work integrates Machine Learning to accelerate aerodynamic design. Clark's [1] inverse design with radial basis functions maps the so-called aerodynamic duty/style to geometry for rapid, accurate profile generation. Bellucci et al. [2] couple automated CFD databases with Artificial Neural Networks (ANN) surrogates to include unsteady effects and deliver real-time performance and flow predictions. Petronio et al. [3] use Gaussian Process (GP) regression with Proper Orthogonal Decomposition (POD) to target informative samples, cutting CFD while accurately predicting losses and loading. Chen et al. [4] combine deep learning with multi-output GPs to automatically infer optimal turbine geometries without iterative optimization. Despite progress, broad adoption of AI in turbomachinery is limited by fragmented, case-specific workflows and the lack of a general, validated process for building, training, and testing models, especially for early-stage constrained design. This work addresses these gaps with a unified framework that systematizes database construction, model training/optimization, analysis, and constrained optimization. A physically consistent database spanning the aerodynamic design space is first constructed, after which machine-learning surrogates are trained and tuned to predict geometry and performances. The surrogates are then embedded in a constrained,

multi-objective optimization, where model predictions of shapes and performance guide the search to satisfy target cost functions and feasibility requirements.

Numerical Methods

The workflow used to build the high Reynolds 2D uncooled blades database comprises three automated stages: blade geometry parametrization, target features definition, and flow computation and post-processing. Blade shapes are generated by combining a smooth camberline definition with a flexible thickness law. The camber line is represented by a 4th-order B-spline (five control points), ensuring up to C_3 continuity with low dimensionality. Its four design parameters are the inlet metal angle χ_1, the outlet metal angle χ_2, the x-location of the camber-line maximum x_p, and the value of the maximum y_p.

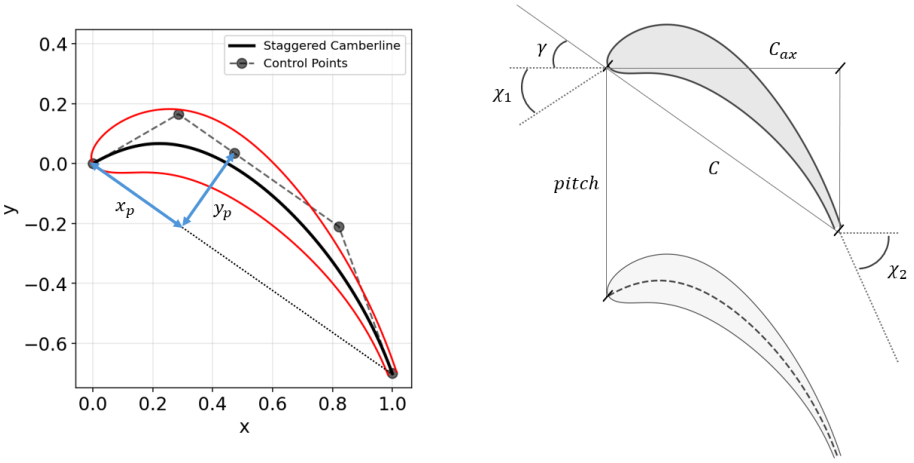

Figure 1: Camberline parametrization through 4-th order B-Spline using 5 control points.

The B-spline camber line is defined as follows:

$$\mathcal{C}(u) = \sum_{i=0}^{n} N_{i,p}(u)\mathcal{P}_i \tag{1}$$

where $p = 4$ is the degree, $N_{i,p}$ are the B-spline basis functions, and $\mathcal{P}_i$ are the control points. Thickness is modeled with Kulfan's modes [5]. Along the normalized chord $\psi \in [0, 1]$, the thickness distribution $\zeta(\psi)$ is:

$$\zeta(\psi) = C_{N_2}^{N_1}(\psi) \sum_{i=0}^{n} A_i \; S_{i,n}(\psi) \qquad S_{i,n}(\psi) = \binom{n}{i} \psi^i (1-\psi)^{n-i} \tag{2}$$

$$C_{N_2}^{N_1}(\psi) = \psi^{N_1}(1-\psi)^{N_2} \qquad \zeta_{TE}(\psi) = \psi \frac{R_{TE}}{c} \qquad R_{LE} = \frac{A_0^2 \, c}{2} \tag{3}$$

The coefficients N_1 and N_2 were set to 0.5 and 1, respectively, to generate a round leading edge and a pointed trailing edge, consistent with Kulfan's formulation. The first Kulfan's mode controls the leading-edge radius, while the last mode sets the wedge angle; coefficients can differ between suction and pressure sides for added flexibility. The final blade surface is obtained by superposing the thickness on the camber line along the local normal $\mathrm{n} = (\mathrm{n_x}, \mathrm{n_y})$. This parametrization achieves smooth, high-quality airfoils with limited parameters, enabling efficient exploration of large and diverse design spaces and supporting robust optimization and database generation. Blade design targets are defined through a combination of aerodynamic duty and aerodynamic style. The aerodynamic duty specifies boundary conditions: inlet flow angle α_1, outlet flow angle α_2, and

Materials Research Proceedings 69 (2026) 724-729 https://doi.org/10.21741/9781644904251-128

outlet Mach number M_2. The outlet Reynolds number Re_2 is derived from the inlet axial Reynolds number $Re_{1,ax}$, while specific heat coefficient γ and axial-velocity-density-ratio (AVDR) remain constant (respectively 1.4 and 1). The aerodynamic style parametrizes the surface Mach distributions using four control variables, namely the ratio of peak suction-side Mach to outlet Mach (M_{peak}), axial position of peak Mach on suction side (L_{peak}), the ratio of leading-edge pressure-side Mach to outlet Mach number (M_{ps}) and the ratio of leading-edge suction-side Mach to outlet Mach number (M_{ss}). Surface isentropic Mach numbers are normalized by the trailing-edge value (M/M_{te}) and plotted against non-dimensional surface length (L/L_{surf}) for better control over loading characteristics.

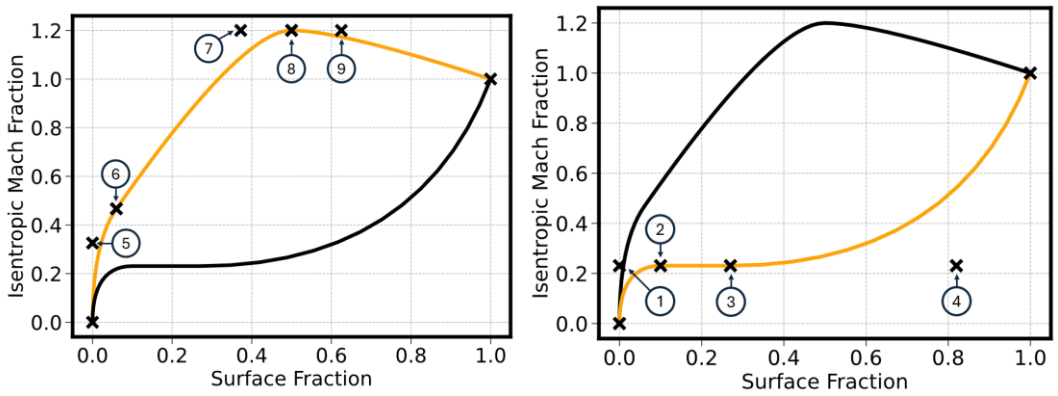

Figure 2: Loading parametrization for suction (left) and pressure (right) side.

The distributions are designed using a combination of linear functions and B-splines to ensure smoothness and derivability. The target Mach distribution and outlet flow angle guide the shape optimization process, aiming to align the real blade performance with the target input requirements. Flow computations are performed using MISES (Multiple blades Interacting Streamtube Euler Solver) [8] to obtain real flow angles and Mach distributions along blade surfaces. Boundary conditions include inlet flow angle, inlet axial Reynolds number, and outlet Mach number, with the real outlet Mach driven toward the target value. Turbulence intensity is fixed at 3.5\% with boundary layer tripping at 3\% axial chord, ensuring fully turbulent simulations throughout the design space. All simulations were executed on a dual-socket AMD EPYC 7551 machine. A single simulation required approximately 0.5 s of wall-clock time on a single CPU core. A total of 128 cores were used in parallel for the database creation of ~ 30.000 points over the course of 15 days.

Kolmogorov-Arnold Networks based model

A fast surrogate is developed to predict, with minimal cost, both blade-section geometries and key aerodynamic outputs for 2D, uncooled, high–Reynolds number profiles. The model delivers accurate estimates of kinetic-energy losses, Mach number distributions, outlet flow angles, and tangential force coefficient, enabling rapid screening of candidates and broad exploration of the design space in place of repeated CFD runs. The surrogate is built with Kolmogorov–Arnold Networks (KAN) [6], inspired by the Kolmogorov–Arnold representation theorem, which expresses multivariate functions as compositions of univariate functions and additions. Unlike Multi Layer Perceptron (MLP) that use fixed neuron activations, KAN employs learnable, edge-based activation functions parameterized by B-spline polynomials. These features provide fast, accurate predictions and immediate insight into geometry–performance couplings, accelerating early-stage turbomachinery design.

Materials Research Proceedings 69 (2026) 724-729 https://doi.org/10.21741/9781644904251-128

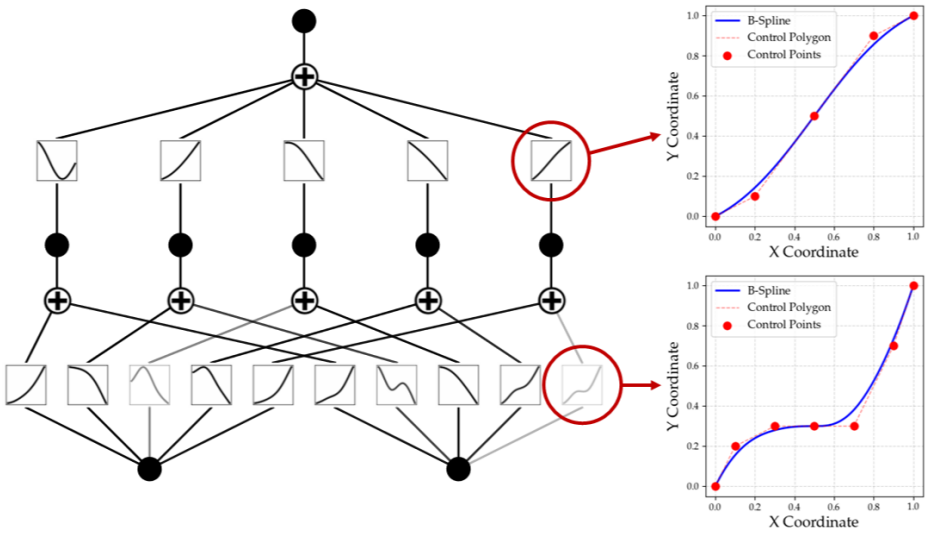

Figure 3: Example of KAN, with an highlight of the parametrization of the B-splines.

An initial trial-and-error sweep highlighted strong sensitivity to first-layer edge count, B-spline order k, number of multiplication subnodes, grid uniformity/size, and training steps; deeper networks frequently degraded performance, so a single-layer KAN was adopted. Four separate models were trained to predict: blade geometry, Mach RMS, outlet-angle error, and kinetic-energy loss. Hyperparameters were optimized with Optuna [7], while training employed Adaptive Moment Estimation (ADAM) with a learning rate set within the range $\in (0.0001, 0.005)$ and a spline grid size of 5. Validation monitoring indicated convergence after ~ 100 iterations. Compared with the initial setup, the optimized KAN markedly improved accuracy.

Constrained Optimization

In the following section, the framework for the constrained optimization is described. The trained models are used to predict the turbine's kinetic energy loss coefficient ξ and the tangential force coefficient C_y, which measures the circumferential turning effect of the cascade. The design target is defined by selecting the aerodynamic duty coefficients (α_1, α_2, M_2 and Re). The Pareto front is found by varying the aerodynamic style, defined by the aforementioned parameters M_{peak}, L_{peak}, M_{ss}, and M_{ps},. Additional geometric constraints can be introduced to control the blade design.

Materials Research Proceedings 69 (2026) 724-729 https://doi.org/10.21741/9781644904251-128

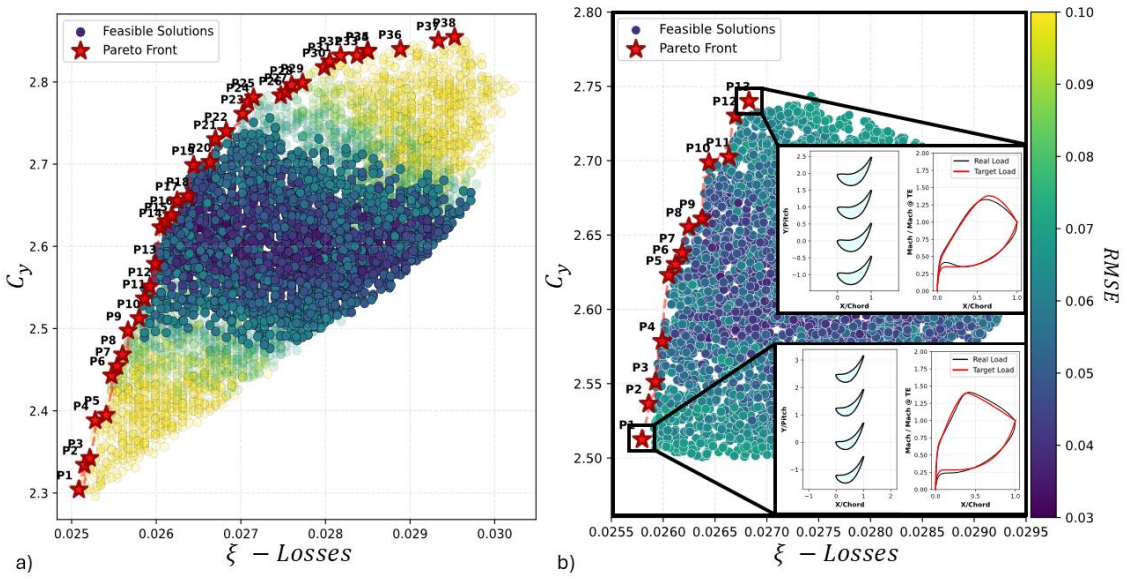

Figure 4: Tangential force coefficient versus kinetic energy loss coefficient. Figure (a) illustrates the entire population of solutions, while Figure (b) highlights the feasible subset with an RMSE below 0.06.

The optimization process was conducted with two objectives: minimizing the kinetic energy loss coefficient ξ while simultaneously maximizing the coefficient C_y. The example case study features to the following aerodynamic conditions: $\alpha_1 = -30°$, $\alpha_2 = 65°$ and $M_2 = 0.5$. The geometrical model was employed to rapidly populate the design space, while the performance models were used to evaluate each configuration in terms of loss characteristics and tangential force coefficient. However, the model exhibited difficulties in certain regions of the design space, leading to predictions that were not fully accurate or reliable. To assess and control these discrepancies, the root mean square error (RMSE) between the actual and target aerodynamic load distributions was evaluated. An acceptable threshold of 0.06 was defined in order to ensure that the predicted blade geometries remained physically consistent and representative of realistic performance. Figure 4.b presents the distribution of the acceptable solutions, highlighting the two extreme configurations. The results emphasize the evident trade-off between aerodynamic efficiency and blade loading.

Conclusions

A unified, automated framework for early-stage turbomachinery blade design is presented, integrating a physics-consistent database built through an automated workflow. The database (~30.000 2D high-Re uncooled blades) supports training of Kolmogorov-Arnold Network-based surrogate models that, after hyperparameter tuning, achieve accuracy sufficient to guide optimization at negligible evaluation cost. These models are integrated within an optimization framework to identify the optimal trade-off between minimizing kinetic energy losses and maximizing blade loading, while ensuring geometric feasibility (e.g., pitch-to-chord ratio and area constraints). An example case is discussed for operating conditions $\alpha_1 = -30°$, $\alpha_2 = 65°$ and $M_2 = 0.5$. The proposed AI-driven methodology enables reliable, CFD-free inverse and constrained aerodynamic design. The surrogates capture the nonlinear coupling between geometry and performance, reproducing the trade-off between efficiency and loading while preserving physical and geometric consistency. As a result, the proposed framework offers a fast, robust, and flexible solution for concept-level turbine design and provides a solid foundation for future extensions to fully three-dimensional and unsteady configurations.

Keywords: Electrification, Batteries, Virtual Design, Scale-Resolved Simulation, Firedrake

Abstract. The decarbonization of the civil aviation sector is a challenging task which relies heavily on electrification. Independent of the concept and amount of electrification, e.g. more electric aircrafts (MEA) or even fully electric propulsion systems, the battery plays an important role. The latter are often criticized to be immature in terms of gravimetric energy density. But even if a high-energy cell with a value exceeding 750 Wh/kg on the pack level would be available [1], it is not guaranteed to fulfill corresponding power requirements. Batteries suffer from an energy-power-dilemma and, hence, call for design and optimization of the electrode structure. Inspired by the success of scale-resolved simulations for design and optimization in conventional jet engines, we present a scale-resolved methodology for batteries. The toolbox' potential to increase battery performance is showcased for a Lithium-Sulfur cell. The aforementioned chemistry is broadly anticipated as promising candidate for aerospace applications due to the exceptional high gravimetric energy density.

Introduction

Civil aviation is considered as part of the hard to abate sector [2]. Hence, several parallel technological routes are explored to reach decarbonization and emission goals set by regulatory frameworks [3]. On the commercially established side of the spectrum, optimized combustion-based propulsion is progressed, whereas on the other prospective side of the spectrum electric propulsion is under development.

For the first route it is broadly acknowledged that scale-resolved simulations, i.e. large eddy simulations (LES) [4,5], give invaluable insights to reach the full potential of novel technological adaptions. This concerns immediate short-term improvements through better flow understanding and control, e.g. [6,7], or potential long-term solutions based on sustainable fuels like hydrogen, even requiring a re-design of the injector [8,9]. These recent examples are also supported by the number of R&D codes with industrial relevance available in the community, e.g. AVBP, OpenFOAM, PRECISE-UNS, YALES2 and many more [10].

The second, perspectively more sustainable route of electric propulsion is currently approached by several hybridization concepts that usually involve batteries as key enablers [2,3]. This holds

Materials Research Proceedings 69 (2026) 730-734 https://doi.org/10.21741/9781644904251-129

independent of the amount of electrification, from more electric aircrafts (MEA) to all electric aircrafts eventually. However, batteries are often criticized in the aerospace context to be immature because of their inherent energy-power-dilemma, i.e. high-energy cells suffer from insufficient power output and vice versa. Considering this battery bottleneck, which physically is an optimization problem of a multiscale reactor somewhat comparable to the traditional combustor, it is indeed surprising that scale-resolved simulations have much lower significance. The only R&D codes we are aware of are BEST/BLIR [11] and 4C [12].

Motivated by this deficiency and the potential to support aerospace electrification, we developed a performant, scale-resolving framework for Lithium-Sulfur batteries based on the open source solver Firedrake [13,14]. The aforementioned batteries are anticipated as a promising candidate for aerospace applications due to the exceptional high gravimetric energy density of 750 Wh/kg on pack level [1]. In [15], the framework was developed for traditional carbon-sulfur (C-S) composite cathodes, which lack significant power capability due to sluggish reaction kinetics. Here, we will show preliminary results for a polymeric cathode material, i.e. sulfurized polyacrylonitrile (SPAN), which eradicates these performance bottlenecks even without optimization measures derived from scale-resolved simulations, holing an untapped optimization potential.

Methods & Results

Our goal is to describe and optimize SPAN pouch cells currently under development in the BMFTR funded project SulForFlight (No. 03XP0491). The current rate performance on pouch cell level is shown and compared in Fig. 1 (a) to a traditional C-S system with similar sulfur loading and an idealized Li-Ion cell of a Boeing 787 MEA [16,17]. Obviously, the overall material system has a large influence on the energy-power-dilemma and the natural question is whether the slope of the SPAN cell, resulting from kinetic limitations at higher currents, can be flattened by structural design.

Therefore, we developed a coarse-grained continuum model (LES-like as in [15]) of the SPAN pouch cell that will be detailed elsewhere. Essentially, it physically describes electric charge and species mass transfer (i) in the SPAN cathode, (ii) in the novel electrolyte system and (iii) at the pristine Lithium anode interface. The developed base reaction scheme from [18] was slightly adapted (Fig. 1 (b)) and eventually, yet consistently, reduced to a one-step reaction

$$\frac{1}{6}\,\mathrm{PAN-S_4-PAN\,(S)} + \mathrm{Li^+\,(L)} + e^-\,\mathrm{(S)} = \frac{1}{3}\,\mathrm{PAN-S-Li\,(S)} + \frac{1}{3}\,\mathrm{Li_2S\,(S)}\,. \qquad (1)$$

This reduction to a one-step scheme allows us to construct a model, which in spirit very similar to usual Li-Ion battery models. The numerical solution is then obtained using Firedrake after discretization with a Discontinuous Galerkin (DG) approach and an implicit Euler time-stepping, which is embedded into a naive feedback controller [15]. Moreover, the resulting coarse-grained continuum model is calibrated by means of a fully homogenized 1D model (red lines) and experimental pouch cell data (grey lines) for discharge profiles as shown in Fig. 1 (c) with a near to perfect match. This is possible under species diffusion dominant scaling conditions [15,19].

Materials Research Proceedings 69 (2026) 730-734 https://doi.org/10.21741/9781644904251-129

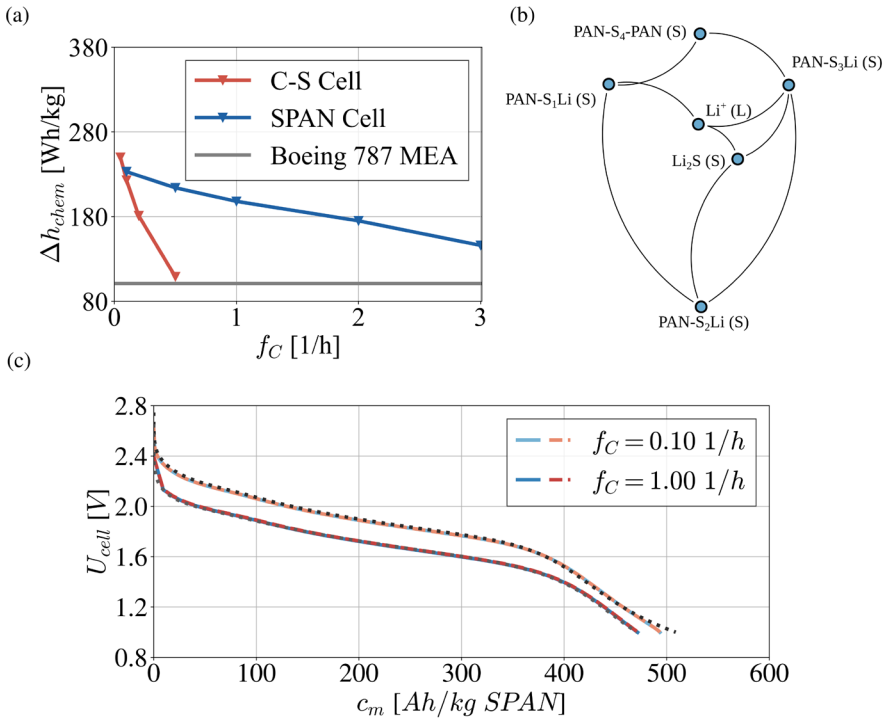

Figure 1: a) Rate performance comparison measured in gravimetric energy density over C-rate, (b) Considered base reaction mechanism for SPAN, (c) Discharge profiles for different C-rates measured in cell potential over discharge capacity.

Based on the resulting parametrization, 3D scale-resolved simulations (blue lines in Fig. 1 (c)) at the same operating conditions were performed. The underlying cathode structure was obtained from a computed tomography (CT) scan with a resolution of 0.6 µm and is highlighted in Fig. 2. The resulting discharge curves verify a posteriori that the assumption of species diffusion dominance on the coarse-graining scale above was justified. This manifests in an expected match of the global characteristics. Naturally, however, it prompts the question why one should perform such costly 3D simulations? A rather intuitive point can be made by looking at the Lithium distribution in the cathode material at the end of discharge (Fig. 2) for a C-rate of $f_C = 1.00\ 1/h$. Even if global characteristics between scale-resolved 3D models and fully homogenized 1D models are identical, the statistical information of inhomogeneous distributions are lost in 1D models by construction. This is not only relevant for degradation phenomena but also the reason why at higher currents, beyond the considered calibration range, fully homogenized 1D models are certain to give wrong predictions as the 3D structure starts to matter [15]. Then, 3D scale-resolved simulations are the only reliable way to tackle the energy-power-dilemma illustrated in Fig. 1 (c). Such simulations are currently a task at hand.

As a final note, we want to shortly comment on the computational cost of the considered 3D model in Fig. 2. Although it comprises only a part of the complete cathode, the emerging discrete problem possesses roughly 110 Mio. degrees of freedom (DoF) and inevitably requires high performance computing (HPC) capabilities. The virtual discharge in Fig. 2 was computed on the bwUniCluster3.0 located at the Scientific Computing Center (SCC) at Karlsruhe Institute of Technology (KIT) using 1536 cores. The virtual discharge took 1.5h, which requires the near to ideal strong scaling behavior of our approach up to 50000 DoF/process [15].

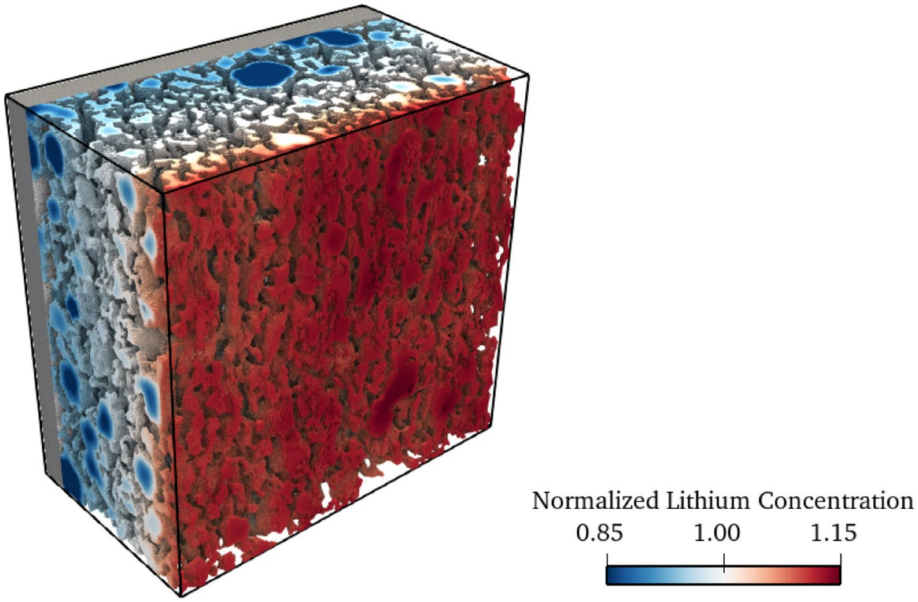

Figure 2: Normalized Lithium distribution in the SPAN cathode structure.

Summary

In this work, we presented preliminary results from scale-resolved simulations of a novel SPAN pouch cell developed in the BMFTR funded project SulForFlight (No. 03XP0491). Therefore, our recently developed 3D scale-resolved framework for Lithium-Sulfur batteries in Firedrake [15] was successfully applied for the first time to a model system similarly used for Lithium-Ion cells. This is as an important step to optimize this polymeric, next-generation Lithium-Sulfur cell in terms of the energy-power-dilemma in Fig. 1 (a). Hopefully, this enables us to tap the full potential of the SPAN cell and contributes to the electrification of the civil aviation sector.

Keywords: Honeycomb, Seal, Leakage, Pressure Loss, Turbine Stator Well

Abstract. The continuous improvement in aeroengine performance necessitates higher turbine inlet temperatures, presenting significant challenges to operational safety and imposing stricter requirements on secondary air system design. The high-temperature gas exiting the combustor subjects the high-pressure (HP) turbine to extreme conditions. To prevent ingress of this hot mainstream gas into the HP turbine disk cavity, a flow of coolant must be introduced into the secondary air system to seal the rotor-stator interface at the rim. The coolant supplied to the rim seal behind the first-stage HP turbine rotor blades is typically introduced below the second-stage nozzle guide vanes (NGVs) called turbine stator well. A portion of this coolant feeds the rim seal, while the remainder passes through the inter-stage seal located beneath the second-stage NGVs to reach the rim seal of the subsequent stage. Optimizing the flow allocation between the rim seal and the inter-stage seal within this configuration remains a critical design challenge. The goal is to achieve effective sealing with minimal total leakage flow by designing appropriate seal clearances and adjusting the rim seal coolant flow rate. However, during engine operation, seal clearances dynamically change due to centrifugal forces and thermal deformation causing rotor deflection, presenting a major challenge for seal design. To simulate the clearance variations induced by labyrinth tooth deformation under operating conditions, this paper presents an experimental investigation characterizing the flow and pressure behavior within a turbine rear cavity seal configuration. By systematically varying the seal clearance and rotor speed, the study examines the pressure across the inter-stage seal, along with the associated flow characteristics, under the effects of centrifugal deformation. Active, controllable abradable sealing techniques are commonly employed in aeroengine seal design. Honeycomb structures have seen increasing application in engine inter-stage seals in recent years. Incorporating a honeycomb layer onto the stator provides sufficient structural integrity while enhancing tolerance to high-speed rotor contact, minimizing damage during rub events. The inter-stage seal used in this experiment featured a hybrid design combining a honeycomb structure with labyrinth teeth. The experiment measured the pressure across inter-stage seal, along with the flow rates, under various inter-stage seal clearance settings. This yielded comprehensive data on flow allocation and pressure distribution for different clearances. Recognizing that honeycomb structures are prone to rub interactions with labyrinth teeth under engine operating conditions, the experiment deliberately induced deliberate and sufficient rub between the seal teeth and honeycomb at the minimum clearance setting and high rotational speed. Subsequent measurements revealed significant alterations in the sealing performance of the honeycomb structure following this rub event. Given that this experiment primarily focuses on flow allocation within the stationary turbine cavity and does not measure sealing efficiency, the turbine main gas path is simplified as a uniform HP plenum. Actual main

Materials Research Proceedings 69 (2026) 735-740 https://doi.org/10.21741/9781644904251-130

flow blades are omitted, and HP air is supplied to the main flow region to simulate the core gas path pressure. Currently, many scholars have conducted research on turbine stator well. Feng Zhang,et al[1] established a two-stage main gas path model incorporating a turbine stator well, studying the effects of sealing flow rate, annular pressure ratio, and rotational speed on the flow characteristics of the rim cavity and sealing effectiveness. D.D. Coren,et al[2] employed a combined experimental and CFD approach to develop a turbine stator well structure, achieving improvements through geometric optimization, increased coolant delivery momentum, and strategic coolant injection positioning. A. Andreini,et al[3] utilized CFD simulations to examine several sealing air supply geometries, aiming to identify the impacts of coolant injection location, swirl number, and jet penetration depth on cavity sealing performance. D. Eastwood,et al[4] designed a two-stage turbine test rig to investigate hot gas ingestion phenomena in turbine stator wells under varying coolant flow rates. J.A. Dixon,et al[5] presented a high-fidelity experimental database for a two-stage turbine stator well and constructed corresponding CFD and FE models for the turbine test rig, achieving strong agreement with the experimental database. Previous studies have conducted extensive research on honeycomb seals. K.T. Han[6] introduced how to design and process honeycomb structures in aeroengines. Jun Li, et al[7] studied the flow characteristics of the through honeycomb seal by numerical simulation, and compared with the labyrinth seal, the dimensionless flow coefficient of the honeycomb seal is smaller than that of the labyrinth seal, because the leakage flow is divided into a smaller recirculation flow by the honeycomb seal than that of the labyrinth seal. Tony B. Sprowl, et al[8] studied the problem that the labyrinth seal is easily blocked by debris. The leakage flow rate of the blocked honeycomb seal increases, and the stiffness and dynamic stability also decrease. Thomas Zierer, et al[9] experimentally compared the leakage characteristics of standard membrane seal, flexible seal and honeycomb seal, in which honeycomb seal has stable and good performance under all pressure loads. Xin Yan, et al[10] studied the gap, element depth and element diameter of honeycomb seal by simulation. With the increase of gap, the leakage increases linearly, and with the increase of element depth, the sealing efficiency increases first, and then remains unchanged. The influence of element diameter is smaller than that of gap. Current research on inter-stage seals combining honeycomb and labyrinth structures within turbine stator well remains limited. This experiment measured pressure distribution inside the turbine stator well by varying seal clearances over a very small range , providing high-precision experimental data.

Test Rig

This experiment was conducted on a high-pressure rotor test rig, which was designed in a 1:1 scale with the actual engine. The inter-stage sealing structure between the second-stage guide vane and the rotor was simulated, with a honeycomb structure welded beneath the second-stage guide vane to mimic real engine conditions. To simulate rotor deformation caused by centrifugal force under engine operating conditions, different sealing gaps were designed.

The structure of the experimental bench is shown in Fig. 1. The air supply system of the experimental bench is as follows: atmospheric air is drawn into the air compressor and stored in the pressure regulating tank, which ensures stable airflow pressure. The pressure regulating tank provides stable airflow, which is dried by a filter and a drying tower, and the opening of the mechanical valve is controlled to adjust the supply pressure. Then, the flow rate is measured by a thermal flowmeter, and the air enters the shunt chamber, where it is divided into multiple paths to supply air to the experimental components.

The pressure in the experiment is measured by a Rosemount differential pressure sensor, and the flow rate is measured by an FCI thermal flowmeter. Both the flowmeter and the differential pressure sensor have analog signal output modules that can convert the measured values into 4-20mA analog signals. These signals are collected by an Adam analog signal acquisition module

Materials Research Proceedings 69 (2026) 735-740 https://doi.org/10.21741/9781644904251-130

and transmitted to the computer, where Labview software is used for programming and data acquisition.

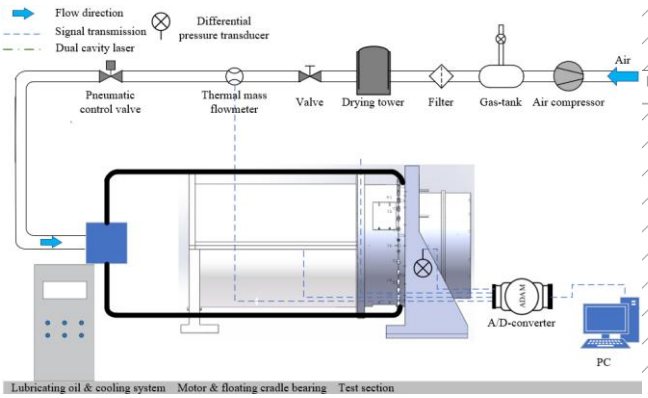

Figure 1:Test Rig

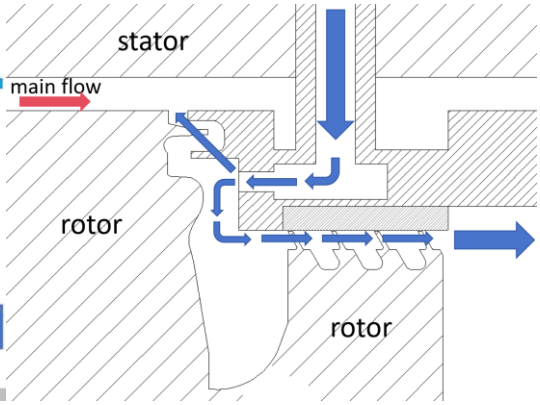

Figure 2:2-D detail of Test Part

The rotary static sealing test device is shown in Fig. 2. The airflow enters the test piece from the air supply pipe. The airflow then passes through the cavity below the second-stage guide vane and enters the cavity through the air supply hole. The honeycomb sealing structure is welded below the air supply cavity, and the honeycomb structure is followed by the rotor structure of the labyrinth seal.

The rotor is driven by a high-precision integrated motor with a rated power of 30 kW and a maximum speed of 10,000 rev/min. The motor's speed is precisely controlled by a frequency converter, achieving a control accuracy of 1%. The axial run out of the motor during operation is 0.03 mm.

The honeycomb is a thin ring structure with a diameter of 441mm, a width of 25mm, a height of 3.65mm, a single honeycomb grid of 1.6mm, and a thickness of 0.05mm. The material is Alloy HX.

Measurements and Parameter

The following are the experimental data measured in this experiment:

1)Mass flow through the honeycomb seal:m_1;
2)Mass flow through the rim seal:m_2;
3)Pressure of the honeycomb seal upstream:p_0;
4)Pressure of the honeycomb seal downstream:p_1;
5)Pressure of the main flow:p_2;
6)clearance between honeycomb and rotor:s;

The flow rate is measured using an FCI thermal flowmeter at the inlet of the experimental gas supply system (as shown in Figure 1). The flowmeter integrates a temperature and pressure calibration module inside, and the measured flow rate is the volumetric flow rate under standard conditions (20℃, 1atm). The uncertainty of flow measurement is ±3%.

The pressure is measured using a Rosemount differential pressure sensor, and the measurement location is shown in Fig. 3. The uncertainty of pressure measurement is ±1%.

measured the clearance with a thickness gauge in inter-stage seal. The uncertainty of flow measurement is 0~+0.05mm.

Materials Research Proceedings 69 (2026) 735-740 https://doi.org/10.21741/9781644904251-130

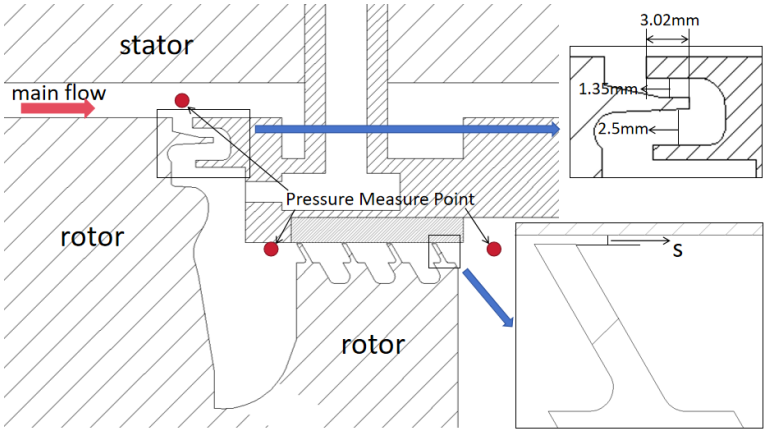

Figure 3:Honeycomb Sealing Clearance and Measure Point

Define the dimensionless parameters in this experiment:

Seal rotating Reynolds number:$Re_{\varphi} = \frac{\rho\omega r^2}{\mu}$; Seal flow Reynolds number:$Re_{\Phi} = \frac{m}{2\mu r}$; Pressure ratio before and after honeycomb seal:$\pi = \frac{p^0}{p^1}$.

The experimental conditions for this experiment are as follows:

1)Re_{φ}:$0\sim3.181\times10^6$;

2)π:1~1.7;

3)s:0.15mm-0.6mm.

To simulate the honeycomb cutting during engine operation, the honeycomb gap is set to the working clearance of 0.15mm when the engine is operating in a stationary state. With the honeycomb intact, the rotor rotational Reynolds number is set to aforementioned value, and the flow characteristics of the honeycomb seal are measured. Subsequently, the rotational speed is increased to 10000 rev/min, allowing the honeycomb to be fully worn out. The flow characteristics of the worn honeycomb are then tested at the same rotor rotational Reynolds number.

The deformation of the rotor labyrinth teeth Δs caused by rotation was obtained through strength simulation calculation, with a total of 4 labyrinth teeth. The average radial deformation value was taken, as shown in Table 1.

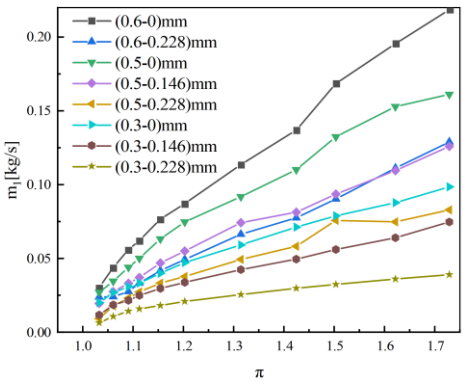

Table 1:Rotational Deformation Δs

Re_{φ}	1.909×10^6	3.181×10^6
Δs(mm)	0.146	0.228

Result And Discussion

Fig. 4 illustrates the flow characteristic curve of the honeycomb. It records the initial flow characteristics of the honeycomb seal at different rotational speeds, at which the honeycomb is not worn.Convert the rotation of the labyrinth teeth into clearance *s* changes and annotate them in the legend, for example:(0.6-0.228)mm,0.6 means design clearance,0.228 means rotational deformation when $Re_{\varphi} = 3.181\times10^6$, therefore actual clearance was 0.372mm.

Materials Research Proceedings 69 (2026) 735-740 https://doi.org/10.21741/9781644904251-130

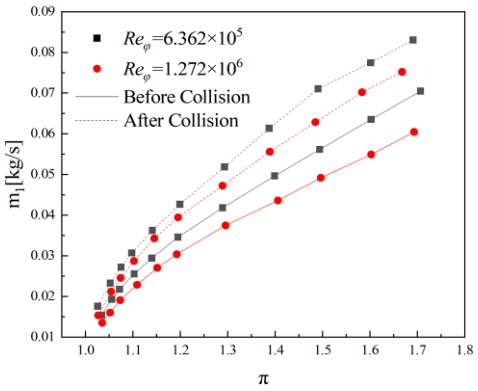

Figure 4:Flow Characteristic Before Collision *Figure 5:Flow Characteristic After Collision*

Under the same pressure ratio, the flow capacity of the seal decreases as the rotor rotation Reynolds number increases. This is because under the action of centrifugal force, the distance between the labyrinth seal on the rotor and the honeycomb decreases.This experiment was designed with different rotational speeds and clearances to obtain a wide range of flow characteristics.

When the static clearance is 0.15mm and the Re_φ is increased to 3.181×10^6, the honeycomb is fully worn, and the theoretical penetration depth of the honeycomb is 0.078mm.

Fig. 5 shows the comparison between the flow characteristic curve of the honeycomb after sufficient rubbing and before rubbing.

After the honeycomb is fully worn, the through-flow Reynolds number increases significantly under the same pressure ratio, especially for operating conditions with higher rotational Reynolds numbers. Fig. 6 will show the percentage increase in leakage before and after rubbing.

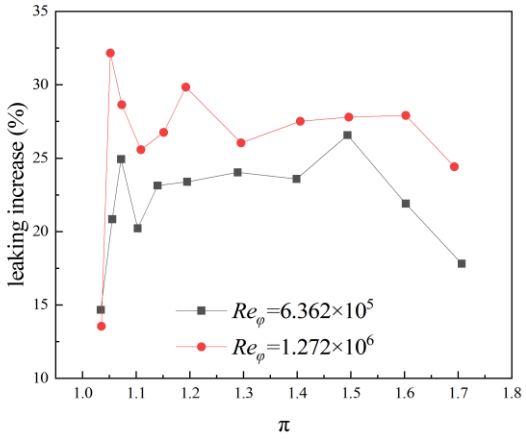

Figure 6:Leaking Increase After Collision

When the rotational Reynolds number is 6.362×10^5, the average leakage before and after honeycomb collision increases by approximately 22%. At a rotational Reynolds number of 1.272×10^6, the leakage rises by about 26%.

Summary

This experiment tested the flow characteristics under multiple gaps ranging from 0.15mm to 0.6mm. And the influence of wear on the leakage characteristics of the honeycomb was tested after

sufficient wear of the honeycomb. When the theoretical penetration depth of the honeycomb was 0.078mm, there was an increase of about 24% in sealing leakage at a gap of 0.15mm.

Development and Characterization of Solid Propellants Based on Environmentally Friendly Sugar and Oxidants for Aerospace Applications

Gerardo Raúl CABALLERO MORALES[1,a *], Italo Paolo AMBROSIO HUANAY[1,b]

[1]Universidad Nacional de Ingeniería UNI, Lima, Peru

[a]gerardo.caballero.m@uni.pe, [b]italo.ambrosio.h@uni.pe

Keywords: Propellant, Small-Scale Rocketry, Low-Toxicity, Oxidizers, Bio-Based Energy

Abstract. The current commercial solid propellants for experimental rocketry are based on barium nitrate, ammonium perchlorate and black powder among others, all of which present potential toxicity. Besides, diphenylamine, an additive to avoid deterioration of nitrocellulose, is likely carcinogenic, and solid or liquid particles are deposited in the respiratory tract depending on their size, in addition to gaseous by-products such as SO_2 and NO_x that threaten environmental health. The main objective of this study was to develop a safe solid propellant, maintaining safety standards, aiming at sustainability by reducing the toxicity of solid propellant combustion. For our solid propellant SP1, we maintained a ratio of 65% anhydrous D-glucose to 35% potassium nitrate, with ferric oxide and calcium carbonate as oxidant. Thermochemical analysis was performed by Cantera simulation platforms, confirming that SP1 produces cleaner combustion than current commercial propellants, with CO_2, H_2O and N_2 as main products, as well as few NO_x emissions (< 5 %), and no halogenated by-products. Combustion temperature was between 1430 to 1730 °C, ignition temperature between 180 and 200 °C, specific impulse 120 and 140s, calorific value between 3.5 and 4.5 MJ/kg, and combustion velocity between 3 and 10 mm/s. Combustion simulation performed with ANSYS Mechanical, Open Rocket and MATLAB supported the predictions on fluid dynamics, structural integrity and flight. Laboratory tests were also performed to validate the results, calorimetry and combustion velocity. Data collection was performed on a static test bench, determining thrust and monitoring gas emissions. The propellant exhibited low sensitivity to impact and friction, moderate hygroscopicity, thermal stability at 180°C and a shelf life of 12 months without moisture. Thus, safe handling, low production cost and accessibility to raw materials make SP1 an interesting, secure and efficient alternative for experimental rocketry, CubeSat and aerospace platforms.

Introduction

Experimental rocket research is very useful for the evolution towards aerospace missions in the foreseeable future. Experimental vehicles can be launched from temporary sites throughout the country, can be used for remote field studies, and they can be used to develop and test new scientific instruments for measurement and observation [1].

Experimental rocketry is an effective tool for conducting scientific research [2]. Among the fields of application are biometeorology, photobiology, pollution monitoring and telecommunications [3]. It can also be applied to territory observation (security and defense) and aerial imaging, although aerial observation is increasingly and gradually being performed through drone technology. In addition to their contribution to science and technology, experimental rocket missions also provide excellent tools for scientific training [4, 5]. Experimental rocket research in Peru is a field where university initiatives and independent missions are gradually emerging, contributing to its growth. In particular, the National Institute for Research and Training in Telecommunications (INICTEL-UNI), the National University of Engineering (UNI), and the

Materials Research Proceedings 69 (2026) 741-746 https://doi.org/10.21741/9781644904251-131

National University of San Marcos (UNMSM) have led efforts to create and test experimental rockets.

This study aims to promote experimental rocketry in Peru through the support of universities and research centers that demonstrate the country's interest and potential in this field, followed by the inauguration of the Aerospace Engineering degree program at the Faculty of Mechanical Engineering (FIM) of the UNI. On the other hand, the choice of propellant is key, as it directly influences the performance of the rocket. Globally, research into solid fuels has advanced significantly, particularly in relation to propellants based on perchlorates and other high-efficiency compounds that offer high specific impulse [6, 7, 8]. However, these compounds have significant disadvantages, such as high production cost and complex handling, and considerable risk due to their explosive and unstable nature due to micromechanical changes (cracks) [9]. Potassium nitrate (KNO_3), combined with fuels such as sucrose, is a viable option for experimental rocketry applications due to its low cost, wide availability, and greater relative safety [10]. In this context, it is essential to implement an efficient propellant design that minimizes risks during storage, transport, and ignition [11, 12].

Residual biomass from different sources such as potato (starch), is a promising option for application as propellant ingredient in rocketry in Peru, through biomass hydrolytic conversion into simple sugar molecules such as glucose. The development and optimization of a solid propellant based on potassium nitrate mixed with residual biomass as fuel source would not only benefit experimental rocketry projects in Peru, but could also position the country as an emerging competitor in aerospace research, given that there is a current project for construction of an aerospace port together with NASA in the city of Talara, in Peru, which would allow the launching of rockets in the near future [13].

Goal of this study was the design and optimization of formulation of a solid propellant composed of potassium nitrate and residual biomass, in order to improve its performance in propulsion systems, by means of a controlled combustion system that allows for uniform and efficient burning of the propellant, minimizing the generation of hot spots and preventing structural failures during the start-up of the propulsion system, ultimately reducing the environmental impact of the propellant.

Materials and methods

Solid propellant SP1 was prepared, with a mass ratio 65: 35 anhydrous D-glucose to potassium nitrate, 2% w/w ferric oxide and 3% w/w calcium carbonate as oxidant. D-glucose anhydrous $C_6H_{12}O_6$ (DGrace & ChJ, Lima) was used as pure powder; for the referential comparison propellant, commercial granulated refined sugar (sucrose) was employed. Table 1 shows the SP1 mixture content.

Table 1. *SP1 propellant composition. M_W = wet basis moisture content.*

D-glucose	7.00	$\xrightarrow{0.04\%}$	≈ 7.00
KNO_3	13.00	$\xrightarrow{0.04\%}$	≈ 13.00
Fe_2O_3	0.40	$\xrightarrow{0.04\%}$	≈ 0.40
$CaCO_3$	0.60	$\xrightarrow{0.04\%}$	≈ 0.60
• **Mixture (dry basis)**			≈ 21.00

Chemical reactions:

$$5\ C_6H_{12}O_{6\ (s)} + 24\ KNO_{3\ (s)} \xrightarrow{Fe2O3\ (s)} 18\ CO_{2\ (g)} + 30\ H_2O_{\ (g)} + 12\ K2CO_{3\ (s)} + 12\ N_{2\ (g)}$$

$$CaCO_{3\ (s)} + O_{2\ (g)} \xrightarrow{Fe2O3\ (s)} CO_{2\ (s)} + CaO_{\ (s)} + \text{energy}$$

Materials Research Proceedings 69 (2026) 741-746 https://doi.org/10.21741/9781644904251-131

$CaCO_{3\,(s)} \rightarrow CaO_{\,(s)} + CO_2$ (endothermic decarbonation)

Iron oxide FeO_3 acts as a catalyzer ingredient. It generates a homogenous chemical reaction through all the grain structure and releases heat (~2000 °C). Also, calcium carbonate $CaCO_3$ contributes to a longer but less intense combustion, which can improve ignition stability, although it decreases the brightness of the flame. It also facilitates self-ignition and reduces the delay time. The greater release of heat promotes faster expansion, which can increase thrust, but also the risk to be moistened if confinement is not controlled.

Pure KNO_3 has a high melting point (334 °C), but when mixed intimately with sucrose and heated, a eutectic mixture is formed. This mixture has a much lower melting point than its individual components, melting in the temperature range of sucrose (160-190 °C). KNO_3 dissolves in the molten sucrose. It should be noted that this does not mean that the components necessarily degrade or decompose to achieve the mixture.

Results and discussion

Figure 1 shows concentric cylindric grains of the SP1 propellant and the refined-sugar-based reference propellant. The SP1 propellant preparation resulted in a mass that had more homogeneity and less plasticity than the reference propellant.

The following simulation studies were conducted:

a. Thermochemical modelling and simulation of gas emission with stoichiometric balances was performed with MATLAB / Python. It was shown that SP1 produced cleaner combustion than current commercial propellants, with CO2, H2O and N2 as main products, as well as fewer NOx emissions (< 5 %), and no halogenated by-products.
b. Structure and grain design simulation was performed with SolidWorks to calculate thermal and structural stress that can lead to deformation and cracks.
c. Trajectory simulation was performed with OpenRocket to calculate maximum height, acceleration and stability.

(a)  (b) 

Figure 1. (a) *SP1 propellant.* ***(b)*** *Refined sugar-based propellant.*

Important parameters to consider are adiabatic flame temperature T_c at chamber pressure p_c. Equilibrium gas composition x_j, engine design parameters (average molecular weight M, specific heat ratio $\gamma = c_p/c_v$, characteristic speed c^* and specific impulse I_{sp}).

The simulation model was based on a closed combustion chamber, adiabatic, at constant pressure p_c in equilibrium. Ideal gas phase: CO_2, H_2O, CO, H_2, N_2. Solid phase: K_2CO_3, $CaCO_3$, CaO, Fe_2O_3.

The graphs obtained from the Cantera thermodynamic simulation platform of the green propellant reaction are shown below, analyzing how the energy released by the solid fuel is transformed into thermal energy from the combustion gases and, finally, into thrust.

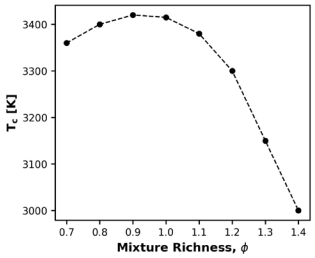

Figure 2. *Chamber temperature against mixture richness ϕ.*

Materials Research Proceedings 69 (2026) 741-746 https://doi.org/10.21741/9781644904251-131

Chamber temperature as a function of mixture richness ϕ as seen in Figure 2 shows that the maximum temperature obtained (3050 °C) of the sucrose-KNO_3 system is reached at ϕ = 0.9, i.e., for a mixture slightly rich in oxidant - and therefore not quite stoichiometric. At this point, the greatest release of energy per unit mass of mixture is achieved, which translates into a higher c^* and specific impulse, improving the overall performance of the engine. At the same time, the slight excess of oxidizer favors more complete combustion (less CO and carbonaceous residues).

Figure 3 shows that c^* of the sucrose–KNO_3 system is maximum (1600 m/s) at ϕ = 1.15, i.e., for a mixture slightly rich in fuel. At this point, the best compromise between T_c and M is achieved, so that the performance (and, consequently, I_{sp}) is maximized. For a green propellant, this operating range allows maximum thermodynamic performance to be extracted without resorting to more energetic but environmentally aggressive oxidizers.

The ideal specific impulse curve in vacuum, shown in Figure 4, indicates that the sucrose–KNO_3 propellant reaches its maximum performance at ϕ = 1.15, with I_{sp} = 320 s, showing that a slightly fuel rich mixture offers the best thermodynamic compromise for nozzle expansion.

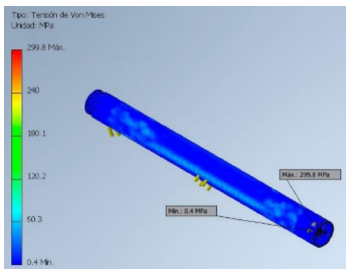
NH_2	1.966 e-06

Values obtained from measurement of combustion temperature were between 1430 and 1730 °C, the ignition temperature between 180 and 200 °C, average specific impulse 130 s, calorific value between 3.5 and 4.5 MJ/kg, and combustion velocity between 3 and 10 mm/s. The structure design simulation result was expressed by the von Mises stress, which is shown graphically in Figure 5. As can be seen, a maximum stress of approx. 220 MPa takes place at the ignition ports; this value is lower than 290 MPa, which in turn represents the yield strength of AISI 316 stainless steel used as material for the rocket structure.

Materials Research Proceedings 69 (2026) 741-746 https://doi.org/10.21741/9781644904251-131



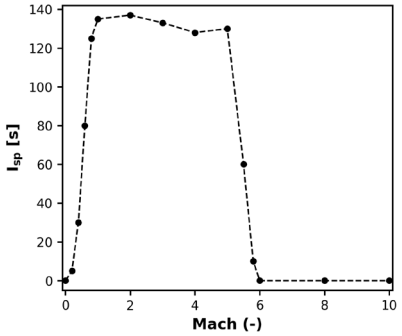


Figure 5. *Von Mises stress simulation results.*

In a Mach range from 1 to 5 an average specific impulse I_{sp} of approx. 130 s (sea level) was obtained Figure 6a shows the results of I_{sp} against Mach number. By comparison, Space X Merlin 1D engine (working with kerosene fuel) for Falcon 9 launch rocket vehicle has a I_{sp} = 310 s, while Ariane 6 launcher rocket booster engine P120C (working with solid fuel) has a I_{sp} = 278 s. A calorimetric test was also performed with the aid of a load cell to validate the calculations. Data collection was performed on a static test bench, determining thrust and monitoring gas emissions. Figure 6b shows a picture of the combustion test performed with SP1 propellant.

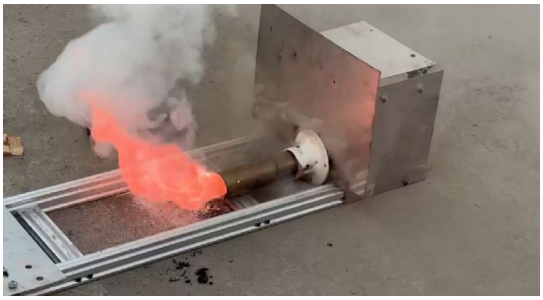

Figure 6. (a) *Specific impulse Isp for propellant SP1.* ***(b)*** *Combustion test SP1 propellant*

Conclusions and summary

The thermodynamic results show that the sucrose–KNO_3 mixture reaches its maximum performance at $\phi = 1.15$, where gas composition contains mostly H_2O, CO, and H_2, with significant fractions of N_2 and CO_2. At this point, the best compromise between chamber temperature, specific heat ratio, and molecular weight of the gases is obtained, so that the specific impulse and efficiency of chemical energy conversion into thrust are maximized for this solid propellant.

The presence of a lower environmental footprint compared to traditional propellants due to the gas plume consists mainly of H_2O, CO, H_2, N_2 and a moderate fraction of CO_2, with no presence of chlorinated species or halogenated compounds typical of perchlorate-based propellants. This means no subsequent generation of gaseous HCl, metal chloride particles or other highly corrosive and toxic products, significantly reducing the impact on the environment.

Keywords: Scaling Methodology, Anode Layer Hall Thruster, Low Power, Argon

Abstract. Electric propulsion (EP) has gained significant importance for space applications due to high specific impulse and increasing onboard power availability. This work focuses on the scaling and design of a low-power (~100 W) Anode Layer Hall Thruster (TAL) optimized for Argon propellant. Unlike conventional Stationary Plasma Thrusters (SPT), TALs feature metallic walls and a shorter acceleration channel, offering improved durability and compactness. A novel scaling methodology was developed by improving a phenomenological model to account for TAL-specific physics, including refined wall and anode loss relations. The methodology was validated against a performance database of 21 TAL thrusters, demonstrating excellent agreement. Two design configurations were derived, a baseline 100 W version and a 150 W version with a coaxial hollow cathode. Benchmarking shows promising performance metrics, establishing a robust framework for low-power TAL development.

Introduction

Electric propulsion generates thrust by accelerating ionized propellant via electromagnetic fields, offering superior efficiency over chemical propulsion for long-duration missions. Hall Thrusters (HTs) are widely used for station-keeping and orbit-raising due to their simplicity and adaptability [1]. Thrusters with Anode Layer (TALs) are a distinct category with a narrow acceleration zone and metallic channels biased at cathode potential. This configuration results in higher plasma densities and a stronger electric field compared to ceramic-channel SPTs Figure 1.

The shift toward small satellites has increased demand for compact, sub-500 W thrusters. Furthermore, the high cost of Xenon has driven interest in alternative propellants like Argon, which is abundant and affordable despite its higher ionization energy. This paper addresses the lack of unified scaling laws for low-power TALs by presenting a refined phenomenological model tailored for Argon operation.

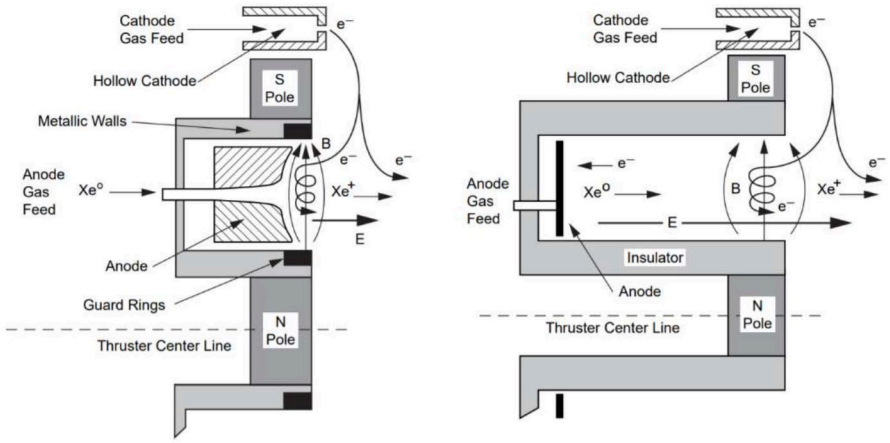

Figure 1 Comparison between SPT and TAL configuration

Scaling Methodology

Scaling methods establish relationships between geometry and operating parameters to preserve performance at different power levels from a well-known thruster to the new one [2]. This work builds upon the flexible methodology developed at the University of Pisa [4], which utilizes a matrix-based approach to allow independent control of design parameters.

TAL-Specific Improvements. To adapt the general model for TALs, non-standard relations for loss mechanisms were introduced.

- *Wall Losses*: In TALs, the metallic walls are at cathode potential, eliminating the zero-net current condition found in SPTs. The wall loss coefficient ϵ_w is modeled as proportional to the ratio of channel length L to width b and the beam efficiency η_b:

$$\epsilon_w \propto \frac{L}{b}\eta_b \tag{1}$$

- *Anode Losses*: Representing the dominant loss in TALs, anode losses ϵ_a were modeled as a function of magnetic field B and discharge voltage V_D with two parametric coefficients (z & χ) which values were refined during the scaling procedure:

$$\epsilon_a \propto B^z V_D^{\chi-1} \tag{2}$$

- *Ionization Losses*: The power loss fractions are obtained by non-dimensionalizing the power losses with the discharge power. The ionization loss coefficient is obtained by using the power spent for propellant ionization, P_i:

$$\eta_i \propto \frac{\eta_b}{L_{ia}} \tag{3}$$

Design Objectives and Validation

The primary target was a 100 W class thruster with a discharge voltage of ~300 V using Argon. Key performance goals included a thrust efficiency $\boldsymbol{\eta > 0,3}$ and a specific impulse $\boldsymbol{I_{sp} > 1000s}$.

Model Validation. The scaling model was validated using a database of 21 TAL models (e.g., D-30, D-55, D-100). By scaling the D-55 reference thruster [3] to various operating points, the model demonstrated high accuracy in predicting thruster performances. Among the available solutions that maximized thrust efficiency, specific impulse and thrust, the ones that best balanced competitive dimensions, comparable to those of existing thrusters operating at similar power levels, with manufacturing considerations were selected. The results of the preliminary design are presented in Figure 2.

Proposed Configurations. Two designs were developed:

- *Standard TAL (100 W)*: Features an externally mounted cathode. The channel length was adjusted to enhance Argon ionization.
- *Coaxial cathode TAL (150 W)*: Incorporates central housing for a hollow cathode, improving compactness and beam neutralization.

Materials Research Proceedings 69 (2026) 747-750 https://doi.org/10.21741/9781644904251-132

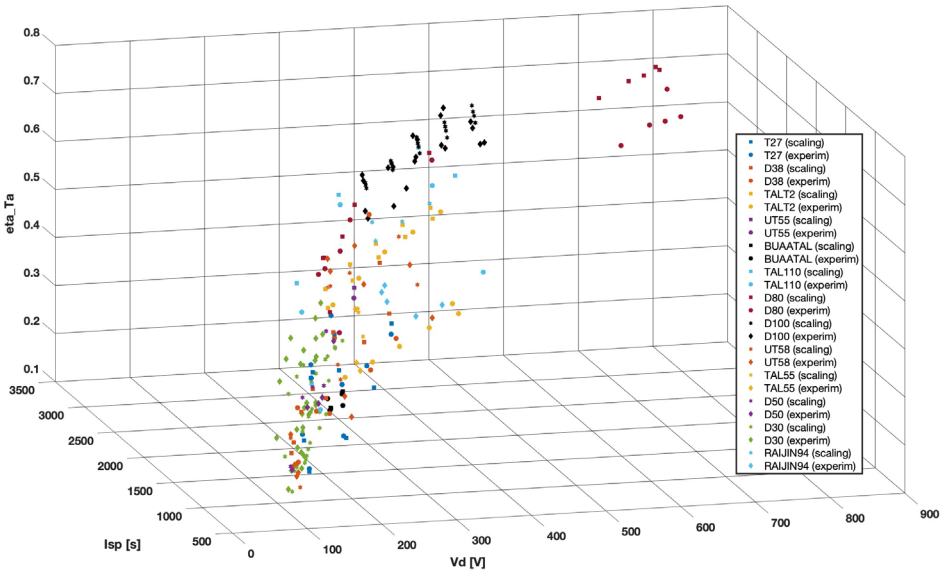

Figure 2 Scaling results: V_D - I_{sp} - η_{Ta}

Benchmarking and Conclusions

The final designs were benchmarked against current market HTs Figure 3. Despite the challenges of Argon (lower thrust efficiency compared to Xenon), the optimized TAL geometry and magnetic topology ensure performance suitable for CubeSat missions.

The proposed scaling methodology offers a robust tool for the preliminary design of TAL thrusters across various power levels. Future work will focus on experimental validation of the 100 W prototype and thermal-magnetic coupling simulations.

Keywords: Hybrid-Electric Aircraft, Cryogenic Motor, Pure Aluminum, Litz-Wire Winding, Copper Hairpin, FEM Simulation, AC and DC Losses

Abstract. This paper compares an oil-cooled copper hairpin motor with a cryogenic pure-aluminum Litz-wire motor for hybrid-electric aircraft propulsion [1] under identical operating constraints. The study is motivated by fuel-cell architectures that enable winding temperatures near 70 K, where aluminum exhibits higher electrical conductivity than copper [2] and can therefore reduce stator direct-current (DC) losses and conductor mass. Finite-element models are employed to quantify electromagnetic behavior, including torque capability, DC and alternating-current (AC) winding losses, and efficiency. The results show that the aluminum concept achieves a lower total loss density despite slightly stronger proximity and eddy-current effects, because the Litz-wire configuration significantly mitigates AC losses. At the rated operating point of 750 kW and 21,000 rpm, peak efficiency reaches 99.0 % for the aluminum design versus 98.1 % for the copper reference. Mission-profile evaluation with a 750 kW rated load indicates up to 0.8 percentage-point higher instantaneous efficiency and an average improvement of about 0.65 percentage points over the cycle. These findings highlight the potential of cryogenic aluminum Litz-wire windings for lightweight, high-efficiency propulsion in future hybrid-electric aircraft.

Introduction

At Fraunhofer IISB, in collaboration with industrial partners and within the framework of European Clean Aviation AMBER project [3], a 12-phase, 750 kW copper hairpin motor operating at 21,000 rpm was previously designed and manufactured, demonstrating distributed windings, oil cooling, and a modular inverter interface as shown in Fig. 1. This design serves as the electromagnetic and geometric baseline for the present comparison.

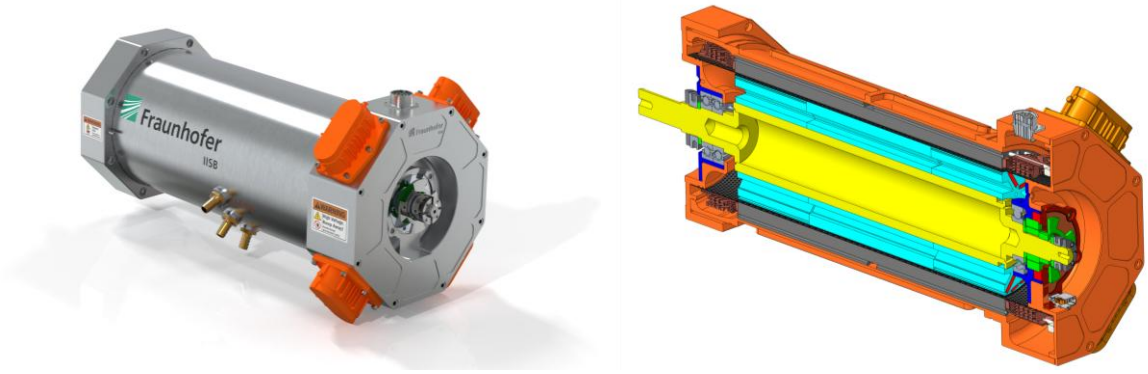

Fig. 1. Multi-phase (4x3) copper hairpin winding for hybrid-electric aircraft propulsion.

Materials Research Proceedings 69 (2026) 751-756 https://doi.org/10.21741/9781644904251-133

Although copper hairpins offer excellent manufacturability and a high slot-fill factor, their rectangular conductors exhibit pronounced high-frequency losses caused by skin and proximity effects, and the high density of copper limits further mass reduction. Fuel-cell aircraft architectures can provide cryogenic cooling near 70 K, where aluminum surpasses copper in electrical conductivity. To address these limitations, this study develops a cryogenic pure-aluminum Litz-wire motor designed to reduce AC losses associated with high conductivity while maintaining identical constraints. Both concepts are evaluated and compared through finite-element modeling and a representative hybrid-electric aircraft mission profile. Mechanical integrity and insulation aspects are beyond the scope of this work and will be investigated in future studies.

Reference Multi-phase Copper Hairpin Winding Motor

The reference machine considered in this work is a high-speed, high-power-density copper hairpin motor, which was developed and manufactured at Fraunhofer IISB based on the overall system boundary conditions of the ATR 72-600 aircraft. The electrical specifications of the motor are listed in Table 1. The machine was specifically designed for hybrid-electric aircraft propulsion and represents a mature technological benchmark for the present comparative analysis. The detailed design process has been described in [4]. The manufactured stator is shown in Fig. 2, which demonstrates the realization of four magnetically decoupled inverter systems, providing independent and redundant operational behavior.

Table 1. Specification of the electric machines for hybrid-electric aircraft

Parameter	Specification Value
Machine type	PMSM
DC link voltage U_{DC}	825 V
Rated output power P_{mech}	750 kW
Target efficiency η_{motor}	95 %
Rated speed n_{r}	21 000 rpm
Rated torque T_{r}	341 Nm
Target power density	8 kW/kg
Thermal class	H (180°C)
Coolant system	Oil cooling

The 12-phase machine is supplied by four silicon carbide inverters. Four independent three-phase subsystems are implemented through a dedicated connector and winding layout, as detailed in [4]. This configuration with magnetically decoupled systems improves fault tolerance, harmonic suppression, and modularity, which are essential for aviation safety. The motor delivers 750 kW at 21,000 rpm and 341 Nm of torque with an efficiency above 95 percent. Direct oil cooling through ducts in each stator tooth ensures effective thermal management. The complete system, including cooling, weighs about 90 kilograms and achieves a specific power of 8.3 kW per kilogram. This validated copper hairpin motor serves as the electromagnetic baseline for the cryogenic aluminum Litz-wire design.

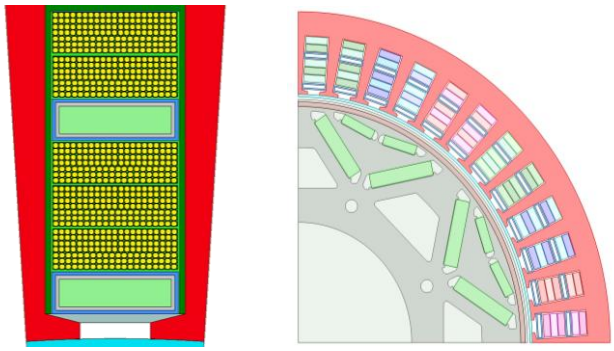
Fig. 2. Realized 12 phases stator with four magnetic decoupled systems and copper hairpin windings.

Materials Research Proceedings 69 (2026) 751-756 https://doi.org/10.21741/9781644904251-133

Cryogenic Pure-Aluminum Litz-Winding Motor

The cryogenic pure-aluminum Litz-wire motor was developed from the reference copper hairpin design while maintaining the same geometric, magnetic, and operational boundary conditions. The objective was to evaluate the electromagnetic performance of aluminum conductors under cryogenic operation and to quantify the influence of temperature-dependent conductivity on both DC and AC losses. The design assumes a cryogenic environment with a winding temperature below 70 K, where pure aluminum exhibits higher electrical conductivity than copper, which reduces DC losses but may increase AC losses in winding.

The stator winding was completely redesigned using a Litz-wire configuration in place of rectangular hairpins, which can reduce the AC losses in winding. Each phase comprises 144 parallel strands with a diameter of 0.3 mm, transposed over a defined pitch length to minimize skin and proximity effects at high frequency. The Litz-wire bundles were modeled as equivalent conductors in the finite-element domain, incorporating the strand count and twisting factor to ensure electromagnetic calculation. The strand diameter and the number of strands were chosen to match the effective cross-sectional area of the copper hairpin winding. The resulting stator and rotor configuration is illustrated in Fig. 3.



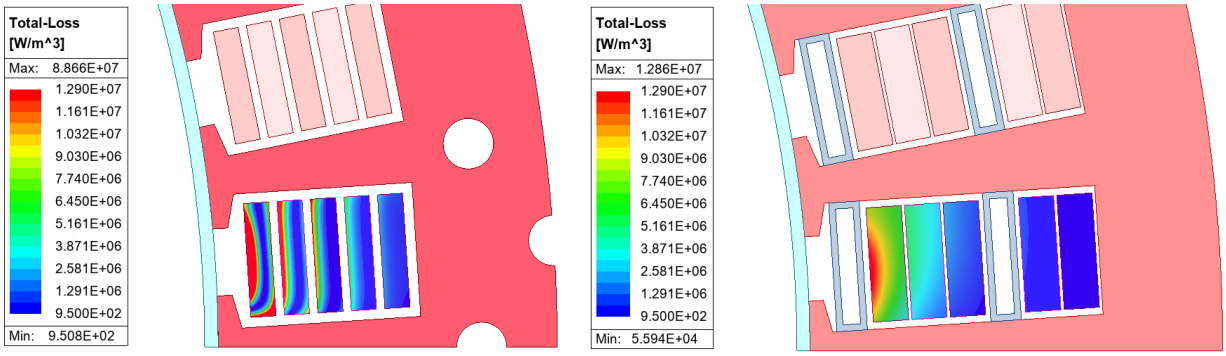


Fig. 3. FEM-model of the electric motor with cryogenic pure-aluminum Litz-wire winding.

Comparative Results

The finite element results of the total losses in the copper hairpin and aluminum Litz-wire windings are shown in Fig. 4. The aluminum Litz-wire concept incorporates a cooling channel within the stator slot, located close to the heat source, and supplied with gaseous helium to maintain a conductor temperature of approximately 70 K. The results indicate that the total loss density in each Litz-wire bundle is lower than that of the copper hairpin winding. Although pure aluminum exhibits higher electrical conductivity lower than 70 K, which increases the proximity and eddy-current effects, the overall loss density remains lower because the Litz-wire configuration effectively reduces AC losses.

Since the motor operates at cryogenic temperature, the ambient temperature of the permanent magnets must also remain within this range. Cryogenically rated magnets, VACODYM 131TP/DTP [5], were selected because they provide a remanent flux density between 1.57 T and 1.62 T from 77 K to 150 K, with 150 K considered as the worst-case design condition. Table 2 summarizes the main design and electromagnetic parameters of both motors. The cryogenic version maintains a geometry similar to the reference machine but incorporates several optimizations for low-temperature operation. The stator outer diameter increases from 195 mm to 206 mm to accommodate cooling channels and larger Litz-wire bundles, while the active length decreases from 429 mm to 352 mm due to the use of stronger cryogenic magnets. The rotor and magnetic circuit remain unchanged for consistent electromagnetic comparison.

a) b)

Fig. 4. FEM of total losses in a) copper hairpin winding and b) aluminum Litz-wires at time=0.011 ms.

FEM results confirm that both motors deliver the same average torque of 348 Nm at 21,000 rpm, demonstrating that the redesign preserves torque capability. The cryogenic aluminum Litz-wire motor achieves a significant reduction in losses. The DC losses in winding decrease from 5.1 kW to 0.27 kW, mainly due to the higher electrical conductivity of aluminum at 70 K. The AC losses also drop from 4.4 kW to 1.71 kW as a result of the Litz-wire configuration. As a consequence, efficiency at rated speed improves from 98.1 percent to 99.0 percent, and total power density increases from 8.1 kW/kg to 10.7 kW/kg.

Fig. 5 and Fig. 6 present the FEM-based efficiency maps and the winding losses distributions of both motors. In the copper hairpin motor, the loss density is concentrated near the slot openings, where strong proximity effects occur because of the rectangular conductor geometry.

These results confirm that the cryogenic Litz-wire concept maintains high electromagnetic performance while significantly improving efficiency and reducing total loss density compared with the copper reference design.

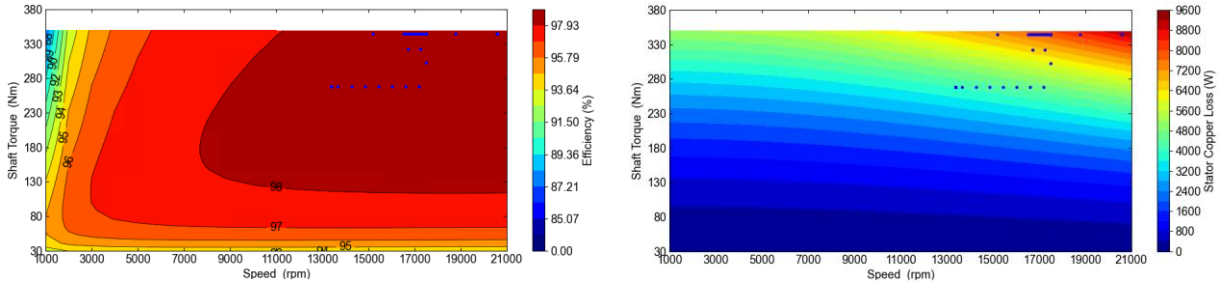

Fig. 5. Efficiency map and winding losses of copper hairpin winding in stator

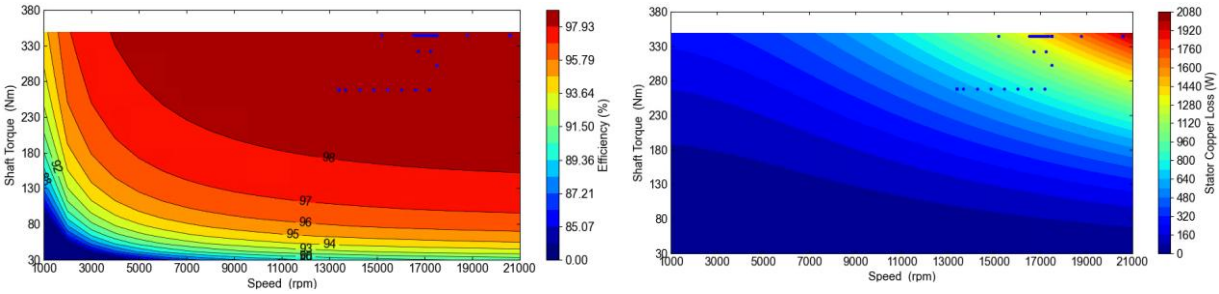

Fig. 6. Efficiency map and winding losses of pure-aluminum Litz-wire in stator

Load Profile Simulation

To evaluate overall propulsion-system efficiency, both the copper hairpin and cryogenic aluminum Litz-wire motors were analyzed under a representative hybrid-electric aircraft mission profile. The power and speed trajectories were derived from the operating cycle of an ATR 72-600-class regional aircraft. The original 850 kW peak load was scaled to 750 kW while maintaining the same speed envelope of 21,000 rpm, as shown in Table 3. The efficiency maps from Fig. 5 and Fig. 6 were combined with the mission load profile to calculate instantaneous machine efficiency throughout the cycle. Fig. 7 compares the mission efficiencies of both designs. During takeoff and climb, the aluminum Litz-wire motor achieves about 0.4 percent higher efficiency. In cruise, where torque demand increases, the efficiency advantage becomes more pronounced and remains in favor of the aluminum Litz-wire design. The maximum improvement over the mission reaches 0.8 percentage points, reflecting a measurable reduction in total losses.

Although the higher electrical conductivity exhibits slightly stronger proximity and eddy-current effects, the aluminum Litz-wire configuration significantly reduces AC losses, and the lower DC losses at cryogenic temperature yield a higher overall efficiency. The improved performance and reduced conductor mass demonstrate the potential of cryogenic aluminum windings for lightweight, high-efficiency hybrid-electric propulsion systems.

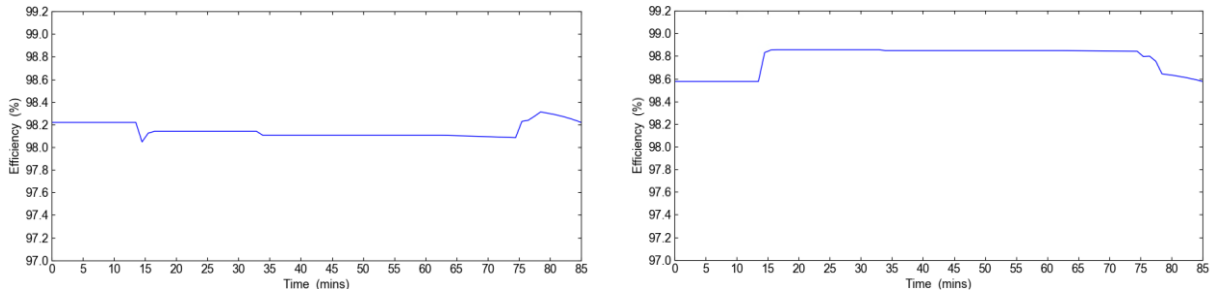

Fig. 7. Efficiency comparison between the concepts with a) hairpin winding and b) aluminum Litz-wire.

Summary

This paper presented a comparative electromagnetic analysis of a copper hairpin motor and a cryogenic pure-aluminum Litz-wire motor for hybrid-electric aircraft propulsion.

The results demonstrated that, although pure aluminum exhibits higher electrical conductivity at cryogenic temperatures, which enhances proximity and eddy-current effects, the use of Litz-wire conductors effectively suppresses these AC losses. As a consequence, the aluminum Litz-wire achieved a substantially lower total loss density and reduced winding losses compared with the copper hairpin winding. When evaluated over a representative hybrid-electric aircraft mission profile, the cryogenic aluminum Litz-wire motor delivered up to 0.8 percentage points higher efficiency and an average improvement of approximately 0.4 percentage points over the complete mission cycle. In addition to improved efficiency, the lower conductor density offers a meaningful reduction in total motor mass.

These findings confirm that cryogenic aluminum Litz-wire technology provides a promising path toward lightweight, high-efficiency electric propulsion systems. Future work will focus on thermal and mechanical validation, as well as experimental verification of the cryogenic prototype under representative operating conditions.

Keywords: Superconducting Electric Motor, Permanent Magnet Machine, Electric Aircraft, Electric Excitation

Abstract. Currently, there are different future aircraft concepts considering hybrid electric and fully electric propulsion system. To achieve an electric aircraft there is the need for electric motors with a higher power density and lower weight than conventional solutions currently available [1]. Using hairpin stator windings increases the power density of the machine due to their high slot fill factor and good thermal properties. Furthermore, they enable automated manufacturing and decreasing costs. To achieve a further step regarding higher power densities, the use of superconductors in electric motors is proposed [2]. They have minor DC resistance in the superconducting state, which could minimize the motor losses and enable a generation of high flux density motors. Both stator and rotor could be realized using superconductors. A rotating magnetic field is generated in the stator, which is why AC currents are required. Consequently, AC losses still occur in machines with super-conducting stator (SC-stator) and must be considered to prevent quenching [3]. When using SC-rotors, an electrically excited synchronous machine is designed. Here, DC currents are used to generate a constant magnetic pole system. These AC losses are disregarded in the first place which simplifies the initial design process.

Introduction

In [4], a multi-phase electric motor for hybrid electrical aircraft applications is presented (Fig. 1, left). It uses a stator with hairpin winding and direct oil cooling and a permanent magnet excited rotor. The machine achieves a continuous power of 750 kW at a DC voltage of 800 V. A total power density of 8.33 kW/kg is realized including active and passive components such as bearings and housing. In this paper, the motor presented in [4] has been retrofitted with a superconducting rotor. For this, the same stator design and installation space is maintained. The new rotor design uses high temperature superconductor (HTS) winding for electrical excitation. Liquid hydrogen could be used as the cooling medium, which is on board as an energy storage anyway, depending on the aircraft design [5]. Different electromagnetic designs are presented, and the achievable power density is discussed. The maximal speed of the machine is 21000 rpm [4]. With the SC-technology the maximum torque could be increased by means of higher flux density values attained by an order of magnitude increased current density in the HTS-coils compared to conventional field windings in electrically excited synchronous machines (EESM). This would result in changes to the motor map and characteristics. To optimize the overall propulsion system, either the operating rotational speed can be changed, or the motor aspect ratio could be minimized.

Retrofitting of the machine

From the initial electromagnetic design presented in Fig. 1 on the left, the interior permanent magnet rotor (IPM-rotor) is replaced by a rotor with electrically excited coils while keeping the overall machine dimensions (Fig. 1, on the right).

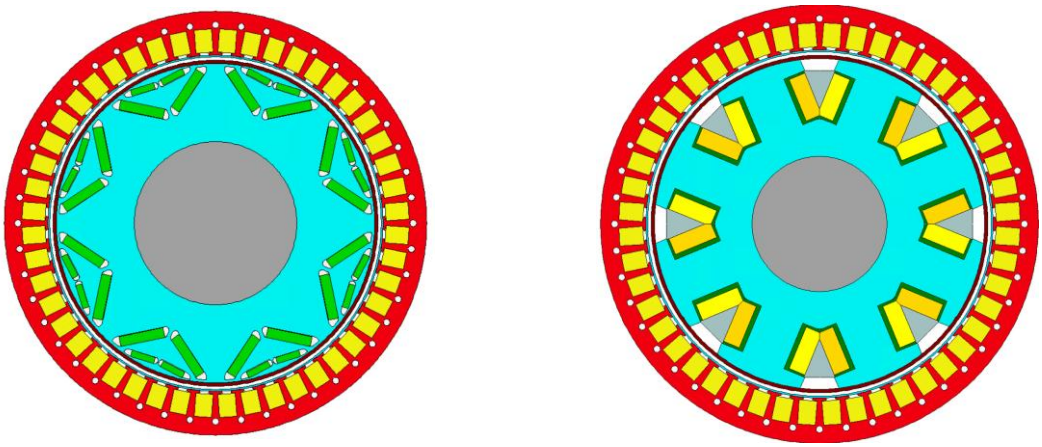

Fig. 1. Comparison of the machine designs of an interior permanent magnet rotor (left) and the superconducting rotor (right) in the same hairpin winding stator.

Then, the excitation current is adjusted to generate the same machine torque. This can be achieved using increased field current densities e.g. 23 A/mm^2 for which forced liquid rotor cooling in conventional technology already needs to be employed.

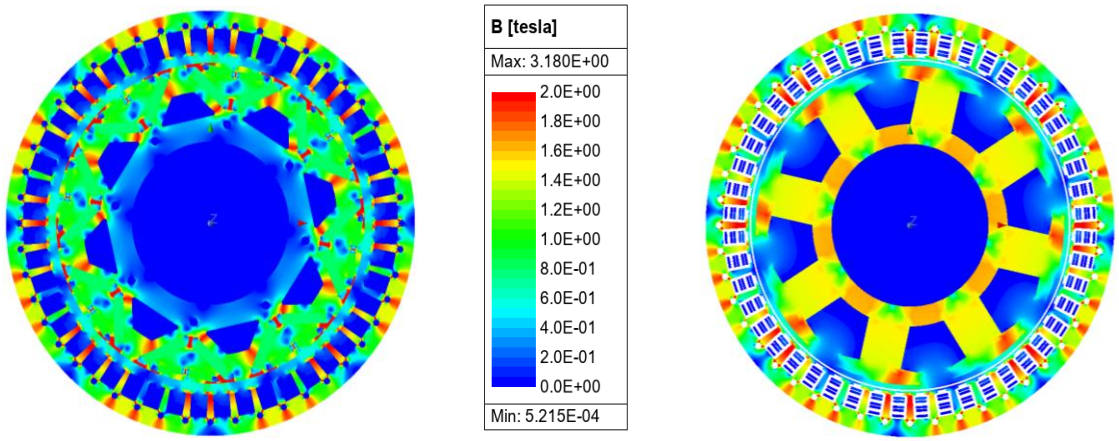

Fig. 2. Flux-density distribution of original (left) and electrically excited design (right) machine design at low current densities exhibiting the same torque behavior.

The resultant distribution of the magnetic flux density is presented in Fig. 2. The IPM shows some saturation particularly in the rotor iron bridges while the EESM is partly saturated within the stator teeth, in the tooth tip of the rotor and is generally magnetically more loaded (Fig. 2, on the right) than the IPM.

Employing super-conductivity

The EESM-design requires a continuous current flowing in the field-winding (FW) which creates the rotor pole system of the machine. To generate the same torque with the EESM-design the field-current densities are already very high. This was expected whereas the high energy rare-earth permanent magnets create a rotor excitation field which ampere-turns can only hardly be realized by a current driven field-winding. The magnetic energy density of rare-earth permanent magnets is generally unmatched in electrical machine design. Therefore, a more sophisticated technology needs to be employed to outperform the torque performance of the IPM-machine. This is

Materials Research Proceedings 69 (2026) 757-763 https://doi.org/10.21741/9781644904251-134

essentially achieved via super-conductivity exemplary in the rotor part. With this technology two orders of magnitude higher current-densities in the field-winding compared to conventional EESM-design are achievable without sacrificing the thermal limits of the FW [6]. However, the rotor of the partly SC-EESM must be held constantly at cryogenic temperatures by means of a special rotor cooling system.

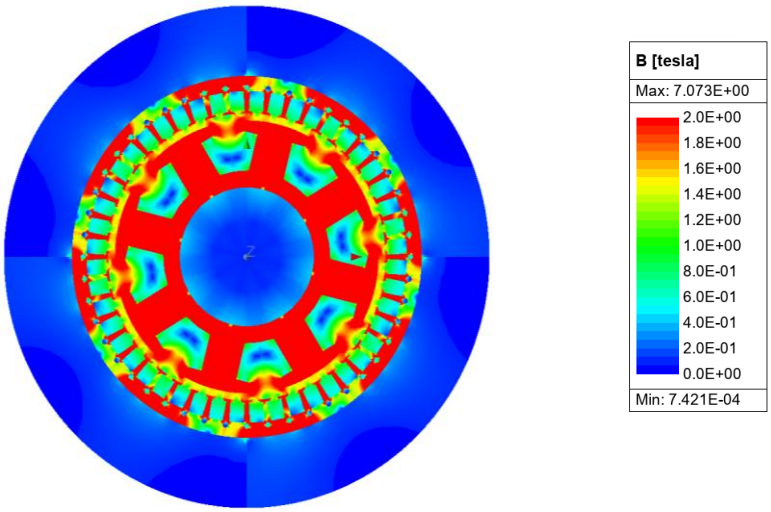

Fig. 3: Flux-density distribution of a partly SC-EESM

Depending on the used super-conductor, the employed cryogenic temperature and critical technical current densities for REBCO-tapes can range up to 3.3 kA/mm^2 [6]. However, to keep a sufficient distance to the critical current densities and magnetic field limits of the SC-tapes it is decided to use an intermediate engineering current density of $J = 300$ A/mm^2 for the SC-FW within EESM design. Fig. 3 shows the magnetic flux-density distribution of the machine showing large, saturated iron parts compared to Fig. 2 on the right. Due to the high magnetic saturation, the outer area is additionally magnetically modelled.

Rotor soft magnetic material

Three different motor variants of the partly SC-machine are magnetically simulated by exchanging the soft magnetic material of the rotor. For this, the magnetic properties of two different soft magnetic materials need to be examined in more detail.

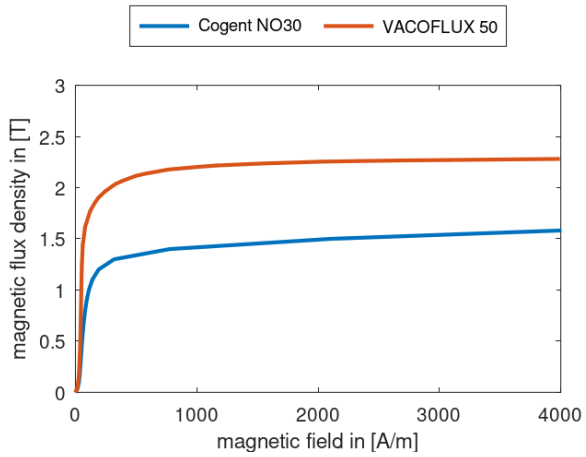

Fig. 4: Magnetization curve of conventional silicon-iron steel and cobalt-iron taken from Ansys MotorCad

Materials Research Proceedings 69 (2026) 757-763 https://doi.org/10.21741/9781644904251-134

Fig. 4 shows two different magnetization curves of a conventional silicon-iron steel (Fig. 4, Cogent NO30) and a high-performance cobalt-iron steel (VACOFLUX 50) exhibiting superior magnetization characteristics with saturation magnetization values of up to 2.4 Tesla. Both steels are now considered as rotor materials. Moreover, an air-cored rotor structure for the EESM will also be designed.

Torque development

From the saturation level displayed in Fig. 3 it is clear, that both soft magnetic materials will be highly saturated in terms of a partly SC-machine. However, it is expected that the cobalt-iron steel has more torque performance (Fig. 4, about +30%) even at high magnetic fields. Moreover, the flux guiding effect of the iron within the rotor of the EESM is not fully vanished.

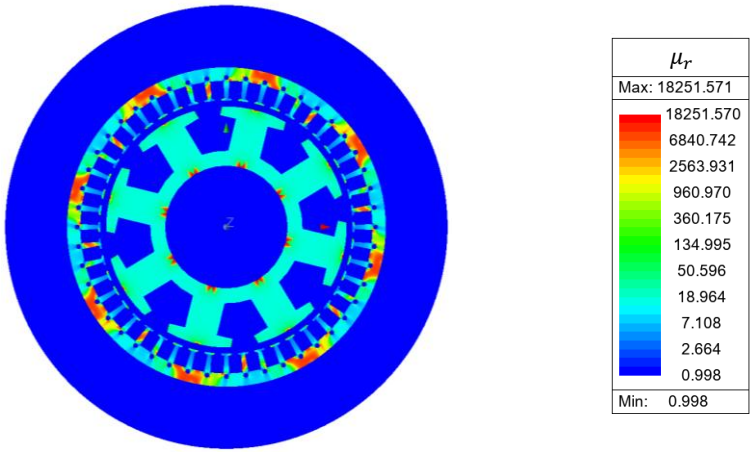

Fig. 5: Logarithmic relative magnetic permeability μ_r within a cobalt-iron SC-EESM rotor

Fig. 5 shows in this context the logarithmic distribution of the relative magnetic permeability μ_r of the machine which is several factors ($\mu_r \approx 15 \dots 20$, $\mu_r \approx 3 \dots 6$ for silicon-iron) above unity within the iron-cobalt rotor. To clarify this, the torque development of an air-cored rotor is also simulated.

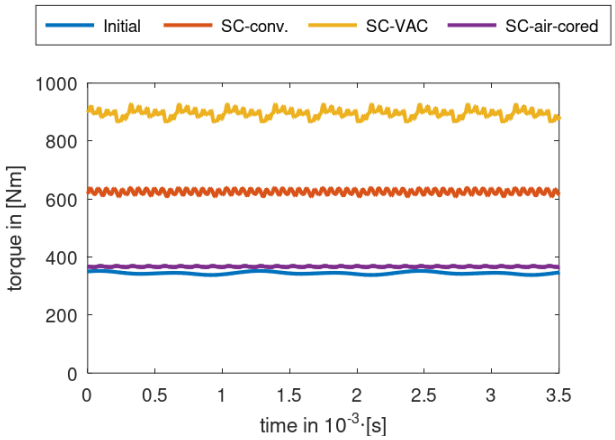

Fig. 6: Machine torque of different SC-configurations and the original torque

Fig. 6 illustrates a direct comparison of the machine design presented in Fig. 2 on the left and its equivalent SC-EESM design (Fig. 3) employing different magnetic rotor materials. From Fig. 5 and Fig. 6 it can be concluded, that the SC-rotor largely increases the torque of the machine whereby the torque of the NO30 conventional silicon steel is 43% lower than that of the iron-cobalt rotor presented in Fig. 5. A machine with an air-cored rotor has almost the same

Materials Research Proceedings 69 (2026) 757-763 https://doi.org/10.21741/9781644904251-134

performance as the non-superconducting machine. In this case the current density of the SC must be increased to achieve more performance as the magnetic flux in the rotor is not guided anymore. All partly SC-machine designs show an increased torque ripple.

Iron and solid losses

Partly SC-EESMs are highly magnetically loaded machines. For the core loss calculation the classical Bertotti equation [7] is used Eq. (1) where k_h, k_c and k_{exc} remark the coefficients for the hysteresis, classical eddy-current and excess losses, respectively.

$$p_v = k_h f \hat{B}^{\alpha} + k_c f^2 \hat{B}^2 + k_{exc} f^{\frac{3}{2}} \hat{B}^{\frac{3}{2}} \tag{1}$$

The magnitude of the flux-density $\hat{B}$ and the frequency f remark the time varying loss components. With the relation in Eq. (1), the loss density of the machine designs is calculated.

Table 1 : Iron loss coefficient and magnetization frequency for the evaluated machine designs

Motor design	α	k_h	k_c	k_{esc}	Frequency in [Hz]
IPM – NO30	2	7.6e-05	0.269	0	1400
SC-EESM-NO30	2	7.6e-05	0.269	0	773
SC-EESM-VAC	4.84	0.02096	2.86e-06	0.003557	540
Air-cored-rotor	2	7.6e-05	0.269	0	1315

Table 1 presents the iron loss coefficients of the magnetic materials displayed in Fig. 4. The air-cored machine has iron losses only in the stator. For the cobalt-iron rotor core the values of NO30 are applied in the stator. The different magnetization frequencies come from the power requirement of the machine (750 kW). Here, a proportional reduction of the rotational speed is possible because of the higher torque production of SC-machine designs.

Table 2: Overview over iron losses in the IPM and SC-EESM machine designs

Motor design	Rotor core losses in [W]	Stator core losses in 10^3·[W]
IPM – NO30	9	1.42
SC-EESM-NO30	6.4	3.38
SC-EESM-VAC	6e-3	2.55
Air-cored-aluminum rotor	1370	4.29

The evaluated iron losses are given in Table 2. The stator losses are the dominant part whereby the SC-EESMs incorporate more losses than the conventional machine design. In terms of an air-cored rotor made of aluminum massive eddy-current losses occur at the tooth tip of the rotor. The same effect will be present if a stainless-steel sleeve in the airgap is introduced to hermetically seal the rotating cryogenic part of the machine.

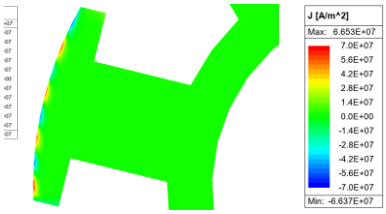

Fig. 7: Eddy-current distribution in SC-EESM ironless air-cored aluminum rotor

Fig. 7 shows the eddy-current distribution at the tooth tip of a rotor pole. Here, the slotting effect of the saturated stator teeth can clearly be seen. Moreover, as the stator teeth are highly saturated and very strong time varying magnetic proximity fields are present in the slot of the

machine. Simulations, which are not presented here, show that the proximity losses in the hairpin stator winding deteriorate efficiency in case of SC-rotor machines by several tens of percentage points. Therefore, the hair-pin winding is not applicable anymore in retrofit designs and the usage of stranded wires for the stator winding is obligatory.

Reduction of motor dimensions

In the previous chapter the iron losses are investigated with reduced rotational speed. Another way to use the high torque performance of the partly SC-EESM is to leave the rotor speed constant (21000 rpm) and reduce the axial machine dimension.

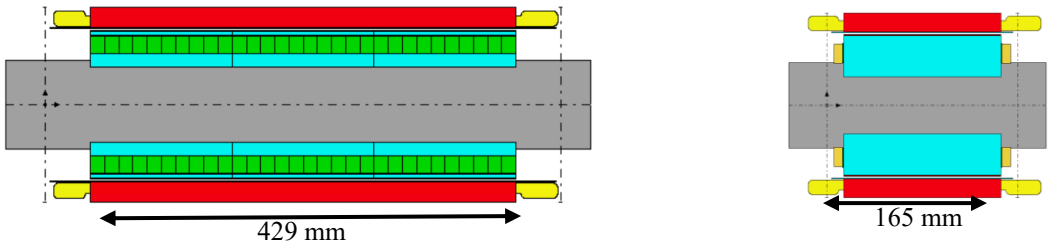

Fig. 8: Comparison of conventional IPM (left) and SC-EESM (right) having the same power

Fig. 8 shows a direct comparison of the axial dimension of conventional IPM-technology (Fig. 8, left) and its partly SC equivalent (Fig. 8, right). The machine volume and weight are more than two times reduced. The iron losses in the stator are four times higher due to the massive saturation (Fig. 3) and high frequency, which is approximately 0.8% of the machine efficiency. However, Fig. 8 shows the full potential of the SC-technology. The power density of an already highly utilized motor can be further increased to values above 20 kW/kg.

Summary

In this paper a retrofit design of a high-power electrical machine for hybrid aircraft propulsion is investigated. For this, a conventional IPM rotor is exchanged by a SC-EESM rotor carrying SC-field excitation coils. In this case one gets a highly saturated machine even when intermediate current densities are applied. Three machine designs with conventional, high-performance electrical steel and an air-cored rotor have been evaluated. Here, the application of iron within the rotor, even in high saturation state (Fig. 3), provides more torque than the air-cored machine variant (Fig. 6). If one can afford the losses in the cryogenic part (Fig. 7) a standard stator design can be used. Otherwise, a stator yoke in ring shape must be employed whereby losing 30 % torque in this case. Anyway, litz-wire is obligatory for the stator winding of SC-machines because high magnetic proximity fields.

Keywords: Drone Capture, Airflow Compensation, Nonlinear Control, Downwash Model

Abstract. This paper addresses the autonomous capture of a target drone by a shuttle drone in a cooperative scenario, focusing on modeling and compensating aerodynamic disturbances caused by environmental factors and proximity flight. The work integrates a nonlinear model of multirotor drones, incorporating aerodynamic effects such as rotor and frame drag, and designs a nonlinear controller to follow trajectories and mitigate disturbances. Additionally, a downwash model based on momentum theory is included to compensate for airflow disturbances during close-proximity capture maneuvers, enhancing stability and precision. Simulation results validate the proposed control strategies, demonstrating improved trajectory tracking and disturbance mitigation in various scenarios, including high-speed single drone operations and close-proximity two-drone maneuvers.

Introduction

Unmanned Aerial Vehicles (UAVs) have seen widespread adoption [1] across diverse applications including search and rescue operations,commercial package delivery,and precision agriculture. Recent advances have shifted focus toward cooperative multi-drone systems that share tasks, loads, or resources, enabling enhanced capabilities such as optimized search patterns and synchronized aerial displays.

Aerodynamic modeling research has identified critical factors affecting proximity flight, including frame drag impacts on trajectory tracking [2], rotor-air interactions in ground effect and formations [3], and downwash phenomena requiring safe operational regions [4]. While Momentum Theory applications enable modeling vehicles hovering beneath others [5] and differential flatness properties reduce tracking errors during agile maneuvers [6], existing studies primarily evaluate horizontal-plane interactions. Despite these advances, a critical gap exists in developing integrated control strategies that simultaneously address autonomous flight, vertical proximity aerodynamic effects, and cooperative capture execution.

This work addresses these gaps, within the CAPTURE project framework [7], by developing an integrated solution for cooperative capture maneuvers between quadrotors. The main contributions are threefold: (1) an integrated control framework that simultaneously handles autonomous flight and proximity aerodynamic effects, towards capture maneuver requirements, in a unified approach; (2) development of simple aerodynamic models and compensation strategies specifically addressing vertical proximity effects between quadrotors; and (3) validation through simulations, demonstrating effectiveness in managing environmental disturbances and inter-drone aerodynamic forces.

Vehicle Modeling and Control

Quadrotors are underactuated systems with six degrees of freedom, controlled by only four inputs, mapped to the rotor speeds. Motion control requires simultaneous speed variation.

Materials Research Proceedings 69 (2026) 765-770 https://doi.org/10.21741/9781644904251-135

Two reference frames are essential for modeling: the world frame W, a fixed local tangent plane, considering North-East-Down coordinates, and the body frame B, attached to the vehicle's center of mass. The rotation matrix $R \in SO(3)$ transforms coordinates from frame B to frame W, whereas the position of B in W is denoted as $p \in \mathbb{R}^3$, the velocity of B described in W is $v \in \mathbb{R}^3$, and the angular velocity of B relative to W, described in B is denoted as ω.

Thus, the system state vector $x = [p^T \ \mathrm{vec}(R)^T \ v^T \ \omega^T]^T$, resulting in the vehicle kinematics, $\dot{p} = v$ and $\dot{R} = RS(\omega)$, with dynamics

$$\dot{v} = -gz_W + \frac{u_1}{m} z_B \tag{1}$$

$$\dot{\omega} = J^{-1}(-S(\omega)J\omega + u_\tau) \tag{2}$$

where g is gravitational acceleration, m is mass, J is the inertia matrix, $z_W = [0\,0\,1]^T$, $z_B = Rz_W$, and $S(\omega)$ is the skew-symmetric matrix of angular velocities, that also satisfies $S(a)b = a \times b$ for $a, b \in \mathbb{R}^3$. The control input vector to this model is defined as $u = [u_1 \ u_\tau^T]^T \in \mathbb{R}^4$, where $u_1 \in \mathbb{R}$ is collective thrust, $u_\tau \in \mathbb{R}^3$ represents torque inputs.

A nonlinear controller based on [8] can be designed to minimize tracking errors relative to a desired reference trajectory, defined by the desired yaw angle, ψ_d, position, p_d, velocity, v_d, and acceleration, a_d. Towards this end, a desired force vector is defined as

$$f_d = -K_p e_p - K_v e_v - K_{ip} e_{ip} + mgz_W + ma_d \tag{3}$$

where $e_p = p - p_d$ and $e_v = v - v_d$ are position and velocity errors, e_{ip} is the integral of the position error, whereas K_p, K_v, and K_{ip} are positive definite diagonal gain matrices. From this desired force, the thrust input is obtained through scalar projection, $u_1 = f_d^T z_B$, whereas the attitude control requires computing the desired rotation matrix $R_d = [x_{B,d} \, y_{B,d} \, z_{B,d}]$. The desired body z-axis aligns with the force direction, defining $z_{B,d} = f_d / ||f_d||$, and using the intermediate frame with $x_{C,d} = [\cos\psi_d \ \sin\psi_d \ 0]^T$, the remaining axes are defined as $y_{B,d} = (z_{B,d} \times x_{C,d}) / ||z_{B,d} \times x_{C,d}||$ *and* $x_{B,d} = y_{B,d} \times z_{B,d}$.

As such, the rotation error quantifies orientation discrepancy as $e_R = 1/2 S^{-1}(R_d^T R - R^T R_d)$ where $S^{-1}(\cdot)$ denotes the inverse operation of $S(\cdot)$. The desired angular velocities, ω_d are derived from the jerk (third derivative) of the trajectory, as detailed in [8], resulting in the torque control inputs $u_\tau = -K_R e_R - K_\omega e_\omega$, where $e_\omega = \omega - \omega_d$ is the angular velocity error, and K_R, K_ω are positive definite diagonal gain matrices.

Aerodynamic Modeling and Control

Rotorcraft vehicles motion is significantly influenced by aerodynamic forces opposing movement, formulated as $f_a = f_{rd} + f_{fd}$, where f_{rd} and f_{fd} represent rotor and frame drag forces respectively. A central concept in aerodynamic effects is the velocity of the air flow relative to the body frame B, expressed in B, here denoted as $v_{Bair} \in \mathbb{R}^3$. This accounts for the velocity of the vehicle and the velocity of the wind, which when described in the world frame W can be written as $v_{air} = Rv_{Bair} = v - v_w$.

Single vehicle aerodynamic forces modeling and compensation

Following [6], a simple model for the rotor drag force is defined as

$$f_{rd} = -RC_{rd} v_{Bair} \tag{4}$$

Materials Research Proceedings 69 (2026) 765-770 https://doi.org/10.21741/9781644904251-135

where C_{rd} is a diagonal matrix of rotor drag coefficients. Frame drag, modeled according to [2], represents air resistance due to the quadrotor shape, here defined as

$$f_{fd} = -\frac{1}{2}\rho C_d A v_{Bair} \odot |v_{Bair}| \tag{5}$$

where ρ is air density, C_d is the drag coefficient, $A = \mathrm{diag}(a_x.a_y, a_z)$ with a_i represents the projected area along axis i of the body frame, and the product $v_{Bair} \odot |v_{Bair}|$ denotes an element-wise multiplication between the two vectors, while a slight abuse of notation is used in $|v_{Bair}|$, denoting also the element-wise absolute value operator. The symmetry assumption simplifies modeling by using constant drag coefficients along body axes.

The complete velocity dynamics incorporating both effects becomes

$$\dot{v} = -g z_W + \frac{1}{m}(u_1 z_B + f_{rd} + f_{fd}) \tag{6}$$

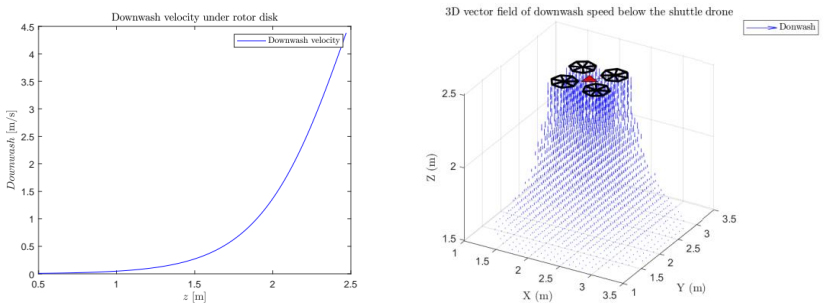
Recalling the nonlinear controller presented above, which controls the attitude of the vehicle according to a desired force vector, with the addition of aerodynamic effects presented here, compensation is achieved through feed-forward control terms in the desired force as

$$f_d = -K_p e_p - K_{ip} e_{ip} - K_v e_v + m g z_W + m a_d - f_{rd} - f_{fd} \tag{7}$$

which can have both rotor-drag and frame-drag compensation, just one of these, or none, as will be explored in the results presented below.

Two-vehicle aerodynamic interactions

When two rotorcraft operate in proximity, the dynamics of the airflows of both vehicles might become coupled, possibly resulting in control authority loss. The scenario considered in this paper assumes a shuttle drone (drone 1) which generates downwash affecting the target drone (drone 2) flying below the shuttle drone, assuming identical vehicles.



Using momentum theory [5], the induced air velocity of drone 1 is $V_{i_1} = \sqrt{T/(2\rho A_d)}$ where T is total thrust and A_d is rotor disk area. A possible estimate of the vertical air velocity $V_{d_1}(z)$, at a given vertical distance z (below the rotor height, z_r), can be defined as

$$V_{d_1}(z) = V_{i_1} + V_{i_1} \tanh\left(-k\frac{z_r - z}{h}\right) \tag{8}$$

where parameters h and k define the shape of the curve, as depicted in Fig. 1a.

Momentum theory assumes that $V_{d_1}(z)$ is uniform over the xy plane for a given z position. However, as the boundary of the downwash contracts due to acceleration, the radial condition

Materials Research Proceedings 69 (2026) 765-770 https://doi.org/10.21741/9781644904251-135

(a) 2-D plot (b) 3-D plot

Figure 1: Air flow beneath drone 1 analysis

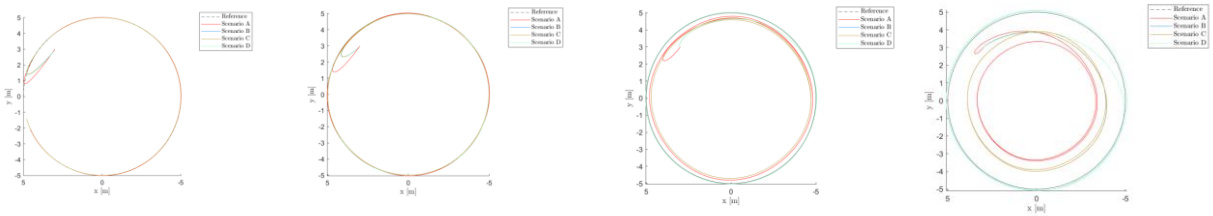
for the vertical velocity reaching zero changes, expanding as the air goes down. Considering the radial distance $r_d(x, y)$ and the rotor radius r, the downwash velocity can be computed at any 3-D point, (x, y, z), below the rotor disc as

$$V_{dw_1}(x, y, z) = \begin{cases} V_{d_1}(z), & \text{if } r_d(x, y) < \frac{r}{\sqrt{1+\tanh\left(-k\frac{z_r - z}{h}\right)}} \\ 0, & \text{otherwise.} \end{cases} \tag{9}$$

This airflow can be seen in Fig. 1b, where 4 rotors for drone 1 are considered.

The downwash air flow velocity from drone 1 can be accounted for in drone 2 air flow velocity, by redefining

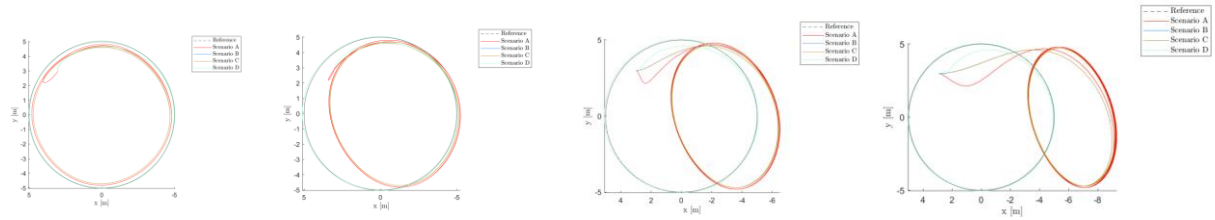
$$v_{air_2} = v_2 - v_w - v_{dw} \tag{10}$$



where v_{dw_1} represents the 3-D downwash velocity vector as $v_{dw_1} = [0\,0\,V_{dw_1}]^T$. This additional airflow component modifies both rotor and frame drag calculations for drone 2, according to the axpressions above, resulting also in a compensation of this factor in the controller.

Simulation Results

The proposed control strategies were implemented using MATLAB/Simulink, with separate modules for the quadrotor controller and dynamic model. The controller receives reference values for position, velocity, angular velocity, and rotation matrix, computing control inputs $u = [u_1\, u_\tau^T]^T$ that drive the quadrotor dynamics. Empirically tuned control gains were determined as: $K_p = \text{diag}(10, 10, 6)$, $K_v = 5I_3$, $K_R = 15I_3$, $K_\omega = I_3$, and $K_{ip} = 0.01I_3$.

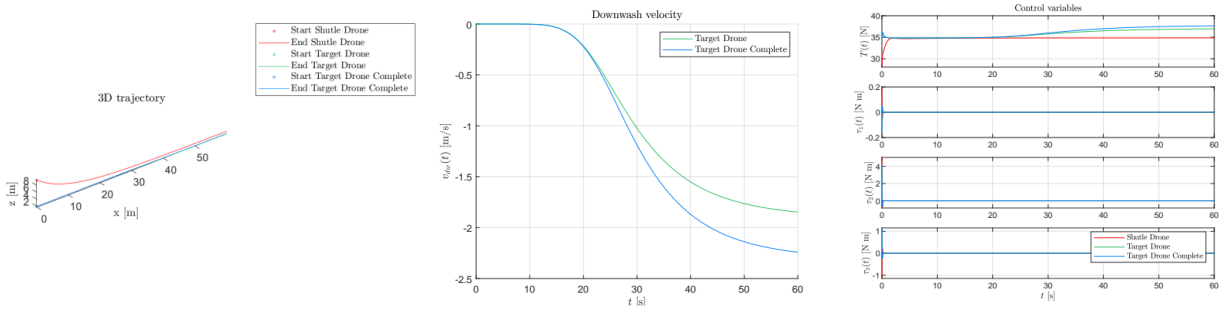


Four scenarios evaluated aerodynamic compensation effectiveness: (A) baseline without any feed-forward compensation, (B) with basic feed-forward terms (no aerodynamic terms), (C) with rotor drag compensation, and (D) with both rotor and frame drag compensation. Testing with circular trajectories ($x(t) = 5\cos(\omega_{ref}t)$, $y(t) = 5\sin(\omega_{ref}t)$, $z(t) = 3$) at varying speeds revealed significant performance improvements with compensation strategies, as presented in Figure 2, demonstrating progressive improvement from Scenario A to D. Wind disturbance analysis at different flight speeds demonstrates the controller effectiveness, as presented in Figure 3, showing how compensation strategies maintain tracking accuracy even under strong headwind conditions.

Materials Research Proceedings 69 (2026) 765-770 https://doi.org/10.21741/9781644904251-135

(a) $\|v\| = 1$ m/s (b) $\|v\| = 2$ m/s (c) $\|v\| = 5$ m/s (d) $\|v\| = 10$ m/s

Figure 2: Drone trajectories at different vehicle speeds.



(a) No wind. (b) $v_{wx} = -5$ m/s (c) $v_{wx} = -10$ m/s (d) $v_{wx} = -15$ m/s

Figure 3: Drone trajectories under varying wind conditions.

These results indicate frame drag compensation provides the most significant improvement, reducing errors by approximately 50% for high-speed flight and nearly 10 times for extreme wind conditions. Feed-forward terms significantly reduced attitude oscillations, while complete compensation (Scenario D) maintained consistent performance across all conditions, with 89% and 91% RMSE error reduction when compared with no compensation (Scenario A), respectively, for 10 m/s vehicle velocity and for 15 m/s wind disturbances.

Two-drone proximity flight simulations evaluated downwash effects during capture operations. Drone 1 descended following $z(t) = 7\exp(-0.3t) + 2.00 + h$ while drone 2 maintained horizontal flight at $z = 2$ m, with identical horizontal trajectories, as shown in Figure 4a The downwash effects and corresponding control responses are visualized in Figure 4b.

These results show that downwash compensation reduced z-axis trajectory errors by 38\% at 0.5 m separation, with diminishing benefits beyond 1 m where aerodynamic interactions become negligible. The target drone required increased thrust (up to 37.65 N) to counteract downwash forces at close proximity, as illustrated in Figure 4c.

Figure 4: Cooperative capture maneuver results.

Concluding Remarks

This paper presented a modeling and control framework for cooperative quadrotor capture maneuvers, focusing on aerodynamic interactions in close-proximity flight. Key contributions

include a nonlinear controller for accurate trajectory tracking, comprehensive aerodynamic modeling, and a novel downwash compensation approach enabling stable flight at close distances between drones. Simulations showed up to 89\% reduction in position RMSE at 10 m/s velocities and 91\% reduction in 15 m/s headwinds. Cooperative scenarios saw a 38\% error reduction at 0.5 m separation. Future work includes experimental validation and integration with realistic simulation environments.

Keywords: Weapon-Target Assignment (WTA), Cooperative Guidance, Multi-Agent Systems, Online Task Assignment, Combinatorial Optimization, Missiles, Air-Defense

Abstract. As modern threats evolve through coordinated swarm attacks, static or pre-launch assignments for air-defense systems become outdated mid-engagement, necessitating in-flight reassignment. Therefore, cooperative guidance is introduced, extending dynamic Weapon-Target Assignment (WTA) from launch-time coordination into the mid-course flight phase. A decentralized architecture is proposed that couples WTA with trajectory guidance via informed cost functions. The information consensus-based WTA optimization procedure enables real-time adaptability under communication constraints. The Hungarian algorithm is chosen for its deterministic, low-complexity performance for the repeated optimizations. A simulation example illustrates mid-course reassignment triggered by target maneuvering, demonstrating the feasibility of collaborative flight-path adaptation.

Introduction

This work discusses cooperative guidance for air-defense systems, extending state-of-the-art launch coordination with dynamic Weapon-Target Assignment (WTA) in the mid-course phase. As modern threats evolve through coordinated swarm attacks [1, 2], we assume that static launch-time coordination becomes insufficient. While dynamic WTA improves responsiveness through sequenced launches [3, 4], a continuous in-flight cooperation is the next step. Enabled by network-centric warfare [5, 6], cooperative guidance allows effectors to jointly reassign targets in-flight, adapting to dynamic threats in real time. We propose a cooperative guidance concept for an onboard module, that integrates WTA and trajectory guidance via cost-informed assignments. It enables real-time adaptability with limited computational resources. The decentralized approach avoids single points of failure [7].

A dynamic optimization of assignments and collaborative adaption of intercept flight paths in real-time throughout the unpropelled mid-course of the missiles after their boost-phase, shall maximize intercept success probabilities. This cooperation allows to dynamically react to erratically evolving environments. The approach is expected to increase effectiveness for the air-defense while additionally saving on costly resources.

Background on Weapon-Target Assignment

The WTA problem can be approximated as a linear assignment problem. The best combination of all possible effector/target assignments is evaluated by a combinatorial optimization. To solve the linear assignment problem mathematically, scalar cost values c_{ij} for the assignment of each effector $i \in [\![1, N]\!]$ to each target $j \in [\![1, M]\!]$ are to be defined. This relationship is schematically shown in Fig. 1.

Materials Research Proceedings 69 (2026) 771-776 https://doi.org/10.21741/9781644904251-136

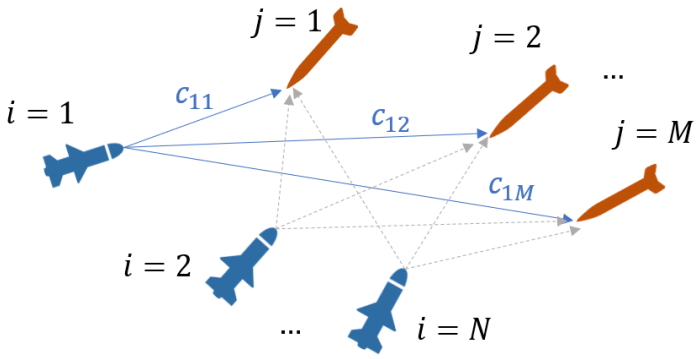

Fig. 1: Assignment Costs Illustration

The sum of these costs ought to be minimized by selecting an optimal assignment which is described by

$$\min_{x}\left(\sum_{i=1}^{N}\sum_{j=1}^{M} c_{ij}\ x_{ij_{,\tau}}\right), \tag{1}$$

where the binary variables x_{ij} represent the assignments of effectors to targets either at time τ or the previous timestep $\tau - 1$ (as in Eq. 3). This optimization shall be subject to the following constraints:

$$\begin{aligned}
&\text{C1 (binary assignment variables):} \quad \forall i \in [\![1,N]\!], \forall j \in [\![1,M]\!], \quad x_{ij} \in \{0,1\} \\
&\text{C2 (exactly one target assigned per effector):} \quad \forall i \in [\![1,N]\!], \quad \sum_{j=1}^{M} x_{ij} = 1 \\
&\text{C3 (bounds on effectors per target):} \quad \forall j \in [\![1,M]\!], \quad \left\lfloor \frac{N}{M} \right\rfloor \leq \sum_{i=1}^{N} x_{ij} \leq \left\lceil \frac{N}{M} \right\rceil
\end{aligned} \tag{2}$$

The first constraint (C1) enforces that the assignment variables x_{ij} are binary, indicating whether worker i is assigned to task j. The second constraint (C2) ensures that each worker is assigned to exactly one task. The third constraint (C3) limits the number of effectors assigned to any target between the floor and ceiling of the ratio $\frac{N}{M}$ for an even distribution of effectors across targets.

Cooperative Guidance Architecture

Cooperative guidance integrates WTA and trajectory guidance. While simultaneous optimization of assignment and trajectory is theoretically optimal, it is computationally prohibitive [8, 9] for onboard use. We instead adopt a separated approach: the trajectory guidance law is recognized in the cost function c_{ij} (e.g., via time-to-go estimates), enabling good performance with low complexity. A closed loop is created: the assignment defines the target for the mid-course guidance and in turn, guidance-relevant metrics feed into the cost function. A fully connected mesh enables decentralized cooperation (Fig. 2). Each effector exchanges state or cost estimates with peers (depending on the WTA algorithm selection in the next section), while receiving target data from a central node.

Materials Research Proceedings 69 (2026) 771-776 https://doi.org/10.21741/9781644904251-136

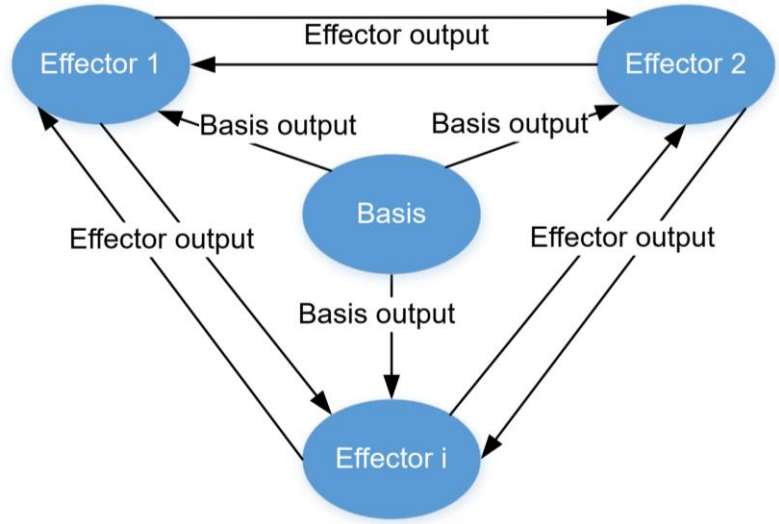

Fig. 2: Ideal Communication Scheme

Since cost function design bounds the decision quality for any optimization algorithm, the assignment optimization is assumed to be predominantly driven by a sound exploitation of flight mechanical and operational knowledge (e.g. regarding target/asset classification). As [10] outlines, WTA optimization objective is usually either based on minimization of target survivability or maximization of asset survivability. We suggest a multi-objective, cost-driven WTA optimization approach that achieves the following set of high-level objectives:

1) maximization of asset-survivability (e.g. by distance to predicted intercept area),
2) minimization of general threat level imposed by targets (e.g. via time-to-go) and
3) maximization of energy reserves (e.g. through predicted speed at intercept).

These objectives ought to be cast into combined cost parameters for any assignment of effectors to targets via a weighted sum, such that the WTA problem can be optimized by selecting a combination of assignments which minimize the overall costs. The systematic exploitation of domain-knowledge for the cost factors in order to achieve and balance these high-level objectives is not yet clear and should be investigated in future work. A manually tuned additional cost (i.e. switching cost) s can be added to the cost function (cf. Eq. 1) for previously not-assigned combinations as

$$\hat{c}_{ij} = c_{ij} + s\,(1 - x_{ij_{,\tau-1}}) \tag{3}$$

to penalize undesired high-frequency reassignments.

Weapon-Target Assignment Algorithm Selection

For the development from coordination to cooperation, some high-level requirements are derived for the WTA definition and its optimization algorithm. Due to the continuous evaluation, consistent solutions must be ensured in order to avoid wasteful perpetual swapping of assignments. Particularly for development, reproducibility is beneficial. This requires deterministic optimization algorithms. The optimization, including the calculation of a cost function as well as the solution, is time-critical. According to Eq. 2, the optimization algorithm must be able to ensure that every effector has exactly one target assigned to it (if targets are available) and every target can have different numbers of effectors assigned to it, depending on the symmetry of the number of participants.

Materials Research Proceedings 69 (2026) 771-776 https://doi.org/10.21741/9781644904251-136

In conjunction with the type of future connections and expected failures/limitations, a design decision needs to be made between information or assignment consensus. Fig. 3 illustrates a qualitative comparison of both approaches.

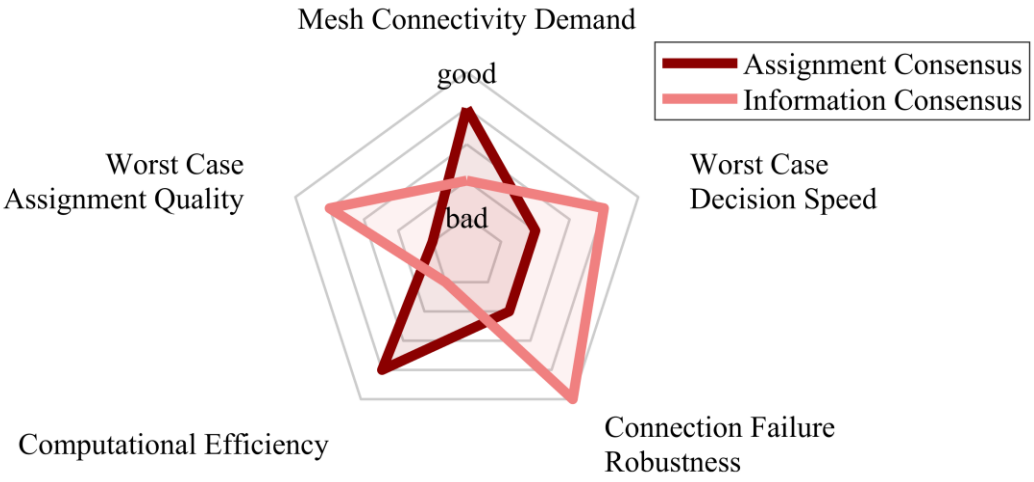

Fig. 3: Assignment vs. Information Consensus Trade-off

In scenarios with stable, short-range connections, assignment consensus methods operating on nearest-neighbor communication schemes can be effective [11]. Contrarily, information consensus tends to demand increased mesh connectivity. The required communication bandwidth varies between the two approaches. For information consensus, it depends on the cost function and its required information, whereas for assignment consensus, it depends on the specific framework used (e.g., transmitting entire bundles of bids simultaneously or one bid at a time, in turn requiring more communication iterations) [11].

However, when frequent connection failures are expected, information consensus enables compensation techniques like dead-reckoning (state estimation) on each effector, allowing to maintain a consistent assignment optimization plan [11]. Given the limited maneuverability of missiles, dead-reckoning techniques should work well for short durations. Particularly if flight dynamics and guidance are known for all effectors, well-informed predictions can then be made with continuous uplinks for target and asset information, reducing the requirements on effector-to-effector communication frequency. Reaching assignment consensus may be delayed due to communication latencies, potentially leading to decisions being made beyond a critical "point-of-no-return" in dynamic environments (worst case decision speed in Fig. 3). Information consensus combined with state estimation can make more up-to-date decisions. Nevertheless, solving the global assignment problem onboard every effector significantly increases computational demands. A simulation study comparing information vs. assignment consensus approaches with missiles under uncertainties and unstable connections should be pursued in future work.

Consulting survey papers on multi-robot task assignment such as [7] suggests that as long as communication network topology is not assumed as too restricted and computational demands are feasible, the simple Hungarian algorithm [12] (extended for rectangular cost matrices) for information consensus is the preferred choice. For cases of numerical superiority, the cost matrix has to be replicated to the right, such that the number of "virtual" (copied) targets is higher than the number of effectors to address C3 in Eq. 2. Computational demands remain feasible as long as no too complex simulations or trajectory optimizations for the WTA cost function are used and computational requirements are dominated by other subsystems (e.g. image processing in infrared seekers). Benefits of the Hungarian algorithm were previously demonstrated in similar multi-agent problems [13].

Materials Research Proceedings 69 (2026) 771-776 https://doi.org/10.21741/9781644904251-136

Simulation Test

The concept is exemplarily tested with a 3 effector vs. 3 targets simulation from launch until target interception (based on a simple proximity collision logic) in Fig. 4. Forward simulations with the model and guidance algorithms are performed in each iteration, to estimate the time-to-go for each effector/target combination as the only WTA cost parameter considered in this example. A simple Proportional Navigation Guidance (PNG) algorithm is used for trajectory guidance. The WTA is performed online with 1 Hz. Effector trajectories (in the back of the figure) are color-coded by assigned target. The effectors launch successively and allocate themselves such that each target is assigned to one effector. Mid-flight, the right-most (purple) target turns to the left. It is consecutively reassigned to effectors from right to left during the maneuver, such that the summed-up time-to-go for all effectors remains lowest. All computations are performed in each effector model. The entire simulation takes only a few seconds on a consumer laptop, demonstrating feasibility on embedded systems under real-time constraints.

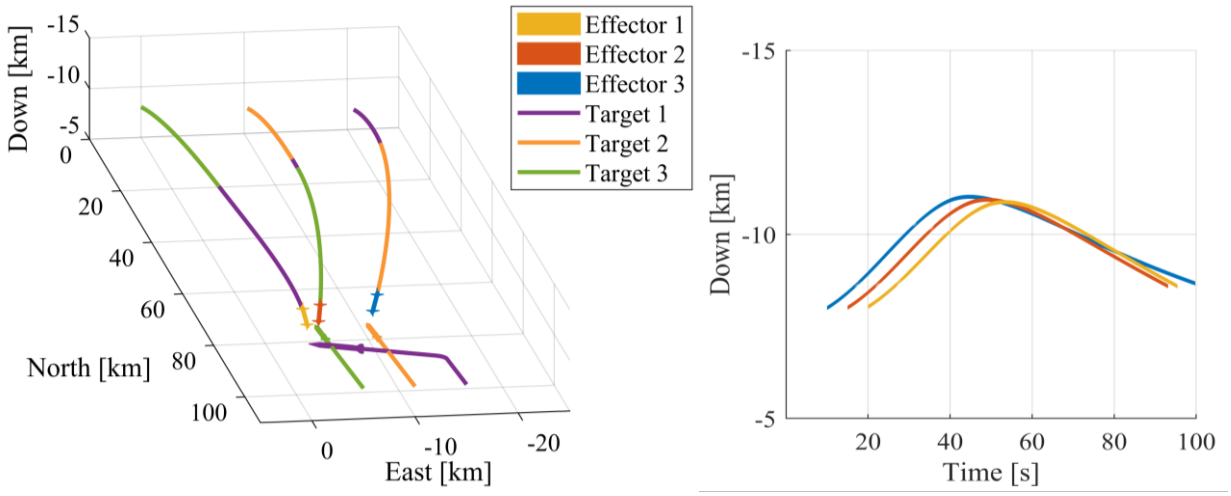

Fig. 4: Illustrative Scenario: Mid-Course Reassignment Triggered by Target Maneuver

Simulation Test

This paper introduces the concept of cooperative guidance for air-defense systems, extending WTA into the mid-course flight phase. We propose a decentralized, onboard architecture that tightly couples WTA with trajectory guidance through cost-informed feedback, enabling real-time adaptation to evolving threats. The integration of well-established components (e.g. Hungarian algorithm) into a lightweight, cooperative missile guidance loop represents a novel approach to adaptive air-defense. This work lays the conceptual foundation for future implementation and evaluation. Quantitative evaluation and cost function design will be presented in follow-up work. The framework paves the way for adaptive, resilient air-defense systems capable of countering next-generation swarm threats.

Keywords: Fixed-Wing UAV, Quadrotor, Forward-Motion Release, Stability

Abstract. This work presents a detailed simulation framework for a novel aerial deployment system that enables mid-air release of a fixed-wing UAV from a quadrotor platform. Traditional launch systems for fixed-wing UAVs often rely on bulky infrastructure or manual intervention. This study proposes and simulates a more flexible and autonomous alternative tailored for constrained, tactical, or remote environments where conventional methods are impractical. The focus of this contribution is on modeling, simulating, and analyzing the system dynamics associated with forward-motion deployment, which adds complexity to the release dynamics and improves transition to autonomous flight post-deployment.

Introduction

Unmanned Aerial Vehicles (UAVs), particularly fixed-wing types, play a significant role in a variety of applications ranging from surveillance to disaster response. However, the launch of fixed-wing UAVs from platforms such as quadrotors faces considerable challenges due to the bulky infrastructure or manual intervention required in traditional launch systems. In constrained, tactical, or remote environments where conventional methods are impractical, an innovative solution is necessary. This study proposes and simulates a forward-motion mid-air deployment system, which enables the autonomous release of a fixed-wing UAV from a quadrotor platform.

Unlike previous studies that primarily focused on combination of both platforms into VTOL [1], this work introduces the novel concept of utilizing the quadrotor's forward motion during the deployment phase. By modeling and simulating the dynamics involved in forward-motion deployment, the proposed system provides initial aerodynamic lift and velocity to the fixed-wing UAV, thus enhancing the stability and transition to autonomous flight. This approach also reduces the risks associated with stall after the UAV's release [2].

The framework for this deployment system is developed using MATLAB Simulink, incorporating both Simscape Multibody and custom control blocks. The simulation includes three core subsystems: environment setup, plant setup for both the quadrotor and UAV, and a control system featuring several PID-based control loops. This method is validated by evaluating the system's performance under various deployment scenarios, including different payload weights, wind speeds, and forward velocities.

Numerical Background and Modelling Approach

The simulation framework in this study integrates key numerical models to simulate the dynamics of both the quadrotor platform and fixed-wing UAV during deployment. The methodology ensures that essential physical properties such as aerodynamics, control
dynamics, and payload interactions are accurately captured.

The quadrotor is modelled as a rigid body using Newton-Euler equations, Eq. 1, for both translational and rotational motion:

Content from this work may be used under the terms of the Creative Commons Attribution 3.0 license. Any further distribution of this work must maintain attribution to the author(s) and the title of the work, journal citation and DOI. Published under license by Materials Research Forum LLC.

Materials Research Proceedings 69 (2026) 777-781 https://doi.org/10.21741/9781644904251-137

$$M(q)\ddot{q} + C(q,\dot{q})\dot{q} + G(q) = u \quad (1)$$

where q includes position and orientation, M is the mass and inertia matrix, C is the Coriolis matrix, and G represents gravity, while u are the control inputs (thrust and torques). These equations model the quadrotor's response to forces generated by its motors, aerodynamics, and the payload during release.

The fixed-wing UAV is similarly modelled, with lift and drag forces calculated using:

$$F_L = \frac{1}{2}\rho v^2 C_L A \qquad F_D = \frac{1}{2}\rho v^2 C_D A \quad (2)$$

These equations, Eq. 2, predict the UAV's post-release flight dynamics and are crucial for determining its transition to level flight.

To model the interaction during release, a Force Interaction Model is used, Eq. 3. This model computes the forces acting on the payload at separation and estimates the resulting trajectory based on aerodynamic principles and initial velocity. A key factor is the change in the quadrotor's moment of inertia due to the payload release, defined in Eq. 3.

$$I_{\text{total}} = I_{\text{quadrotor}} + I_{\text{payload}} \quad (3)$$

This allows accurate prediction of how the release affects the quadrotor's stability and preserves pitch and roll stability.

A two-loop PID control system manages both trajectory and attitude during deployment. The position controller uses spline interpolation to ensure smooth path planning, avoiding sharp turns. These loops are built on basic PID control law, Eq. 4.

$$u(t) = K_p e(t) + K_i \int e(t)dt + K_d \frac{de(t)}{dt} \quad (4)$$

where $e(t)$is the error signal, and $K_p, K_i, K_d$are the control gains. This architecture helps maintain stability during UAV release and prevents destabilization from shifts in the center of gravity (CoG).

The payload release system's disengagement logic dynamically adjusts thrust at separation to prevent unwanted oscillations or instability in the quadrotor's trajectory. The release occurs when certain velocity and stability conditions are met, ensuring the UAV transitions smoothly to level flight.

The simulation framework is built in MATLAB Simulink 2023 with Simscape Multibody for accurate modelling of mechanical dynamics. SOLIDWORKS is used for CAD modelling, and Simscape Multibody Link imports the models into Simulink. Environmental factors, including wind speed and gravity, are incorporated to replicate real-world conditions as closely as possible.

Simulation Scenarios and Objectives

To evaluate the effectiveness of the proposed forward-motion UAV deployment system, a series of simulation scenarios were designed, varying key operational factors to assess the system's performance. These scenarios aimed to analyse the system's stability, level flight initiation, and transition to autonomous flight under different conditions, in comparison to prior work on UAV deployment [1][2].

The primary parameters tested include forward velocities (ranging from 0 to 15 m/s), payload weights (1.2 to 1.6 kg), and wind speeds (0 to 10 m/s). Each of these factors plays a

Materials Research Proceedings 69 (2026) 777-781 https://doi.org/10.21741/9781644904251-137

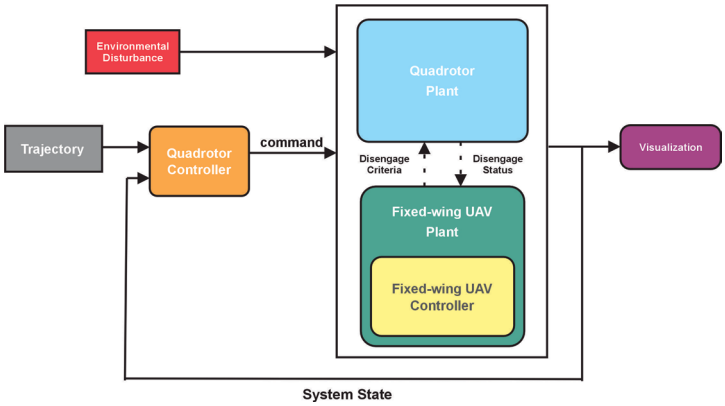

Figure 1 - Block diagram depicting the guidance and control architecture for quadrotor UAV deployment.

Figure 2 - Pre-release

Figure 3 - Post-release

crucial role in influencing the release dynamics. Forward velocity, for example, impacts the aerodynamic lift provided to the UAV during release, enhancing stability and glide performance [3]. Similarly, varying the payload weight allows for the examination of changes in the quadrotor's stability and control during release, as heavier payloads will affect the centre of gravity and moment of inertia. Environmental factors, such as wind speed, were included to assess how external disturbances affect both the quadrotor and UAV during deployment, with wind known to influence trajectory and stability [4].

The simulations aim to validate the system's ability to handle these variations while ensuring a smooth and stable transition to autonomous flight, optimizing the UAV deployment process in constrained or remote environments.

Results: Evaluation of Forward-Motion UAV Deployment System

The UAV deployment performance, influenced by factors like forward velocity, payload mass, and wind speed, reveals crucial insights into its stability, recovery time, and time to achieve level flight. In Figure 4, the relationship between recovery time and forward velocity shows that as the forward velocity increases, the recovery time decreases, especially for lighter payloads (e.g., 1.2 kg), where recovery time drops to as low as 2.5 seconds at 14 m/s. For heavier payloads (e.g., 1.6 kg), recovery times remain higher, reaching over 5 seconds, due to the increased inertia, which slows the UAV's ability to stabilize.

In Figure 5, we observe the time to achieve level flight, where lighter payloads, such as 1.2 kg, require approximately 1.5 seconds at 14 m/s. Heavier payloads take longer, with the 1.6 kg payload reaching 2.5 seconds under similar conditions. Wind speeds play a significant role here, as shown in Figure 6, where stronger winds (e.g., 10 m/s) lead to increased recovery times (over 7 seconds),

Materials Research Proceedings 69 (2026) 777-781 https://doi.org/10.21741/9781644904251-137

while higher forward velocities mitigate the wind's destabilizing effects, reducing the time to level flight.

Attitude deviation, analysed in Figure 7, shows a clear impact of payload mass and wind speed. For lighter payloads (1.2 kg), the attitude deviation is around 3 degrees at 10 m/s

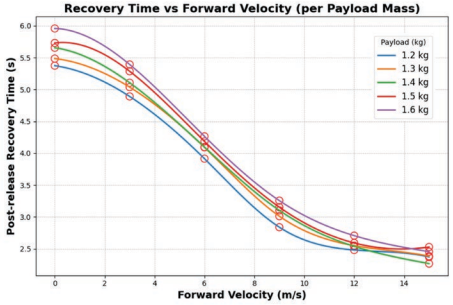

Figure 4 - Post-release Recovery Time

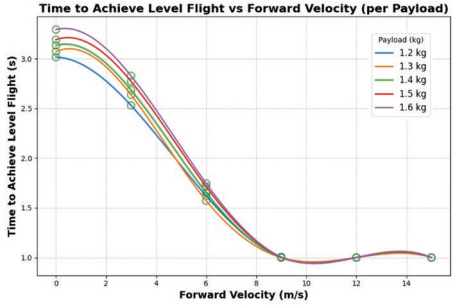

Figure 5 - Tim to Achieve Level Flight post recovery

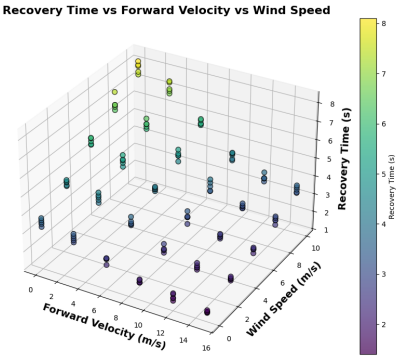

Figure 6 - Recovery Time as a Function of Forward Velocity and Wind Speed

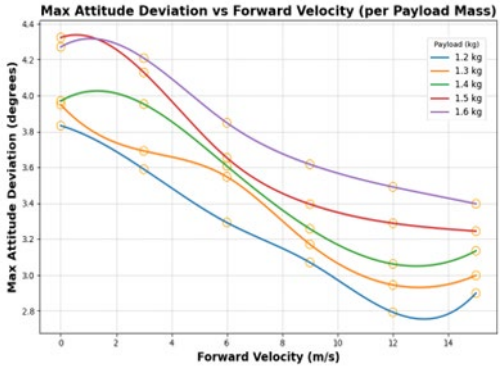

Figure 7 - Max Attitude Deviation with Recovery Time

wind speed, whereas heavier payloads (1.6 kg) exhibit larger deviations, up to 6 degrees. Wind speed further amplifies this effect, highlighting the importance of managing both payload and wind conditions to maintain stability.

Summary

The simulation results show that forward velocity, payload mass, and wind speed significantly affect UAV stability, recovery time, and time to level flight. Higher forward velocities improve stability and reduce recovery time, especially for lighter payloads, while heavier payloads lead to increased recovery times due to greater inertia. Compared to traditional vertical deployment, the forward-motion method enhances stability and reduces altitude loss, making it well-suited for tactical environments.

Optimizing forward velocity is critical for minimizing recovery time and time to level flight, especially with heavier payloads. Additionally, wind conditions should be considered, as they significantly impact recovery time and attitude stability, highlighting the importance of precise deployment strategies. This method could enable more flexible and autonomous UAV operations in constrained or remote areas, paving the way for real-world testing and validation.

Keywords: Electrical Helicopter, Battery-Powered Flight, Sustainable Aviation, Urban Air Mobility, eVTOL, Electric Propulsion

Abstract. The need to reduce aviation emissions is driving focus toward electric propulsion. While eVTOL (electric vertical takeoff and landing) designs face hurdles like system complexity and infrastructure deficits, the electrification of conventional helicopters through retrofitting remains underexplored. This study addresses this gap using a mission-driven approach, analyzing feasibility within realistic operational constraints. The profile specifies a cruise distance of 80 km, a speed of 185 km/h, and a maximum payload of 450 kg, plus an EASA-compliant reserve. The methodology involves: reviewing existing rotorcraft literature, designing a conceptual electric helicopter, and calculating power requirements based on the profile. Suitable electric propulsion configurations are then evaluated against current battery and motor technologies. The study concludes that although electric aviation in general, and electric helicopters in particular, show considerable promise, further advancements in battery energy density and component efficiency are still necessary to fully realize their operational potential.

Introduction

The need to reduce emissions in the aviation sector has led to a growing focus on alternative propulsion systems, with electric flight seen as a promising path toward more sustainable air transport. To support this shift, the EU's Flightpath 2050 targets a 75% reduction in CO2 and 90% in NOx emissions by mid-century [1], and similarly, NASA's N+3 goals aim for significant improvements in propulsion and efficiency.

Accounting for 95% of a helicopter's lifecycle emissions, propulsion is a critical area for carbon reduction [2]. Helicopters are essential for emergency and rescue missions, but their high fuel use and noise make them strong candidates for electrification, offering significant cuts in emissions and costs. Crucially, the retrofitting of existing, certified platforms is underexplored, despite avoiding the major hurdles affecting eVTOLs. Prototypes include the Sikorsky Firefly research demonstrator [3] and the more promising Tier 1 Engineering's e-R44, an electric conversion of the Robinson R44 [4].

Alongside these demonstrators, academic interest in electric rotorcraft design is growing. One study investigated configuration trade-offs for electric helicopters in urban air mobility, exploring single-main-rotor and lift-augmented compound layouts [5]. Another study conducted a preliminary and feasibility analysis of electrifying the conventional EC135 platform using a fuel-cell-based system and superconducting motor, emphasizing performance and energy system integration [6]. A conceptual all-electric retrofit of a lightweight helicopter, based on the Robinson R22, is presented in [7], evaluating several battery and fuel-cell configurations through performance and cost analyses. Existing technology and limitations were also reviewed [8].

This study was developed in alignment with regulatory frameworks set by EASA, aiming to comply with CS-27 and SC E-19. These standards ensure the proposed electric configuration meets both certification and performance expectations.

Mission Profile

The mission profile is adapted from Archer Aviation's operational concept for the Midnight eVTOL. The mission, as illustrated in Fig. 1, encompasses a cruise distance of 80 km, a cruise speed of 185 km/h at an altitude of 2000 ft, and a maximum payload capacity of 450 kg. A 20-minute fuel reserve is added per EASA's Acceptable Means of Compliance (AMC) [9].

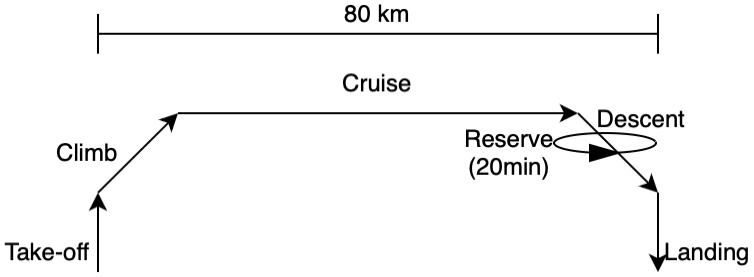

Figure 1. Mission profile for an electric helicopter

Power Calculation

In this work, rotor aerodynamic power is computed for each flight segment using standard momentum-disk relations and blade-element profile models [10]. The main-rotor power coefficient C_P consists of induced, profile, parasite, and climb contributions, expressed as

$$C_P = C_{P_i} + C_{P_o} + C_{P_p} + C_{P_c}, \tag{1}$$

where the non-dimensional power coefficients C_P relate to their dimensional counterparts by

$$P = \rho A(\Omega R)^3 C_P. \tag{2}$$

For hover calculations, only the induced and profile power components are considered. An induced power correction factor k of 1.10 is applied for hover, whereas for forward flight, in addition to induced and profile power, the parasite drag term also contributes, and the induced power factor is taken as $k = 1.25$. The tail-rotor contribution is obtained from the main-rotor mast torque,

$$Q_{MR} = \frac{P_i + P_o}{\Omega}. \tag{3}$$

The required anti-torque thrust follows from the tail-rotor moment arm about the mast,

$$T_{TR} = \frac{Q_{MR}}{l_{tr}}. \tag{4}$$

Parasite and climb terms do not contribute to mast torque and are therefore excluded from Q_{MR} but included in the total power. The data used to solve the power equations are presented in Table 1, and the resulting power curves with respect to the advance ratio μ are shown in Fig. 2. The total rotor power is:

$$P_{\text{rotors}} = P_{MR} + P_{TR}. \tag{5}$$

Materials Research Proceedings 69 (2026) 782-787 https://doi.org/10.21741/9781644904251-138

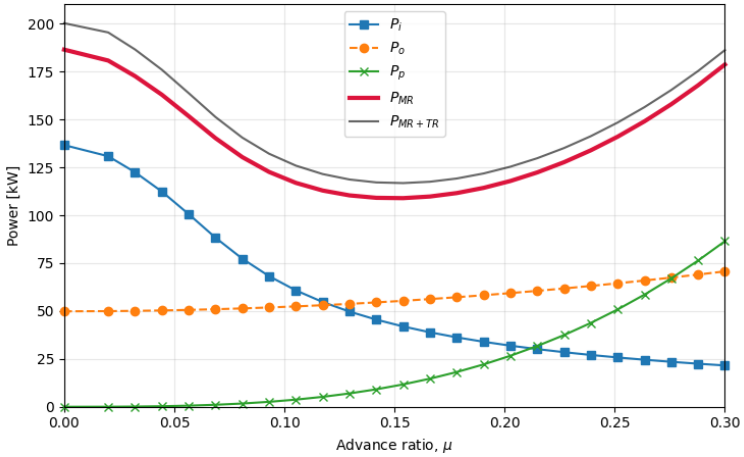

Figure 2. Main-rotor power components and total rotor power variation with advance ratio μ.

The battery power required for the electric retrofit is calculated considering transmission, motor, and inverter efficiencies, as well as auxiliary power demands, using the following equation:

$$P_{\text{batt}} = \frac{P_{\text{rotors}} + P_{\text{aux,shaft}}}{\eta_{\text{mech}}\eta_{\text{mot}}\eta_{\text{inv}}} + P_{\text{aux,elec}} \tag{6}$$

In this study, a slightly conservative mechanical efficiency of $\eta_{\text{mech}} = 0.96$ is adopted, based on technical data from NASA [11]. The motor and inverter efficiencies are taken as $\eta_{\text{mot}} = 0.96$ and $\eta_{\text{inv}} = 0.995$, respectively [12].

Electrically driven auxiliaries are based on Garmin's Electrical Load Analysis for the Bell 206A/B, which reports a typical bus usage of 24.8% of a 28–30 V, 105 A system (≈ 0.73 kW). Accordingly, a uniform auxiliary load of $P_{\text{aux,elec}} = 0.8$ kW is carried across all phases of flight [13].

Shaft-driven auxiliaries ($P_{\text{aux,shaft}}$) include the flight-control hydraulic pump and oil-cooler blower, both of which are mechanically driven by the main and tail-rotor transmissions. Bell technical data specify hydraulic pressures of around 600 psi and pump flows of 1.7–2.0 gpm, corresponding to 0.4–1.0 kW of hydraulic power via P=pQ, with an additional blower demand of comparable magnitude [14]. Accordingly, the shaft-driven auxiliary power is varied by flight phase, with $P_{\text{aux,shaft}} = \{2.0, 2.0, 1.5, 1.2, 1.5\}$ kW assigned to hover, climb, cruise, descent, and reserve, respectively, consistent with manufacturer data and typical light-helicopter operation. The total energy required for the mission is calculated as 145.59 kWh, and the results are summarized in Table 2.

Materials Research Proceedings 69 (2026) 782-787 https://doi.org/10.21741/9781644904251-138

Table 2. Pack-level power, energy, and duration summary for the selected mission profile.

Flight Segment	Power [kW]	Energy [kWh]	Δt [min]
Take-off hover	220.2	7.34	2
Climb	237.7	5.87	1.48
Cruise	160.4	69.37	25.95
Descent	51.5	1.72	2
Landing hover	220.2	7.34	2
Reserve	161.9	53.95	20

Battery Sizing

The state-of-the-art Tesla Panasonic 2170 lithium-ion NCA cell, with an energy density of 322 Wh/kg at the cell level, has been selected for this study [7] due to its high energy density, proven reliability in large-scale production, balanced energy-to-power characteristics, and efficiency in both energy storage and cost control. At the pack level, where structural and thermal components reduce usable energy density, an efficiency factor $\eta_{\text{pack}} = 0.65$ is applied [15]:

$$e_{\text{pack}} = \eta_{\text{pack}}\, e_{\text{cell}}. \tag{7}$$

The required battery pack mass becomes

$$m_{\text{bat}} = \frac{E_{\text{tot}}}{e_{pack}}.$$

With the values given above, this results in $e_{\text{pack}} = 209\ \text{Wh/kg}$ and $m_{\text{bat}} = 695.6\ \text{kg}$. (8)

After the nominal mission, when the reserve segment is not flown, the remaining state of charge is approximately 37%.

Weight Estimation

The baseline operational empty weight of the Bell 206B-3 is m_E = 785 kg, with a MTOW of 1451 kg. The removed and added components for the electric retrofit are detailed in Table 3. With the removed and added components to the electric retrofit helicopter, the new operational empty weight becomes 1419.6 kg, leaving a payload margin of 31.4 kg within the certified MTOW. From the analysis, with the selected mission profile and current battery technology, the maximum payload that can be carried is lower than what Archer's eVTOL promises to carry.

Table 3. Weight of the Removed and Added Components

Component	Removed [kg]
Engine (M250-C20J, dry)	71.7
Starter-generator	10.9
Fuel system hardware	26.0
Subtotal	108.6

Component	Added [kg]
Battery pack	695.6
Electric motor	11.2
Inverter	6.4
Balance-of-plant (HV/LV, cabling, cooling)	30
Subtotal	743.2

Trade-off Study

As a final step in this research, the trade-off study between payload and range is presented in Figure 3, as the intended mission of an 80 km cruise range renders the allowable payload insufficient to support a realistic application. However, for example, for a shorter mission with a 35 km cruise distance, the helicopter can carry approximately 218 kg of payload, which corresponds to two

people and essential equipment, representing a potential mission profile for an emergency service operation such as medical transportation.

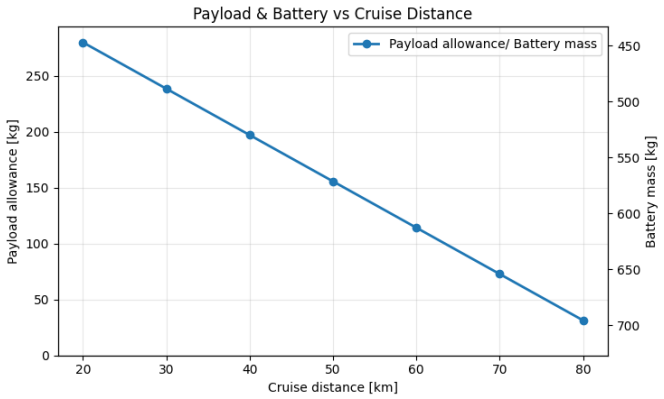

Figure 3. Payload vs Range Trade-off Plot

	eVTOL (Archer Midnight) [16]	**Conventional Helicopter (Bell 206B JetRanger III)**	**E-Heli (Electric retrofit of Bell 206B JetRanger III)**
Propulsion Type	Distributed Electric Propulsion	Turboshaft Engine	Battery Powered Electric Single Main Motor
Max. Payload [kg]	456	567	218
MTOW [kg]	3175	1451	1451
Range [km]	32-80	624 (no reserves)	35
Cruise Speed [km/h]	241	185	185
Certification Path	FAA Special-Class eVTOL	FAA Part27 / EASA CS-27	EASA CS-27 and CS-E-19 compliance

Conclusion

This study evaluated the feasibility of retrofitting a conventional helicopter, the Bell 206B, with an electric propulsion system using current lithium-ion battery technology. The analysis of rotor power requirements, mission energy demand, and overall mass distribution revealed that while electric propulsion can significantly reduce emissions and noise, current battery energy densities remain a major limitation.

For the defined 80 km mission, the retrofit results in a battery mass of approximately 696 kg, leaving only 31.4 kg available for payload within the maximum take-off weight. Reducing the mission range to 35 km increases the payload capacity to approximately 218 kg, allowing for limited applications such as short-range emergency or training operations. These results highlight that full electrification of existing rotorcraft is technically feasible but not yet operationally practical for typical missions.

Future research should focus on improving battery energy density, exploring hybrid-electric configurations, and optimizing weight distribution to enhance performance. Continued progress in certification standards and thermal management will be crucial to achieving broader adoption of electric-powered helicopters and advancing sustainable rotary-wing aviation.

Keywords: Constrained Control, Unmanned Helicopters, Vortex Ring State, Barrier Functions in Control

Abstract. In helicopter flight, the vortex ring state is a critical condition that can lead to a significant loss of lift, potentially resulting in a catastrophic accident. Recent developments in safety-critical control have led to formal methods which guarantee that dynamical systems remain within predefined safe conditions. Among these methods, control barrier functions offer a systematic framework to enforce safety constraints. In this contribution, we present a safety-critical control framework for unmanned helicopters using barrier function–based safety filters, which are integrated into a cascaded inner–outer loop flight control architecture. The safety filter is designed to prevent the occurrence of dangerous vortex ring state conditions, while accounting for external disturbances such as wind within the outer-loop control layer.

Introduction

Vortex ring state (VRS) is a hazardous flight condition that occurs under low forward speed with the vertical velocity approaching the wake-induced velocity [1]. In this state, additional vortices may develop near the rotor hub, resulting in a recirculating airflow that descends through the center of the rotor disk and then flows outward and upward around the edges, reinforcing the vortex ring. As a consequence, lift is significantly reduced, which can lead to a rapid loss of altitude.

Some VRS avoidance strategies for unmanned aircraft systems (UAS) have been published in the literature but, to the best knowledge of the authors, none of them apply control barrier functions (CBFs) for safety filter design. For instance, in [2], an avoidance scheme based on potential functions is proposed. The potential function defines a safety buffer around the region of vortex ring states. Depending on the value of the potential function, the nominal control law is modified. However, the design of the potential function and the altering of the nominal control input require tuning by the user and no safety guarantees are given. The VRS protection approach presented in [3] predicts the airspeed over a fixed time horizon to determine whether the predicted values violate the VRS conditions. In case of a violation, the set point of the controller is shifted to prevent entering the VRS conditions. As only the control reference is shifted, the method is unable to provide hard safety guarantees. In the work of [4], a monitor for early VRS detection and a recovery strategy based on increasing forward speed is introduced. The proposed avoidance concept is restricted to a descending spiral motion.

Control barrier functions, have emerged as a promising approach to formally guarantee that system states remain within defined safe sets. The CBF-based safety filters can be implemented on top of a nominal controller, modifying the control input only when necessary to ensure safety [5]. Original formulations of CBFs are limited to systems with a relative degree of one but recent advances have extended the framework to systems with higher relative degrees [6]. To make CBFs applicable to real world systems it is necessary to consider input constraints as well as disturbances.

Materials Research Proceedings 69 (2026) 788-793 https://doi.org/10.21741/9781644904251-139

Several contributions have been proposed to handle the problem of CBF design under disturbances e.g. [7-11], under input constraints e.g. [12-16], or under input constraints and disturbances [17-19]. Another challenge in the application of CBFs is ensuring feasibility when multiple state and input constraints are present. Among other methods, a practical way to deal with the problem is to use prioritization schemes that may, however, lead to relaxation of the constraints [20], [21]. Also interesting is the reduction of conservativeness of CBFs in case of disturbances using adaptation techniques [22-24].

In this contribution, we consider the design of a CBF-based safety filter that manipulates the nominal helicopter controllers in order to avoid the dangerous vortex ring state conditions. Using the model of Johnson [1], we define the boundaries of our safe set as the complement of the unsafe region defined by the vortex ring state conditions. To enforce the bounds of the safe set, we apply input-to-state stable CBFs [7], which guarantee invariance of the safe set under input disturbances such as wind. A quadratic program (QP) is formulated to keep the deviation from the nominal control input minimal. In theory, we can avoid the VRS conditions by altering the horizontal or vertical speed or both. To regulate which input is predominantly used for avoidance, we introduce a weighting matrix into the QP. The analytic solution of the QP can be obtained using the Karush-Kuhn-Tucker (KKT) conditions.

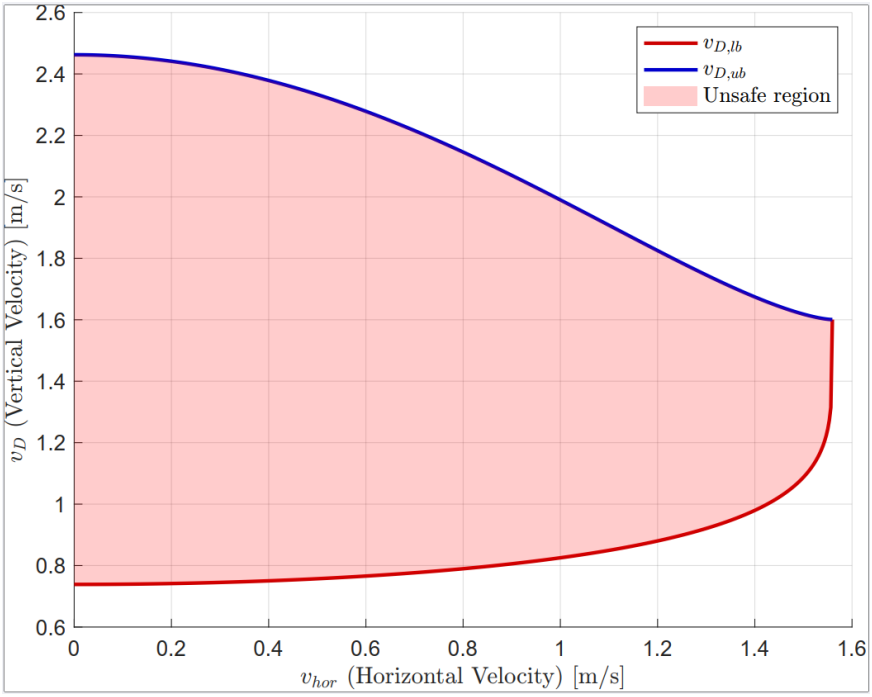

Figure 1: Visualization of unsafe region defined by vortex ring state conditions

Vortex Ring State Model

According to [1], the stability boundaries of VRS are defined by two equations. The upper and lower bounds $v_{D,\text{ub}}$ and $v_{D,\text{lb}}$ of the vertical velocity are given by

$$v_{D,\text{ub}} = v_{i,h}(0.5(V_{zN} + V_{zX}) - 0.5(V_{zN} - V_{zX})(1 - (V_x/V_{xM})^2)^{1.5}) \quad (1)$$

and

$$v_{D,\text{lb}} = v_{i,h}(0.5(V_{zN} + V_{zX}) + 0.5(V_{zN} - V_{zX})(1 - (V_x/V_{xM})^2)^{0.2}) \quad (2)$$

Materials Research Proceedings 69 (2026) 788-793 https://doi.org/10.21741/9781644904251-139

where $V_x = \frac{v_{hor}}{v_{i,h}}$ represents the horizontal flight velocity v_{hor}, normalized by the induced velocity $v_{i,h}$ during hover. The parameters V_{zN} and V_{zX} define the vertical descent region where instability can occur, while V_{xM} defines the boundary for stable horizontal flight. We use the parameter values defined by [1].
Based on the upper and lower bounds of (1) and (2), we define the unsafe state space region as the interior visualized in Figure 1.

Safety Filter Design
The bounds (1) and (2) define constraints on the vertical and horizontal velocities v_D, v_{hor}. Therefore, we implement the safety filter in the outer loop controller that controls position and velocity of the helicopter as shown in Figure 2.

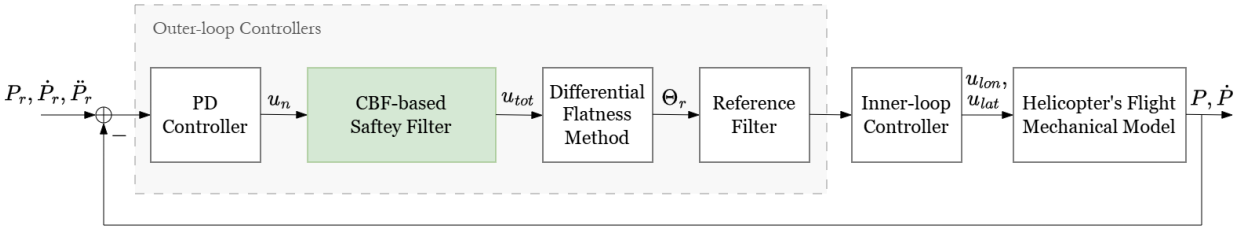

Figure 2: Implementation of the CBF-based safety filter in the outer-loop controller

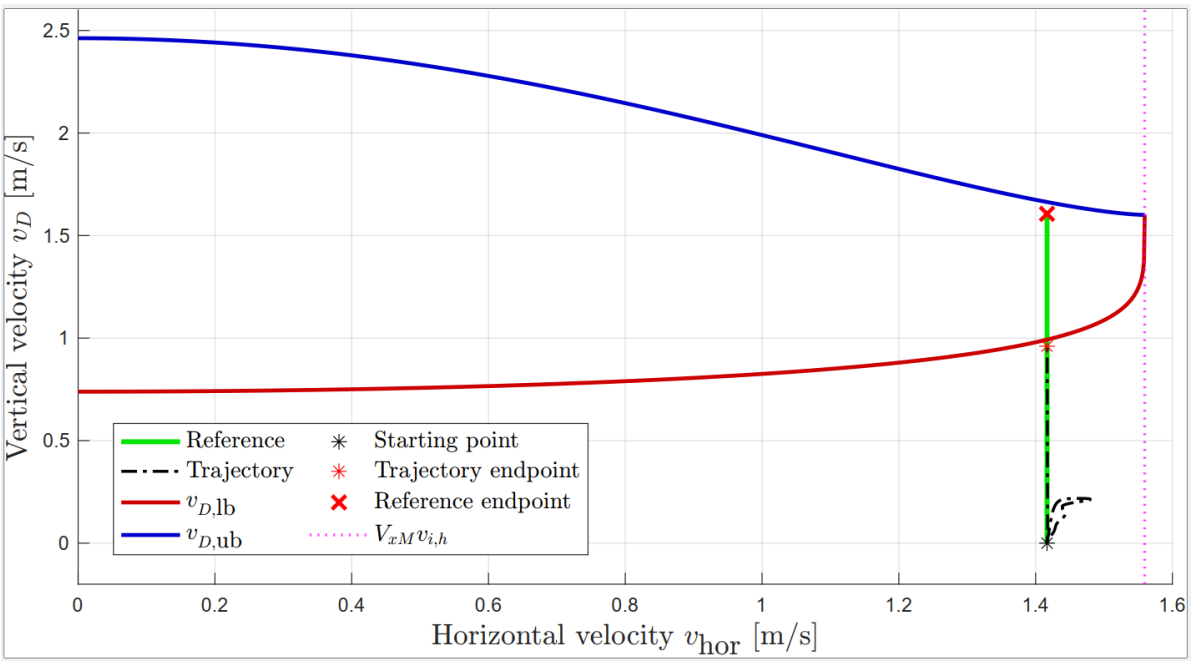
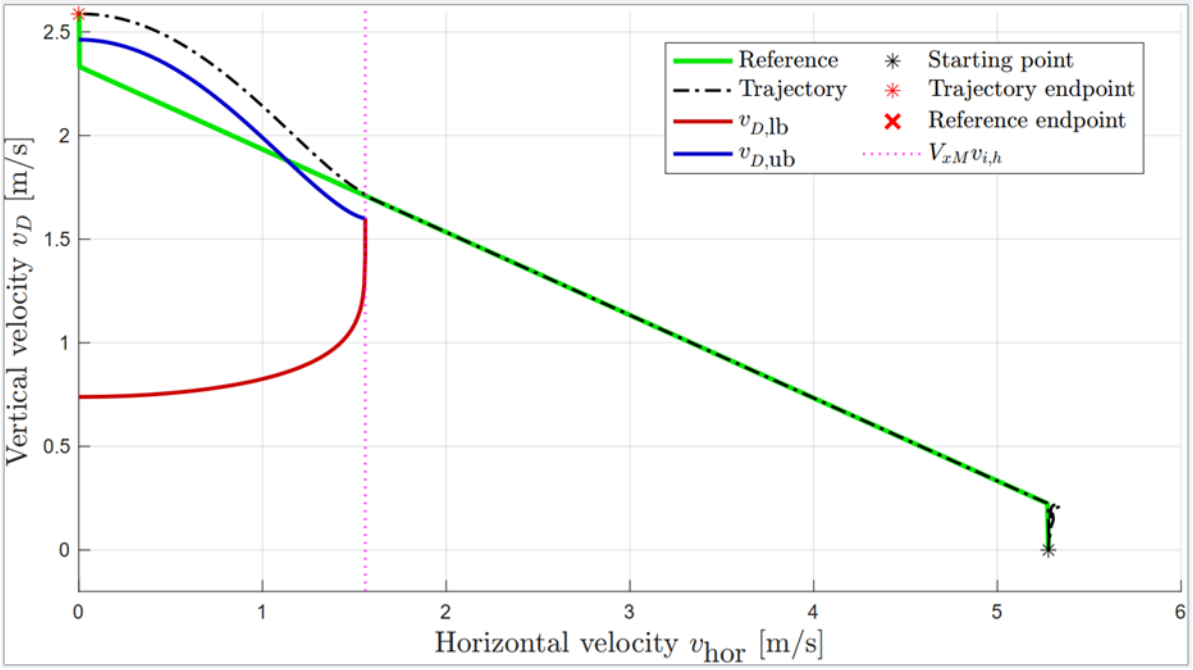


To avoid the VRS conditions we define the two constraint functions

$$h_{\text{ub}}(x) = v_D - v_{D,\text{ub}} \geq 0, \tag{3}$$
$$h_{\text{lb}}(x) = v_{D,\text{lb}} - v_D \geq 0 \tag{4}$$



and the safe set $\mathcal{C} = \{x \in R^6 \mid h_{\text{ub}}(x) \geq 0 \vee h_{\text{lb}}(x) \geq 0\}$ as the complement of the unsafe region in Figure 1. By applying input-to-state safe CBFs, we solve for the QP

$$\min_{u_{\text{tot}} \in R^3} (u_{tot} - u_n)^T W (u_{tot} - u_n) \tag{5}$$
$$\text{s.t.} \quad L_g h_{ub}(x) u_{tot} \geq -\alpha h_{ub}(x) + \frac{||L_g h_{ub}(x)||^2}{\epsilon_0} \tag{6}$$
$$L_g h_{lb}(x) u_{tot} \geq -\alpha h_{lb}(x) + \frac{||L_g h_{lb}(x)||^2}{\epsilon_0} \tag{7}$$

where u_n and u_{tot} are the nominal and safety-filtered control inputs according to Figure 2, W is a positive definite weighting matrix, and ϵ_0 is a tuning parameter that accounts for the disturbances such as wind effects. The Lie derivatives $L_g h_{ub}(x)$ and $L_g h_{lb}(x)$ are determined based on the outer-loop dynamics of the helicopter following the model of [25]. We solve the QP case-dependent, meaning we consider (6) only if $v_D > v_{D,\text{ub}}$ and (7) only if $v_D \leq v_{D,\text{ub}}$.Therefore, we can derive analytical solutions of the QP using the KKT-conditions.

(a) Scenario I

(b) Scenario II

Figure 3: Prevention of VRS conditions by CBF-based safety filter. Nominal reference trajectory with VRS state violations (green line), true trajectory with VRS state prevention (dash-dotted black line), bounds of unsafe region (blue and red lines).

Simulation Results

The simulation results of the CBF-based safety filter are shown in Figure 3. Scenario I describes a descending during forward flight (vertical velocity increasing while horizontal velocity remains constant). Scenario II describes a descending while going from forward flight into hover (vertical velocity increasing while horizontal velocity decreases). In both scenarios, application of the

nominal controller following the reference trajectory would lead to VRS violations. The safety filter alters the applied control inputs in such a way that the helicopter states remain in the safe set, avoiding the VRS conditions. Based on the weighing matrix W, we emphasis the role of the vertical velocity component in order to achieve constraint satisfaction.

Conclusions

In this contribution, we apply the concept of control barrier function-based safety filters to helicopter UAS for prevention of dangerous vortex ring state conditions. The approach is embedded into a cascaded inner-outer loop controller structure with analytic solutions of the safety filter being obtained by solving the QP case-dependent based on KKT-conditions. The approach provides safety guarantees while minimizing deviations from the nominal control action.

Keywords: Anti-Windup Synthesis, Fully-Actuated UAVs, Aerial Physical Interaction, Actuator Saturation, Lateral Force Constraints

Abstract. This work addresses actuator saturation in fixed-tilt multirotor platforms used for aerial interaction. The fixed-tilt configuration imposes lateral force limitations, and exceeding these bounds under external disturbances can degrade performance and stability. To mitigate this, an anti-windup (AW) compensator is synthesized via an LMI-based convex optimization framework derived from the linearized closed-loop dynamics. An external wrench observer is integrated to estimate and counteract interaction and aerodynamic disturbances. The proposed AW augmented compensator structure preserves local stability during saturation, achieving improved transient behavior in simulation on the ARIES tiltrotor platform.

Introduction

The design of control strategies for aerial robots operating under constrained actuation has gained significant attention as unmanned aerial vehicles (UAVs) evolve from purely observational tasks to platforms capable of physical interaction for inspection and maintenance tasks [1]. Within this context, fully actuated multirotors have emerged as a promising class of vehicles capable of generating independent force and torque vectors in all degrees of freedom, enabling versatile interaction capabilities [2]. Among these, the fixed-tilt configuration stands out as one of the most structurally minimal designs, achieving full actuation through a non-coplanar arrangement of propellers. However, such a configuration introduces inherent lateral force constraints, since the available horizontal forces depend on the fixed cant and dihedral angles, which are typically chosen to satisfy nominal interaction requirements [2]. Under external influences such as contact interactions or wind disturbances, the controller may demand forces beyond the feasible envelope, leading to actuator saturation that degrades tracking performance and can compromise stability.

To address these limitations, this work presents the design of an anti-windup (AW) compensator providing stability guarantees under actuator saturation [3]. The compensator is synthesized through a convex optimization procedure based on linear matrix inequalities (LMIs), formulated from the linearized closed-loop dynamics of the system around a nominal equilibrium. The resulting design approximates the ideal unsaturated performance while maintaining stability within the feasible control region. In addition, an external observer is incorporated to reconstruct the forces and torques acting on the multirotor, thereby compensating for the reaction effects arising from contact interactions and aerodynamic disturbances. The synthesized AW compensator is integrated with both the dynamic feedback controller and the external observer to prevent wind-up phenomena. The proposed framework is validated in simulation, demonstrating effective suppression of wind-up and improved closed-loop behavior compared to the baseline controller.

UAV Dynamics and Control Architecture

The experimental platform considered in this study is the ARIES tiltrotor, developed by ANT-X s.r.l. [4]. ARIES is a fixed-tilt hexarotor, as illustrated in Fig. 1, designed for aerial interaction and contact-based inspection tasks, capable of maintaining stable flight while exerting forces on the environment.

Figure 1: ARIES fixed-tilt hexarotor.

The motion of the hexarotor is described by the standard six-degree-of-freedom Newton-Euler equations. The translational dynamics are expressed in the inertial frame $\mathcal{F}_I = (O_I, i_1, i_2, i_3)$, while the rotational motion is represented in the body-fixed frame $\mathcal{F}_B = (O_B, b_1, b_2, b_3)$, centered at the platform's center of mass. Here, i_j and b_j $(j \in 1,2,3)$ denote right-handed orthonormal bases of the inertial and body frames, respectively, and O_I, O_B are their corresponding origins. The resulting dynamics are expressed as:

$$m\dot{v}_I = -mg\mathbb{e}_3 + R(f_{ca} + f_r), \quad J\dot{\omega}_B = -\omega_B \times J\omega_B + \tau_{ca} + \tau_r, \tag{1}$$

where $m \in \mathbb{R}_{>0}$ and $J = J^T \in \mathbb{R}^{3\times3}_{>0}$ denote the platform mass and inertia matrix, $R \in \mathrm{SO}(3)$ is the body-to-inertial rotation matrix, and v_I, ω_B are the translational and angular velocities defined in $\mathcal{F}_I$ and $\mathcal{F}_B$ frames respectively. The propeller generated wrench $w_{ca} = [f_{ca}^T \quad \tau_{ca}^T]^T$ acts on the vehicle, while the external wrench $w_r = [f_r^T \quad \tau_r^T]^T$ models aerodynamic and contact effects. The desired control wrench $w_c = [f_c^T \quad \tau_c^T]^T$ is mapped to the individual rotor thrusts through the constant input matrix $\mathbb{F}(\alpha, \beta) \in \mathbb{R}^{6\times6}$, defined by the geometry of the ARIES platform [5]:

$$\begin{gathered} w_c = \mathbb{F}(\alpha,\beta)\begin{bmatrix} k_f\omega_1^2 & \dots & k_f\omega_6^2 \end{bmatrix}^T, \qquad R_B^{R_i} = R_Y(\beta_i)R_X(\alpha_i)R_Y(\beta_a)R_Z(\psi_i), \\ \mathbb{F}_i(\alpha_i,\beta_i) = \begin{bmatrix} -R_{R_i}^B\mathbb{e}_3 \\ \left(-\left[x_{BR_i}^B\right]_\times + (-1)^{i-1}k_f^\tau \mathrm{I}_3\right) R_{R_i}^B\mathbb{e}_3 \end{bmatrix}, \end{gathered} \tag{2}$$

where α, $\beta \in \mathbb{R}^6$ are cant and dehidral angles of each propeller. Fully actuated multirotors allow independent force and torque control, enabling diverse feedback designs such as geometric or linear control [1, 6]. A hierarchical cascade structure is adopted, with outer position and attitude loops and inner velocity and rate loops. The translational controller computes f_c, while the attitude controller determines τ_c, yielding:

$$\begin{gathered} f_c = m\left(K_{vp}R\left(K_{pp}(p_r - p_I) + v_r - v_I\right) - K_{vd}R\dot{v}_I\right) - mgR\mathbb{e}_3 - \hat{f}_r, \\ \tau_c = K_{\omega p}\left(K_{\theta p}(\Theta_r - \Theta_B) + \omega_r - \omega_B\right) - K_{\omega d}\dot{\omega}_B - \hat{\tau}_r, \end{gathered} \tag{3}$$

where $K_{(\cdot)} \in \mathbb{R}^{3\times3}_{\geq0}$ are diagonal gain matrices and the vectors p_r, v_r, Θ_r, and ω_r represent the desired position, velocity, attitude, and angular rate setpoints, respectively. The observer-estimated wrench $\hat{w}_r = [\hat{f}_r^T \quad \hat{\tau}_r^T]^T$ compensates the external effects w_r in Eq. 1. The commanded wrench w_c is distributed through $\mathbb{F}(\alpha, \beta)$ in Eq. 2, ensuring accurate force and torque generation within the actuator range. When the compensated command exceeds feasible actuation, the applied wrench w_{ca} deviates from w_c, related by:

$$w_{ca} = \mathrm{sat}_{[u^-,u^+]}(w_c), \quad \mathrm{sat}_{[u^-,u^+]}(u) = \max\{\min\{u^+, u\}, -u^-\}, \tag{4}$$

where the saturation acts component-wise, with bounds $u^-, u^+ \in \mathbb{R}^{n_u}_{\geq0}$ and input dimension $n_u \in \mathbb{N}$. The next section introduces the external observer that estimates the acting wrench and integrates with the control framework.

Materials Research Proceedings 69 (2026) 794-799 https://doi.org/10.21741/9781644904251-140

External Wrench Observer

Accurate estimation of external forces and moments is crucial for safe aerial interaction, especially when direct sensing is impractical due to payload or hardware constraints. To reconstruct the external wrench acting on the platform, a model-based observer [6] is formulated using the UAV dynamics and onboard inertial measurements. The translational and rotational estimators are defined respectively as:

$$\begin{aligned} m\dot{\hat{v}}_I &= mg\mathbb{e}_3 + R^T\left(\mathbb{F}_f k_f \omega^2 + \hat{f}_r\right) + \Lambda_v(v_I - \hat{v}_I), \qquad \dot{\hat{f}}_r = \Lambda_f R(v_I - \hat{v}_I), \\ J\dot{\hat{\omega}}_B &= -\omega_B \times J\omega_B + \mathbb{F}_\tau k_\tau \omega^2 + \hat{\tau}_r + \Lambda_\omega(\omega_B - \hat{\omega}_B), \quad \dot{\hat{\tau}}_r = \Lambda_\tau(\omega_B - \hat{\omega}_B), \end{aligned} \tag{5}$$

where $\hat{v}_I$ and $\hat{\omega}_B$ are the estimated linear and angular velocities, and $\hat{f}_r$, $\hat{\tau}_r$ represent the estimated external force and torque. The positive definite gain matrices $\Lambda_{(.)} \in \mathbb{R}^{3\times3}_{\geq 0}$ govern estimator dynamics, balancing responsiveness and noise sensitivity. Matrices $\mathbb{F}_f$ and $\mathbb{F}_\tau$ map rotor speeds to translational and rotational components of the applied control wrench as mentioned in Eq. 1. This observer reconstructs external wrench in real time without dedicated sensors, enhancing disturbance compensation; however, when the estimated forces drive control inputs beyond actuator limits, an anti-windup compensator is augmented as discussed in the next section.

Anti-Windup Compensator Synthesis

The nonlinear dynamics of the multirotor, along with the baseline controller and external wrench observer, are linearized around the hovering equilibrium corresponding to zero attitude and steady thrust balancing gravity. The resulting augmented linear model captures the coupled behavior of the plant, controller, and observer, forming the basis for the AW synthesis. Following the methodology of [3], a fixed-structure AW compensator is introduced by embedding additional feedback gains within the controller to preserve stability under actuator saturation. The overall closed-loop system used for AW synthesis can be expressed in compact form as:

$$\begin{cases} \dot{\xi} = A\xi + B_q q_X, \\ z_e = C_z\xi + D_{zq} q_X, \\ y_c = C_y\xi + D_{yq} q_X, \end{cases} \tag{6}$$

Where $\xi = [x_a^T \quad x_{rm}^T \quad w^T]^T$ denotes the augmented closed-loop state, comprising the plant, controller, external wrench observer, and AW compensator states. The reference model represents the ideal system with unconstrained actuation, while w belongs to a specified class of reference inputs. The performance variable is $z_e = z - z_{rm}$, i.e., the deviation between the saturated response and the nominal reference-model output. The signal q_X denotes the AW interconnection term capturing the difference between the controller command and its saturated counterpart.

Based on this representation, the AW synthesis problem aims to determine the compensator gains that minimize the ℓ_2-norm of the performance output z_e, ensuring Lyapunov-based stability within a prescribed region of attraction. The resulting optimization problem is cast as a convex program subject to LMI constraints, whose solution directly yields the AW gain matrices. For detailed derivations and proofs, the reader is referred to [3].

Simulation Results

The closed-loop architecture of the ARIES platform incorporating the AW compensator is depicted in Fig. 2. The baseline controller generates the desired control wrench w_c from the reference signals y_r and w, while the external observer estimates the reaction wrench $\hat{w}_r$ using the measured states y and applied wrench w_{ca}. The control command is mapped through $\mathbb{F}^{-1}$, constrained by actuator limits via the saturation nonlinearity, and subsequently redistributed to the plant through $\mathbb{F}$. The AW compensator processes the input mismatch q_X between the pre and post

Materials Research Proceedings 69 (2026) 794-799 https://doi.org/10.21741/9781644904251-140

saturation signals to synthesize the corrective term v_{AW}, which is fed back to both the controller and observer to ensure consistent dynamic behavior and stability within the saturation region.

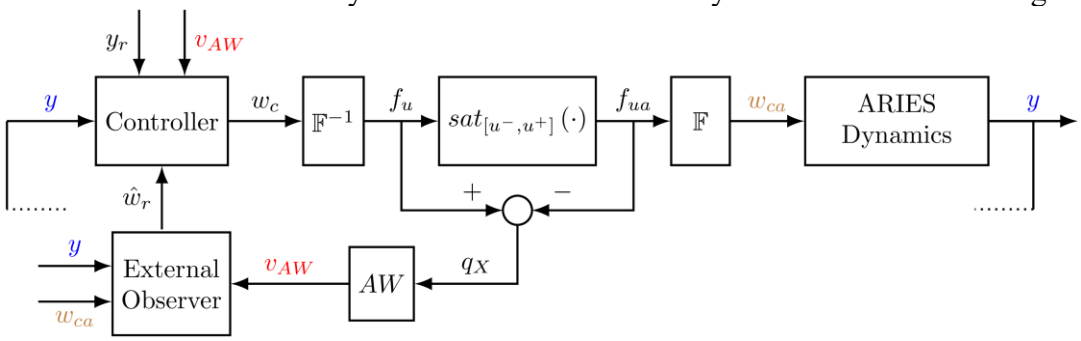

Figure 2: ARIES AW-augmented closed-loop system.

The proposed control framework is validated in simulation using the ARIES dynamic model, where the platform is commanded to maintain a hovering condition while subjected to a step-like external disturbance designed to induce actuator saturation. The simulations evaluate the capability of the AW-augmented controller to preserve stability and tracking accuracy under saturation, demonstrating the compensators effectiveness in mitigating windup effects and maintaining consistent closed-loop performance.

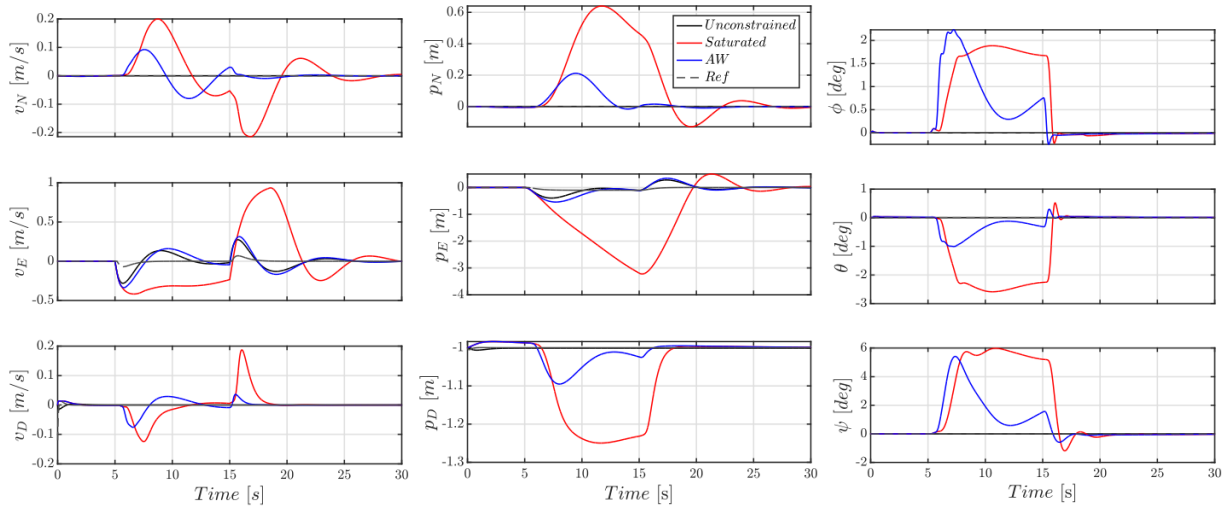

Figure 3: Position (left), velocity (middle), and attitude (right) tracking performance for fixed-tilt hexarotor under various controllers.

Fig. 3 illustrates the position, velocity, and attitude tracking performance of the fixed-tilt hexarotor under three configurations: the unconstrained nominal controller, the saturated controller without compensation, and the proposed AW-augmented controller. When saturation occurs, the nominal controller exhibits significant deviation and oscillatory behavior, particularly in the lateral and yaw dynamics, indicating loss of stability. In contrast, the AW-compensated response closely follows the nominal trajectory, achieving smooth transient behavior and faster recovery once the actuators re-enter the feasible region.

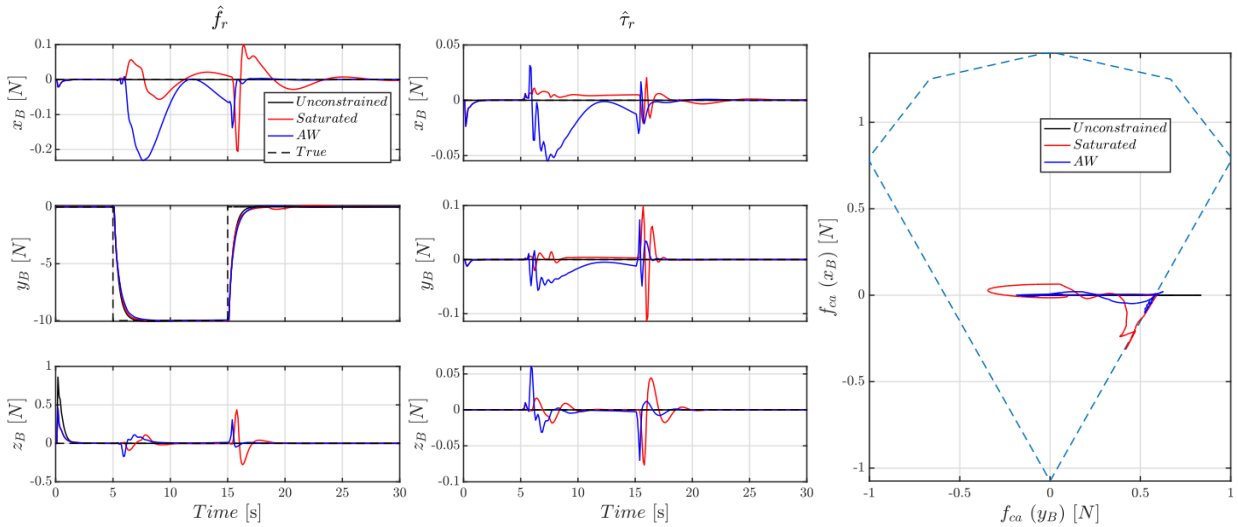

Figure 4: Estimated force (left), torque (middle), and applied force (right) with respect to available force envelope under various controllers (axes scaled for confidentiality).

Fig. 4 presents the estimated force and torque components, along with the applied force envelope in the lateral plane. The AW-compensated controller effectively limits the commanded forces within the feasible actuation range while maintaining consistent disturbance rejection. The force trajectories remain tangent to the saturation boundary, demonstrating how the compensator ensures stable recovery from saturation without inducing excessive overshoot or steady-state bias. These results confirm that the proposed anti-windup strategy effectively preserves nominal control performance within the feasible actuation region while ensuring stable and robust behavior under saturation-induced nonlinearities.

Summary

This work presents an anti-windup compensator for fixed-tilt multirotors operating under actuator saturation and external interaction forces. The framework integrates a model-based external wrench observer with a performance-oriented compensator synthesized through convex LMI optimization. Simulations on the ARIES hexarotor show that the AW-augmented controller mitigates windup, maintaining stability and near-nominal tracking under severe actuation limits. Future efforts will extend the approach to experimental validation for contact interaction scenarios.

Keywords: Ground Effect, Martian UAS, Thrust-Lift Conversion, Deflected Slipstream

Abstract. As interest in Mars exploration grows, there is an increasing demand for versatile unmanned aerial systems (UAS) capable of vertical takeoff and landing (VTOL), driving the development of lightweight, high-lift configurations. Among these, the propeller–wing configuration with a deflected slipstream (DS) system, known as a DS-blown wing, enables efficient thrust–lift conversion. However, during VTOL, the ground effect can substantially alter the flow field and affect this conversion efficiency. Three-dimensional unsteady Reynolds-Averaged Navier–Stokes (URANS) simulations with fully resolved propeller-blade geometry were conducted to evaluate the thrust-lift conversion efficiency at various ground clearances and to examine the aerodynamic interactions among the propeller-induced flow, the deflected flap, and the ground surface. The results show that the DS-blown wing exhibits reduced efficiency in ground effect compared with out-of-ground-effect conditions, primarily due to a recirculation region beneath the wing that modifies the pressure distribution. When the wing operates in very close proximity to the ground, a rebound in thrust-lift conversion efficiency is observed. Moreover, at certain intermediate heights, a resonance phenomenon occurs, leading to large-amplitude lift fluctuations at the blade-passing frequency. This work enhances the understanding of DS-blown wing aerodynamics in ground effect under Martian conditions and provides valuable guidance for the design of future Mars UAS.

Introduction

Achieving efficient vertical takeoff and landing (VTOL) performance remains a significant challenge for unmanned aerial systems (UAS) operating on Mars, particularly when structural simplicity and low mass are required. Conventional rotorcraft can generate sufficient lift but suffer from poor aerodynamic efficiency in forward flight, whereas fixed-wing aircraft offer efficient cruise performance but face difficulties in achieving VTOL capability. To bridge this gap, the present study focuses on blown-wing configurations employing deflected slipstream (DS) systems, in which the high-momentum propeller slipstream is deflected by a flap to generate lift. This configuration has emerged as a lightweight and mechanically simple approach to achieving VTOL in fixed-wing UAS.

DS technology has been widely investigated and applied in aircraft designs aimed at achieving V/STOL performance [1]. Under Martian conditions, several studies have examined the interaction between propeller-induced flow and wing structures [2,3]. Other lift-augmentation concepts, such as the CoFlow Jet integrated into a DS-blown wing configuration, have also been explored [4]. During take-off and landing operations, the wing ground effect plays a crucial role in influencing aerodynamic performance, and it has been extensively investigated for various airfoils operating at low Reynolds numbers [5,6]. However, despite extensive research on blown wings and ground effect individually, the coupled influence of ground proximity on the deflected slipstream and its impact on thrust-lift conversion remains insufficiently understood. In particular, for DS-blown wing configurations, the interaction between the deflected jet flow and the ground significantly alters the overall flow behavior. In this study, we consider a blown wing with a 90° flap deflection,

as shown in Fig. 1. Unlike the ground effect in a conventional isolated wing configuration, the DS-blown wing exhibits strong aerodynamic coupling among the slipstream, the wing, and the ground. On one hand, the ground blockage modifies the trajectory of the propeller slipstream, disturbing its deflection and consequently reducing the efficiency of thrust-lift conversion. On the other hand, varying levels of ground proximity lead to the formation of distinct recirculation regions, where the resulting bubble can alter the inflow conditions to the propeller blades.

Building on previous studies of DS technology and the wing ground effect, this work investigates how the flow physics of a DS-blown wing is modified when it operates near a solid surface under Martian conditions. Using computational fluid dynamics (CFD), we analyze the interaction between the propeller-induced flow and the deflected flap at various heights above ground. The ground effect, which arises from the proximity of the wing surfaces to the ground plane, can generally be categorized into two types: chord-dominated and span-dominated. The chord-dominated ground effect is characterized by the accumulation of ram pressure, a dynamic air cushion formed within the narrowed flow passage between the lower surface of the airfoil and the ground. In contrast, the span-dominated ground effect is associated with the breakdown or outward displacement of wingtip vortices [5]. In this study, periodic boundary conditions are applied to the spanwise boundaries; therefore, only the chord-dominated ground effect is considered.

The primary objective of this study is to quantify the influence of ground proximity on the aerodynamic characteristics of the DS-blown wing and to evaluate how these ground-induced effects modify the efficiency of thrust-lift conversion during low-altitude VTOL. Furthermore, the analysis reveals specific fluid interactions among the propeller-induced flow, the deflected flap, and the ground surface. The remainder of this paper is organized as follows: Section 2 describes the methodology and computational setup, Section 3 presents the main results and discussion, and Section 4 summarizes the key findings.

Methodology

In this study, we employed the commercial CFD software Simcenter STAR-CCM+ to perform three-dimensional unsteady Reynolds-averaged Navier–Stokes (URANS) simulations with fully resolved propeller-blade geometries using the sliding-mesh approach. Turbulence was modeled using the SST k-ω model developed by Menter, coupled with the γ-Reθ transition model to predict the laminar-to-turbulent flow transition under simulated Martian conditions.

The Ishii airfoil was selected for this investigation owing to its favorable aerodynamic performance at low Reynolds numbers [7]. An angle of attack (AOA) of 5° was adopted based on its good aerodynamic efficiency. The wing chord was set to 1 m. The flap, accounting for 25% of the chord length, was hinged at 75% of the wing chord and deflected by 90°. The chord-based Reynolds number was 25,500, with the reference velocity defined as the mean induced velocity. The employed propeller has a diameter of 0.4 m, and was optimized by Carreño Ruiz [8] for Martian conditions. The computational domain extended 80 chord lengths upstream and 80 chord lengths downstream of the wing to minimize boundary interference. A Cartesian grid consisting of approximately 5 million cells was employed, with prism layers refined to maintain a y+ value below 1, ensuring accurate resolution of strong wall-normal gradients, as shown in Fig. 2. The ground plane was modeled as a stationary no-slip wall, while periodic boundary conditions were applied in the spanwise direction. Simulations were conducted for different heights above the ground. The tested distances between the wing leading edge and the ground were 0.4 m, 0.6 m, 0.8 m, 1 m, 1.5 m, and an out-of-ground-effect condition.

Results and Discussion

The simulation results demonstrate that the DS-blown wing operating in ground effect undergoes significant modifications in flow topology. Figure 3 presents the time-averaged pressure and velocity fields at the mid-span of the DS-blown wing. The main differences between the configurations operating in and out of ground effect are associated with the recirculation region beneath the wing and the high-pressure zone on the pressure side of the deflected flap. As the wing approaches the ground, the low-pressure region corresponding to the recirculation becomes compressed and constrained within the narrowing space between the wing's pressure surface and the ground. The lift-to-thrust ratio at different heights above the ground is summarized in Table 1. Unlike the typical lift enhancement caused by ram pressure beneath a conventional wing operating in ground effect, the DS-blown wing exhibits a reduction in thrust-lift conversion efficiency. This reduction can be attributed to ground-induced blockage which limits the effectiveness of the redirected slipstream. Interestingly, as the wing nears the ground, the lift-to-thrust ratio initially decreases but then rebounds when the airfoil is in very close proximity to the surface. The spanwise-averaged mean pressure coefficient distribution is shown in Fig. 4, where the blade-tip velocity is used as the reference velocity. This figure highlights how the lift varies with ground clearance. It is evident that, across the examined heights, the pressure distribution on the suction side remains nearly identical to that of the out-of-ground-effect case, whereas the pressure on the pressure side is noticeably altered.

Table 1: Lift–thrust ratio at different heights above ground

Height above ground [m]	Thrust-lift conversion efficiency	Thrust [N]
0.4	0.365	1.032
0.6	0.312	1.085
0.8	0.331	1.081
1.0	0.341	1.039
1.5	0.368	0.996
Out of ground effect	0.466	1.101

As the height decreases, a low-pressure recirculation region develops beneath the wing, which can be clearly observed in Fig. 3. Meanwhile, a local pressure increase appears near 60% to 70% chord region on the pressure side in the in-ground-effect cases, except for the H = 0.6 m case. However, this increase cannot compensate for the pressure loss generated by the recirculation region between 20% to 50% chord region. As the wing approaches the ground to a height equal to one propeller diameter (0.4 m), the recirculation bubble becomes increasingly compressed. The

Materials Research Proceedings 69 (2026) 800-805 https://doi.org/10.21741/9781644904251-141

intensified ram pressure on the pressure side extends over a broader region, leading to a rebound in lift compared with other in-ground-effect cases. Although a closer configuration could

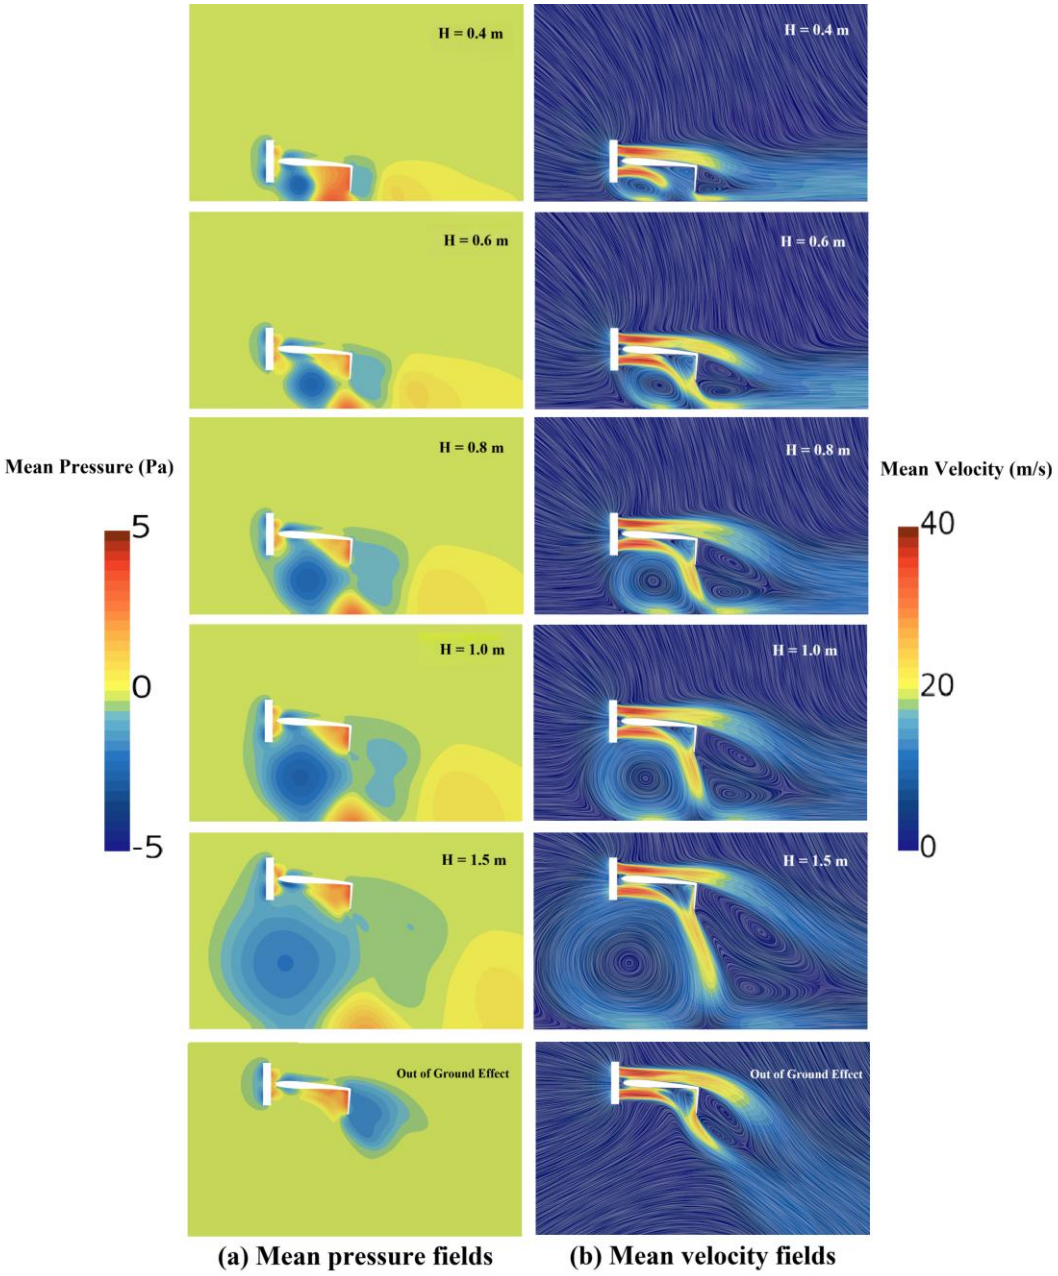

Figure 3: Time-averaged pressure and velocity fields at different wing heights above ground.

potentially enhance lift through stronger ram pressure, it has not been investigated here, as under realistic Martian conditions, a certain clearance between the flap and the ground is required due to the uneven and rocky terrain during VTOL operations.

In addition to quantifying the influence of ground proximity on thrust-lift conversion efficiency, we further examine the instantaneous behavior of lift and thrust. The lift force at different heights above the ground is shown in Fig. 5. As the DS-blown wing approaches the ground, the lift becomes increasingly unsteady, primarily due to the low-frequency vortex shedding behind the wing flap. Moreover, in the tested cases, the dominant low-frequency component of the vortex

Materials Research Proceedings 69 (2026) 800-805 https://doi.org/10.21741/9781644904251-141

shedding increases as the DS-blown wing moves closer to the ground. Another notable observation is that when the height falls below 0.8 m, the lift-force fluctuates at the blade-passing frequency (BPF) become more pronounced. The lift exhibits oscillations at the BPF with amplitudes reaching

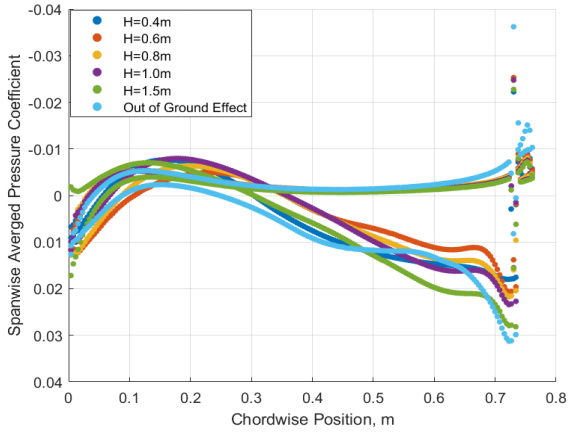

Figure 4: Mean pressure distribution at different heights above ground.

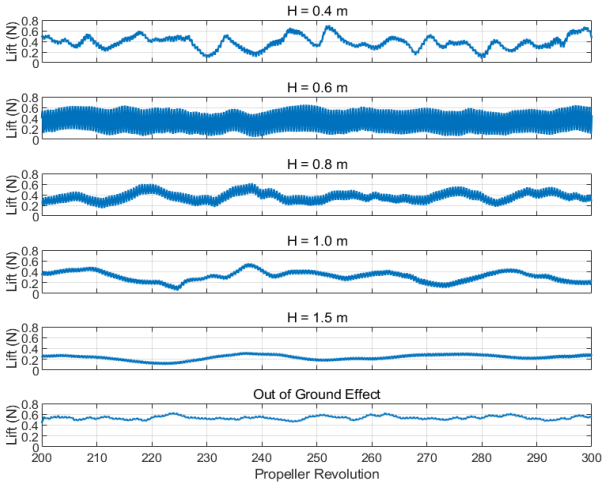

Figure 5: Lift force at different heights above ground.

approximately 50% and 100% of the mean lift at heights of 0.8 m and 0.6 m, respectively. However, these fluctuations decrease to roughly 15% of the mean lift when the height is reduced to 0.4 m, indicating that the resonance is amplified only for certain sizes of the recirculation bubble.

The observed fluctuations at the BPF are likely linked to a resonance phenomenon involving the propeller-induced flow, the recirculation region beneath the wing, and the propeller inflow. As seen in Fig. 3, the mean velocity fields reveal that cases exhibiting large-amplitude fluctuations share a common feature: the recirculation bubble is contained below the wing and shows a weakened interaction with the propeller's intake stream tube. In contrast, in other cases, the recirculation bubble feeds the rotor inflow. This observation is consistent with the thrust data presented in Table 1. When the propeller inflow is affected by the recirculation region, the local AOA decreases as the blade passes through this region, resulting in a reduction in thrust. In such

cases, the thrust loss ranges from 5% to 10%, whereas for cases with high-amplitude fluctuations, the thrust loss is less than 2% compared with the out-of-ground-effect condition.

Conclusions

This work studies the complex mechanisms governing the ground effect in the DS-blown wing configuration. The interactions among the propeller-induced flow, the deflected flap, and the ground have been preliminarily investigated. As the DS-blown wing approaches the ground, the thrust–lift conversion efficiency initially decreases and then rebounds; however, it remains lower overall under ground-effect conditions for the cases examined, unlike what happens with conventional wings in ground effect. In addition, a resonance phenomenon between the propeller-induced flow and the recirculation region beneath the wing has been observed, which may lead to potential instability and structural issues during VTOL operations. Understanding the relationship between thrust–lift conversion efficiency and height above ground is therefore essential for achieving smooth and stable VTOL and transition phases. This study provides valuable insights to guide the design and development of fixed-wing UAS for Mars, particularly regarding VTOL operations. Future work will consider different flap deflection angles and propeller positions to further enhance understanding of the ground effect in DS-blown wing configurations.

Keywords: Recursive Gaussian Process, Feedback Linearization, Reference Tracking, UAV

Abstract. High-precision UAV tracking is hindered by hard-to-model aerodynamic effects. We propose a *learning-based controller* for a simplified quadrotor that uses Feedback Linearization (FL), to cancel modeled dynamics, and a sparse Bayesian inference method called *Recursive Gaussian Process* (RGP), to learn and compensate residual nonlinearities in real time. Simulations and experiments conducted on a real 1D quadrotor platform demonstrate reduced tracking error and practical feasibility for *real-world implementation*.

Introduction

High-precision reference tracking for Unmanned Aerial Vehicles (UAVs) is one of the main challenges in the aerospace control community, primarily due to aerodynamics effects. These effects are difficult to model accurately and, therefore, are often neglected. As a result, model-based control methods frequently fail to achieve the desired performance. With the growing popularity of machine learning techniques, a promising research direction is the integration of model-based control with data-driven approaches.).

In this context, a popular model-based controller is *Feedback Linearization*, which employs the system model to cancel its nonlinear dynamics and render the system into a linear one. Past works used FL tuned with reinforcement learning [1] or combined with neural networks [2].

However, these approaches lack rigorous stability analysis. In contrast, Gaussian Processes (GPs) offer probabilistic guarantees and have therefore attracted significant attention within the control community. In fact, Greeff and Schoellig [4] demonstrated that using GPs online alongside FL substantially improves tracking performance and enhances robustness. Yet the approach was validated only in simulation and the computational constraints of onboard GP inference were not addressed.

In this paper, we propose a similar approach to control a 1-D quadrotor system. Specifically, we model the residual of the FL using a *sparse GP*, which significantly reduces the computational load of inference. We validate the approach on a real platform.

Baseline controller

Model assumptions. We consider a *SISO control-affine* system with state $x \in \mathbb{R}^n$ and input $u \in \mathbb{R}$:

$$\dot{x} = f(x) + g(x)u \tag{1}$$

Content from this work may be used under the terms of the Creative Commons Attribution 3.0 license. Any further distribution of this work must maintain attribution to the author(s) and the title of the work, journal citation and DOI. Published under license by Materials Research Forum LLC.

Materials Research Proceedings 69 (2026) 806-811 https://doi.org/10.21741/9781644904251-142

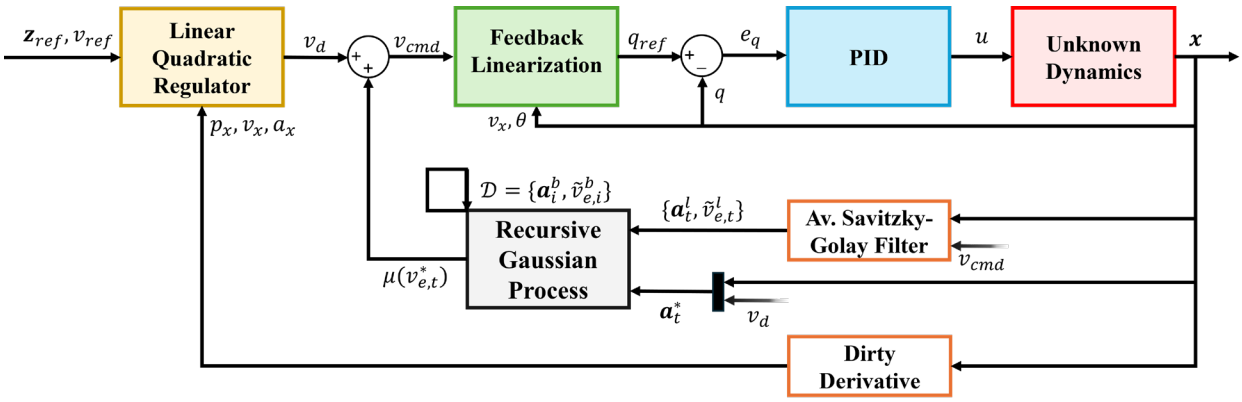

Figure 1: Controller scheme.

where $f(x)$ and $g(x)$ are unknown functions. *Assumption 1*: The system in 1 is differentially flat with respect to the known output $y = h(x) \in \mathbb{R}$. *Assumption 2*: A SISO nominal model of the system, also differentially flat in the output $y = h(x)$, is known:

$$\dot{x} = \hat{f}(x) + \hat{g}(x)u \tag{2}$$

Model specifications. The proposed controller (shown in Fig. 1) is formulated for a *2-DOF quadrotor system*, which dynamics is

$$\begin{cases} \dot{p}_x(t) = v_x(t) \\ \dot{v}_x(t) = -c v_x(t) - \bar{k} \sin(\theta(t)) \\ \dot{\theta}(t) = q(t) \\ \dot{q}(t) = -2\,\xi\,\omega_n q(t) - \omega_n^2 \theta(t) + \mu m_{c_x}(t) \end{cases} \tag{3}$$

where $c, \bar{k}, \xi, \omega_n$ and μ are obtained from grey-box identification. It is easy to show that the system is differentially flat. The angular velocity is controlled using a PID, which is a standard practice in quadrotor control. The resulting closed-loop is assumed fast enough to neglect it in the proposed control design. This allows us to consider the system a third-order one by approximating the pitch dynamics as

$$\dot{\theta} \simeq q_{ref} \tag{4}$$

where q_{ref} is the PID imposed dynamics.

Feedback Linearization and LQR. Using the above model, FL takes the form

$$\begin{aligned} q_{ref} &= \hat{\alpha}(\boldsymbol{z}) + \hat{\beta}(\boldsymbol{z}) v_{cmd} \\ &= \frac{c^2 v_x + c\,\bar{k} \sin\theta - v_{cmd}}{\bar{k} \cos\theta} \end{aligned} \tag{5}$$

where $v_{cmd} = \frac{u - \hat{\alpha}(\boldsymbol{z})}{\hat{\beta}(\boldsymbol{z})}$ is the imposed dynamics, *i.e.*, the third derivative of the output, and $\hat{\alpha}$ and $\hat{\beta}$ indicate approximations, obtained from the identified model, of the unknown true functions α and β. $\boldsymbol{z}$ is the states vector that contains the horizontal velocity v_x and acceleration a_x. $u = m_{c_x}$ is the system input, *i.e.*, the normalized pitch torque. The imposed dynamics v_{cmd}, *i.e.*, the desired third derivative, is calculated via the LQR from the setpoints and measurements.

Materials Research Proceedings 69 (2026) 806-811 https://doi.org/10.21741/9781644904251-142

Learning-based controller

We define the *nonlinear mismatch* v_e as the residual nonlinear dynamics that remain after the application of the FL, namely:

$$v_e(z,v) = v_{cmd} - v = \frac{\alpha(z) - \hat{\alpha}(z)}{\hat{\beta}(z)} + \frac{\beta(z) - \hat{\beta}(z)}{\hat{\beta}(z)} \tag{6}$$

Gaussian Process. The Gaussian Process is a Bayesian machine learning technique that approximates a function $f(x)$ at a new input x^*, using a dataset of stored observations $D = \{(x_i, \hat{y}_i) | i = 1, \dots, n\}$ [3]; this process is called inference and is performed under the assumption that all observations follow a multivariate Gaussian distribution. A GP is fully characterized by its prior distribution, which depends on the input values. This prior is specified by a mean function $m(x) = \mathbb{E}[f(x)]$ and a covariance function (or kernel) $k(x,x') = \mathbb{E}\big[\big(f(x) - m(x)\big)\big(f(x') - m(x')\big)\big]$. This structure makes GP a *nonparametric model*, offering a versatile and flexible properties.

Recursive algorithm. To reduce GP computational complexity for real-time implementation, a sparsity method introduced by Huber [5], called *Recursive Gaussian Process*, is used: this method completely *avoids inversion* of the data-points covariance matrix by fixing a priori a set of basis vectors, *i.e.*, the stored dataset inputs. Their outputs are updated iteratively as the new observations of v_e are obtained, using an algorithm which reminds the Kalman filter. This modification reduces the computational complexity of GP inference *from cubic to quadratic*.

Controller integration. The RGP operates in two phases: *running and update*.

In the running phase, using the states of the systems z and v_d, the RGP infers the nonlinear mismatch v_e from the RGP basis vectors dataset and adds it to v_d, *i.e.*, $v_{cmd} = v_d + v_e(z, v_d)$.

While in the update phase, previously collected observations of the input $[z, v]$ and the output $\tilde{v}_e$ are refined and used to update the RGP basis-vector outputs, improving the predictions. Refinement employs a *Savitzky–Golay filter* [6], a non-causal signal-processing technique that enables high-precision and efficient smoothing of signals.

The basis vectors are initialized in a *grid structure*, where the user defines for each input dimension x_i the number of samples n_i in the selected range $[x_{i,min}, x_{i,max}]$. The total number of basis vectors is $\prod n_i$.

To tune the kernel hyperparameters, for this application we choose the Squared Exponential (SE) kernel function, we use a gradient based minimization algorithm using data collected during a previous experiment, aiming at reducing the prediction error.

Implementation

The RGP part is run on a ground station that communicates via ROS1 with the drone during the experiments, providing also the setpoints for following the trajectory. This is done to limit the computational effort carried by the drone, which CPU and memory is very limited. The whole controller is running at $250Hz$, while the RGP component at $10Hz$ to avoid interference with the PID component that controls the angular velocity.

The experimental platform is the *ANT-X 2-DoF drone* (Fig. 2) produced by ANT-X (https://antx.it/about-us-antx/); a simulator that accurately mimics the behavior of the platform is also available. All experiments were performed in the Aerospace Systems Control Laboratory (ASCL) at Politecnico di Milano.

Parameters values. On the platform, the parameters useful for the FL control law are set to $c = 1.168\ \mathrm{s}^{-1}$ and $\bar{k} = 4{,}748\ \mathrm{m/s}^2$. To prove the efficiency of the controller, in the simulation

Materials Research Proceedings 69 (2026) 806-811 https://doi.org/10.21741/9781644904251-142

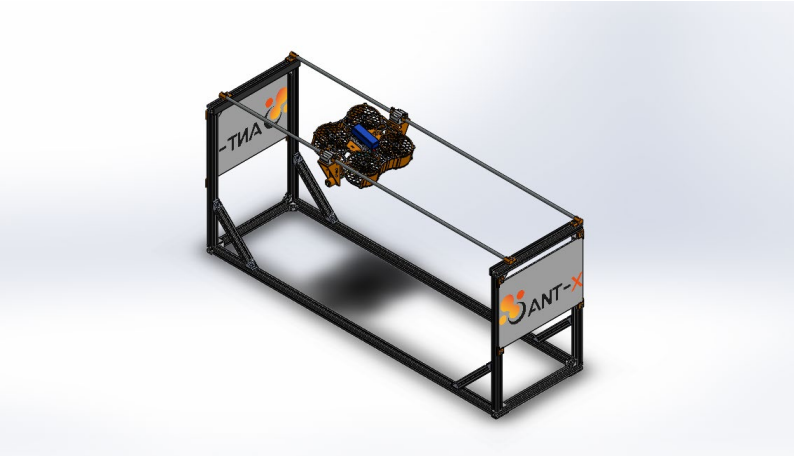

Figure 2: ANT-X 2-DoF drone.

moreover the measurement noise is added and in FL control action a slightly modified parameters respect to the identified model (*i.e.*, $\hat{c} = 2\ \mathrm{s}^{-1}$ and $\hat{\eta} = 12.5\ \mathrm{m/s}^2$) are used.
In both implementations, the grid of basis vector is initialized over the ranges $v_x \in [-0.3, 0.3]$, $\theta \in [-0.2, 0.2]$, and $v_{cmd}/v \in [-5, 5]$. For the physical platform, v_x, θ, and v_{cmd}/v are discretized into 4, 4, and 6 points, respectively, while for the simulator, they are discretized into 6, 6, and 8 points, respectively. The tuning algorithm produced different hyperparameter values for the RGP: for the platform, $l_{v_x} = 0.5\ \mathrm{m/s}$, $l_\theta = 0.5\ \mathrm{rad}$, $l_v = 1\ \mathrm{m/s}^3$, $\sigma_f = 1$, and $\sigma_n = 0.01$; for the simulator, $l_{v_x} = 0.4113\ \mathrm{m/s}$, $l_\theta = 0.4379\ \mathrm{rad}$, $l_v = 1.0272\ \mathrm{m/s}^3$, $\sigma_f = 0.9798$, and $\sigma_n = 0.016$.
The LQR parameters for the platform are set as $Q = [200, 1, 1]$ and $R = 1$, while for the simulation $Q = [100, 1, 1]$ and $R = 1$. The SGF parameter for the platform is $w_{size} = 51$; for the simulation $w_{size} = 21$.
The PID controller, pre-tuned by ANT-X, uses identical parameters for both the platform and simulation: $K_P = 0.009\ \mathrm{s/rad}$, $K_I = 0.21\ \mathrm{rad}^{-1}$ and $K_D = 0.0016\ \mathrm{s}^2/\mathrm{rad}$.

Results

To evaluate the performance, we used the *root-mean-square error (RMSE)* of the response with respect to the setpoint. The result shown for each reference signal is the *average of 5 experiments*. We performed two batches of simulated experiments: in the first batch the reference signal is a *sinusoid with constant amplitude* $r(t) = 0.2\sin(\omega t)$, while in the second one the signal is a *sinusoid with linear-varying amplitude* $r(t) = \frac{0.2}{60} t \sin(\omega t)$. The experiments are conducted varying the angular velocity: $\omega = 0.5, 0.8, 1, 1.5\ \mathrm{rad/s}$ for the first batch and $\omega = 1, 1.5\ \mathrm{rad/s}$ for the second one. We used sinusoidal signals because the time-domain results show the RGP's learning effect and the resulting reduction in error over time. Results in Fig. 3a and Fig. 3b show that *our proposed controller outperforms the baseline* (the same controller with no RGP contribution) with both types of signals.
In the real-world experiments, the reference signal is the *sinusoid with constant amplitude* $r(t) = 0.2\sin(\omega t)$ and the system is tested with angular velocities $\omega = 0.5, 0.8, 1.5\ \mathrm{rad/s}$. Improvements are significant in Fig. 3c at $\omega = 0.8\ \mathrm{rad/s}$, while at lower angular velocities the static friction can hinder the RGP's ability to accurately map v_e and at higher ones unmodeled nonlinear dynamics may adversely affect the RGP inference. In Fig. 4, a comparison between baseline and the full controller for reference tracking experiment with signal $r(t) = 0.2\sin(0.8\,t)$ is shown.

Materials Research Proceedings 69 (2026) 806-811 https://doi.org/10.21741/9781644904251-142

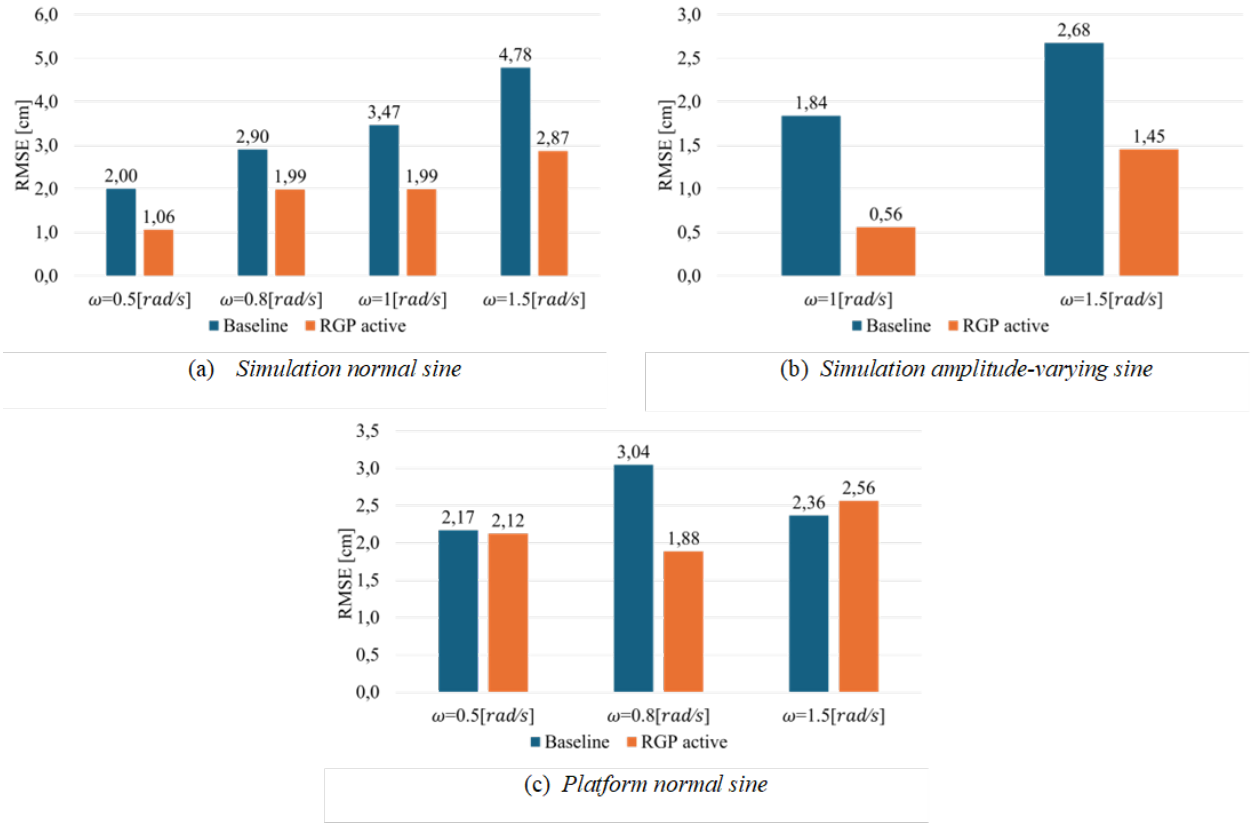

Figure 3: RMSE values for different angular velocities

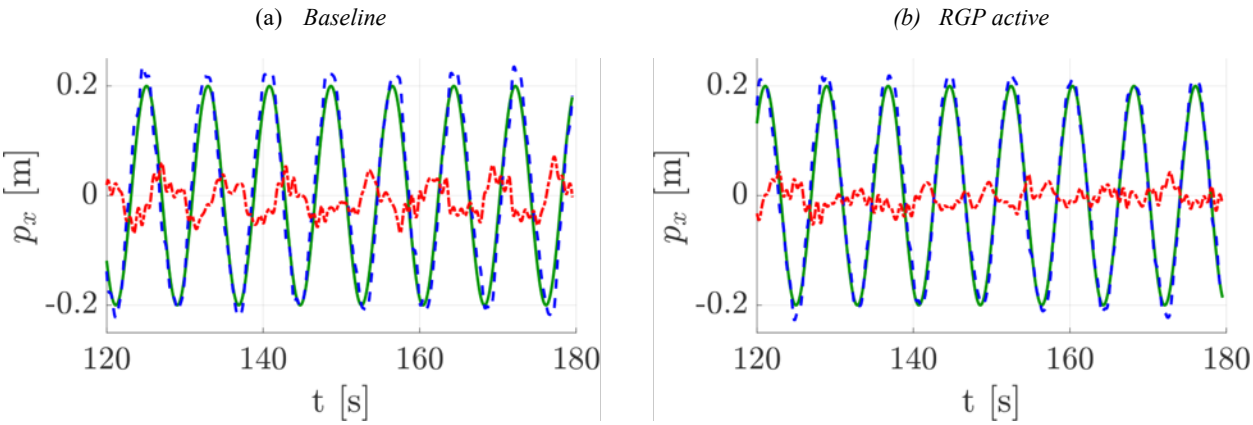

Figure 4: Platform tracking error for $r(t) = 0.2\,sin(0.8\,t)$

Conclusions

This paper aimed to design a learning-based tracking controller for a differentially flat system, which is proven to work effectively both in simulation and on the experimental platform. The computational issues associated with standard GP formulations were addressed using a sparsity method.

Future work includes the extension to an unconstrained drone, controlling all 3 axis, and the implementation of the RGP component directly onboard.

Abstract. Accurate localization of an Uncrewed Aerial Vehicle (UAV) in GPS-denied environments remains a fundamental and unresolved challenge in robotics. Traditional approaches treat state estimation, trajectory planning, and control as separate modules, often assuming perfect state information. However, when visual sensors are used for localization, this assumption often breaks down under challenging conditions, such as poor lighting or textureless environments, resulting in significant drift and unreliable control decisions. Yet, perception performance can be significantly improved if the UAV's motion is planned with the constraints and capabilities of onboard vision in mind. In this context, Perception-Awareness (PA) emerges as a strategy to adapt a UAV's maneuvers based on the real-time perception of the environment. In this paper, we implement and evaluate a PA quadrotor controller through an extensive experimental campaign, demonstrating a reduction in odometry drift of up to 70% compared to a non-PA control approach.

Introduction

Perception-Awareness (PA) consists in adapting UAV's maneuvers based on the real-time perception of the environment. Previous works in PA control have focused on improving the performance of vision based odometry [1]. These efforts typically incorporate feature-based objectives such as:

1. Enforcing the visibility of a given set of landmarks.
2. Minimizing the reprojection error for certain landmarks.
3. Keeping the centroid of observed features centered in the image [1].
4. Minimizing the projected velocity of features to reduce motion blur.
5. Maximizing co-visibility across consecutive frames [2].

Depending on the formulation, PA strategies may influence only the timing of the trajectory, or they may directly affect the UAV's position [3], yaw angle, or both. A widely used method to incorporate such perception objectives into the control loop is Model Predictive Control (MPC). A notable example is PAMPC [1], which integrates perception objectives directly into the MPC optimization problem. This approach explicitly accounts for feature visibility within the camera's field of view (FOV) and penalizes motion that induces image blur.

The main contributions of the paper are the seamless integration of the PAMPC framework into a PX4-based quadrotor (equipped with a forward-looking stereo camera), and the comprehensive experimental evaluation of the resulting Visual Inertial Odometry (VIO) performance. We systematically compare PAMPC against a conventional, non-perception-aware MPC strategy, demonstrating the benefits of coupling perception and control in real world flight scenarios.

Methodology

The perception-aware control problem is formulated as an Optimal Control Problem (OCP):

$$\min_{u(\cdot)} \int_0^T \big[L_a\big(x(t),u(t)\big) + L_p\big(z(t)\big)\big]\,dt \dot{x}(t) = f\big(x(t),u(t)\big), x(0) = x_0, x(t) \in \mathcal{X}, u(t) \in \mathcal{U}, \tag{1}$$

where, $x = [p_{WB}, v_{WB}, q_{WB}]^{\mathsf{T}}$ is the quadrotor state, including position, velocity and orientation of the body frame B with respect to the world frame W, expressed in world frame. The perception state $z = \left[s, \dot{s}\right]$ includes the image coordinates of the centroid of observed features, referred to as Point Of Interest (POI), expressed in pixel coordinates in the image plane, $s = (u, v)$, as well as its velocity on the image plane, $\dot{s}$. The cost L_a penalizes deviations from a reference trajectory, and L_p penalizes deviation from the null perception state $z = 0$, thus introducing perception objectives that keep the centroid of observed features centered in the image and minimize their projected velocity on the frame, a detailed derivation can be found in [1]. The optimized quadrotor control input is $u = [c, \Omega_B]$, where c is the mass-normalized thrust along the vertical axis in the body frame B, and $\Omega_B = \left[\omega_x, \omega_y, \omega_z\right]^{\mathsf{T}}$ is the angular velocity in body frame. The quadrotor state dynamics is described by:

$$\dot{p}_{WB} = v_{WB}, \dot{v}_{WB} = g + q_{WB} \odot c, \dot{q}_{WB} = \frac{1}{2}\Lambda(\Omega_B) \cdot q_{WB}, \tag{2}$$

where $\odot$ denotes the multiplication between a quaternion and a vector, and

$$\Lambda(\Omega_B) = \begin{bmatrix} 0 & -\omega_x & -\omega_y & -\omega_z \\ \omega_x & 0 & \omega_z & -\omega_x \\ \omega_y & -\omega_z & 0 & \omega_x \\ \omega_z & \omega_y & -\omega_x & 0 \end{bmatrix}. \tag{3}$$

The constraints imposed ensure the thrust, angular and linear velocities remain within feasible limits:

$$X = \{v_{WB} s.t. -v_{max} \le v_{WB} \le v_{max}\}, U = \begin{Bmatrix} c_{min} \le c \le c_{max} \\ -\Omega_{max} \le \Omega_B \le \Omega_{max} \end{Bmatrix}. \tag{4}$$

The POI coordinates in world frame are computed as follows: first, grayscale images from left camera are processed using an ORB feature detector to identify relevant landmarks, then, depth

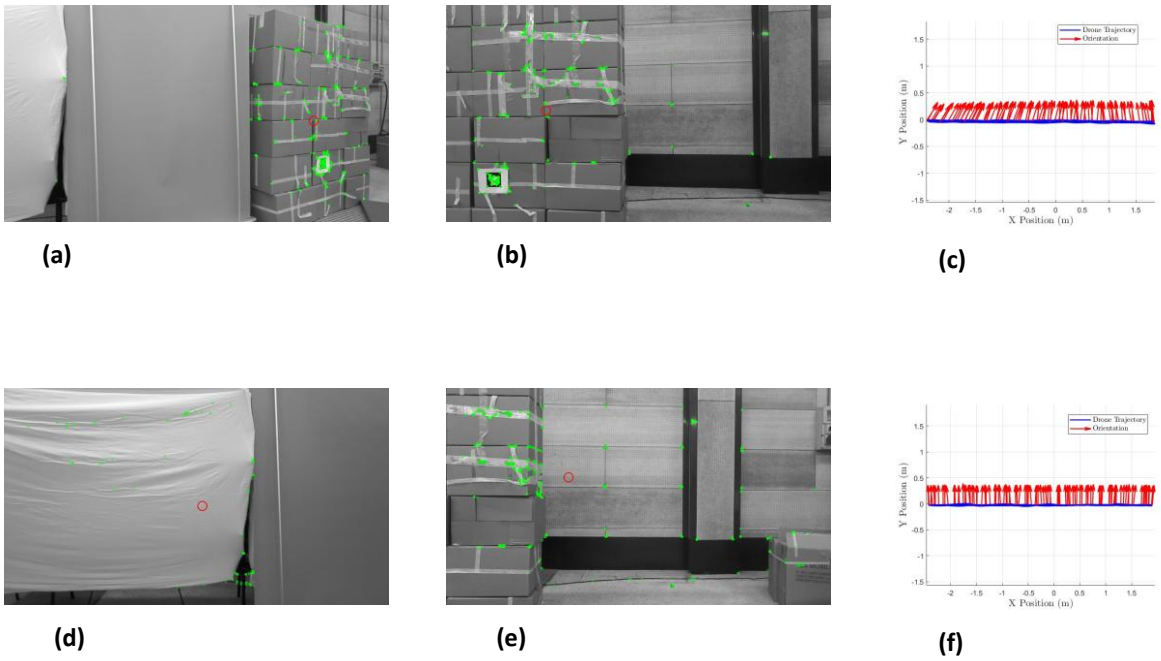
Materials Research Proceedings 69 (2026) 812-816 https://doi.org/10.21741/9781644904251-143

information is used to map 2D frame coordinates to 3D space in the camera frame using the pinhole model; finally, camera pose information is utilized to transform this information into the 3D world frame. Figure 1(a) shows an example of the POI computed. The resulting OCP is discretized using Direct Multiple Shooting within ACADO and solved in a receding horizon fashion.

Experimental results

The solver runs in real time on the quadrotor companion computer at 50 Hz, the resulting velocity and acceleration commands are tracked by PX4's cascaded P-PID running at 250 Hz. Perception metrics (POI and s) are computed onboard using ORB feature detection and stereo triangulation. The experiments have been conducted inside the Flying Arena for Rotorcraft Technologies (FlyART) of the Aerospace System and Control Lab (ASCL). The FlyART is an indoor facility whose flight volume is $12 \times 6 \times 4$m. The quadrotor used in the experimental campaign is equipped with a forward-facing stereo camera, the ZED 2i and a Jetson Xavier NX. Communication between the various components is performed through Robot Operating System (ROS).

Experiments include straight-line flights at 0.3 m/s under both good and low-light conditions. Figure 2 shows the Experimental setup, while Figure 1(c) and 1(f) show the quadrotor's heading during the experiment. The Motion Capture system (MoCap) is used as the ground truth to evaluate the VIO performance. Figure 3 shows the odometry experimental result, with good illumination conditions PA reduced the in-plane drift rate from 0.49cm/s to 0.1cm/s. With low illumination conditions drift rate with and without PA are 0.20cm/s and 1.14cm/s, respectively.



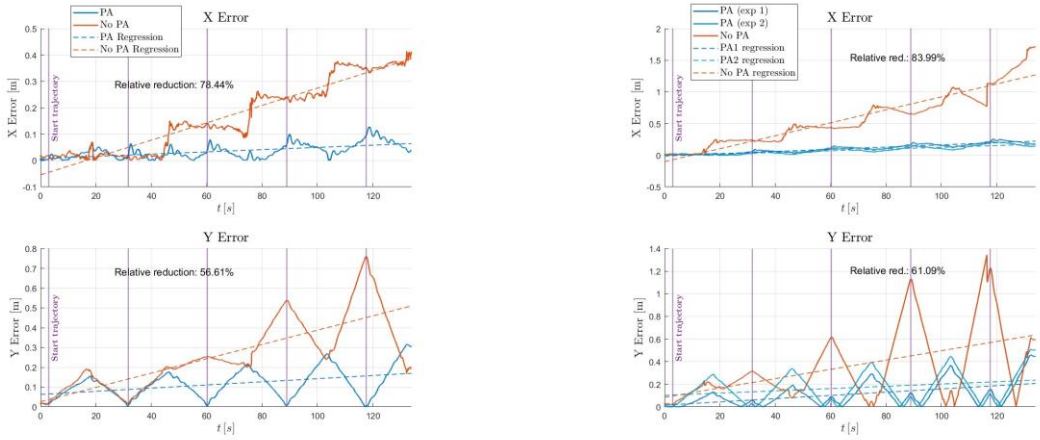


Figure 1. The top and bottom rows illustrate drone orientation with and without PA, respectively, during a linear trajectory. With PA, the quadrotor consistently adjusts yaw to keep the feature-rich region in the FOV. In contrast, without PA, the drone's camera captures mostly blank sheet (left bottom image).

(a) Good illumination (b) Low illumination

Figure 2. Experimental setup.

(a) Good illumination (b) Low illumination

Figure 3. Absolute x- and y-coordinate odometry error (w.r.t MoCap position estimate) in linear flight.

Conclusion

By integrating perception objectives, maximizing the visibility of the feature centroid and minimizing its projected velocity on the camera plane, into the control strategy, the resulting control actions enhance VIO performance. Experimental results demonstrate that the PA framework enhances overall VIO accuracy, even under challenging low-light conditions, ultimately leading to better decision-making based on visual information.

Keywords: HEMS, eVTOL, Agent-based Simulation, Operational Cost

Abstract. With the ongoing hospital centralization in Germany, novel effective solutions for inter-hospital transport are required, a role mostly fulfilled by understaffed emergency ambulances. Electric vertical takeoff and landing (eVTOL) vehicles, promising fast and affordable transportation, have emerged as a potential solution for building up an effective patient transportation fleet. This work explores the feasibility and performance of eVTOL vehicles in inter-hospital patient transport, using Bavaria, Germany, as a real-world case study. An agent-based simulation framework was developed to compare ambulance, helicopter, and both battery-electric and hybrid eVTOL fleets as well as a combined hybrid eVTOL and ambulance fleet under realistic demand conditions. Simulation results show that a network with only 25 hybrid eVTOLs achieves 94% demand coverage with 41% fewer personnel and a 54% reduction in waiting time compared to a similar-performance ambulance network, at only a 33% increase in costs per patient kilometer. Compared to helicopters, the simulated eVTOL fleet offers significant cost savings, primarily in variable operational expenses. Battery-powered eVTOL vehicles offer locally emission-free operation at similar per-mission costs to hybrid eVTOLs, albeit at reduced demand coverage due to range limitations.

Approach

eVTOL vehicles present a significant opportunity to accelerate patient transport compared to road vehicles, while potentially requiring fewer personnel. With efficient wing-borne cruise, they provide a novel transport solution between ground ambulances and helicopters by offering a unique combination of fast, smooth and quiet rides. Inter-hospital transport furthermore presents a unique opportunity to rapidly develop functional eVTOL networks as it profits from existing helipad infrastructure that is otherwise not readily available.

The costs and benefits of aerial medical services have been widely discussed, as indicated by *[1]*, which systematically reviewed studies on helicopter emergency services. Studies specifically on eVTOL vehicle integration and operation in medical use cases have emerged only recently, such as by *[2]*, *[3]*, *[4]*, and *[5]*. Across prior work, a clear gap emerges: the lack of integration between real-world operational data and network-level assessments of eVTOL fleet performance. This study addresses that gap by combining specific operational patterns of medical transport with a simulation-based analysis approach.

An agent-based simulation framework was developed that enables the assessment of eVTOL utilization, cost efficiency, and time savings in patient transportation networks, with a focus on feasibility analysis. Given the computational complexity of the problem, the approach emphasizes

comparative analysis rather than strict optimization, enabling insights into trade-offs between efficiency, cost, and service quality.

The simulation is based on the total real-world demand of 34,200 inter-hospital transport cases per year in Bavaria, Germany, and demand patterns obtained from *[6]*. Figure 1a illustrates the weekly demand pattern, Figure 1b depicts the simulated transport routes.

Four vehicle types are simulated and analyzed in detail: ambulances, helicopters, battery eVTOLs, and hybrid eVTOLs. The eVTOL aircraft specifications were obtained through sizing by the author following a configuration-agnostic point mass approach for lift and cruise eVTOLs, based on the required payload mass. Ambulance and helicopter data were obtained from the commercial vehicles Mercedes-Benz Sprinter 515 CDI and Airbus H135.

Operational assumptions were derived from interviews with 22 professionals including HEMS pilots, emergency physicians, nurses, operators, and industry experts, conducted across 17 sessions with a median duration of 51 minutes.

The simulation was validated by a Monte Carlo-based sensitivity analysis, using 20 random vehicle-to-base assignment and demand samples. Deviations in demand coverage and pickup waiting times showed median relative deviations from the reference simulation results of at most 2%, while cost per patient kilometer differed by less than 4%, confirming the robustness of the original results. The applicability of the findings is limited to Central European conditions; variations in infrastructure or vehicle allocation strategies could alter results.

Results & Discussion

Results were obtained in two steps. First, networks of varying fleet sizes were analyzed for all vehicle types. The results, shown in Figure 2, compare demand coverage, pickup waiting time, cost per patient kilometer, and vehicle utilization across fleet sizes. Hybrid eVTOLs show very good performance with high coverage and cost-efficiency. Helicopters offer slightly higher coverage at significantly higher cost, while battery eVTOLs are limited by range.

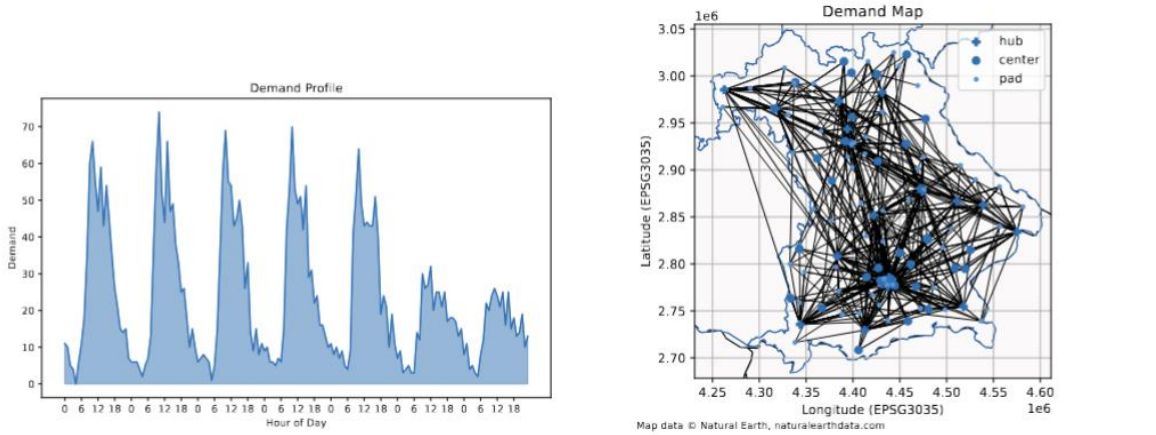
In addition to the single vehicle type networks, combined hybrid eVTOL and ambulance networks with varying fleet compositions were analyzed. Figure 3 highlights pickup waiting time, cost, and utilization across these fleet configurations, showing how integration of hybrid eVTOLs and ambulances improves overall network performance. A combined network of 20 ambulances and 10 hybrid eVTOLs was found to be particularly promising, offering 30% lower waiting times at only 10% increased costs compared to a purely ambulance-based network.

An assessment of network cost-effectiveness, judged by cost per patient kilometer plotted against the patient pickup waiting time in Figure 4, showed that the performance of a hybrid eVTOL fleet can be improved if combined with ground ambulances.

A fleet size of about 20 to 25 hybrid vehicles was found to be optimal based on the Bavarian hospital and transport demand structure. With a deployment of approximately one eVTOL vehicle per 500,000 inhabitants this implies a fleet of up to approximately 150 medical transport eVTOLs in Germany.

In a second step, the key performance metrics of the respective five most promising network configurations, specifically only 20 battery-electric eVTOLs, only 25 hybrid eVTOLs, a combined network of 10 hybrid eVTOLs and 20 ambulances, only 50 ambulances and only 25 helicopters, were analyzed in more detail. The combined hybrid eVTOL and ambulance fleet offers 41% reduced staff and 40% reduced median waiting times compared to the ambulance-only fleet at 11% increased cost per patient kilometer. Compared to helicopters, the combined hybrid eVTOL and ambulance fleet offers 32% reduced cost per patient kilometer at 28% longer median pickup waiting times. The hybrid eVTOL-only fleet offers similar waiting times as the helicopter-only fleet, at 18% reduced costs per patient kilometer. Hybrid eVTOL transport furthermore reduced simulated en-route transport time by about 80% compared to ambulances, significantly lowering transport strain on patients.

Materials Research Proceedings 69 (2026) 817-821 https://doi.org/10.21741/9781644904251-144

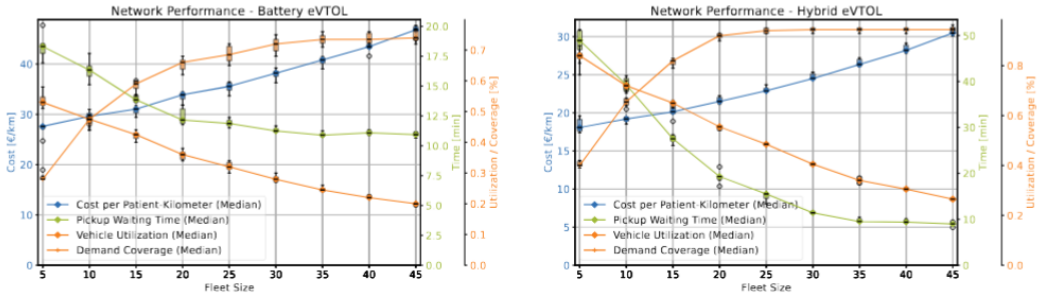


Detailed analysis of mission cost showed that the 18% operating cost reduction of hybrid eVTOLs compared to helicopters stems from a 41% reduction in variable costs per kilometer. Crew cost dominates the costs of operation of all fleets. Depreciation and maintenance costs exceed energy costs in eVTOLs, while helicopters' high energy consumption drives their expenses. The simulated hybrid eVTOL network consumed 2.3 times the amount of fuel as the ambulance-only fleet and 76% less fuel than the helicopter-only fleet. Respectively, the helicopter-only fleet showed a 4.16-fold increase in emissions over the hybrid eVTOL network. High utilization proved to be essential to realize the cost advantage of hybrid eVTOLs.

Regarding potential network congestion through additional aerial vehicles, it was found that 44% of hospitals were visited less than once per day on average, suggesting that shifting inter-hospital transport from ground to air with eVTOLs would not significantly block hospital landing pads for primary rescue missions.

Optimization potential in operational cost efficiency for future aerial patient transportation networks was identified mainly in reducing vehicle maintenance costs and enhancing patient loading and unloading processes, given that the cruise segment of hybrid eVTOL transport flights represents only 14.5% of the median mission.

Conclusion



This study demonstrates the technical and economic feasibility of implementing eVTOL vehicles in Bavaria's inter-hospital patient transport system, supplementing previous studies by in-depth analysis with a novel comparative approach. The findings position hybrid eVTOLs as a viable and cost-effective alternative to helicopters and a high-performance complement to ambulance networks, offering tangible benefits for future medical transport.

Keywords: Drone, In-Flow Distorsions, Urban Mobility, Simulations

Abstract. The interaction between coherent turbulent structures across multiple scales and UAV dynamics is highly complex, particularly during maneuvering phases. In this context, the present study introduces a comprehensive simulation framework to model UAV quadcopter dynamics within urban wind environments. A key innovation of this approach is the integration of inflow distortion effects into the Gazebo Sim platform, which has already been validated for accurate representation of drone dynamics. In-flow distortions are implemented in Gazebo Sim through a custom Python script, following a progressive modeling strategy. The process begins with simplified analytical boundary layer profiles, specifically parabolic and logarithmic velocity versus altitude distributions, to evaluate the impact of canonical turbulent boundary layers on quadrotor performance. These foundational models are then enhanced by superimposing von Kármán and Rankine vortex structures, allowing the simulation of coherent turbulent features such as swirling gusts and vortex shedding generated by the urban canopy.

Introduction

The integration of Unmanned Aerial Vehicles (UAVs) into urban environments represents a transformative shift[1] in aerial mobility, offering new opportunities across various sectors, such as infrastructure inspection, emergency response, surveillance, and last-mile delivery. In particular, small multirotor drones provide unmatched operational flexibility due to their ability to maneuver in low-altitude, confined, and complex airspaces where manned aircraft cannot safely operate[2]. However, the deployment of UAVs in dense urban settings introduces a set of significant challenges that must be addressed to ensure safety, reliability, and environmental compatibility[3,4]. Among these challenges, in-flow distortions caused by complex urban aerodynamics play a critical role, as buildings and surface irregularities generate unsteady and spatially non uniform wind fields[5]. These perturbations can severely affect flight stability, control performance, and energy consumption, particularly for lightweight multirotor platforms[6,7]. In this context, the present study introduces a comprehensive simulation framework to model UAV dynamics within urban wind environments. A key innovation of this approach is the integration of in-flow distortion effects into the Gazebo Sim platform, which has already been validated for accurate representation of drone dynamics[8]. In-flow distortions are implemented in Gazebo Sim through a custom Python script, following a progressive modeling strategy. The process begins with simplified analytical wind profiles, specifically parabolic and logarithmic vertical distributions, to evaluate the impact of canonical turbulent boundary layers on quadrotor performance. These foundational models are then enhanced by superimposing von Kármán and Rankine vortex structures, allowing the simulation of coherent turbulent features such as swirling gusts and vortex shedding generated by the urban canopy. To ensure stable flight within these perturbed flow fields, a Python-based PID (Proportional–Integral–Derivative) controller was

Materials Research Proceedings 69 (2026) 822-826 https://doi.org/10.21741/9781644904251-145

developed and integrated into the Gazebo environment. The controller actively compensates for trajectory deviations induced by the previously described aerodynamic disturbance models, adjusting motor thrust and torque. This closed-loop control system enables the UAV to maintain its desired flight path despite unsteady aerodynamic loads, while its modular Python implementation allows flexible tuning of control parameters and seamless interaction with the simulated urban wind environment.

Methodology

The foundation of this study is a comprehensive simulation framework developed in the Gazebo Sim platform, which provides a physics-based environment validated for accurate drone dynamic behavior. Inflow distortions are introduced through a custom Python script that interfaces with Gazebo using the topic-based communication mechanism. This setup enables the definition of spatially and temporally varying wind fields acting on the UAV model in real time. To represent the complex nature of urban airflow, a progressive modeling strategy was adopted. The first stage employs simplified analytical wind profiles, specifically parabolic vertical velocity distributions, to characterize the influence of canonical turbulent boundary layers on quadrotor dynamics. The parabolic boundary layer profile can be expressed as:

$$U(z) = \begin{cases} U_{\max}\left(\frac{z}{H}\right)\left(2 - \frac{z}{H}\right), & 0 \le z \le H \\ U_{\max}, & z > H \end{cases} \quad (1)$$

where U_{max} is the maximum horizontal velocity and H represents the height of the boundary layer. This formulation captures the quadratic velocity distribution typical of low-altitude urban flows, where wind velocity increases with height up to a maximum, then it remains constant. Subsequently, these baseline models are enriched by superimposing von Kármán and Rankine vortex structures, which enable the representation of coherent turbulent phenomena such as swirling gusts, shear layers, and vortex shedding generated by buildings and other urban obstacles. The tangential velocity magnitude of a single Rankine vortex, confined to the horizontal (x, y) plane, is expressed as:

$$v_\theta(r) = \begin{cases} \frac{\Gamma}{2\pi R^2}\, r, & r \le R \\ \frac{\Gamma}{2\pi r}, & r > R \end{cases} \quad (2)$$

where Γ indicates the circulation of the vortex, R is the radius of the vortex core, and r is the radial distance from the center of the vortex. This formulation ensures a smooth transition from a solid-body rotation inside the core to a potential vortex behavior in the outer region. To represent the unsteady and spatially varying structure of urban wind fields, the Rankine vortex model is extended to a multivortex configuration. Instead of a single vortex centered at (x_o, y_o), an array of N vortices is generated along the x axis, each separated by a distance D and with alternating circulation sign to emulate a counter rotating vortex street. For each vortex i, centered at (x_i, y_i) with circulation Γ_i, the tangential velocity field in polar coordinates is defined as:

$$v_{\theta,i}(r_i) = \begin{cases} \frac{\Gamma_i}{2\pi R_c^2}\, r_i, & r_i \le R_c \\ \frac{\Gamma_i}{2\pi r_i}, & r_i > R_c \end{cases} \quad (3)$$

where R_c is the core radius of the Rankine vortex and $r_i = \sqrt{(x - x_i)^2 + (y - y_i)^2}$. Since the Gazebo simulation environment operates in Cartesian coordinates, each tangential contribution is decomposed into horizontal components:

Materials Research Proceedings 69 (2026) 822-826 https://doi.org/10.21741/9781644904251-145

$$v_{x,i} = -v_{\theta,i}\frac{(y-y_i)}{r_i} \qquad v_{y,i} = v_{\theta,i}\frac{(x-x_i)}{r_i} \tag{4}$$

The total velocity field induced by the entire vortex array is then obtained as the superposition of every individual contribution:

$$v_x(x,y) = \sum_{i=1}^{N} v_{x,i}\,(x,y) \qquad v_y(x,y) = \sum_{i=1}^{N} v_{y,i}\,(x,y) \tag{5}$$

This formulation reproduces a spatially oscillating flow pattern, where regions of positive and negative circulation alternate along the streamwise direction, generating a simplified but physically consistent model of unsteady gusts and vortical disturbances. To reproduce periodic vortex shedding effects, a von Kármán vortex street configuration is introduced, consisting of an alternating array of counter rotating vortices positioned along the streamwise direction. The induced velocity v at each point (x, y) is obtained by the linear superposition of N vortices:

$$\mathbf{v}(x,y) = \sum_{i=1}^{N} \begin{bmatrix} -v_{\theta,i}(r_i)\frac{y-y_i}{r_i} \\ \\ v_{\theta,i}(r_i)\frac{x-x_i}{r_i} \end{bmatrix} \tag{6}$$

where (x_i, y_i) and Γ_i represent the position and circulation of each vortex, respectively, with alternating signs to mimic realistic wake structures. Finally, the complete inflow field is obtained by summing the contributions of the analytical boundary layer and the vortex-induced perturbations:

$$\mathbf{U}_{\text{total}}(x,y,z) = \begin{bmatrix} U(z) + \sum_i v_{x,i}\,(x,y) \\ \sum_i v_{y,i}\,(x,y) \\ 0 \end{bmatrix} \tag{7}$$

Details of the generated gust profiles are reported in Figure 1.

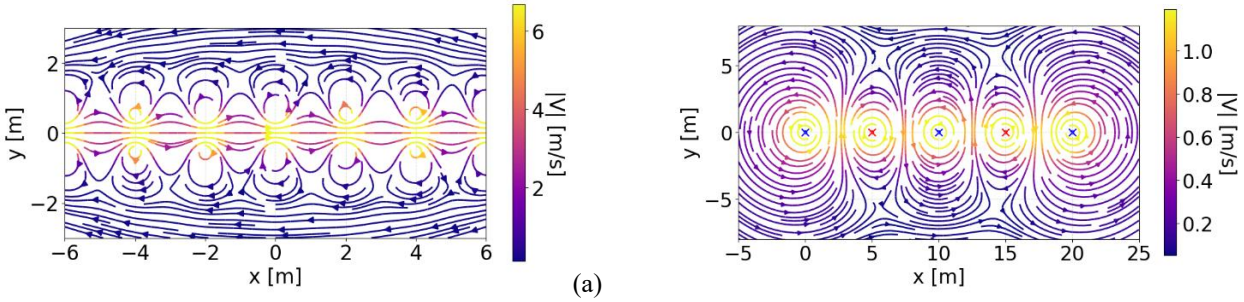

Figure 1:Streamlines of the perturbed velocity field: (a) Rankine vortices; (b) von Kármán wake.

Results

To assess the impact of coherent vortex structures on UAV dynamics, several simulations were conducted using the aforementioned methods to analyze their effects on the trajectory and stability of a quadrotor subjected to such inflow disturbances. In each simulation, the drone was controlled by a PID-based flight controller designed to achieve a stable hover at an altitude of 2 m before transitioning into a straight horizontal trajectory. By systematically varying the circulation strength, vortex core radius, and lateral offset of the UAV with respect to the vortex centers, it was possible to isolate the distinct dynamic effects produced by Rankine and von Kármán configurations, providing a clear basis for comparison across all test cases. The first set of simulations investigates the interaction between the UAV and a simplified gust field generated by

Materials Research Proceedings 69 (2026) 822-826 https://doi.org/10.21741/9781644904251-145

a pair of counter-rotating Rankine vortices (N = 2). Each vortex induces a tangential velocity field according to the formulation described in (3), with circulations of alternating sign (+Γ and −Γ), resulting in a symmetric flow pattern composed of two opposite swirling regions. The UAV is commanded to follow a straight trajectory along the x-axis, while the vortex field acts as a crosswind disturbance. To assess the sensitivity of the flight controller to the vortex-induced perturbations, three different lateral offsets were tested: y = 0 m, y = +1 m, and y = +2 m. Two different circulation strengths were considered, $\Gamma = 3$ m^2/s and $\Gamma = 7$ m^2/s, while keeping the vortex core radius constant at R = 0.1 m.

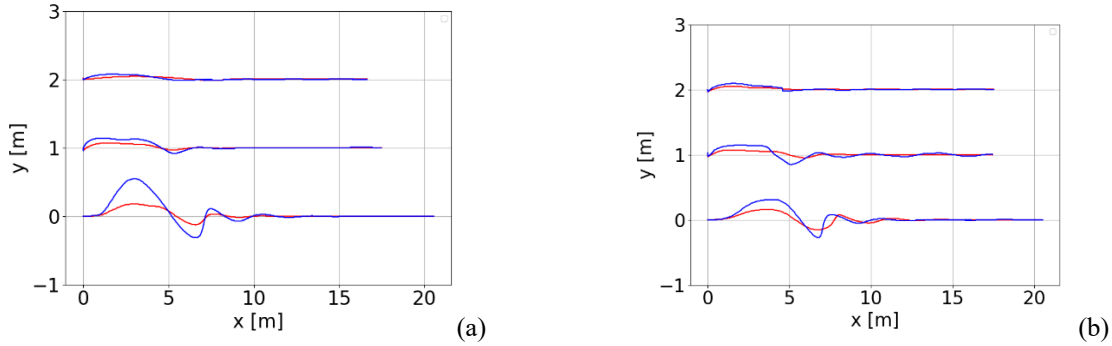

Figure 2: UAV trajectories under the influence of a pair of counter-rotating Rankine vortices. Blue ones are performed at Γ = 3, red ones at Γ = 7. (a) Simulations performed using Rankine vortices with vortex core radius R = 0.1; (b) vortex core radius R = 0.3.

Figure 2 (a) reports the resulting UAV trajectories. When the reference path lies at y = 0 m, the vehicle crosses the region of highest tangential velocity, directly intersecting the vortex cores. As a result, the quadrotor experiences stronger lateral accelerations, and the PID controller must generate larger corrective actions to maintain the desired trajectory. In contrast, when the flight path is shifted from y = 0 m, the vehicle moves through regions where the induced velocity decays with radial distance, leading to significantly milder perturbations and smoother trajectory corrections. A second set of simulations, shown in Figure 2 (b), was conducted with an increased vortex core radius of R = 0.3 m while keeping all other parameters identical. The resulting trajectories show only minor differences compared to the previous case, indicating that for the considered circulation magnitudes and vortex spacing, the flow structure outside the core region dominates the disturbance experienced by the UAV. The final set of simulations investigates the UAV response when flying through a von Kármán vortex street, generated by an alternating array of counter-rotating vortices. Again, the vehicle is commanded to follow a straight trajectory along the x axis, with a PID-based controller compensating for the flow-induced disturbances in real time. Three lateral offsets were tested (y = 0, 1, 2 m), and two circulation magnitudes were considered ($\Gamma = 10$ m^2/s and $\Gamma = 20$ m^2/s).

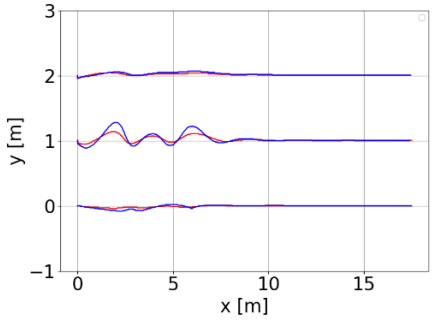

Figure 3: UAV trajectories under the influence of an alternating array of counter-rotating von Kármán vortices. Blue ones are performed at Γ = 10, red ones at Γ = 20.

The resulting trajectories, shown in Figure 3, reveal a markedly different behavior compared to the Rankine vortex cases. In this configuration, the strongest perturbations occur when the UAV flies at y = 1 m, while the paths at y = 0, 2 m experiences milder deviations. This inversion of the disturbance pattern is directly linked to the structure of the von Kármán wake. Unlike the Rankine configuration, where the velocity field is maximum along the vortex cores, the von Kármán vortex street generates alternating regions of high and low induced velocity that are displaced laterally from the symmetry axis of the wake.

Final Remarks

This study presented a comprehensive simulation framework for analyzing the interaction between small UAVs and complex urban wind environments. The approach integrates analytical aerodynamic models and vortex-based representations of coherent structures within the Gazebo Sim platform. A key contribution of this work lies in the incorporation of inflow distortion effects directly into a validated UAV simulation environment, along with the implementation of a Python-based PID controller capable of dynamically compensating for trajectory deviations induced by analytical flow perturbations.

Abstract. This work deals with the development of a numerical code for the evaluation of aerodynamic performance of UAV propellers combining the Blade Element Momentum Theory (BEMT) with empirical corrections for the extension to the post-stall behaviour of blade sections. The formulation also takes into account low-Reynolds effects and starts from the aerodynamic data of blade airfoils in 2D flow. The results of the developed model are verified against manufacturer database for two types of fixed-pitch propellers, over a wide range of advance ratio, aiming to cover the flow conditions related to hovering and cruise phases of a reference VTOL UAV. The results stability is demonstrated by a discretization convergence analysis, assessing the influence of sectional resolution on blades. Owing to the fast convergence of the solver, the proposed approach is expected to be effectively employed as a starting point of propeller design optimization loops.

Introduction

The aerodynamic performance of propellers can be evaluated using models with different levels of fidelity and computational cost. Early formulations, such as the Froude's actuator disk theory, later extended by Betz and Joukowsky, idealized the rotor as a uniformly loaded disk imparting a pressure jump to the flow, establishing the theoretical efficiency limit of 59.3% [1].

A major improvement came with Glauert's Blade Element Momentum Theory (BEMT) [2], which coupled one-dimensional momentum conservation with sectional aerodynamics. By combining Joukowsky's momentum theory, Prandtl's tip-loss correction, and Drzewiecki's blade-element approach, the BEMT actually enabled accurate performance prediction with low computational requirements, laying the foundations of modern rotor analysis.

The increasing demand for electric Vertical Take-Off and Landing (eVTOL) aircraft and UAVs [3] has reinforced the need for fast and reliable aerodynamic modelling tools supporting the conceptual and preliminary design phases [4]. High-fidelity approaches, such as Computational Fluid Dynamics (CFD) or wind tunnel testing, remain indispensable for a final validation, but they are often impracticable in the early-stage design. Steady-state Reynolds-Averaged Navier–Stokes (RANS) simulations typically require hundreds of CPU hours per configuration [5], depending on mesh resolution and turbulence model. On the other hand, a reduced-order method based on BEMT, providing a favourable balance between accuracy and computational costs, is more suitable for preliminary optimization studies.

Experimental and numerical investigations have demonstrated the reliability of BEMT for small- and medium-scale propellers. Jdiobe et al. [6] validated BEMT predictions against wind-

Materials Research Proceedings 69 (2026) 827-832 https://doi.org/10.21741/9781644904251-146

tunnel measurements of an APC propeller for a medium-sized eVTOL, reporting deviations below 10% across a wide range of advance ratios, and highlighting the influence of diameter and pitch variations. Moello and Liscouet [7] developed a coupled CFD–BEMT framework for propeller geometry definition, significantly reducing the number of fully CFD-based optimization iterations and halving the computational time. Andria et al. [8] employed a BEMT method for the design and rapid prototyping of fixed-pitch drone propellers, with experimental tests confirming the predicted thrust performance. Nevertheless, in most cases the BEMT methods disregard post-stall behaviours and low-Reynolds effects.

This work proposes an extension of conventional BEMT models, aiming at broadening the operational range of the underlying airfoil data. Empirical post-stall models and low-Reynolds penalization functions are thus combined with BEMT predictions in order to evaluate aerodynamic coefficients beyond the linear regime. These improvements permit to evaluate relevant trends on predictions extending their applicability over a wider range of operating conditions, including high angles of attack and low Reynolds numbers, quite common in small-size fixed-pitch propellers typically employed in lightweight eVTOL platforms. The results of the developed code are verified against the database of two propellers manufactured by APC, and a mesh-refinement analysis is performed to assess the numerical convergence of the code.

Materials and Methods

For a propeller with diameter $D=2R$ and number of blades B, rotating at angular speed Ω, and with an axial free-stream velocity V_∞, corresponding to an advance ratio $J=V_\infty/(\Omega D)$, the local tangential V_θ and axial V_x velocities on the blade element at a radial position r (Fig. 1), are defined in Equations (1) and (2). In these expressions, a and a' are the axial and tangential induction factors, respectively, and the actuator-disk theory speed induced by the thrust T on the propeller area $A=\pi R^2$ is used under hovering condition (i.e., $J=0$). The effective angle of attack $\alpha(r)$ is thus given by the difference between the local twist angle $\theta(r)$ and the calculated inflow angle $\phi(r)=\tan^{-1}(V_x/V_\theta)$ formed between the relative velocity V_{rel} and the propeller plane.

$$V_\theta(r) = \Omega\, r\, \left(1 + a'(r)\right) \tag{1}$$

$$V_x(r) = \begin{cases} V_\infty + 2\,a(r)\sqrt{|T|/2\rho A}\,, & J = 0 \\ V_\infty\left(1 + a(r)\right), & J \neq 0 \end{cases} \tag{2}$$

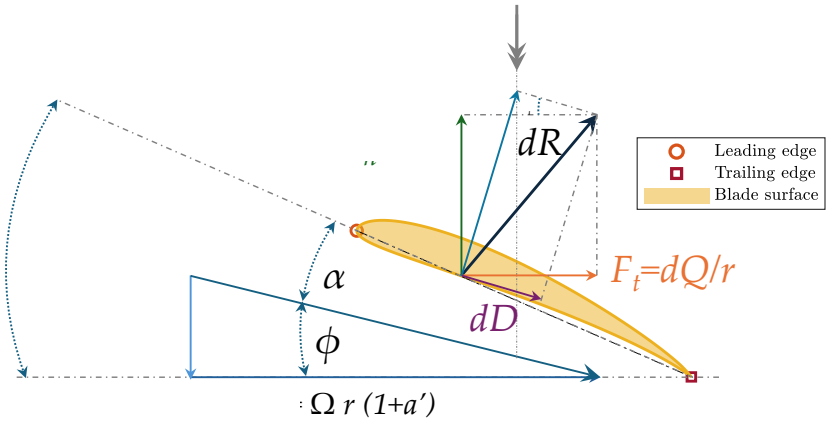

Figure 1. Velocity triangle and aerodynamic forces on a blade element at radial position r.

The aerodynamic coefficients have been derived from precomputed steady XFOIL simulations over a limited range of angles of attack [α_{min}, α_{max}] and discrete chord-based Reynolds numbers, resulting in 2-D lookup tables of lift $C_L(\alpha,Re)$, drag $C_D(\alpha,Re)$, and moment $C_m(\alpha,Re)$ coefficients. Intermediate values are instead obtained by applying cubic splines with respect to the angle of

Materials Research Proceedings 69 (2026) 827-832 https://doi.org/10.21741/9781644904251-146

attack and linear interpolation across the Reynolds number. In case that the Reynolds number of the blade section is calculated as lower than a pre-defined minimum value (5×10^4), empirical penalization functions are applied to reduce the maximum lift and increase drag, reproducing the degradation of aerodynamic performance observed in laminar flow regimes [9]. Beyond the stall angle, the lift and drag coefficients are then extrapolated using a modified Viterna–Corrigan model [10], while the moment coefficient is set to zero to represent fully separated flow. The original formulation has been actually refined to increase accuracy for the NACA 4412 wind-tunnel data reported in [11], as well as to enhance the numerical convergence of the BEMT solver. In the developed code, the post-stall lift and drag coefficients are thus reconstructed from the pre-stall boundary values ($C_L^{\alpha_{min}}$, $C_D^{\alpha_{min}}$) at α_{min} and ($C_L^{\alpha_{max}}$, $C_D^{\alpha_{max}}$) at α_{max}, using the sinusoidal relationships given in Equations (3-4), where α_0 denotes the zero-lift angle. The resulting global behaviour is illustrated in Fig. 2.

$$C_L = \begin{cases} -0.5\, C_L^{\alpha_{min}} \sin[2\,(\alpha-\alpha_0)], & \alpha < \alpha_{min} \\ 0.80\; C_L^{\alpha_{max}} \sin[2\,(\alpha-\alpha_0)], & \alpha > \alpha_{max} \end{cases} \tag{3}$$

$$C_D = \begin{cases} C_D^{\alpha_{min}} + 1.6\, \sin^2[2\,(\alpha-\alpha_0)], & \alpha < \alpha_{min} \\ C_D^{\alpha_{max}} + 1.6\, \sin^2[2\,(\alpha-\alpha_0)], & \alpha > \alpha_{max} \end{cases} \tag{4}$$

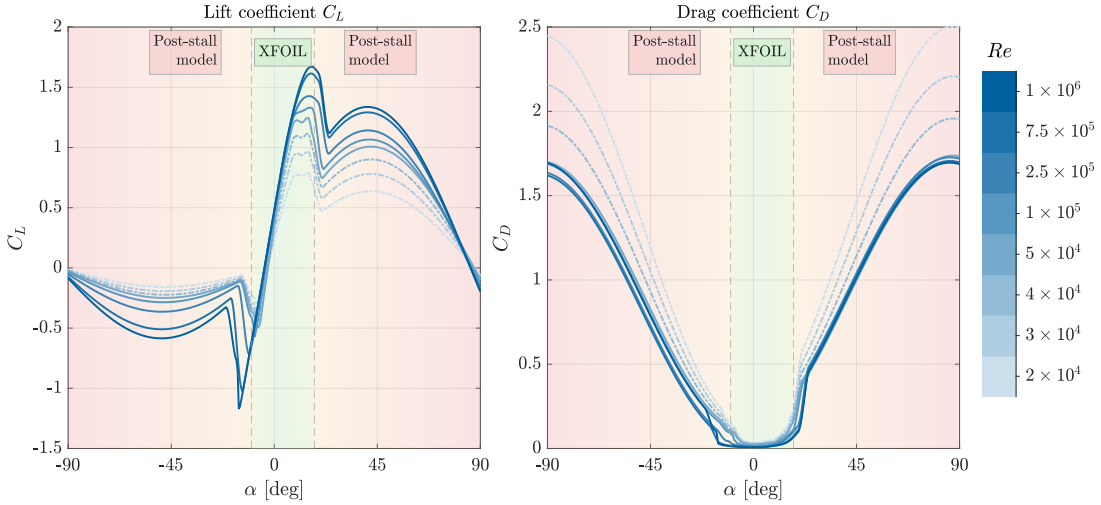

Figure 2. NACA 4412 lift and drag coefficients including post-stall and low-Reynolds effects

The aerodynamic forces per unit span (dr) are computed using Equations (5-6), where $c(r)$ is the local chord length and ρ is the air density; the corresponding elemental thrust dT and torque dQ are obtained from their projections, as expressed in Equations (7-8).

$$dL(r) = 1/2\,\rho V_{rel}^2 c(r) C_L(\alpha, Re) dr \tag{5}$$

$$dD(r) = 1/2\,\rho V_{rel}^2 c(r) C_D(\alpha, Re) dr \tag{6}$$

$$dT(r) = F_n = B(dL\cos\phi - dD\sin\phi) \tag{7}$$

$$dQ(r) = rF_t = Br(dL\sin\phi + dD\cos\phi) \tag{8}$$

The total thrust and torque, and consequently the power (P=QΩ), are obtained by spanwise integration. A parasitic drag component associated with the propeller hub is included by a constant drag coefficient $C_{D,h}$=0.55 referred to the hub frontal area.

Tip-loss effects are finally modelled through a modified Prandtl correction (Eq. 9), with the parameters and F_{min}=0.1 and $\varepsilon=10^{-4}$, preventing numerical instabilities.

$$F_{raw} = \frac{2}{\pi}\cos^{-1}\left[\exp\left(-\frac{B(R-r)}{2r(|\sin\phi|+\varepsilon)}\right)\right], \quad F = F_{raw} + (1 - F_{min})F_{raw} \tag{9}$$

The axial and tangential induction factors (a and a') are updated through the coupled momentum equations (10), where $\sigma=Bc(r)/2\pi r$ is the local blade solidity, while respectively, $C_n=C_L\cos(\phi)-C_D\sin(\phi)$ and $C_t=C_L\sin(\phi)+C_D\cos(\phi)$ are the normal and tangential forces coefficients.

$$a = \left[\frac{4F\sin^2\phi}{\sigma C_n} + 1\right]^{-1}, \quad a' = \left[\frac{4F\sin\phi\cos\phi}{\sigma C_t} - 1\right]^{-1} \tag{10}$$

To ensure robust convergence under hovering conditions, where the standard BEMT formulation may yield indeterminate induction factors as ϕ approaches zero, an iterative actuator-disk-based procedure is implemented. Starting from an initial thrust estimate, the induced axial velocity is computed according to Equation (2) at $J=0$, and the aerodynamic forces are iteratively updated until convergence. This approach enables stable initialization also in low-J simulations and ensures a continuous performance prediction from hover to forward flight.

A counter-based convergence criterion is adopted to ensure stable solutions of the induction factors. Convergence is achieved when the variation of a and a' between iterations remained below 10^{-4} for ten consecutive steps, preventing false positives due to transient oscillations. Under-relaxation by arithmetic averaging and a near-final safeguard are applied to enhance numerical stability, limiting global iterations at 1000. In the hovering iteration loop, convergence is monitored on both thrust and power to ensure consistency of the actuator-disk coupling.

Results and Discussion

Two APC propellers have been selected for the verification of the developed BEMT-based code: the APC 14×5.5MR, optimized for hovering flight, and the APC 14×10E, designed for cruise operation. The predictions of thrust (T), power (P), propulsive efficiency (η) and Figure-Of-Merit (FOM) are compared with the manufacturer data across the entire advance-ratio range and at three rotational speeds (4000, 8000, and 12000 rpm). As shown in Fig. 3 and Fig. 4, the model accurately reproduces the variation of the performances with the advance ratio. Relative errors remain consistently below 20% for all conditions, except where the reference quantity approaches zero. Minor discrepancies in power at the highest rotational speed are attributed to the neglect of compressibility effects, which slightly underestimates sectional drag at high Mach numbers at the blade tip. A residual bias also arises from the simplified assumption of a uniform distribution of NACA 4412 airfoil, whereas the APC blades employ Eppler E63 profiles near the hub.

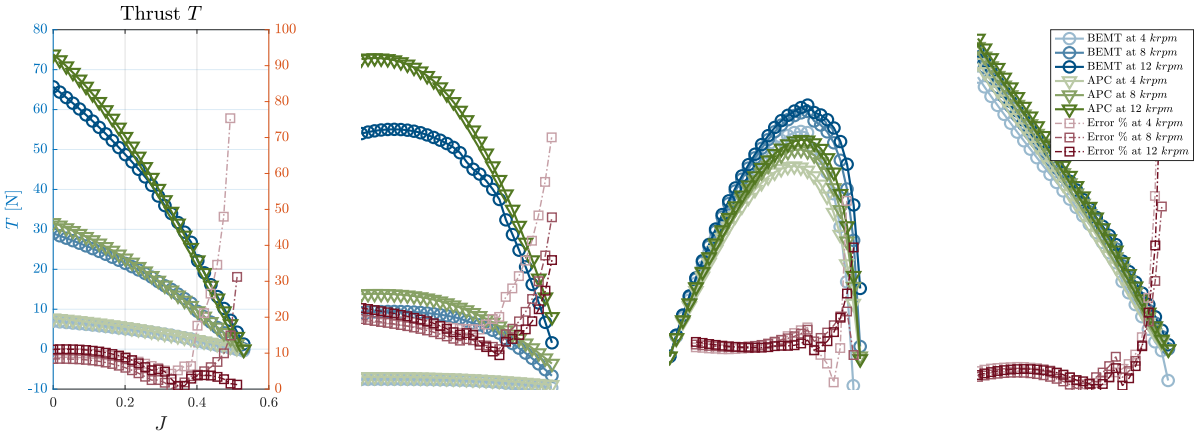

Figure 3. APC 14×5.5MR: comparison of manufacturer data and model results at 4000, 8000 and 12000 rpm

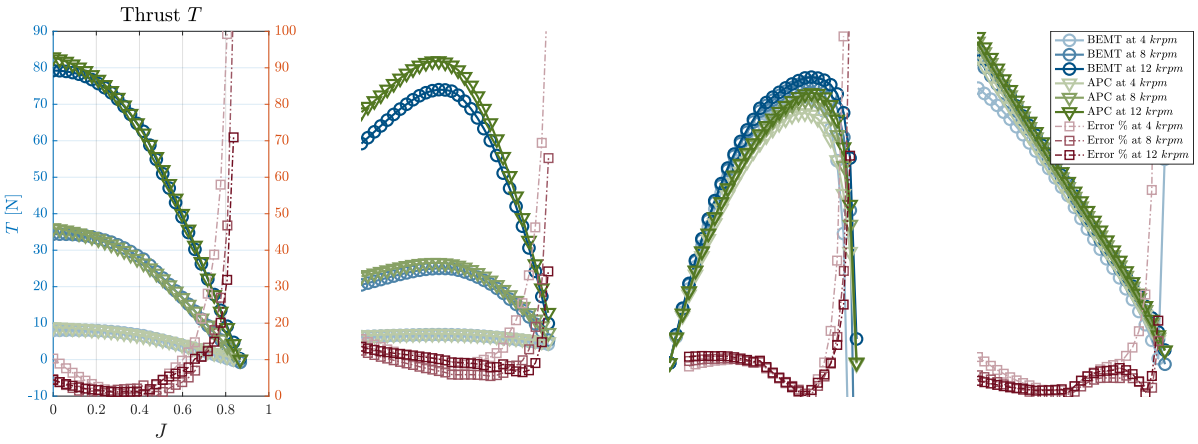

Figure 4. APC 14×10E: comparison of manufacturer data and model results at 4000, 8000 and 12000 rpm

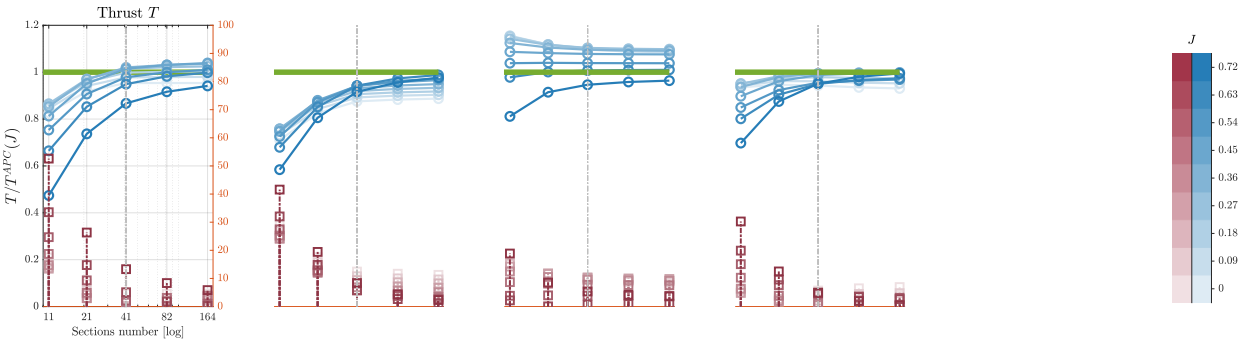

Figure 5. Performance sensitivity to the number of blade sections (simulations with APC 14×10E)

A mesh-refinement study on the APC 14×10E confirmed the numerical convergence of the BEMT-based code. As shown in Fig. 5, relative errors decreased monotonically with finer discretization, while the manufacturer's baseline mesh (41 sections) already ensured satisfactory accuracy. Further refinement yielded marginal gains, with runtime increasing almost linearly—from about 2 s to 6 s per operating point on a standard laptop PC.

Conclusions

The developed BEMT-based code represents an efficient tool for predicting the aerodynamic performance of small-size propellers for UAVs over a wide range of conditions, related to both hovering and cruise flight, by achieving satisfactory accuracy with respect to manufacturer data (maximum relative errors <20%). The inclusion of post-stall and low-Reynolds corrections enhances stability and extends the prediction trends. The solver generates complete performance maps within a few minutes, making it very suitable for preliminary design and optimization studies. Future developments will address multi-airfoil blades, compressibility effects, and the application to complex geometries such as toroidal propellers [12].

Abstract. This paper outlines a comparative analysis of acquisition, operation & maintenance and overall mission costs carried out on three test cases, where existing flying machines currently flying operational missions (specifically, a multi-copter UAV, a fixed-wing UAV and a manned helicopter) are compared to a novelly designed unmanned airship. The analysis was carried out designing a specific airship for each mission by employing a well-proven technique implemented in the Morning Star suite at Politecnico di Milano. Furthermore, costs are evaluated through estimation relationships accounting for the specific features of an airship, in a fashion suggested by cost estimation methods available for fixed-wing aircraft. The results allow for interesting comparisons, and show where a small-scale unmanned LTA may reduce the cost associated to procurement and operation compared to other flying platforms, while successfully capturing the same mission target as current solutions.

Introduction

The recent development of lighter-than-air (LTA) platforms for low-altitude missions, witnessed by the growing number of new companies offering services based on this type of machine (like Kelluu [1], HyLight [2], Roboloon [3] or FloFleet [4] in Europe), has been fuelled by the advancement of some key enabling technologies. Among them, electric motors for powering propellers offer a higher power-to-weight ratio compared to internal combustion engines. The adoption of these motors is especially advantageous on airships, since they can supply thrust for both propulsion and attitude control when suitably positioned in a distributed fashion, at multiple locations in an airship layout [5], [6], [7], [8], [9]. Additionally, the comparatively low expenditure of energy for propulsion and the reduced peak power required even in terminal maneuvers, compared to either fixed-wing aircraft or rotor-craft, make the sizing of the batteries far less penalizing than heavier-than-air platforms, both in terms of battery mass for the mission, and corresponding battery volume. Similarly, fuelled by the boom of the market of multi-copter UAVs over the past decade [10], effective on-board electronics constitutes a key enabler for unmanned LTAs, especially since the removal of the crew and crew-related masses (e.g. a cockpit, physical control stick and related power lines, etc.) from an airship starkly saves on its buoyant volume as well.

The combined use of these technologies is making LTA technically-viable solutions, with clear performance advantages especially in terms of endurance in forward flight and time-over-target in hovering or station-keeping phases, compared to other flying machines like fixed-wing aircraft (incapable of hovering) and rotor-craft (dramatically limited in terms of endurance and time-over target). However, even for those missions where LTAs could be employed from a technical stand-point, their consideration by potential industrial end-users is still hindered by an uncertainty on the costs associated with procurement or operation & maintenance (O&M).

Materials Research Proceedings 69 (2026) 833-838 https://doi.org/10.21741/9781644904251-147

In this regard, the present work aims to shed some light, by firstly introducing a simple analytic method for the most relevant components of the life cycle cost of a LTA platform for low-altitude use. Secondarily, this work provides a detailed analysis of three case studies, where the cost associated to flying machines currently operating a mission, namely a quadcopter UAV, a fixed-wing UAV and a manned helicopter, obtained as much as possible by processing relevant company data from actual operators, are compared to the outcome of a cost prediction made for an LTA capable of capturing the same mission target.

Methodology

Among the cost prediction methods [11], in the scenario at hand where practical realizations are still not many, a parametric estimation (PE) method [12] based on cost estimating relationships (CER) for sub-components of each major cost chapter has been adopted, trying to capture all major potential contributions to a specific cost. The advantage of a PE approach is that of binding cost estimation to quantities typically available at a preliminary design stage, like the break-down of take-off mass, the installed thrust, etc. [13], [14]. In order to feed CERs in the case of a LTA and obtain a cost prediction, it is possible to employ data on a LTA design solution obtained from a suitable preliminary design exercise (like volume, mass, etc.), considering a specific target mission. Such design exercise can be carried out in a largely automated fashion, thanks to consolidated procedures (Figure 1) available in the literature, bearing credible results once values pertaining to the mission at hand have been assigned [14], [15] [16], [8].

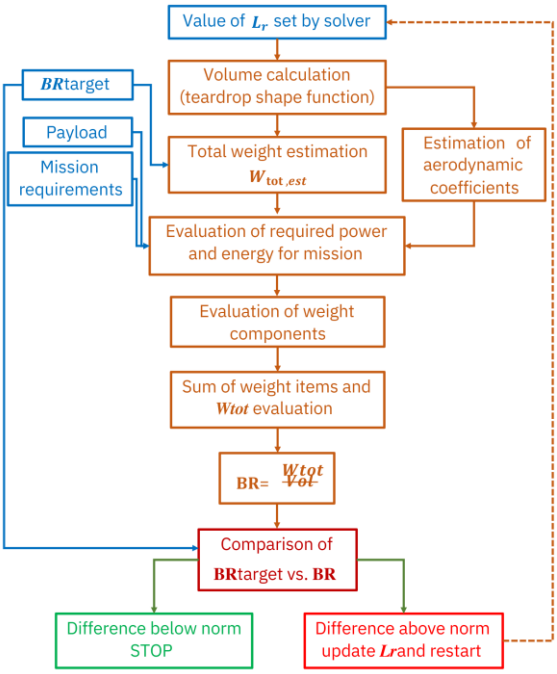

Figure 1 Schematic representation of the considered preliminary sizing algorithm for LTAs.

For some components of cost, a good commonality with respect to other applications in the industrial field can be expected (e.g. the cost of engineering). For components more typical to the LTA case, the build-up of simple CER has been attempted (especially for material cost), mostly based on current industrial data-sheets. Furthermore, CERs for research, development, test and engineering (RDTE) cost, as well as manufacture, have been considered for LTAs (Figure 2). Conversely, the estimation of O&M cost has been treated in a slightly different way for each case study at hand, on account of some specific features of each mission analysed, yielding the need for such customization.

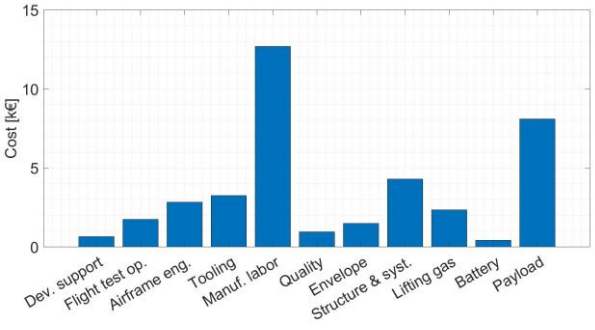

Figure 2 Example split of production cost for an LTA for solar plant inspection (for a production run of 50 exemplars).

Materials Research Proceedings 69 (2026) 833-838 https://doi.org/10.21741/9781644904251-147

Case studies and results

Three missions have been considered, among those currently flown by either UAV or manned machines (Figure 3), which could be flown by a low-altitude LTA at the current level of technology, and without the need for an unrealistically big sizing of the envelope. Care was taken to compare LTA solutions to existing ones flown only in fair weather, to increase the fairness of the analysis.

Figure 3 Competitors for LTA solutions: the DJI Matrice 210 RTK (left) employed for power-plant monitoring, the Tekever AR5 Evolution (center) for sea-life monitoring, and the Airbus AS350B3 (right) for pipeline inspection.

By knowing the target of the mission, a corresponding unmanned LTA UAV was designed for each of these missions, employing the design technique mentioned in the previous paragraph, implemented in the airship sizing suite Morning Star at Politecnico di Milano [15] [16].
Costs available from partners cooperating in this analysis was compared to values obtained from the methodology cited above, yielding the following results.

Solar power-plant inspection. This mission is currently carried out recurring to multi-copter UAVs, which overfly the plant from close distance with visual and infra-red sensors, looking for debris and dust accumulation and wear or damage to the cells. As a reference case for a quantitative analysis, the 87 MW plant of Trino Vercellese (VC) in Northern Italy has been selected. The corresponding LTA solution from the design method is reported in Table 1. The comparison of costs is portrayed in in Table 2. Here the cost per mission has been obtained from a depreciation scheme of 5 years for the quadcopter UAV (optimistic) and of 10 years for the LTA, corresponding to the life span of the envelope. It can be noted how the procurement cost is starkly in favour of the existing quadcopter solution. Yet the operation cost is much higher for that solution than for the LTA, on account of the much higher endurance of the latter. This in turns reduces the time for the mission from 4 days to 1 days, thus also significantly reducing the cost for the crew.

Sizing parameter	Value
Volume [m³]	20.74
Length [m]	9.24
Fineness ratio [-]	4.02
Battery mass [kg]	1.55
Battery energy [kWh]	209.25
Total mass [kg]	25.66

Cost component	Acquisition cost [EUR per item]	O&M cost [EUR per mission]	Overall cost [EUR per mission]
Quadcopter	22,005	2,031	2,091
Airship	44,655	813	825

Table 2 Cost comparison between as-is and LTA solutions for solar plant inspection.

Sea-life monitoring. This type of mission is nowadays flown with a fixed-wing UAV, which takes off from a suitable airstrip and flies to a monitoring area over high waters, where it spends most of the mission in a loiter, observing sea-life through electro-optical, infra-red or mirror-less digital camera sensors. As a reference case, the cetacean study mission carried out by a joint group including the Italian Coast

Fineness ratio [-]	4.02
Battery mass [kg]	6.24
Battery energy [kWh]	805.95
Total mass [kg]	61.08

Table 3 Design parameters for LTA UAV for sea-life monitoring.

Guard near the Pelagos sanctuary in the Ligurian Sea in Northern Italy has been considered. The LTA solution designed for this case is significantly bigger than that for the previous one (Table 3). The LTA solution profits from the ability to take-off and land closer to the inspection target, thanks to the need for a reduced ground infrastructure. Furthermore, the lower emitted noise allows to capture good imagery while flying closer to the target (lower altitude) even when employing a cheaper and sensor suite *[17]*. In this specific analysis, the procurement cost of the fixed-wing UAV is extremely high compared to that of the LTA. Of course, such a rig may be very versatile and might be employed for additional missions than just the one considered here. The O&M cost for the LTA is low, thanks to the need for a minimal crew. Mixed with the lower overall mission range to be covered, as just commented, the overall cost per mission is starkly in favour of the LTA solution (Table 4).

Cost component	Acquisition cost [EUR per item]	O&M cost [EUR per mission]	Overall cost [EUR per mission]
Fixed-wing	1,460,000	4,642	5,042
Airship	96,241	826	852

Table 4 Cost comparison between as-is and LTA solutions for sea-life monitoring.

Pipeline inspection. This mission is currently flown typically with manned helicopters, crewed by two technicians with manual cameras, who inspect the pipeline in search of leaks and wear of the pipeline structure, while also checking the safety of the surroundings. The practical case of the Italian section of the Transalpine Oil Pipeline (TAL), linking Trieste (IT) to Ingolstadt (DE), has been considered for this analysis. The sizing results for an unmanned LTA solution on this mission are shown in Table 5. Notably, the overall sizing is generally similar to that obtained for the sea-life monitoring mission. The altitude on the target can be reduced with respect to that of a helicopter, on account of the lower noise emission of the airship *[18]*, *[19]*. Correspondingly, the quality (hence cost) of the optical sensors can be reduced. Table 6 shows the cost corresponding to the as-is and LTA solutions for the pipeline inspection mission. Similar to the previous test scenario, the acquisition cost is starkly in favour of the LTA (even though of course the helicopter can perform several more missions beside the one at hand). However, the LTA UAV is penalized by its low speed, which is inherent to a small-size LTA machine. For this reason, the LTA solution has been designed to cover only the outbound leg, which is flown in roughly one day. This saves on the cost of the pilot (which is hired for one day instead of two), but requires a rental truck to cover the return leg of the mission. The resulting O&M cost per mission, while keeping lower than for the helicopter case, is not so reduced as in other cases. The overall cost per mission is similarly penalized by this result.

Sizing parameter	Value
Volume [m³]	46.98
Length [m]	12.14
Fineness ratio [-]	4.02
Battery mass [kg]	6.07
Battery energy [kWh]	819.45
Total mass [kg]	58.13

Table 5 Design parameters for LTA UAV for pipeline inspection.

Cost component	Acquisition cost [EUR per item]	O&M cost [EUR per mission]	Overall cost [EUR per mission]
Helicopter	3,259,560	3,000	3,000
Airship	72,430	2,318	2,338

Table 6 Cost comparison between as-is and LTA solutions for pipeline inspection.

Conclusions

In this work we provided a first estimation of the acquisition, O&M and overall mission cost for innovative LTA UAVs, to be employed in replacement of existing flying solutions (specifically a multi-copter UAV, a fixed-wing UAV and a manned helicopter) on specific missions. A set of cost estimation relationships was established, based on the specific features of LTAs. The suite Morning Star was employed to preliminarily size a LTA for each specific mission. Interestingly, the comparison of cost showed a general advantage on the overall cost per mission of the LTA on these specific missions (selected on purpose as compatible with a LTA solution). However, procurement and O&M cost vary significantly from one case to another, and when considered separately, acquisition cost can be bigger for the LTA machine than for the existing platforms *[20]*. Future work should try to extend this approach further to include missions potentially flown by high-altitude airships (HAA).

Abstract. In this research, a preliminary identification testing of some modelling parameters pertaining to the aerodynamic model proposed by Munk-Jones-DeLaurier for airships has been carried out. Identification trials have been carried out in virtual environment employing an output-error method, solving a non-linear optimization problem on the norm of the error between the output of an estimated model and that corresponding to a reference model, assumed as ground-truth. The practical results show how some of parameters in the aerodynamic model appear identifiable even employing a rather limited dataset also in presence of noise.

Introduction

The availability of accurate and reliable simulators represents a key-asset in the design, performance assessment and certification of any flying system. Lighter-than-air (LTA) flying vehicles are no exception. However, the substantial absence of well-validated and proven simulators accepted at an industrial level is just a result of complexity of embracing all airships via a simple unified theory (like the lifting line for slender wings, or BEM for rotors). Actually, the practical realization of LTA [1] may range significantly in terms of overall shape (including a larger or smaller fineness ratio, multi-lobed envelopes, multiple and freely positioned fins, etc. [2] [3] [4]) as well as in terms of the values of the Reynolds number, spanned in the typical speed domain of flight operations [5]. The latter, in combination with the relative bluntness of the envelope (which has to be compared in this regard to higher lift-to-drag bodies like a wing), provokes separation phenomena on the tail cone of the airship envelope. These are typically present also in standard forward flight for an airship, and their modelling is generally not trivial. Actually, where potential-flow-based theory, with corrections for cross-flow motion is still the reference for aerodynamic modelling (at least for computationally-fast flight dynamics simulators), the actual assignment of the parameters in that class of models is generally not easy to perform. In a similar fashion, the modelling alternative represented by aerodynamic specifications assigned as lumped coefficients (e.g. stability and control derivatives) is generally coupled for airships with CFD computational models, or data coming from experimental (i.e. wind tunnel) testing, which provide predictions not spared from a strict dependence on the specific geometry and flight regime (i.e. Reynolds number).

These considerations point out the need for model tuning procedures, which are especially required in the fine tuning phase of the setup of a virtual model for airship dynamics. For LTA flying vehicles, the employment of such techniques has been attempted only sporadically and with

Materials Research Proceedings 69 (2026) 839-845 https://doi.org/10.21741/9781644904251-148

mixed results, in association primarily with the identification of lumped parameters in a simplified (linearized) dynamic formulation [6].

In the present work, the focus is moved to the tuning of a model based on the Munk-Jones-DeLaurier theory [7] [8], which basically mixes potential-flow aerodynamics with cross flow effects from cylinders and fins. The literature indicates that some coefficients in this formulation can be only guessed in a preliminary phase (for instance, when the airship is under design and no practical data is available), yet they need to be corrected when possible, by mixing experimental data and what is more accurately known of the model.

After shortly reviewing the features of the aerodynamic model of interest, the present paper shows a proposed application of a parameter estimation method which might be employed for the task. Finally, some preliminary results showing the potential of the proposed technique will be presented.

Methodology

A model capable of capturing the driving aerodynamic phenomena intervening on an airship in flight, with sufficient accuracy for flight dynamic computations, has been elaborated from the original theory of Munk [7] by Jones and DeLaurier [8]. Munk's theory has been developed from Lamb's solution of the potential flow around a generic ellipsoid [9], where the axis of the ellipsoid is misaligned with the prevalent direction of the flow. The contribution from Jones and DeLaurier has been the inclusion of separation phenomena, to supply the non-viscid (potential) theory with information of the separation effects taking place both on the envelope and on the tails on board an airship. This allows to correctly account for effects typically found at higher angles of attack or sideslip, which are typical to airships especially at low speed and in terminal maneuvers (i.e. close to hovering conditions). Besides the validation of the theory via fluid dynamics testing, including the experimental verification of effects bound to a rotary motion of a scaled test airship specimen (i.e. when the components of the rotational speed are not all zero) [8], the results of this aerodynamic modelling approach have been applied to the Lotte airship in the early 2000s [10]. In the latter case, experimental results in the wind tunnel have proven the generally very good likelihood obtained through this modelling approach, in that case in static flight conditions, yet considering the complete setup of the airship (i.e. including the tails) and flight at very high angle of attack, where separation phenomena are clearly intense [5].

An implementation of this aerodynamic model has been included in the Airship class of SILCROAD (SImulation Library for CRaft–Object Advanced Dynamics) [11] [12] [13] [14], an object-oriented flight simulation library working in Matlab®/Simulink, conceived for the computationally fast simulation of interacting flying objects.

Among the parameters that define the aerodynamic characteristics of the airship, according to this model, are the following related to the airship hull (including interference effects from the tail) [8]:

- $C_{D_0}^{hull}$, $C_{D_{cf}}^{hull}$. These represent the components of the hull drag coefficient accounting for viscosity in attached flow, typically modelled from a thin plate analogy, and cross-flow, obtained from the estimation of cylinder cross-flow.
- η_k^{hor}, η_k^{ver}. These represent an interference effect between the tail and the hull. In particular, in the original theory [8] only a single parameter was included for the entire fin, whereas in the SILCROAD implementation a slightly more refined model was introduced, allowing to split the two contributions, thus potentially allowing for a more elaborated and generic arrangement of the empennages in a specific design.
- k_1, k_2, k_3, k_3'. These represent the apparent inertia coefficients, and for the specific case of a slender body obtained as a solid of revolution have been tabulated by Munk starting from Lamb's solution of potential flow [7] [9].

Materials Research Proceedings 69 (2026) 839-845 https://doi.org/10.21741/9781644904251-148

Due to the uncertainties typically associated to the these quantities, they have been shortlisted as interesting candidates within a parameter estimation effort.

This work has been carried out in virtual environment (future developments will make use of data made available through the first flying demonstrator now available at Politecnico di Milano within project IPROP [15]). In this context, the virtual model of an airship test-bed has been assembled, and a preliminary estimation of the identifiability of these parameters has been carried out, perturbing one by one the candidate parameters for estimation, and employing a doublet on elevator and rudder controls. The results of this preliminary analysis have allowed assembling Fisher's information matrix. The latter confirmed the likely good identifiability of the parameters k_2, k_3, k_3' (notably, $k_2 = k_3$ for an axial-symmetric body), as well as η_k^{hor}, η_k^{ver}. Conversely, parameters $C_{D_0}^{hull}$, $C_{D_{cf}}^{hull}$ have tested harder to identify according to this analysis, possibly indicating that the proposed doublet on aerodynamic controls of the tail empennages (i.e., elevator and rudder controls) is not effective in stimulating the effect on dynamics of these two parameters.

In this work, after evaluating possible ways of carrying out parameter identification [16] [17] [18], an output-error approach was selected [19]. The parameters selected for identification have been collected in an array $\boldsymbol{p} = \{\eta_k^{hor}, \eta_k^{ver}, k_3, k_3'\}$. The output-error approach calls for the definition of an optimal problem, where parameters $\boldsymbol{p}$ are iteratively corrected by an optimal solver so as to obtain the best matching of the simulated system output and field data, when both the real machine and the simulated model are subject to the same input. In this case, the input was the same for which the analysis of Fisher's matrix had been carried out, i.e. a doublet of elevator and rudder.

In analytical terms, the response of the system $\boldsymbol{y} = g(\boldsymbol{p}, \boldsymbol{x}, \boldsymbol{u})$ is a function of the parameters, as well as of the system state $\boldsymbol{x} = \boldsymbol{x}(t)$ and controls $\boldsymbol{u} = \boldsymbol{u}(t)$. The time history of controls is assigned (i.e., the doublet on elevator and rudder, other controls are not stimulated), whereas the state solves the dynamic equilibrium equation $\dot{\boldsymbol{x}} = f(\boldsymbol{p}, \boldsymbol{x}, \boldsymbol{u})$. Assuming to know the output $\boldsymbol{z} = \boldsymbol{z}(t)$ from a test in the field, carried out subjecting the real machine to the same input as the value as the simulated system, it is possible to compute a quadratic norm of the error $\boldsymbol{e}(t) = \boldsymbol{z}(t) - \boldsymbol{y}(t)$, as

$$J = \frac{1}{t_f - t_0} \int_{t_0}^{t_f} \boldsymbol{e}(t)^T \boldsymbol{Q} \boldsymbol{e}(t) dt, \tag{1}$$

where the diagonal matrix $\boldsymbol{Q}$ is employed as a weight matrix, which might be set as the inverse of the squared covariance of the noise of each channel in array $\boldsymbol{e}(t)$. The identification of the parameters is then configured as the optimal problem

$$\min_{\boldsymbol{p}} J. \tag{2}$$

Working in virtual environment, the actual value of the coefficients, named $\boldsymbol{p}^*$, is known. Therefore, instead of employing data from the field, a simulation where $\boldsymbol{z} = g(\boldsymbol{p}^*, \boldsymbol{x}, \boldsymbol{u})$ is employed as a ground-truth dataset. For added realism, the channels in the so-obtained $\boldsymbol{z}(t)$ have been artificially polluted with random noise.

Results

In this work, a virtual model of the Lotte airship [5] has been employed as a test-bed. Reference values of the measures $\boldsymbol{z}(t)$ have been produced by running the simulation model in SILCROAD in forward, horizontal, steady and symmetric flight, at a reference horizontal speed of 8 m/s. A corresponding trimmed solution has been computed automatically. A time history $\boldsymbol{z}(t)$ extending from $t_0 = 0$ s to $t_f = 20$ s has been obtained running an integration over time on a model of the airship, with assigned values of the parameters $\boldsymbol{p}^* = \{1.0, 1.0, 0.86, 0.69\}$, corresponding to the Lotte airship.

The measures considered in the identification process are the three body velocities, the three body rotational rates, the attitude angles and the position of a point (center of buoyancy) with

respect to a ground observer (12 channels in total). All these quantities are realistically obtainable even from a relatively cheap, small-scale airship test-bed, like the one currently available within project IPROP [15].

The optimal problem in Eq. (2), based on the norm in Eq. (1), has been solved numerically, based on a gradient algorithm, starting from an initial guess artificially polluted so as to simulate an uncertainty in the values of the parameters. In particular, the initial guess $\boldsymbol{p_0} = \{1.05, 1.05, 0.93, 0.77\}$, where the latter two values, referring to k_3 and k_3' respectively, have been chosen from Munk's tabulated functions [7] so that they correspond to a higher fineness ratio of the hull than the actual one.

The period of the doublet on elevator and rudder controls have been selected so as to excite respectively the two oscillatory modes of the airship, namely the pendulum in the longitudinal domain (via the elevator control), and the roll mode in the lateral-directional domain (via the rudder control) [6]. For the test-bed at hand, the corresponding (positive) intervals of the doublet is 6.92 s for the elevator and 0.85 s for the rudder. A deflection amplitude (positive) of 1.0 deg has been employed for both controls, and the behaviour of the airship in flight was visually checked not to diverge towards unrealistic flight conditions over the duration of the simulations. In this regards, however, it should be remarked that, thanks to employing buoyancy as a lifting force, the range of flight dynamics states for an airship is generally much broader than for winged aircraft.

Several cases corresponding to different levels of artificial noise in the measures have been considered. Considering the different nature of the sensors providing the measures, the following reference noise levels have been considered:

- for velocity components (GPS differentiation), a $\sigma_V = 0.01$ m/s
- for rotational rate components (IMU), a $\sigma_\omega = 0.002$ rad/s
- for attitude angles (IMU), $\sigma_a = 0.001$ rad
- for position (GPS), $\sigma_P = 0.05$ m

The value of σ_P is comparatively higher on account of the low-value/low-accuracy of GPS sensors commonly employed on low-budget measurement units, like for scaled flying models [15].

Table 1 summarizes the results of the identification analysis, for changing values of the actual noise levels, artificially added to the measure channels in the reference simulation, and scaled by a same multiplier to simulate a generally higher or lower noise level in the measures. As it can be argued from Table 1, an identification of the selected parameters is indeed possible, and remarkably so even when employing (as done here) a very reduced dataset, corresponding to a single run on the reference test-bed. The most reduced error can be obtained in identifying Munk's parameters k_3 and k_3', even starting from a rather offset initial condition. A comparatively lower accuracy can be observed in the identification of the tail-to-hull interference parameters η_k^{hor}, η_k^{ver}, even though the change on the initial values computed by the solver is acting in most cases in the correct direction (i.e., the artificially-boosted initial values are changed by the algorithm towards the correct value).

Table 1 Results of identification runs, for changing values of the overall noise level multiplier.

Parameter ($\boldsymbol{p}$)	Real value ($\boldsymbol{p}^*$)	Init. Value ($\boldsymbol{p}^0$)	Estimated value ($\overline{\boldsymbol{p}}$) – No noise (0% of reference)		Estimated value ($\overline{\boldsymbol{p}}$) – Noise 1% of reference		Estimated value ($\overline{\boldsymbol{p}}$) – Noise 10% of reference		Estimated value ($\overline{\boldsymbol{p}}$) – Noise 100% of reference	
	Value		Value	Error [%]	Value	Error [%]	Value	Error [%]	Value	Error [%]
η_k^{hor}	1.0	1.05	0.9847	-1.5300	1.0022	0.2200	1.1082	10.8200	1.0571	5.7100
η_k^{ver}	1.0	1.05	0.9022	-9.7800	0.9694	-3.0600	1.0282	2.8200	1.0489	4.8900
k_3	0.86	0.93	0.8694	1.0930	0.8741	1.6395	0.7689	-10.5930	0.7999	-6.9884
k_3'	0.69	0.77	0.6808	-1.3333	0.7854	13.8261	0.7039	2.0145	0.7367	6.7681

Materials Research Proceedings 69 (2026) 839-845 https://doi.org/10.21741/9781644904251-148

To better interpret the results, it should be noted that the dataset (i.e., the simulations) with noise is only one for each overall noise scaling factor, hence the results just presented are not enough for a statistical analysis of correlation between the error on identification and the level of noise. They just serve to preliminary assess the general identifiability of the parameters in the problem at hand, and in this sense they look extremely promising.

As an example, the plot in Figure 1 show the time histories of longitudinal and lateral-directional states, and of controls, corresponding to the reference test-bed ($\boldsymbol{p} = \boldsymbol{p}^*$, in blue, barely visible under the green curves corresponding to estimations), the polluted initial condition ($\boldsymbol{p} = \boldsymbol{p_0}$, in amber), and the set of estimated parameters $\boldsymbol{p} = \bar{\boldsymbol{p}}$ (in green), corresponding to the result of the identification procedure. The figure is referring to a 1% of-reference-noise condition.

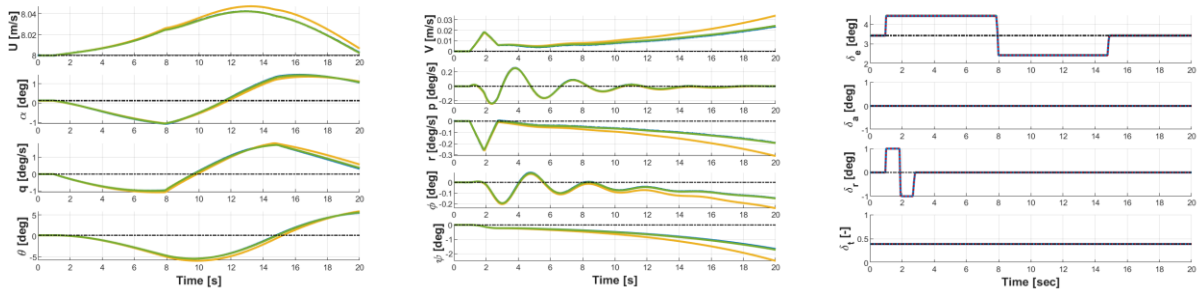

Figure 1 Time histories of longitudinal states (left), lateral-directional states (centre) and controls (right) for a simulation with a noise scaling factor of 1% in the reference test-bed. Blue: test-bed (barely visible under the green line). Yellow: starting point of identification. Green: result of identification.

As noted from Table 1, the result in the figure shows an a clear amelioration of the estimated parameters over the initial condition, with a very good likelihood of the output of the reference model corresponding to $\boldsymbol{p} = \boldsymbol{p}^*$ and the estimated one corresponding to $\boldsymbol{p} = \bar{\boldsymbol{p}}$.

Conclusions

A parameter identification method based on the output-error approach has been employed for the estimation of some parameters appearing in a mid-fidelity aerodynamic model of an airship. Following a shortlisting of the candidate identifiable parameters, and a preliminary synthesis of a time history of controls suitable for stimulating their expression in the dynamic response of the airship, the identification has been carried out employing as a test-bed the virtual model of the Lotte airship. Results obtained up to the present state of the research support the suitability of the technique selected for identification, which can easily work on the free response of the airship, taking advantage of the reduced tendency of barely stable or unstable airships to diverge fast from a trimmed condition even when non artificial stabilization is employed. The excitation input, based on doublets, appears to provide a dataset sufficiently rich for identification purposes, as far as the shortlisted parameters $\eta_k^{hor}, \eta_k^{ver}, k_3, k_3'$ are considered. The effect of noise has been preliminarily evaluated in view of an application of the proposed technique to the identification of parameters pertaining to an existing airship prototype, designed and built in Spring 2025 at DAER-Politecnico di Milano within project IPROP.

Future short-term developments will involve the investigation of additional maneuvers, such to allow the identification of the relevant drag-related coefficients $C_{D_0}^{hull}$, $C_{D_{cf}}^{hull}$, and possibly involving the use of thrusters instead of aerodynamic surfaces.

Keywords: Airship Design, Bezier Curves, Reinforcement Learning, DDPG, Lift-to-Drag Ratio Optimization, Robust Design, Aerodynamic Efficiency, Data-Driven Optimization

Abstract. This paper proposes a data-driven reinforcement learning framework for aerodynamic optimization of airship hulls. It combines Deep Deterministic Policy Gradient (DDPG) with Bezier curve parameterization to adjust the shape of the classic airship ”Lotte” [1,2,3]. A volume-preserving constraint ensures buoyancy consistency. Different from previous studies focused solely on drag minimization, we target lift-to-drag ratio (L/D) and robustness [4,5]. Simulations in SILCROAD [6,7,8,9] demonstrate significant improvement in L/D while preserving volume and smoothness. The approach offers a modular, scalable framework for future multi-objective extensions..

Introduction

Airships are regaining attention for applications like surveillance, communication relay, and environmental monitoring [12]. A key design challenge is aerodynamic shape optimization of the hull, which affects drag, L/D, energy use, and mission range.

Traditional airship shapes often rely on empirical formulas or fixed parametric models, limiting flexibility for mission-specific designs. Prior aerodynamic optimization focused primarily on drag at constant angles, overlooking L/D, a critical factor for propulsion and endurance [11].

Reinforcement learning (RL) offers a flexible alternative for high-dimensional, constraint driven problems. Unlike gradient-based methods, RL learns from interaction and handles noisy evaluations.

This work introduces an RL framework integrating DDPG and Bezier parameterization for airship optimization [10]. The agent modifies control points to maximize L/D while preserving volume. Evaluation is performed using SILCROAD [6,7,8,9].

Main contributions include: (1) reinforcement learning with embedded physical constraints, (2) continuous shape control via Bezier parameters, and (3) performance improvements in L/D and robustness.

Methodology

The upper hull is modeled with a Bezier curve using $n + 1$ control points $\{P_0, \ldots, P_n\}$. The curve is:

$$R(x) = \sum_{i=0}^{n} B_{i,n}(x) P_i, \qquad B_{i,n}(x) = \binom{n}{i} (1-x)^{n-i} x^i \tag{1}$$

where x ∈ [0, 1] is the normalized axial coordinate. Endpoints P_0, P_n are fixed at zero and the agent adjusts the $n - 1$ interior points.

Materials Research Proceedings 69 (2026) 846-849 https://doi.org/10.21741/9781644904251-149

Volume is maintained via scaling factor λ:

$$\lambda = \sqrt{\frac{V_0}{V'}}, \qquad P_i^{\text{scaled}} = \lambda P_i, \tag{2}$$

where V_0 is the volume of the original hull and V' is the volume of the perturbed shape, both computed via

$$V = \pi \int_0^L R(x)^2 dx \tag{3}$$

Here, L denotes the length of the hull.

RL formulation. The state is the set of current radii; the action is a perturbation vector on the interior control points. The reward is:

$$r = \omega_1 \left(\frac{L}{D}\right)_{avg} - \omega_2 \sigma_{\frac{L}{D}} - \omega_3 \|\Delta P\|_1 \tag{4}$$

The weights in (4) trade off performance and regularity. ω_1 scales the primary objective $(L/D)_{avg}$ (suggested range 0.5–1; we use $\omega_1 = 1$ to keep the natural scale and emphasize aerodynamic merit). ω_2 would penalize the variability $\sigma_{L/D}$ across α to promote robustness (typical 0–0.5), but is set to ω_2=0 here because our solver interface returns only the mean L/D. ω_3 regularizes shape smoothness via $\|\Delta P\|_1$ (implemented as the mean absolute first difference of control-point radii), for which 0.05–0.2 keeps the penalty one order below $(L/D)_{avg}$; we choose ω_3=0.1 as it curbs oscillatory updates without suppressing beneficial adjustments. Hence, (ω_1, ω_2, ω_3) = (1, 0, 0.1), matching the implementation $reward = AvgLD - 0.1 * smoothPenalty$.

Learning algorithm. Training uses MATLAB Reinforcement Learning Toolbox's rlDDPGAgent, the built-in implementation of the Deep Deterministic Policy Gradient (DDPG) algorithm—an off-policy, model-free actor–critic method for continuous-action control with a deterministic policy, experience replay, and target networks. Actor and critic networks are two-layer multilayer perceptrons. At each episode, the agent queries SILCROAD to compute the L/D curve over an angle-of-attack grid spanning 0°–30°; the resulting mean (and, when used, dispersion) of L/D across this range feeds the reward in (4).

Result and Discussion

Trained over 10,000 episodes, the agent consistently outperforms the baseline.

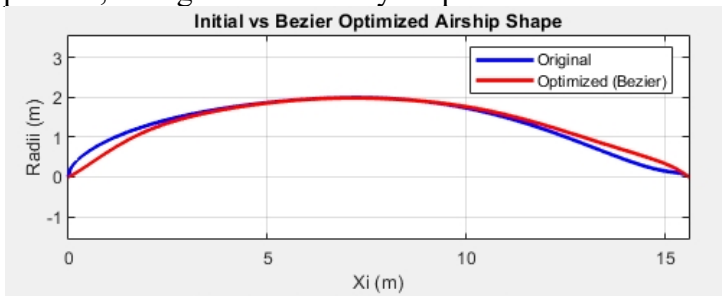

Figure 1: Original and optimized Bezier-based hull shapes.

Figure 1 shows original vs optimized shapes. The optimized hull has a smoother profile with gradual
tapering.

The shape preserves volume:

$$V_0 = V_{final} = 107.5273\ m^3, \quad \lambda = 1.16$$

Figure 2 shows the L/D improvement. Average values:

$$\left(\frac{L}{D}\right)_{\text{initial}} = 4.7766, \quad \left(\frac{L}{D}\right)_{\text{optimized}} = 5.3044, \qquad \text{Gain} = +11.05\%$$

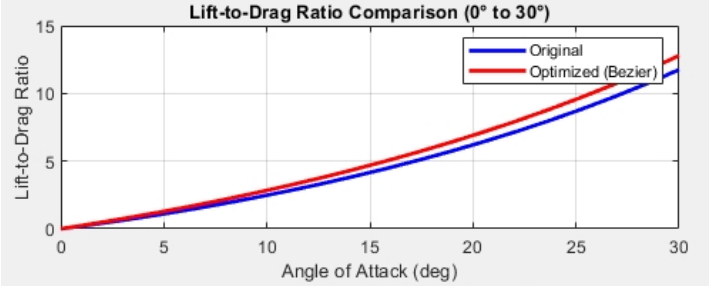

Figure 2: Lift-to-drag ratio comparison (0°–30° angle of Attack).

Perturbation tests showed reduced standard deviation in L/D. Shape smoothness was retained via $\|\Delta P\|_1$.

Conclusion

This study presented a reinforcement-learning-based framework for airship shape optimization. The DDPG agent adjusted Bezier control points while preserving volume. Evaluation in SILCROAD confirmed an 11.05% L/D improvement with retained robustness and smoothness [13]. The framework is modular, supporting future extensions such as tail design and stability control.

Keywords: Hybrid HAPS, Added Mass, Dynamic Derivatives

Abstract. A CFD-based approach is proposed to estimate aerodynamic stability derivatives and added-mass coefficients of a hybrid High-Altitude Pseudo-Satellite (HAPS) with a closed-wing configuration. The combination of buoyant and aerodynamic lift makes the evaluation of added-mass effects crucial for accurate dynamic modelling. Unsteady Reynolds-Averaged Navier–Stokes (RANS) simulations in OpenFoam coupled with Fourier analysis were performed under prescribed harmonic oscillations; this paper focuses on the heave motion, showing the coupling between vertical acceleration and unsteady lift. The results confirm that the aerodynamic response is harmonic, matching the frequency of the imposed excitation, and highlight significant added-mass effects under stratospheric conditions, providing useful input for high-fidelity flight dynamics and control design of future hybrid HAPS platforms.

Introduction

HAPS and hybrid Heavier-Than-Air (HTA) platforms combine buoyant and aerodynamic lift to achieve long endurance, low fuel consumption, and operational flexibility for applications such as surveillance, environmental monitoring, and communications [1-4].

Their hybrid nature introduces specific challenges in flight dynamics due to the influence of added-mass effects, which occur when a moving body accelerates the surrounding fluid, effectively increasing its apparent inertia. These effects are particularly relevant for low-density vehicles such as airships and hybrid HAPS, and their accurate modelling is essential for reliable stability and control predictions [5].

Previous studies addressed this issue using high-fidelity numerical methods: unsteady RANS with Fourier analysis for airships [6], parametric sensitivity studies on geometry [7], and panel methods for full added-mass matrices [8].

Building upon these approaches, the present work applies an unsteady CFD method coupled with Fourier analysis to estimate aerodynamic stability derivatives and added-mass coefficients for a novel closed-wing hybrid HAPS configuration [4], shown in Fig. 1

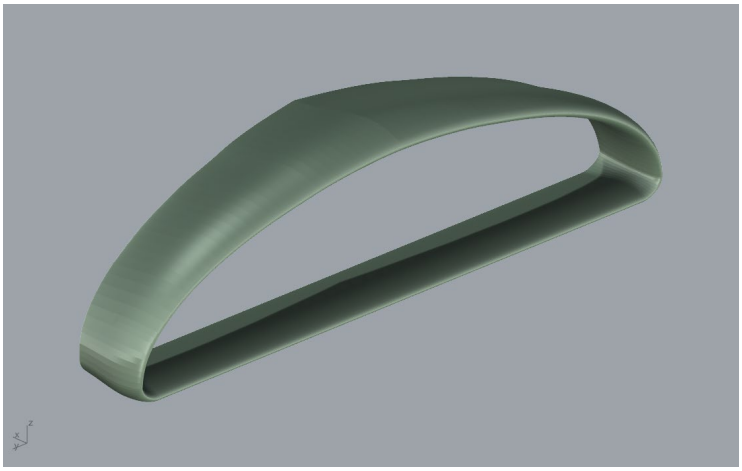

Fig. 1 Three-dimensional CAD model of the closed-wing HAPS configuration [4]

Methodology

Numerical simulations were carried out using the open-source CFD solver *OpenFoam*, solving the unsteady incompressible RANS equations with the $k-\omega$ SST turbulence model.

The computational setup, boundary conditions, and mesh parameters adopted in this study are consistent with those described in [4], to which the reader is referred for additional numerical details and grid-sensitivity assessment.

The computational domain was divided into three regions: an inner zone moving rigidly with the vehicle, an intermediate deforming zone managed through a spring-analogy mesh motion technique, and an outer fixed region extending far from the body and adjacent to the domain boundaries. This multi-zone strategy ensured grid quality and numerical stability during the imposed harmonic oscillations.

The configuration was subjected to prescribed sinusoidal motions representative of the relevant dynamic flight conditions. These motions are defined with respect to the stability-axis reference frame centered at the centre of gravity (CoG).

At the representative altitude of 20 km (air density ρ = 0.0889 kg/m³), these unsteady effects become more significant as aerodynamic damping decreases.

The main geometric and flight parameters of the hybrid platform are summarized in Table 1.

Table 1 Geometric and Flight Parameters of the Hybrid HAPS Platform

Parameter	Value
Wingspan	36 [m]
Maximum chord	7.8 [m]
Wing area	435 [m²]
Internal volume	288 [m³]
Cruise altitude	18–20 [km]
Cruise speed	16 [m/s]
Vehicle mass	127 [kg]

Longitudinal Dynamic Stability Derivatives

For the hybrid stratospheric platform featuring a closed-wing configuration, the longitudinal dynamic behaviour can be described by a reduced set of translational and rotational variables: the forward velocity u, the vertical velocity w, and the pitch rate q. The governing equations are derived under the assumptions of small perturbations and quasi-steady flow conditions.

The longitudinal dynamics of a hybrid vehicle, combining lighter-than-air (LTA) and heavier-than-air (HTA) characteristics, can be expressed as reported in Eqs. (1-3) [7,8], where D_a, L_a, and

Materials Research Proceedings 69 (2026) 850-855 https://doi.org/10.21741/9781644904251-150

M_a denote the aerodynamic drag, lift, and pitching moment, respectively. The terms D_{ext}, L_{ext}, and M_{ext} represent the external contributions due to buoyancy, gravity, or tether forces.

The parameters d_x and d_z represent the longitudinal and vertical distances between the vehicle's center of gravity (CG) and center of buoyancy (CB). These offsets introduce inertial coupling between translational and rotational accelerations, producing the additional moment terms md_x and md_z in the equations of motion.

$$(m - D_{\dot{u}})\,\dot{u} + (m\,dz - D_{\dot{q}})\,\dot{q} = D_a + D_{ext} \tag{1}$$

$$(m - L_{\dot{w}})\,\dot{w} - (m\,dx + L_{\dot{q}})\,\dot{q} = L_a + L_{ext} \tag{2}$$

$$(Iy - M_{\dot{q}})\,\dot{q} + (m\,dz - M_{\dot{u}})\,\dot{u} - (m\,dx + M_{\dot{w}})\,\dot{w} = M_a + M_{ext} \tag{3}$$

In these expressions, the subscripts u, w, and $q$refer to stability derivatives with respect to velocity perturbations, whereas the subscripts $\dot{u}$, $\dot{w}$, and $\dot{q}$ denote the corresponding acceleration-dependent terms, commonly referred to as added-mass derivatives.

The aerodynamic contribution to the longitudinal dynamics, for example the lift component L_a, can therefore be expressed as a combination of steady, velocity-dependent, and acceleration-dependent terms, as shown in Eq. (4).

$$L_a = L_e + L_u\,u + L_w\,w + (L_q - m_x\,U_e)\,q \tag{4}$$

Here, U_e is the steady axial velocity, L_e represents the equilibrium lift, L_u and L_w are the lift derivatives with respect to surge and heave velocities, respectively, and L_q is the lift derivative associated with the pitch rate. The acceleration-dependent (added-mass) derivatives $L_{\dot{u}}$, $L_{\dot{w}}$, and $L_{\dot{q}}$ appear in Eqs. (1-3) and are identified from the unsteady CFD simulations through Fourier analysis.

Pure Heave Motion

The heave motion corresponds to a vertical oscillation along the Z-axis, orthogonal to the freestream velocity vector (Fig. 2). This harmonic displacement induces variations in the effective angle of attack, generating unsteady aerodynamic forces and moments. Fig. 2 illustrates the configuration at the maximum upward ($z = +z_0$), equilibrium ($z = 0$), and maximum downward ($z = -z_0$) positions.

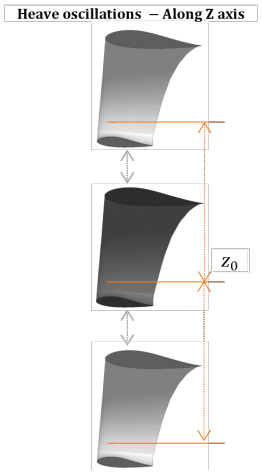

Fig 2 Schematic representation of the heave oscillation along the $\mathbf{Z}$*-axis. The amplitude* $\mathbf{z_0}$ *denotes the maximum vertical displacement from the equilibrium position.*

Materials Research Proceedings 69 (2026) 850-855 https://doi.org/10.21741/9781644904251-150

Assuming linear behaviour near the trimmed flight condition, the unsteady aerodynamic response to the imposed heave motion can be expressed as reported in Eq (5).

$$G(t) = G0 + G_w w + G_{\dot{w}} \dot{w} \tag{5}$$

where G_w and $G_{\dot{w}}$ are the aerodynamic stability and added-mass derivatives, respectively. Here, G denotes a generic aerodynamic quantity, which can refer either to a force (e.g., lift) or to a moment (e.g., pitching moment), evaluated separately.

A prescribed sinusoidal displacement is imposed in the CFD simulations, leading to the following kinematic relations: $z(t) = z_0 \sin(\omega t)$; $w(t) = \omega z_0 \cos(\omega t)$; $\dot{w}(t) = -\omega^2 z_0 \sin(\omega t)$.

The unsteady load history is approximated by a first-harmonic Fourier series, expressed in Eq. (6).

$$G(t) = \frac{1}{2} a_0 + a_c cos(\omega t) + a_s sin(\omega t) \tag{6}$$

By combining Eqs. (5) and (6), the aerodynamic derivatives can be obtained as: $G_w = \frac{a_c}{w_0}$; $G_{\dot{w}} = -\frac{a_s}{w_0 \omega}$. where $w_0 = \omega z_0$ is the velocity amplitude. These coefficients quantify the in-phase (velocity-dependent) and out-of-phase (acceleration-dependent) components of the unsteady aerodynamic response described by Eq. (5). The coefficients were obtained by performing a Fourier analysis of the time history of the aerodynamic force, retaining only the first harmonic of the force signal.

Results and Discussion

The unsteady aerodynamic response in heave was evaluated by prescribing a sinusoidal vertical displacement, producing a periodic variation of the angle of attack expressed as: $\alpha(t) = \alpha_m + \alpha_0 cos(\omega t)$; $\dot{\alpha}(t) = -\alpha_0 \omega sin(\omega t)$. In these equations, $\alpha_m = 4.5°$ and $\alpha_0 = 2.5°$ are the mean and oscillation amplitudes, respectively, and $\dot{\alpha}_0 = \alpha_0\, \omega$ is the peak angular velocity. A reference case was defined for $V = 16 \frac{m}{s}$ and $c = 7.8\ m$. The excitation frequency ω was chosen to keep the non-dimensional angular velocity close to 0.12. This quantity is defined in Eq. (7).

$$\widehat{\dot{\alpha}_0} = \frac{\dot{\alpha}_0}{\frac{2V}{c}} = \frac{(a_0\, \omega\, c)}{2V} \tag{7}$$

where $k = \frac{\omega c}{2V}$ is the reduced frequency ($k = \pi St$). With $a_0 = 2.5° = 0.0436\ rad$, this corresponds to $\omega = 11.40\ \frac{rad}{s}$ ($T = 0.551\ s$).

Fig. 3a shows that the unsteady CFD lift closely matches the first-harmonic Fourier reconstruction, confirming that the aerodynamic response remains linear within the investigated range. In Fig. 3b, the unsteady results describe an elliptical loop in the F_z–α plane, revealing a phase lag between lift and angle of attack that characterizes the non-stationary aerodynamic behavior. The loop remains narrow and nearly symmetric about the steady curve, indicating that the mean lift follows the steady trend and that the oscillation amplitude is small enough for the flow to remain within the linear unsteady regime.

Materials Research Proceedings 69 (2026) 850-855 https://doi.org/10.21741/9781644904251-150

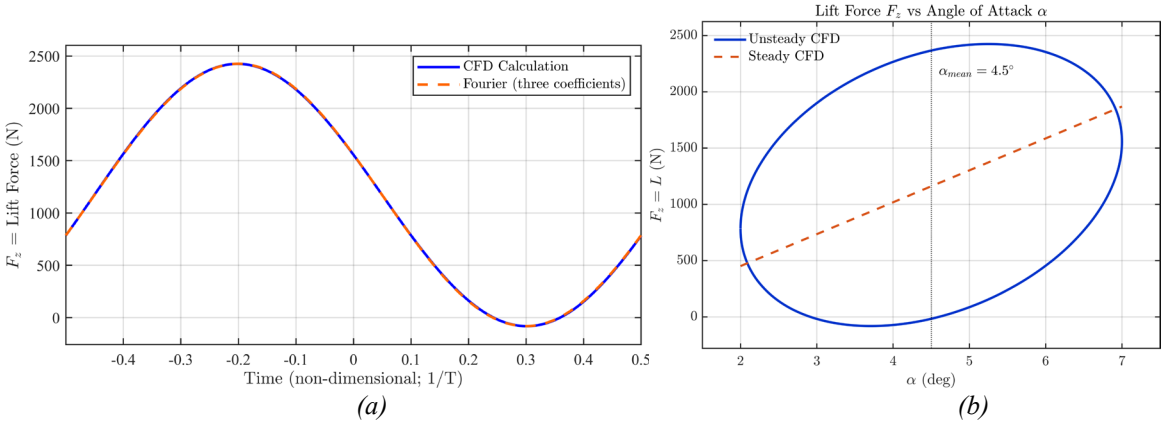

Fig. 3 (a) Time history of lift force $\boldsymbol{F_z(t)}$ and Fourier reconstruction; (b) Steady and unsteady CFD lift as a function of the instantaneous angle of attack $\boldsymbol{\alpha}$.

From the CFD-based heave analysis, the aerodynamic derivatives $L_w = -553.4\ Ns/m$ and $L_{\dot{w}} = -121\ kg$ were obtained, the latter arising from the fluid-inertial contribution. These coefficients were extracted from heave-type excitations, but they do not correspond to a pure heave condition.

Strictly speaking, the added-mass terms ($L_{\dot{w}}$, $M_{\dot{w}}$) are defined for zero forward velocity and non-lifting bodies, where they represent the inertia of the surrounding fluid at rest. For lifting configurations and finite forward velocity, the same physical mechanism gives rise to unsteady aerodynamic derivatives associated with $\dot{\alpha}$, which contribute to lift and pitch damping.

Accordingly, L_w and M_w correspond to the lift- and pitching-moment slopes (L_α, M_α), while $L_{\dot{w}}$ and $M_{\dot{w}}$ represent the unsteady aerodynamic derivatives ($L_{\dot{\alpha}}$, $M_{\dot{\alpha}}$). The resulting aerodynamic and added-mass derivatives obtained from the CFD analysis are summarized in Table 2.

Table 2 Aerodynamic and added-mass derivatives from heave-based CFD analysis.

Derivative	**Effect**	**Value**
L_w	Lift slope (equiv. L_α)	$553.4\ [\frac{Ns}{m}]$
$L_{\dot{w}}$	Unsteady Lift (equiv. $L_{\dot{\alpha}}$)	$121\ [kg]$
M_w	Pitching moment slope (equiv. M_α)	$113.6\ [N\ s]$
$M_{\dot{w}}$	Pitch-rate damping (equiv. $M_{\dot{\alpha}}$)	$-206.7\ [kg\ m]$

The relation $\alpha \approx w/V$ allows converting these quantities into the corresponding angle-of-attack derivatives, leading to the expressions: $L_\alpha = VL_w$; $L_{\dot{\alpha}} = VL_{\dot{w}}$; $M_\alpha = VM_w$; $M_{\dot{\alpha}} = VM_{\dot{w}}$. where V is the flight velocity. In the quasi-steady limit, the added-mass effects vanish, and the coefficients reduce to the static stability and pitch-damping derivatives.

Conclusion

A CFD-based methodology combined with Fourier analysis was applied to estimate aerodynamic stability derivatives and added-mass coefficients for a hybrid closed-wing High-Altitude Pseudo-Satellite (HAPS).

The results obtained from the heave motion analysis confirm that the aerodynamic response remains harmonic and follows the frequency of the imposed excitation. The analysis also highlights the relevance of added-mass effects under stratospheric operating conditions.

The extracted coefficients provide essential input for high-fidelity flight dynamics models and support the development of reliable stability and control strategies for future hybrid high-altitude platforms.

Keywords: Unmanned Aerial Systems, Drone Swarms, Agent-Based Simulation, Multi-Agent Systems, Requirements, System of Systems, Performance Analysis, Counter-UAS Systems, Defense

Abstract. Swarm attacks composed of *Unmanned Aerial System* (UAS) have rapidly evolved into a sophisticated and constantly evolving threat to modern air defense strategies. By exploiting overwhelming numbers, high agility, and a coordinated behavior, drone swarms are able to penetrate and overwhelm traditional, multi-layered, defense architectures. Recent conflicts have highlighted critical vulnerabilities and challenges in maintaining robust defense and deterrence postures against drone swarms. As counter-UAS technologies, systems, and *Concepts of Operations* (CONOPS) continue to evolve, a method to evaluate their effectiveness and to quantify their relative performance becomes crucial. This paper details the adaptation of an agent-based modeling and simulation environment, developed by the German Aerospace Centre (DLR), to assess the operational performance of counter-UAS architectures from a holistic *System of Systems* (SoS) perspective. To address the computational challenges of large-scale swarm engagements, the approach integrates surrogate models informed by *high-fidelity* (hi-fi) simulations, into *low-fidelity* (lo-fi) models to approximate the behavior of counter-UAS systems, thereby enabling scalability and simulation on the theater scale. Combined with well-defined *Measures of Effectiveness* (MoEs), this methodology provides a novel approach for comparing counter-UAS solutions. It provides stakeholders and decision-makers with the information needed to evaluate system performance and make informed decisions in shaping future air defense strategies and architectures.

Introduction

UAS swarms pose a rapidly escalating threat to military forces worldwide, both in increasing technological sophistication and operational scale [1]. For example, in 2019 the Houthi militant group used a swarm of 18 drones and 7 missiles in a coordinated strike on Saudi oil facilities. The incident demonstrated the challenges that traditional air defense systems can face when encountering swarm tactics [2,3]. More recently, during the Russian invasion of Ukraine, Russian forces repeatedly launched attacks involving hundreds of drones interlaced with cruise and ballistic missiles to overwhelm Ukrainian air defenses.

Traditional countermeasures - electronic warfare, *Anti-Aircraft Artillery* (AAA), and missiles - are effective against individual drones but are often costly or logistically unsustainable when facing large swarms [4]. As a result, research and development is increasingly focused on scalable, cost-effective counter-swarm strategies and systems.

To support informed decision-making on fleet composition and system procurement for counter-UAS missions, it is essential to evaluate how different air-defense architectures perform against swarms with varying compositions and tactics. This paper proposes a novel framework that combines hi- and lo-fi simulation models to compare system performance against large-scale UAS swarm threats. The method provides a scalable and quantitative means to assess performance and interactions within the complex drone-warfare SoS.

Methodology

The proposed approach integrates hi- and lo-fi *Agent-Based Modeling and Simulati*on (ABMS) environments into a unified framework to evaluate the effectiveness of counter-UAS architectures. It is designed to balance fidelity and scalability, enabling engagements involving thousands of agents. This framework is demonstrated in Figure 1.

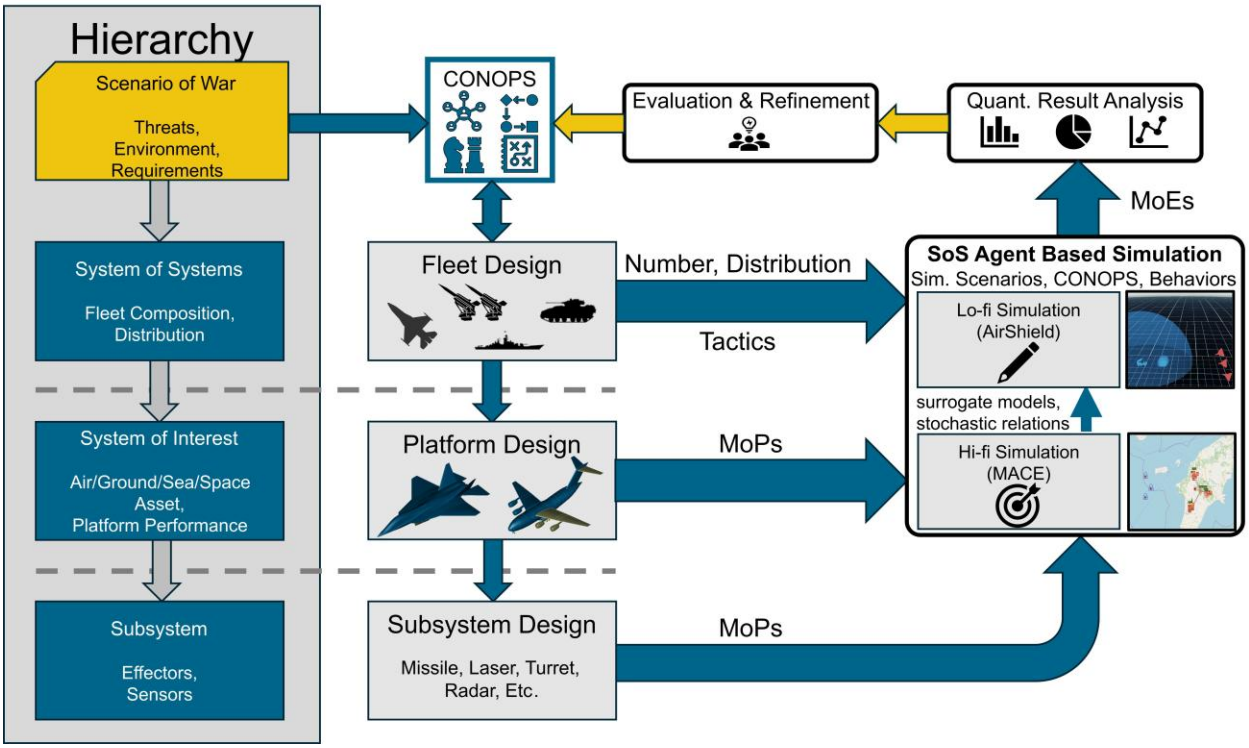

Figure 1: System-of-Systems framework to quantify counter-UAS system effectiveness

The implementation uses the off-the-shelf hi-fi ABMS environment *Modern Air Combat Environment* (MACE), developed by BSI[1], together with the *AirShield Simulation Environment*, as the lo-fi ABMS environment. The latter was developed by DLR to enable the evaluation of counter-UAS systems within a broader SoS context and to translate those evaluations into optimized system requirements and is based on the work shown in [5].

The two complementary simulation layers are:

1. **Hi-fi layer:** Detailed digital models represent threat and defensive systems, including the complex modeling of communication networks, electronic warfare, and C2. Engagement dynamics, sensor performance, and effector lethality are modeled deterministically by simulating the physics that govern them. Thus, these simulations effectively represent the complex interactions between individual drones and

[1] https://www.bssim.com/mace/

Materials Research Proceedings 69 (2026) 856-860 https://doi.org/10.21741/9781644904251-151

countermeasures. Due to the high complexity and computational demand, this layer is limited to engagement-level scenarios.

2. **Lo-fi layer:** This layer scales the analysis from engagement to theater level by using simplified digital surrogate models, allowing thousands of agents to interact. These surrogate models are generated to bridge the fidelity gap between the hi- and lo-fi layers. Engagement dynamics are modeled stochastically, informed by relationships derived from the hi-fi layer (e.g. rounds-to-kill as a function of target altitude, speed, and aspect) through one-on-one engagements.

To demonstrate the framework, a notional baseline scenario is created in the AirShield environment, as illustrated in Figure 2. In this scenario, 200 Shahed-like adversary drones conduct an attack at an altitude of 200 m—a noteworthy detail since both simulation layers operate in three dimensions and therefore account for line-of-sight effects, including Earth's curvature. The attack targets a layered air defense architecture consisting of a long-range air defense element protected by five short-range gun-based AAA units. This study evaluates variations in *Measures of Performance* (MoPs) of the AAA and translates the effects of these MoPs to SoS-wide MoEs. The influence of the altered MoPs on the kill dynamics of the AAA typically are based on running one-on-one engagement studies within the hi-fi environment. In the following analysis, this is not done, and instead the AAA's kill dynamics are modeled as a normal distribution around a mean *rounds-to-kill* (RTK) and its standard deviation. The values for the mean and standard deviation originate from preliminary analyses in the Hi-fi environment. However, they are also evaluated as sensitivities in this paper to illustrate the modularity of the design variables and the underlying models.

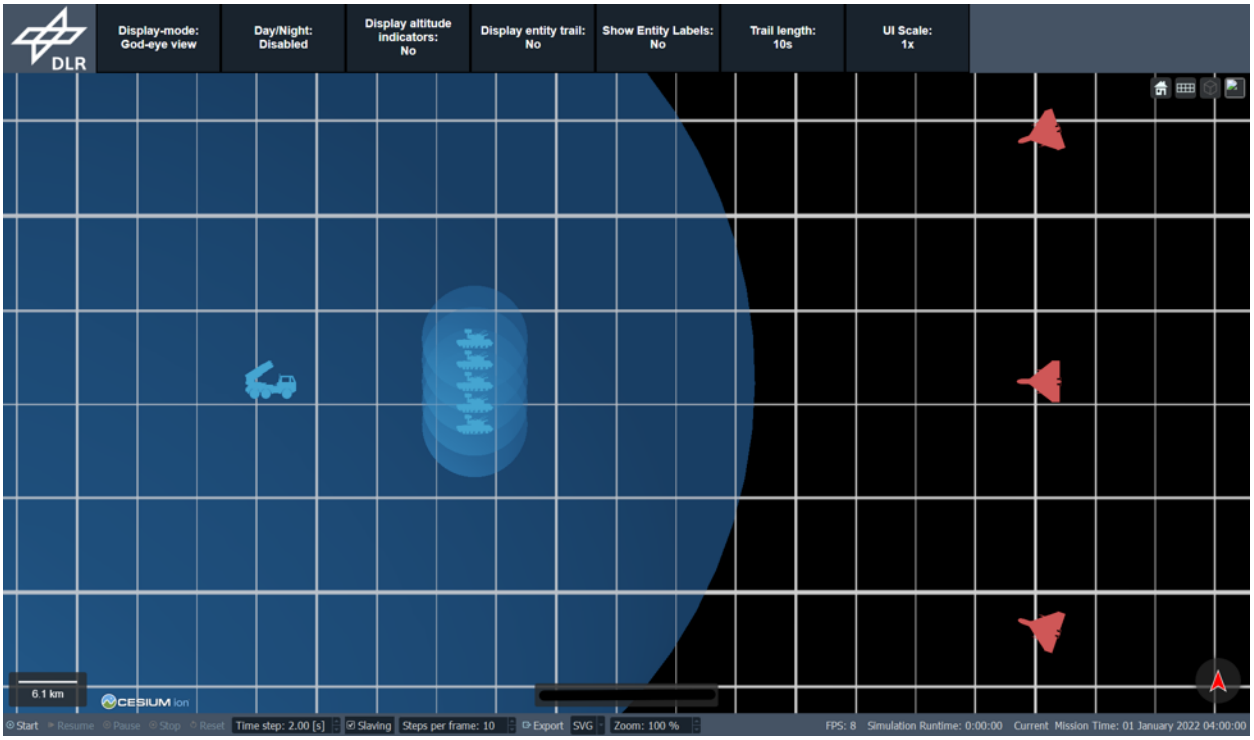

Figure 2: Baseline scenario in the AirShield user interface. Each cell width represents 6.1km. Blue zones show the engagement areas of counter-UAS systems, limited by Earth's curvature (not detection zones).

Materials Research Proceedings 69 (2026) 856-860 https://doi.org/10.21741/9781644904251-151

To evaluate the SoS effectiveness, a set of normalized MoEs is defined. Each MoE component - survivability (number of undamaged systems, $\hat{S}$), lethality (number of killed drones, $\hat{L}$), expended munition cost ($\hat{C}$), and infiltration rate (shortest distance to the drone's target, $\hat{I}$) - is normalized and averaged over multiple simulation runs for each data point. This weighted sum is shown in Eq. 1. The weights of the MoE variables originate from subject matter experts' opinions, a method detailed in [6].

$$MoE = 0.42\hat{S} + 0.36\hat{L} + 0.16\left(1 - \hat{C}\right) + 0.06(1 - \hat{I}) \quad (1)$$

Results

For the demonstration, variations in the AAA's turret slew rate and effective engagement range are investigated to understand their influence on overall SoS effectiveness. As previously noted, the hi-fi study is not conducted for this simplified scenario and therefore these parameters are not linked to the lo-fi kill dynamics. Instead, the mean RTK value and its standard deviation are incorporated into the analysis. Furthermore, to illustrate potential future offensives, the adversary swarm size is also included. The design space shown in Figure 3 is created and represents the MoE values for each data point using a color. The standard deviation of the mean RTK was found to have a negligible impact, likely due to the high number of rounds being fired by the AAA units, and is therefore excluded from this analysis. Instead, the plot shows values for varying the mean RTK at three standard deviations of spread.

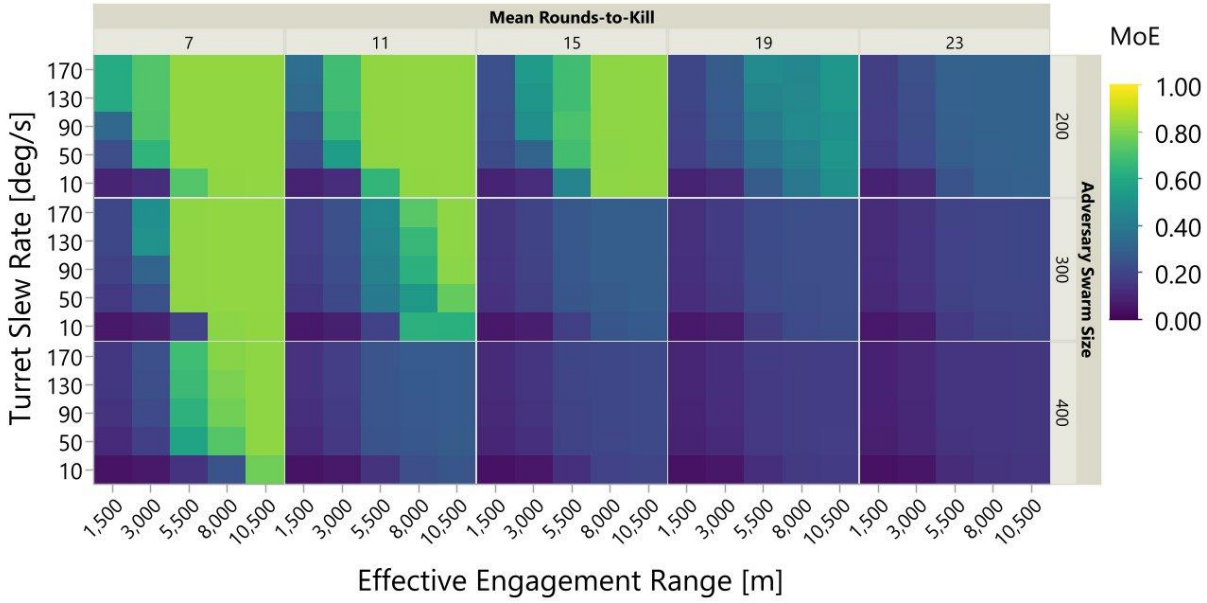

Figure 3: Design space exploration of the AAA system

Upon inspection of the results, three interesting patterns emerge:

Firstly, MoEs are highest when the AAA operates with large effective engagement ranges. This becomes apparent when the engagement range is increased beyond 5.5 km. However, it still requires that the mean RTK is low for the SoS to become effective. Thus, a combination of long engagement ranges with sufficient lethality (through low RTK) produces more desirable outcomes.

Secondly, for larger swarms, the system must possess a lower mean RTK for the SoS to remain effective. This dependency arises from a greater lethality, which logically increases the SoS effectiveness. Alongside this, reducing the mean RTK shortens required engagement lengths per

target, and thereby reduces ammunition expenditure. This enables longer sustainment and lethality, which is particularly interesting considering that one AAA caries only 640 rounds.

Lastly, the increase of turret slew rate has a positive but small influence. Increasing the slew rate increases the MoE, especially at the extreme low end (10 deg/s). With reduced slew rates, the system can only maintain effectiveness if the effective engagement range is large enough to compensate. This seems logical, as an increased mean RTK increases the *engagement time per UAS*, which reduces the distance between the UAS and the AAA, increasing relative angular velocities of the UAS. However, this secondary effect of the slew rate should be investigated further as in the baseline scenario the swarm spread is relatively limited.

Conclusion

This paper presented a scalable agent-based simulation framework for assessing counter-UAS architectures within a system-of-systems context. By coupling high- and low-fidelity simulation environments, the framework enables quantitative evaluation of counter-swarm performance while maintaining computational feasibility for large-scale scenarios. The demonstrated case study of a layered air defense architecture illustrated how variations in subsystem Measures of Performance propagate to system-wide Measures of Effectiveness.

The results of the simplified demonstration indicate that effective engagement range and lethality, expressed as mean rounds-to-kill, are the primary drivers of the system-of-systems effectiveness, while the turret slew rate plays a secondary role. The influence of mean rounds-to-kill becomes particularly dominant as the adversary swarm size grows, increasing combat sustainment and lethality. Based on the mock scenario, the framework was able to identify the system's most influential design traits that provided the most favorable operational effectiveness within the system-of-systems. Importantly, the model demonstrates that assessing different configurations of the same resource can reveal solutions that are more scalable than focusing solely on technological enhancements.

Although not explored in this study, operational strategy, such as defense system positioning/ placement and fleet combinations could be evaluated, garnering further insights to the system-of-systems, exemplifying the framework's capabilities in supporting informed decision making for system designers. Lastly, AI methods, drone design, and their dynamics could be applied to the framework to expand its application potential and utility.

Keywords: Close-Proximity Operations, Tumbling Target, Semi-Analytical Guidance, H-Infinity Control, Performance Assessment

Abstract. This paper assesses the performance of a Guidance and Control architecture designed to rendezvous with a tumbling space target. Specifically, it demonstrates its robustness against the uncertainties in the knowledge of the chaser parameters (including the actuators' mounting configuration), and the variability in the target initial conditions in terms of attitude and angular velocity. Finally, the impact on performance of failures in the actuation system is also analyzed.

Introduction

The increasing interest to In-Orbit Servicing (IOS) and Active Debris Removal (ADR) missions has highlighted the need to develop and demonstrate advanced technologies enabling autonomous Rendezvous and Proximity Operations (RPOs), particularly in scenarios involving non-cooperative space targets [1-3]. In such scenarios the autonomous Guidance, Navigation, and Control (GNC) system shall guarantee compliance with stringent accuracy and safety requirements, especially during the final approach phase, when the chaser must reduce its relative distance and align its attitude with the docking interface [4, 5].

Within the *Space It Up* (Spoke 1) project [6], two guidance strategies for the close-range rendezvous toward a tumbling target have been investigated: (i) an optimization-based method relying on the Sequential Convex Programming (SCP) algorithm [7]; (ii) a multi-step strategy, that combines analytical and optimization techniques [8]. Following this line of research, this work focuses on the latter methodology, due to its lower computational cost. Then, the trajectory generated by such guidance strategy is tracked using a coupled orbit–attitude H-infinity controller synthetized using a mixed-sensitivity, loop-shaping formulation [7]. A key point to validate the resulting G&C architecture is to demonstrate its capability to provide adequate control accuracy under highly variable conditions in terms of target's initial attitude and angular rate. Thus, an extensive campaign of numerical simulations is conducted in a virtual environment realistically reproducing target/chaser orbital and rotational dynamics, as well as sensors and actuators operations. The remainder of the paper is organized as follows. The section on reference frames and rendezvous phases introduces the problem formulation. Subsequently, the guidance and control algorithms are presented, followed by a description of the simulation environment and mission scenario. The numerical results are then discussed, and final remarks conclude the paper.

Notation and Reference frame

The following reference frames are adopted. The Spacecraft Centred Reference Frame (SCRF) and the Target Reference Frame (TRF) are body-fixed coordinate systems centered in the Centre of Gravity (CoG) of the chaser and target, respectively. The Grasping Reference Frame (GRF) is a coordinate system parallel to the TRF, centered at the target's berthing point. The Hill Reference

Materials Research Proceedings 69 (2026) 862-867 https://doi.org/10.21741/9781644904251-152

Frame (HRF) is an orbiting coordinate system, centered at the target CoG, with the x axis in the radial direction, the z axis (cross-track) along the target orbital angular momentum vector, and the y axis (along-track) completing the right-hand triad.

Rendezvous Maneuver

The considered rendezvous scenario consists of two main phases. In the former (Close-range Rendezvous, CR), a translational maneuver is defined to drive the chaser to the entrance of the approach corridor while satisfying a keep-out zone (KOZ) constraint. At the same time, a slew maneuver synchronizes the chaser angular motion to the target one. Such maneuver is completed by a stabilization phase executed to perform health and safety checks before the final approach. In the latter phase (Final Approach, FA), the servicer moves along the approach corridor, while maintaining a constant relative attitude, up to the capture point. Again, this is followed by a stabilization step to meet a set of capture requirements.

Guidance Function

While details can be found in [8], the proposed guidance strategy is briefly recalled hereinafter.

During the CR Phase, the servicer maneuvers toward the approach axis while remaining outside a spherical KOZ. An original contribution of this work lies in the adaptive computation of the CR phase time duration (t_{CR}), which is derived from the current estimates provided by the navigation function, rather than being treated as a tuning parameter. This approach is conceived to improve the feasibility of the maneuver when considering targets with relatively high tumbling rates. Specifically, t_{CR} is determined so that the approach axis is aligned (at least with a certain margin) with the target-chaser line of sight, according to the following procedure. First, the target's rotational dynamics is propagated over the interval [t_{min}, t_{max}] and the angle φ between the two above-mentioned directions is evaluated. Then, t_{CR} is selected as the instant time corresponding to the minimum value of φ.

The translational reference trajectory is defined as the result of a set of ($N_{CR} - 1$) two-impulse rendezvous maneuvers, where N_{CR} is the number of corresponding impulsive nominal burns. The algorithm analytically ensures compliance with the KOZ constraint, modeled as a sphere of radius, r_{KOZ}, centered on the target. Then, a slew maneuver is defined via an iterative optimization that minimizes propellant consumption while also enforcing target visibility within the field of view (FOV) of a relative navigation sensor (i.e., a LIDAR in this work).

During the FA phase, the chaser moves along the approach corridor (i.e. the volume of a cone whose axis is normal to the target face hosting the berthing port), maintaining a constant relative attitude with respect to the target. The servicer proceeds from initial relative position along a straight line in TRF. The intermediate positions are computed using a modified Hablani algorithm [9] and are subsequently rotated into the HRF.

Control Function

The H-infinity controller provides the commanded force and torque required to nullify the deviation from the reference relative trajectory. The plant dynamics of the H-infinity controller, i.e., the coupled roto-translational dynamics of the satellite, is modeled using a first-order state space representation obtained by linearizing the nonlinear relative dynamics around a nominal operating point. The Clohessy–Wiltshire linear equations are employed to define the state matrix of the translational component, while details on the linearization of the relative attitude and rotational dynamics are provided in [7].

Simulation environment and scenario definition

Performance assessment is carried out within a numerical simulator reproducing the coupled translational and rotational dynamics of the target and chaser accounting for main environmental perturbations. A robotic arm is activated once the chaser is stabilized during the FA phase, in order

Materials Research Proceedings 69 (2026) 862-867 https://doi.org/10.21741/9781644904251-152

to demonstrate robustness against additional disturbances it induces in main body dynamics. The simulator includes a LIDAR-based relative navigation block to reproduce realistic relative state estimates and a dispatching function to account for non-idealities in the execution of control commands from the actuators [7, 8]. A typical Rendezvous mission toward a tumbling target is considered as an operational scenario. The chaser and target characteristics are taken from the e.Deorbit mission [8]. A statistical analysis of 100 Monte Carlo (MC) runs is performed considering uncertainties on the knowledge of chaser parameters, actuators mounting parameters and initial conditions (Table 1). For each run, the target mainly rotates around the direction of the approach axis (*-x TRF axis*) with small oscillations along the other two axis. Specifically, the target angular velocity varies in the range [-0.3 0.3] °/s for the second and third components, while the first component lies within the range [0.5 2] °/s. The initial attitude of the target is also randomized. Finally, an additional set of 100 simulations is carried out to account for thruster-failure scenarios. Specifically, in each run, one thruster is randomly selected and permanently disabled at a random time of the rendezvous maneuver. Consequently, the servicer must complete the run using the remaining thrusters.

Table 1. Uncertainties of MC analysis

Uncertainty	**3σ**	**Uncertainty**	**3σ**
Percentage of Chaser mass	1	Initial Position [cm]	30
Percentage of Chaser inertia	5	Initial Velocity [cm/s]	3
Chaser Centre of Gravity [mm]	3	Initial Attitude [°]	5
Displacement RCS [mm]	3	Misalignment RCS [°]	0.10

Results

The main results of the MC analysis are provided in this Section. Fig. 1 illustrates the reference relative position and velocity computed by the guidance function in the two phases, for a single random simulation. The minimum and maximum duration of the CR phase are set to 400 s and 1000 s, respectively. According to the procedure described previously, the resulting CR phase duration is 472 s. Therefore, the servicer moves from its initial position to the approach axis while staying outside the KOZ radius. In the FA phase, the servicer reaches the berthing point. In the CR phase, the largest nominal burns occur at the beginning and at the end, whereas in the FA phase the first two burns are the largest, while the final one has a lower magnitude (Table 2). Fig. 1 illustrates the reference relative attitude, angular velocity and the resulting nominal torque of the slew maneuver. In CR phase, the chaser maneuvers to reach the desired final relative attitude. Furthermore, this reference rotational trajectory is designed to ensure target visibility. Finally, the computational cost for guidance function execution is approximately 0.162 s. The algorithms are implemented on MATLAB/Simulink R2022b (×64) and tested on Intel(R) Core(TM) i510210U CPU @ 1.60GHz and 16.0 GB of RAM.

Regarding control performance, the control errors are defined as the deviations between the current true state of the chaser and the nominal state provided by the guidance function. The weights of the H-infinity controller are presented in [8]. Fig. 3 shows the control performance for the same random simulation. The peaks in relative position (with a maximum value of 1.20 m in the radial direction) are caused by the nominal burns which are not executed instantaneously by the chaser's actuation system. Nonetheless, the translational and rotational errors generated by the nominal burns are progressively corrected. At the end of the simulation, when the chaser reaches the berthing point, the relative position error is reduced to the centimeter level, and the relative attitude error is less than 0.2 degree for each component. In conclusion, Table 3 summarizes the performance of G&C architecture by reporting the control errors at the berthing point for all simulation. The results confirm the trend observed in Fig. 3. Specifically, position errors are below

Materials Research Proceedings 69 (2026) 862-867 https://doi.org/10.21741/9781644904251-152

50 cm for all components, and attitude errors remain within 2° for every component in 100% of runs. Computational cost for guidance function execution remains below one second (Table 4). Regarding thruster-failure case, only 4% of the simulations result in a position error greater than 1 m in any component, while the remaining simulations are consistent with the case in which all thrusters are operational (Table 5). Table 6 reports the propellant consumption statistics: a slight increase in mean under failure conditions, while the maximum value remains below 7 kg.

Conclusions

This paper presents a comprehensive analysis of the performance of G&C architecture, demonstrating its robustness with respect to variations in the target's initial attitude and angular rate, as well as actuator failures occurring during the maneuver. The guidance function is based on a semi-analytical approach [7], while a detailed description of the control function can be found in [7,8]. Numerical simulations show high accuracy of the proposed architecture. At the berthing point, the system consistently achieves position errors in the order of few centimeters and attitude errors below one degree. This level of precision can be considered adequate to enable successful rendezvous maneuvers. Similar results are obtained under thruster failure conditions.

Finally, computational cost of the guidance function generally remains below one second. Future work will focus on improving the efficiency of the guidance algorithm to reduce the computational cost and reformulating the guidance function to account for continuous (rather than impulsive) thrust, with the aim of reducing position and velocity control errors.

Keywords: Flight Dynamics, Autopilot, Flight Control System, Incremental Nonlinear Dynamic Inversion, Adaptive Control

Abstract. In this work the effectiveness of an adaptive control augmentation for high-performance fixed-wing aircraft is investigated. An Incremental Nonlinear Dynamic Inversion (INDI) pitch rate control loop is designed within the cascade of a longitudinal autopilot. A minimally invasive $\mathcal{L}_1$-adaptive controller is then designed to counteract system uncertainties and variations, with an hedging procedure that ensures bounded adaptation during saturation events. A time-domain performance analysis is performed, showing that the baseline INDI controller draws a clear benefit from the $\mathcal{L}_1$-adaptive augmentation.

Introduction

Most modern fixed-wing aircraft achieve stability through a Flight Control System (FCS) that relies on Gain-Scheduling (GS). In this method, the varying system dynamics is taken into account by switching the controller parameters in real time, based on some scheduling rules. Although there are techniques that can speed up the scheduling process [1], a significant effort in design and analysis is often required, and the full capabilities of the aircraft may not be exploited. In Incremental Nonlinear Dynamic Inversion (INDI) [2] architectures, a feedback linearization of the system dynamics allows for the desired response to be enforced in the complete flight envelope without the need for scheduling, in a modular and easily interpretable structure. However, the model-based implementations of INDI control laws suffer from model mismatches, whose effect on the response can be mitigated using an adaptive control augmentation. $\mathcal{L}_1$ adaptive control theory [3] offers a promising alternative to comparable architectures, as it avoids inducing the system into dangerous oscillatory behaviors resulting from fast adaptation. In this work we consider a nonlinear model for the longitudinal dynamics of an airframe, where a cascade autopilot controlling the climb angle is designed with a model-based INDI pitch rate control loop. Then, a minimally invasive $\mathcal{L}_1$ Piecewise Constant (PwC) adaptive [3] augmentation is designed to compensate for any uncertainty in the open-loop pitch rate dynamics. With a proposed hedging [4] method for the predictor in the adaptive controller, safe adaptation during actuator saturation events is ensured, which represents a step forward when compared to similar works [5].

Longitudinal Autopilot Baseline Design

Control Structure. A cascade architecture, visible in Fig. 1, is adopted to control a model for the longitudinal dynamics of the airframe shown in Fig. 2, using a tail elevator deflection δ, whose actuator is modeled through a second-order transfer function $G_{\mathrm{a}}(s)$ with position and rate limits δ_{M}, $\dot{\delta}_{\mathrm{M}}$. The two outer loops are closed with proportional gains K_{γ} and K_{az}, controlling respectively the climb angle γ and the vertical acceleration $a_z = \dot{w}$. The inner loop contains a model-based INDI controller, designed so that the pitch rate tracking error $e_q = q - q_{ref}$ remains small.

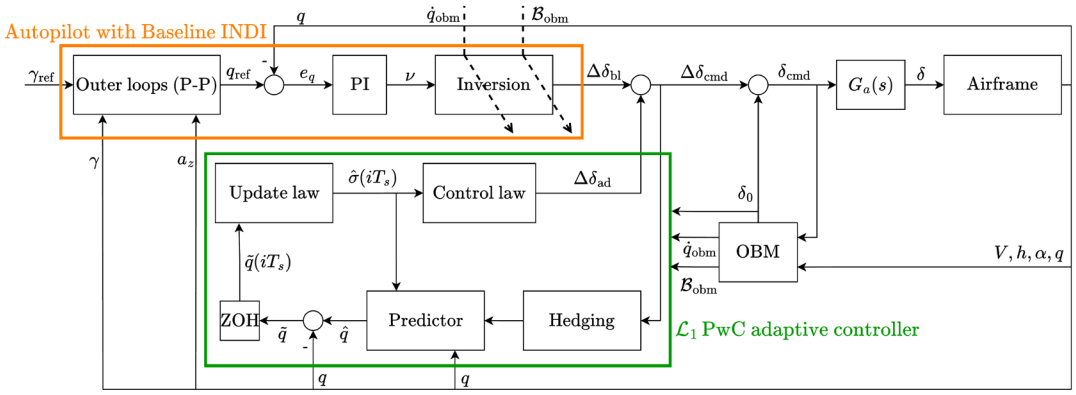

Fig. 1. Full autopilot structure with baseline INDI and $\mathcal{L}_1$-adaptive controllers.

Pitch dynamics. The second body-frame component of the Euler equations with the aerodynamic model adopted from [1] reads

$$\dot{q} = \frac{1}{J} q_\infty S_{\text{ref}} d_{\text{ref}} (C_{\mathcal{M}/q} q + C_{\mathcal{M},\alpha}(\alpha, V, M) + C_{\mathcal{M}/\delta}\delta), \tag{1}$$

where J is the moment of inertia of the airframe, q_∞ is the asymptotic dynamic pressure, S_{ref} and d_{ref} are the reference surface and length, $C_{\mathcal{M}/q}$ is the damping-in-pitch derivative, $C_{\mathcal{M},\alpha}(\cdot)$ is a nonlinear function depending on the angle of attack α, the airspeed V, and the Mach number M, while $C_{\mathcal{M}/\delta}$ is the elevator control derivative.

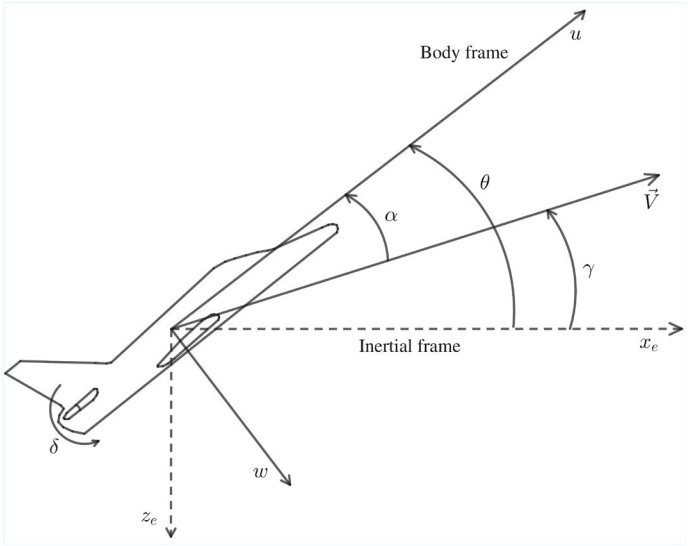

Fig. 2. The motion of the longitudinal airframe in the body and inertial frames.

INDI Baseline Controller. The first-order Taylor expansion of Eq. (1) is computed at each time step around the current condition, denoted by the subscript 0. The assumption of a separation in the timescales between (slow) rigid-body dynamics and (fast) actuator dynamics is adopted to simplify the obtained incremental dynamics [2] down to

$$\dot{y} \approx \dot{y}_0 + \mathcal{B}(\delta - \delta_0) \approx \dot{y}_0 + \mathcal{B}\Delta\delta_{cmd} \tag{2}$$

where $\mathcal{B} = \frac{1}{J} q_{\infty,0} C_{\mathcal{M}/\delta} S_{ref} d_{ref}$ is the control effectiveness and $\Delta\delta_{\text{cmd}}$ is the total incremental command. The baseline INDI incremental command $\Delta\delta_{\text{bl}}$ is then computed as

$$\Delta\delta_{\text{bl}} = \mathcal{B}_{\text{obm}}^{-1}(\nu - \dot{q}_{\text{obm}}) \tag{3}$$

with $\dot{q}_{obm}$ and $\mathcal{B}_{obm}$ representing estimates of $\mathcal{B}$ and $\dot{q}_0$, obtained from an On-Board Model (OBM) using nominal aerodynamics $\bar{C}_{\mathcal{M}/q}$, $\bar{C}_{\mathcal{M},\alpha}$, $\bar{C}_{\mathcal{M}/\delta}$. The total commanded input coming from

the baseline INDI controller is $\delta_{cmd} = \Delta\delta_{\mathrm{bl}} + \delta_0$, with δ_0 estimated with a model of the actuator $\bar{G}_{\mathrm{a}}(\mathrm{s})$. The pseudo control $\nu = K_P\big(q_{ref} - q\big) + K_I\int\big(q_{\mathrm{ref}} - q\big)$, with K_P, K_I positive constants, relates to the desired second-order pitch rate dynamics, achieved almost exactly within the whole flight envelope as long as the OBM estimates are sufficiently accurate.

$\mathcal{L}_1$-Adaptive Control Augmentation Design

In a practical scenario, model uncertainty and exogenous disturbances will affect the pitch rate dynamics of Eq. 1. These effects can be considered through a lumped uncertainty σ_m, matched inside the control channel of the open-loop pitch rate dynamics as

$$\dot{q} = \dot{q}_{\mathrm{obm}} + \mathcal{B}_{\mathrm{obm}}(\Delta\delta + \sigma_m). \tag{4}$$

Predictor. Within the $\mathcal{L}_1$-adaptive controller, the predictor is a dynamical system which computes an estimate of the pitch rate $\hat{q}$ according to:

$$\dot{\hat{q}} = \dot{q}_{\mathrm{obm}} + \mathcal{B}_{\mathrm{obm}}(\Delta\delta_{\mathrm{a}} + \hat{\sigma}_m) + L(q - \hat{q}), \qquad L > 0 \tag{5}$$

Hedging. In Eq. (4), $\Delta\delta_{\mathrm{a}}$ is obtained by estimating the incremental elevator deflection according to

$$\Delta\delta_{\mathrm{a}} = \bar{G}_{\mathrm{a}}(t) * \mathrm{sat}_{\delta_{\mathrm{M}}}\left\{\int_0^t \mathrm{sat}_{\dot{\delta}_{\mathrm{M}}}\left[\frac{d}{dt}(\delta_{\mathrm{cmd}}(\tau))\right]d\tau\right\} - \delta_0, \quad \delta_{\mathrm{cmd}} = \Delta\delta_{\mathrm{ad}} + \Delta\delta_{\mathrm{bl}} + \delta_0 \tag{6}$$

where $*$ is the convolution operator and $\mathrm{sat}_{\delta}(\cdot)$ is the symmetric saturation function. This modification guaranties that adaptation is not mistakenly driven during maneuvers or actuator saturation, avoiding potentially catastrophic events.

Update Law. The prediction error $\tilde{q} = \hat{q} - q$ is used to drive the parameter update law that estimates the uncertainty using a piecewise constant approximation according to

$$\hat{\sigma}_m(t) = K_{\mathcal{L}_1}(T_s)\tilde{q}(iT_s), \quad \forall\, t \in [iT_s, (i+1)T_s), \tag{7}$$

$$K_{\mathcal{L}_1}(T_s) = -\mathcal{B}_{\mathrm{obm}}^{-1}\left(1 - e^{-LT_s}\right)^{-1} L e^{-LT_s}, \tag{8}$$

where the adaptation speed is regulated through L and the sampling time of the controller T_s.

Control Law. The adaptive control law that compensates for the uncertainty is

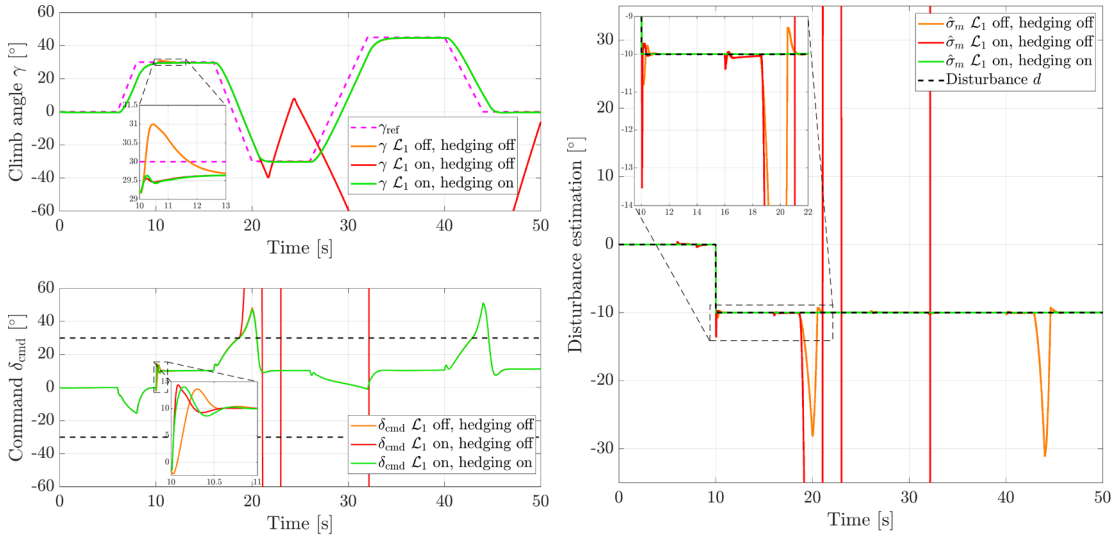
$$\Delta\delta_{\mathrm{ad}} = -C(s)\,\hat{\sigma}_m(s), \qquad C(s) = \frac{\omega_{\mathrm{f}}}{s + \omega_{\mathrm{f}}}, \tag{9}$$

where s is the Laplace variable and $\omega_{\mathrm{f}} > 0$ adjusts the filtering action that prevents exciting the system at high frequencies.

Tuning remarks. The sampling period T_s should be selected as high as the available CPU allows. With $T_s \to 0$, and $F_\sigma(s)$ denoting the transfer function from σ_m to $\hat{\sigma}_m$ obtained by closing the loop in the prediction dynamics with Eq. 7 and Eq. 8, one gets that

$$F_\sigma(s) = -K_{\mathcal{L}_1}\left(s - (-L + \mathcal{B}_{\mathrm{obm}}K_{\mathcal{L}_1})\right)^{-1}\mathcal{B}_{\mathrm{obm}} = \frac{e^{-LT_s}}{1 + s(1 - e^{-LT_s}/L)}, \tag{10}$$

so that $\lim_{t\to\infty}[\hat{\sigma}_m(t) - \sigma_m(t)] \overset{L\to 0}{\to} 0$. The bandwidth of the filter ω_{f} should be as high as possible without exceeding the available bandwidth of the system.



Materials Research Proceedings 69 (2026) 868-873 https://doi.org/10.21741/9781644904251-153

Performance Analysis

The controllers and the airframe model are implemented in MATLAB/Simulink®. The adopted controller parameters are shown in Table 1. The gains of the baseline controller were tuned with the MATLAB® function systune, while the adaptive controller was tuned conservatively using the guidelines described in the previous section.

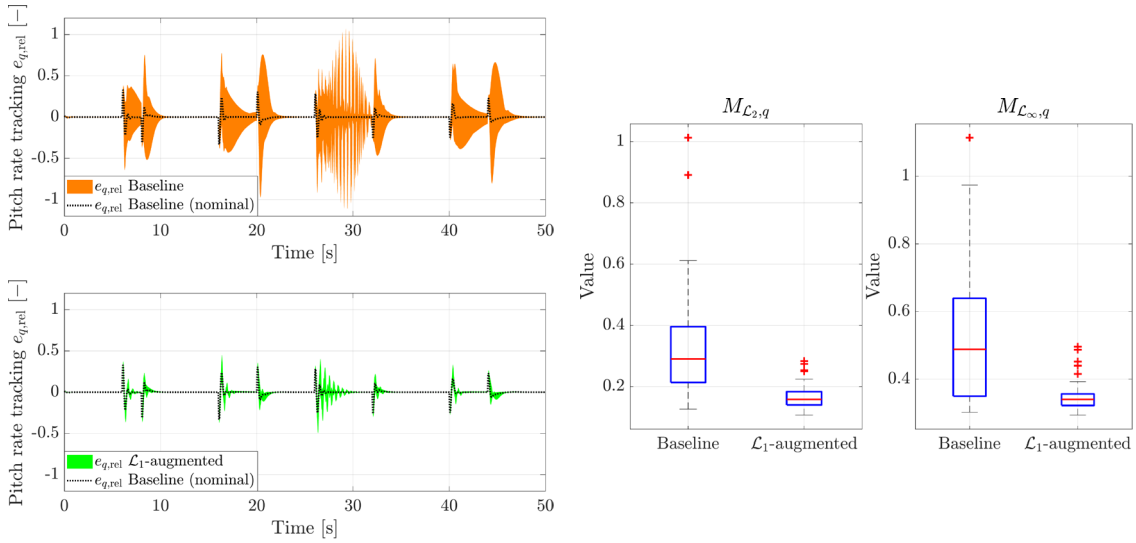
Table 1. Tuned controller parameters

Parameter	Value
K_γ	-1324
K_{az}	-0.0093
K_P	18.55
K_I	67.58
T_s	0.01s
L	0.1
ω_f	50 rad/s

(a) Climb angle γ and commanded elevator deflection δ_{cmd}.

(b) Estimation performance in the adaptive controller with respect to disturbance d.

Fig. 3. Results of nonlinear simulations with injected disturbance d, comparing the baseline and $\mathcal{L}_1$-augmented controllers with and without predictor hedging.



Disturbance Rejection. With a reference signal γ_{ref} that makes the system cross its envelope, a disturbance $d(t) = -10\text{step}(t-10)$ deg is injected in the control channel, with the objective of proving the effectiveness of adaptation and the importance of hedging. Fig. 3a shows the climb angle response and the corresponding total command, while Fig. 3b highlights the estimation performance of the adaptive controller. The $\mathcal{L}_1$ controller slightly increases the system responsiveness. However, with active adaptation, the proposed hedging methodology proves to be fundamental in avoiding instability and providing correct disturbance estimation. The baseline INDI controller also achieves an acceptable performance degradation, thanks to the integral action tuned by the gain K_I.

Monte Carlo Analysis. The following quantities are defined:

Materials Research Proceedings 69 (2026) 868-873 https://doi.org/10.21741/9781644904251-153

$$e_{q,\mathrm{rel}} = \frac{e_q}{\| q_{\mathrm{ref}} \|_{\mathcal{L}_\infty}}, \quad M_{\mathcal{L}_2,q} = \frac{\| e_q \|_{\mathcal{L}_2}}{\| q_{\mathrm{ref}} \|_{\mathcal{L}_2}}, \quad M_{\mathcal{L}_\infty,q} = \frac{\| e_q \|_{\mathcal{L}_\infty}}{\| q_{\mathrm{ref}} \|_{\mathcal{L}_\infty}}; \tag{11}$$

and a Monte Carlo study through nonlinear simulations is performed, considering parametric uncertainties. The relative pitch rate tracking error $e_{q,rel}$ is shown in Fig. 4a, comparing the baseline and the $\mathcal{L}_1$-augmented controllers to a nominal simulation. Undesirable pitch oscillations are greatly reduced by the adaptive augmentation when compared to the responses obtained with the baseline controller. The box plots in Fig. 4b highlight an improved consistency of performance under the varying conditions resulting from uncertainty.

(a) Time histories of the relative pitch rate tracking error

(b) Values for the pitch rate tracking performance metrics $M_{\mathcal{L}_2,q}$, $M_{\mathcal{L}_\infty,q}$.

Fig.4. Results of the Monte Carlo analysis comparing pitch rate tracking performance for baseline and $\mathcal{L}_1$-augmented controllers

Conclusions

The $\mathcal{L}_1$-adaptive augmentation of the INDI controller presented in this paper proved to be beneficial to the dynamic response of the airframe. Moreover, the proposed hedging method is fundamental to avoid inducing the system into unstable behavior in the case of actuator saturation events. Although the observations from time-domain simulations show an increase in tracking and disturbance rejection capabilities, a strict stability analysis would complete the evaluation of the architecture, which can potentially be extended to a complete aircraft model with multiple control channels.

Keywords: Flight Control System, Incremental Nonlinear Dynamic Inversion, Adaptive Control, Automatic Tuning

Abstract. Incremental Nonlinear Dynamic Inversion (INDI) is a promising control framework for systems characterized by significant nonlinearities and uncertainties, such as high-performance aircraft. However, the capabilities of INDI control are limited by its sensitivity to noise, delays, and modeling errors, which hinder its industrial adoption and certification. This paper presents an adaptive INDI extension with systematic synthesis capabilities, thereby enabling formal verification of performance and robustness, and paving the way toward certifiable INDI flight control systems.

Introduction

Given a control-affine nonlinear system $\dot{x} = f(x) + G(x)u$, the starting point of the INDI design is the linearization of the system about the previous time instant (x_0, u_0), obtaining

$$\dot{x} = \dot{x}_0 + F(x_0, u_0)\Delta x + G(x_0)\Delta u, \tag{1}$$

where $\Delta u = u - u_0$, $\Delta x = x - x_0$ are the input and state increments, respectively, $F(x_0, u_0) = \partial(f(x) + G(x)u)/\partial x$ evaluated at (x_0, u_0), $G(x_0)$ is the control effectiveness matrix and $\dot{x}_0 = f(x_0) + G(x_0)u_0$. The INDI control law is given by:

$$u = u_0 + \Delta u = u_0 + G^{-1}(x_0)(\nu - \dot{x}_0), \tag{2}$$

where ν is a virtual control input provided by an external controller [1] that achieves stable tracking of a reference signal x_{ref}.

When applied to the nonlinear plant, the control law approximately reduces the dynamics to a pure integrator, $\dot{x} = \nu$, which holds under the assumption of fast control update time and fast actuators, so that $\|F(x_0, u_0)\Delta x\| \ll \|G(x_0)\Delta u\|$. In the model-based INDI configuration, the On-Board Model (OBM)—a simplified dynamic model embedded in the flight control computer—is used to compute real-time estimates of the nominal state derivative, $\dot{x}_0$, and the control effectiveness matrix, $G(x_0)$. To enable this, both state and input feedback must be available from appropriate onboard sensors.

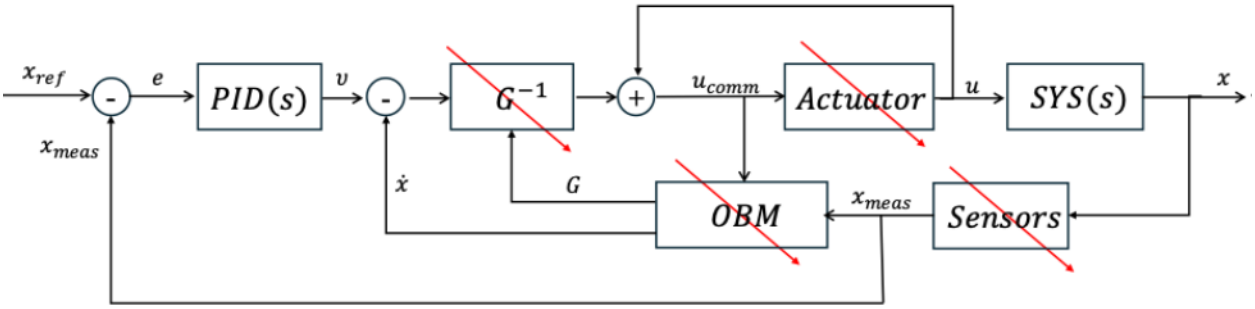

Fig. 1: Typical model-based INDI loop with uncertainty sources indicated with red arrows.

The combined effects of phase lag due to sensor dynamics, delays, actuator dynamics, and model estimation errors (Fig. 1) result in a deviation from ideal integrator behavior. The influence of these non-idealities on the INDI loop dynamics can be explicitly characterized by introducing perturbations in both the state function f and the control effectiveness G as follows:

$$\dot{x} = f(x) + \Delta f(x) + \big(G(x) + \Delta G(x)\big)u. \tag{3}$$

In [2], perturbations are matched in the actuator channel and compensated via an $\mathcal{L}_1$ adaptive controller in augmentation on the inner loop. This approach, however, results in a time-consuming tuning procedure, as the number of the adapted parameters equals the number of control channels. To overcome this issue, a novel adaptive architecture which augments the virtual control signal is presented, where an automatic tuning based on performance and robustness considerations is performed.

Adaptive Augmentation

The perturbation term of Eq. 3 is lumped into a single virtual disturbance $\sigma = \Delta f(x) + \Delta G(x)G^{-1}(x)\big(\nu - f(x)\big)$. Therefore, the INDI dynamics can be rewritten as $\dot{x} = \nu + \sigma$, i. e., a pure integrator with an input disturbance, recasting the whole problem into a classical linear disturbance rejection framework.

We solve the control problem via an adaptive augmentation approach by implementing an Extended State Observer (ESO) [3] that estimates the virtual disturbance and provides a control contribution ν_{ad} equal and opposite to its estimate $\hat{\sigma}$ (Fig. 2).

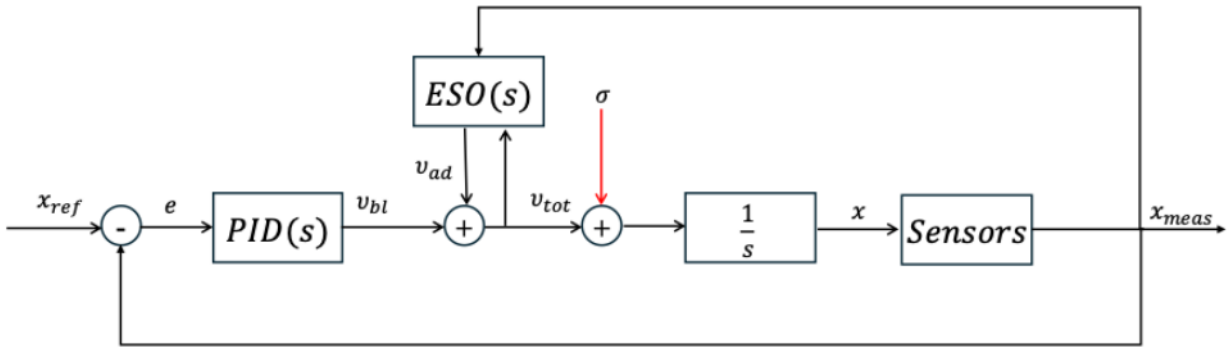

Fig. 2: Adaptive augmentation control architecture.

Materials Research Proceedings 69 (2026) 874-879 https://doi.org/10.21741/9781644904251-154

The considered ESO is described by

$$\dot{\hat{x}}(t) = \nu(t - \Delta T) + \hat{\sigma}(t) + L_1\big(x_{meas}(t) - \hat{x}(t)\big), \tag{4a}$$

$$\dot{\hat{\sigma}}(t) = Proj\big\{L_2\big(x_{meas}(t) - \hat{x}(t)\big)\big\}, \tag{4b}$$

$$\nu_{ad}(t) = -\hat{\sigma}(t), \tag{4c}$$

where x_{meas} is the state value measured by sensors, while L_1 and L_2 are positive definite ESO tunable gains. ΔT denotes a time shift applied to the predictor input. The inclusion of this term aims at compensating for the time misalignment between the predictor's state estimate $\hat{x}$ and the measured state x_{meas} introduced by sensor dynamics and delays. Numerical results show that this modification improves stability margins. Finally, a projection operator $Proj(\cdot)$ is applied to the virtual disturbance estimate to prevent drifting. One can prove that, with a proper tuning of the ESO gains, $\hat{\sigma}(t) \approx \sigma(t)$ and thus pure integral behavior of the INDI loop is approximately recovered.

Structured $\mathcal{H}_\infty$ Synthesis

The resulting proposed architecture (Fig. 2) is suitable for structured $\mathcal{H}_\infty$ synthesis [4] due to its simple structure and linearity in the parameters of the controller. Structured $\mathcal{H}_\infty$ solves a non-convex optimization problem to minimize the $\mathcal{H}_\infty$ norm of selected closed-loop transfer functions while respecting constraints on the controller's structure. These transfer functions represent key performance metrics such as tracking error, disturbance amplification, and control effort. Since the designer focuses on particular frequency ranges, it is common practice to weight each of these functions in the frequency domain. The designer can then tune the control system by adjusting these weighting functions to shape desired performance.

This tuning framework is more transparent and systematic for the designer than the standard manual tuning typically employed in the context of $\mathcal{L}_1$ adaptive control [2].

The presented approach is tested on a longitudinal autopilot of a nonlinear aircraft model in MATLAB/Simulink [5]. The autopilot consists of a cascade of three loops: the outer controls the climb angle γ, the middle the vertical acceleration a_z and the inner the pitch rate q (Fig. 3).

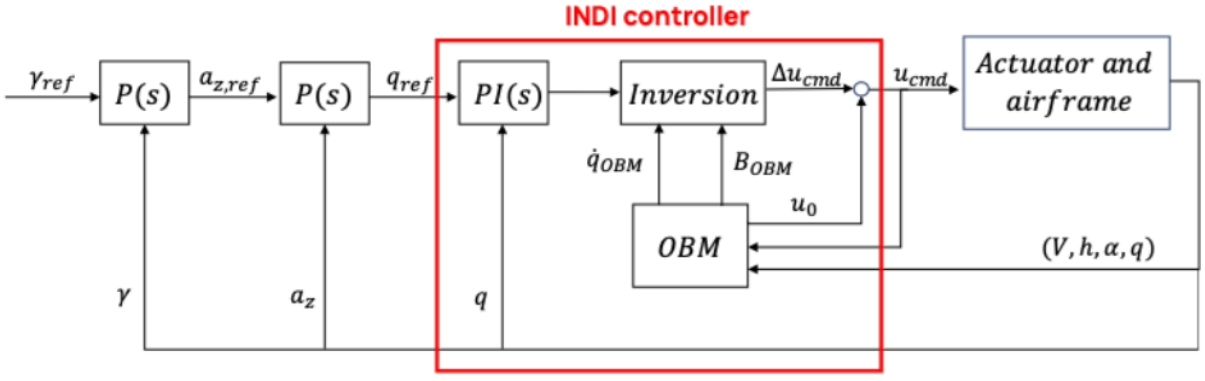

Fig. 3: Longitudinal autopilot baseline control system.

The baseline INDI controller adopted for the inner loop is augmented with the ESO architecture. Structured $\mathcal{H}_\infty$ synthesis is performed using three frequency-domain weighting functions, focusing on tracking performance, disturbance rejection capabilities, and control penalty:

$$W_{track}(s) = 0.1(s + 150\,)/(s + 1.5), \tag{5a}$$

Materials Research Proceedings 69 (2026) 874-879 https://doi.org/10.21741/9781644904251-154

$$W_{dist}(s) = 0.067(s + 15\ )/(s + 0.013), \tag{5b}$$

$$W_{act}(s) = 10(s + 0.15\ )/(s + 1500). \tag{5c}$$

The presented solution is then compared to the baseline INDI controller of Fig. 3 and to the $\mathcal{L}_1$ adaptive plant augmentation presented in [6].

The sensitivity functions in Fig. 4 show that the ESO augmentation retains most of the low-frequency disturbance rejection capability of the $\mathcal{L}_1$ augmentation presented in [6] while smoothing out the high-frequency peak.

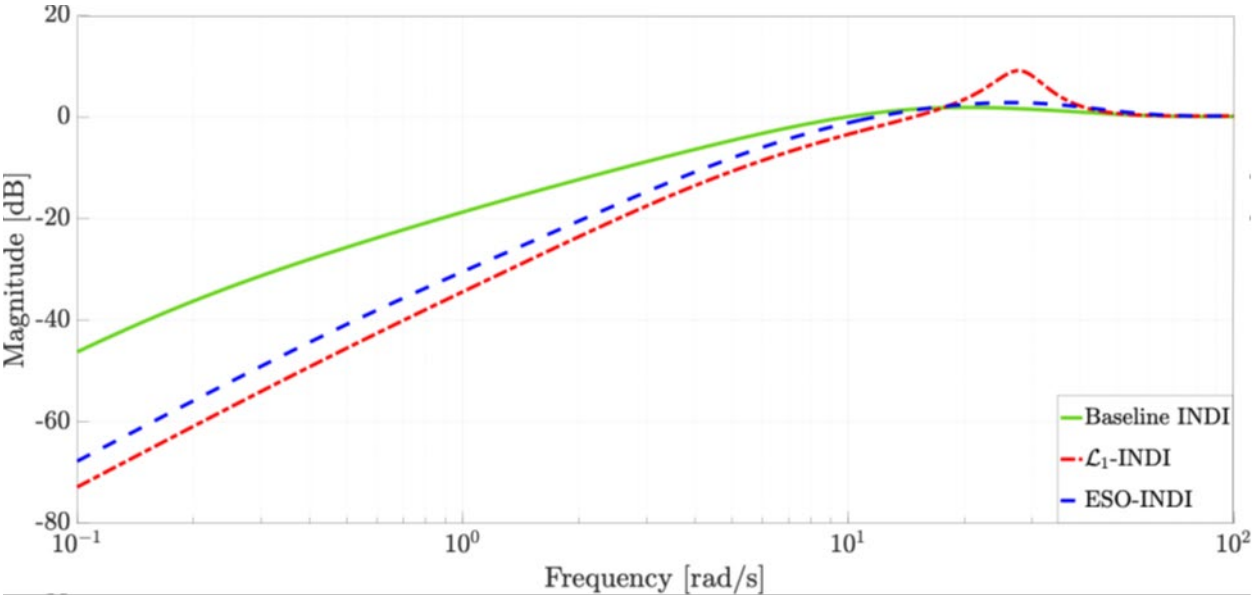

Fig. 4: Sensitivity functions of the INDI architectures.

Moreover, the Bode diagrams of the open-loop transfer function in Fig. 5 show that the ESO solution can recover and expand the stability margins of the baseline INDI controller of Fig. 3. Refer to Fig. 5: the light blue controller prioritizes an ample phase margin, while the dark blue controller prioritizes closed loop bandwidth. The designer can easily regulate the trade-off between the two by modifying the weighting functions of the $\mathcal{H}_\infty$ synthesis.

Materials Research Proceedings 69 (2026) 874-879 https://doi.org/10.21741/9781644904251-154

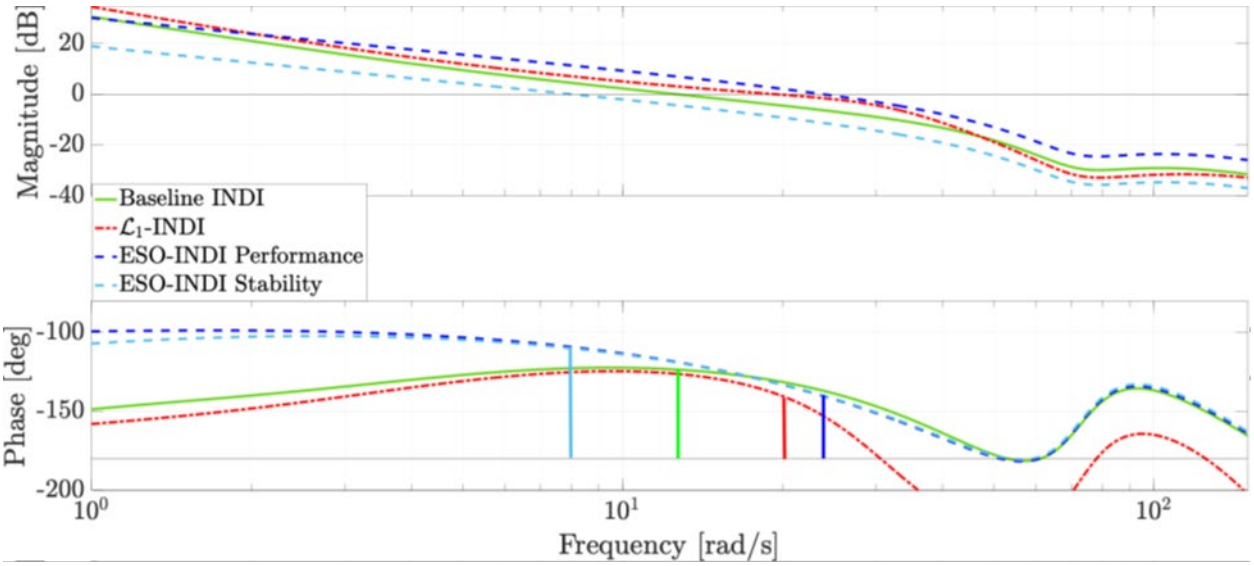

Fig. 5: Open-loop Bode diagrams.

Simulation Results

Performance of the adopted solution are evaluated under model uncertainties (inertia and aerodynamics), actuator degradation (−20% of effectiveness), sensor dynamics (with a bandwidth of 34 rad/s) and a sinusoidal external disturbance. As can be seen in Fig. 6, the ESO architecture shows sensibly improved performance compared to the baseline INDI controller of Fig. 3.

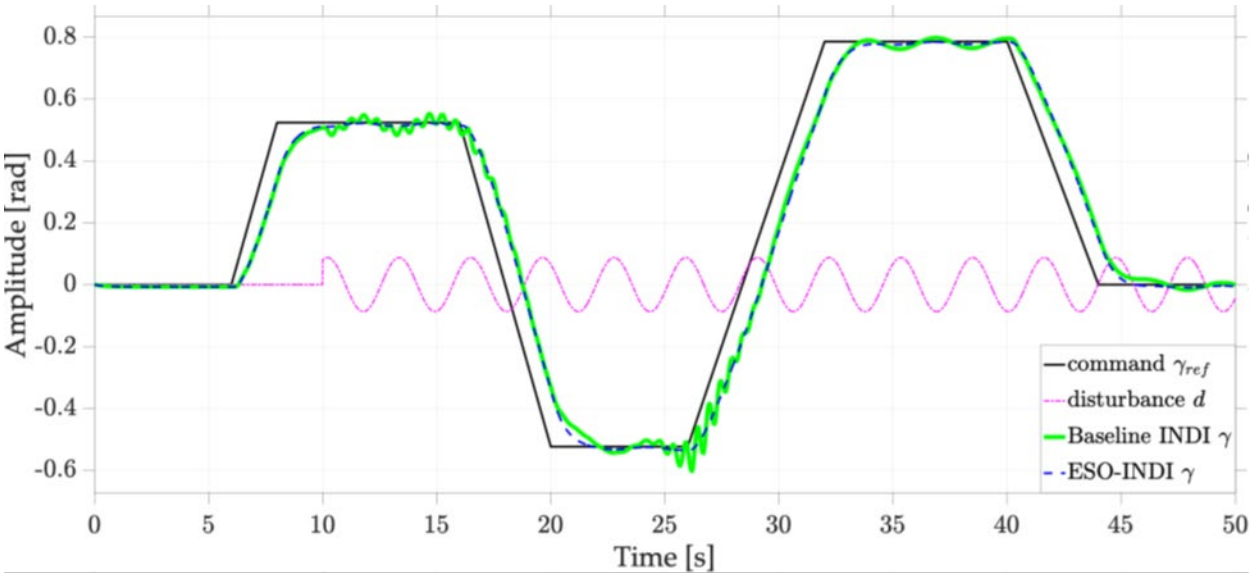

Fig. 6: Tracking of a reference climb angle.

Conclusions and Future Developments

Validation on a longitudinal autopilot case study shows that the $\mathcal{H}_\infty$-tuned INDI–ESO controller surpasses the performance and stability margins of a classical INDI or $\mathcal{L}_1$-adaptive scheme when sensor phase lag is present. The architecture also reduces manual tuning effort.

Several promising extensions can build on this foundation. First, disturbance estimation could be improved by incorporating Gaussian radial basis functions or neural network hybrids within the ESO, providing richer function approximation capabilities. Second, online delay identification algorithms could be embedded in the control loop to adaptively refine the ESO's delay estimate under variable computational or transmission latencies. Finally, a natural progression is to extend

the ESO–INDI framework to a multivariable flight control framework, developing vectorial disturbance observers and structured $\mathcal{H}_\infty$ controllers that explicitly handle pitch–roll–yaw coupling, enabling a unified autopilot for both longitudinal and lateral–directional dynamics.

Abstract. The *BeSaME* (Helicopter Blade State and Loads Reconstruction Through Virtual Sensing for Health Monitoring and Performance Enhancement) project develops a virtual sensing framework for the real-time monitoring of helicopter rotor blades. Strain data from embedded fiber Bragg grating sensors are processed using inverse finite element methods and state estimation algorithms to reconstruct blade deformation and sectional loads. Aeroelastically scaled composite blades are manufactured and experimentally tested under static, dynamic, wind-tunnel, and rotating conditions, supported by a validated digital twin. The placement of the sensors is optimized to maximize the accuracy of reconstruction. Preliminary results show sub-percent shape estimation errors and load reconstruction errors below 5%.

Introduction

The *BeSaME* (Helicopter Blade State and Loads Reconstruction Through Virtual Sensing for Health Monitoring and Performance Enhancement) project aims to contribute to the ambitious ACARE SRIA and Flightpath 2050 targets—namely, an 80% reduction in rotor- craft accident rates and a 65% reduction in perceived noise emissions by 2050—by advancing structural health monitoring and performance optimization of helicopter rotors.

By leveraging fiber Bragg gratings (FBG), inverse finite element methods (IFEM), and augmented Kalman filtering, BeSaME seeks to deliver an experimentally validated real-time virtual sensing system capable of measuring axial and shear strains in rotating blades, reconstructing bending and torsional generalized strains, estimating blade shape, and inferring rotor states and aerodynamic loads under operational conditions.

The experimental program involves manufacturing aeroelastically scaled composite blades with embedded FBG sensors and intentionally introduced defects (delaminations, porosity) for damage-detection validation. Comprehensive testing includes static surveys, modal characterization under free and clamped conditions, aerodynamic and aeroelastic evaluation in a wind-tunnel, and trials on a rotating rig. Strain gauges and accelerometers provide cross- validation of optical sensor signals.

On the numerical side, a digital twin integrates detailed finite element structural models, multibody dynamics for full rotorcraft simulation, and comprehensive aeromechanics analysis to

assess virtual sensor performance. Continuous model updating with experimental data ensures convergence and improves prediction fidelity.

The virtual sensing framework employs a hybrid strategy: inverse FEM for full-field deformation estimation, augmented Kalman filtering for spatially distributed load reconstruction, and neural networks for extracting critical load parameters and detecting anomalies indicative of damage. Sensor redundancy enhances resilience to individual failures while supporting accuracy validation with a minimal measurement network.

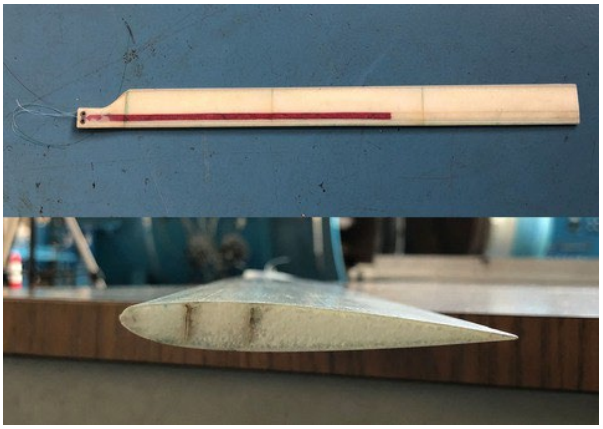

Figure 1: Example of blade specimen manufactured at POLIMI's technological lab.

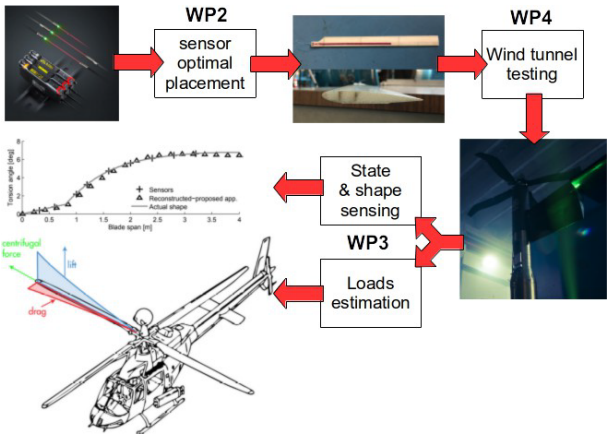

Figure 2: Block diagram of the project execution plan.

Expected outcomes include achieving TRL 5 (component/breadboard validation in relevant environment) for optical sensors in a rotating environment and TRL 4–5 (component/breadboard validation in laboratory or relevant environment) for virtual sensing algorithms, along with defining real-time and quasi-real-time metrics for blade health monitoring and control. The BeSaME system promises reduced maintenance costs, enhanced flight safety, and lower acoustic footprint, directly contributing to ACARE 2050 objectives and the Italian National Advanced Air Mobility (AAM) Strategic Plan.

The project, funded under the PRIN 2022 scheme and coordinated by Politecnico di Milano in collaboration with University Roma Tre, started in early 2025 and builds upon experience from earlier joint initiatives [1, 2, 3].

Shape and load sensing algorithm

The shape and load reconstruction approach is based on a modal method that leverages finite element analysis (FEA) to develop the blade monitoring algorithm. The algorithm consists of two main steps: first, the blade shape is reconstructed using a reduced set of eigenfunctions obtained from the FEM model; second, the loads are reconstructed using the computed displacement field along with the mass and stiffness matrices derived from the same model. Both shape and load reconstructions rely on strain measurements provided by FBG embedded sensors.

Preliminary analysis indicated that the algorithm is highly sensitive to sensor placement. Consequently, a bi-objective optimization is performed to determine the optimal sensor configuration, aiming to maximize reconstruction performance. The objective function combines the Fisher information factor and the conditioning of the reconstruction matrix. Figure 3 shows all the configurations obtained from the bi-objective optimizations, together with the corresponding Pareto front. The solution closest to the utopia point is selected as the optimal sensor layout.

The performance of the algorithm, based on the optimal sensor configuration, is evaluated using a three-dimensional beam model with an I-shaped cross-section. Reconstruction capabilities are assessed under both static and dynamic loading conditions chosen to reproduce the typical load

Materials Research Proceedings 69 (2026) 880-884 https://doi.org/10.21741/9781644904251-155

states experienced by a rotor blade in flight. In all cases, the results are consistent and satisfactory. For dynamic loads, the most demanding scenario, the mean percentage error in reconstructing the displacement at the tip of the beam along the elastic axis is 0.27%. For load reconstruction, the maximum error observed for the in-plane load component is 4.37%. Figure 4 shows an example of the reconstructed load distribution, where the precision in reproducing the FEM reference data can be inferred.

.

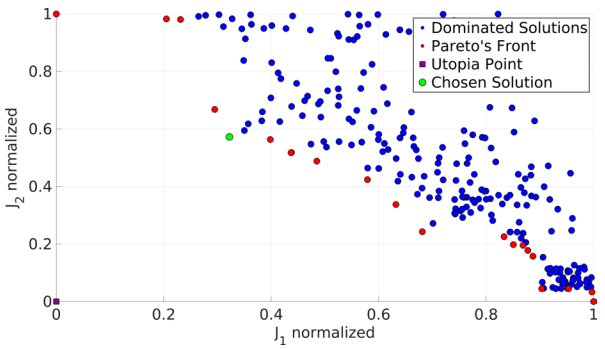

Figure 3: Optimal solutions from the bi-objective optimization, Pareto front, and selected optimal sensor configuration.

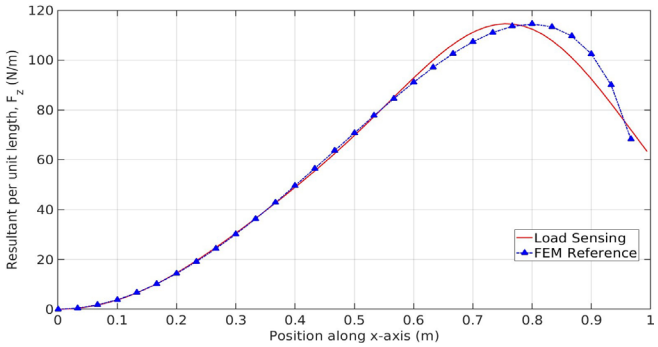

Figure 4: Comparison between reconstructed and FEM reference out-of-plane resultant per unit length.

Overall, the algorithm developed shows excellent capability to reconstruct the shape of the structure and good performance in identifying the section loads acting on it.

Blade manufacturing and testing

The current blade design is based on the one developed in [3], although minor modifications may be introduced to address issues and exploit improvement opportunities identified during the critical design review phase. The blade is constructed as a set of elements, each designed to perform a specific structural or functional role. The spar consists of two glass-reinforced unidirectional (UD) straps running along the entire span of the blade, with fibers oriented along the blade axis. These straps are designed to withstand axial forces from centrifugal loads and transfer them to the bearings around which the straps are wrapped. In the constant-section portion of the blade, each strap comprises four plies of 0.21 mm thickness, which split near the root to accommodate the bearings (Fig. 5).

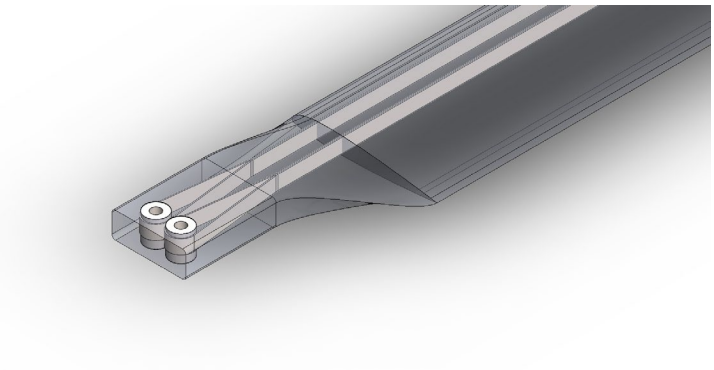

Figure 5: Detail of the root part of the blade, where straps split to wrap the bearings (adapted from [3]).

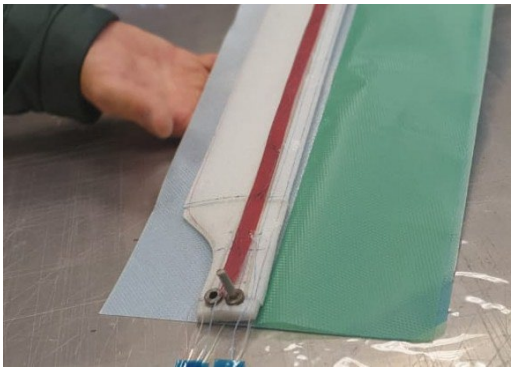

Figure 6: Final assembly of the blade (adapted from [3]).

Unlike more conventional designs, the ±45 deg wrapping that typically forms the torsional box is omitted to intentionally increase the blade's compliance and amplify torsional strains. A

Rohacell 51 WF polyurethane foam core provides the blade profile and the necessary support and pressure during manufacturing. The external skin consists of two plies of glass fabric, 0.12 mm thick, with fibers oriented at ±45 deg to ensure adequate torsional stiffness. A distinctive feature of this blade is the incorporation of two optical fibers that carry the torsion sensors. These fibers require special care to maintain proper orientation during assembly. To address this, an innovative technique called Quick-Pack (QP) is employed [4, 5]. The QP consists of a thin ribbon embedding a well-protected fiber optic along a predefined path (shown in red in Fig. 6). Its flexibility, enabled by the minimal thickness, allows it to adhere perfectly to curved surfaces, while the reinforced glass fiber protective layer ensures the integrity, functionality, and accurate orientation of the fiber optic.

Blade production involves three polymerization steps: fabrication of the UD straps, polymerization of the two QPs (one for the top and one for the bottom surface), and final curing of the external skins after assembly. Prior to polymerization, the Rohacell core is machined and the optical fibers positioned during assembly.

To evaluate the blade sensing capabilities under inertial and aerodynamic loads representative of a rotating rotor, a dedicated test rig is planned. It will feature a rigid mount for a pair of blades clamped at the root, with adjustable root pitch, actuated by an electric motor. Both blades will be instrumented, though limitations may exist in the number of optical channels that can be simultaneously acquired. This part of the project is currently under development.

Conclusions

The BeSaME project is developing a comprehensive framework for real-time virtual sensing of helicopter rotor blades, integrating fiber Bragg grating sensors, inverse finite element modeling, and augmented Kalman filtering. Preliminary numerical studies demonstrate excellent capability in reconstructing blade shape (sub-percent errors) and satisfactory performance in estimating sectional loads (errors below 5%).

The manufacturing and assembly of aeroelastically scaled composite blades with embedded sensors have been successfully designed, incorporating innovative techniques such as Quick-Pack for precise fiber placement. A dedicated test rig is currently under development to evaluate blade performance under representative inertial and aerodynamic loads.

Overall, the BeSaME framework shows strong potential to improve rotor blade health monitoring, support predictive maintenance, and enhance flight safety while reducing operational costs. Ongoing work will focus on experimental validation of the sensing algorithms, optimization of sensor networks, and extension to full rotorcraft systems.

Keywords: Hierarchical Control, Space Robotics, GNC

Abstract. This paper extends a previously developed task-priority control algorithm for space robots to higher task dimensions, such that no degrees of freedom remain uncontrolled. The proposed design adopts an inner–outer loop paradigm and leverages a hierarchical formulation of the imposed tasks. This structure ensures modularity, robustness to singularities, and safe task execution in complex space operations.

Introduction

Space robotics has become a vital element of modern space missions, particularly in applications such as In-Orbit Servicing (IOS) and Active Debris Removal (ADR) [1]. These systems typically consist of a manipulator mounted on a satellite base, resulting in kinematic redundancy, where the number of actuated degrees of freedom (DoFs) exceeds those required to control the end-effector's pose. This redundancy provides flexibility to execute tasks in multiple ways—by moving either the base or the manipulator—while optimizing secondary objectives such as dexterity enhancement or joint-limit avoidance.

In many space scenarios, robots must perform multiple tasks simultaneously with different priorities. Redundancy can be exploited using the task-priority control framework, which assigns hierarchical importance to each control goal via nullspace projection [2]. A singularity-robust version of this method was developed in [3] and later generalized to multiple tasks in [4]. Building on this, in [5] we extended the approach to space robotic systems operating on nonlinear configuration manifolds, providing stability guarantees and demonstrating its effectiveness in an orbital capture scenario involving a tumbling target.

The present work advances the methodology introduced in [5] by extending the algorithm to tasks of higher dimension than the system dimension, thus fully exploiting all DoFs. This generalization leverages the methodology presented in [6], which utilizes a projection mechanism that activates a lower-priority task whenever a higher-priority one becomes singular.

The main contribution of this work is the extension of the approach of [6] to the case of space robots. Furthermore, the kinematic task-priority controller is embedded within a hierarchical inner–outer loop architecture that, following [7], ensures almost-global attitude tracking. This modular design enables independent tuning and stability analysis of each layer while maintaining task prioritization, unlike unified structure [6].

Furthermore, the inner loop incorporates a proportional–integral (PI) controller synthesized via H_∞ methods [8], which enhances robustness to spacecraft inertial uncertainties—a key requirement for future space operations.

Notation.

Readers may refer to [9] for a complete description of the spatial notation adopted. We recall here the definition of the pose matrix of a frame j with respect to a frame i, later used in the development of this work:

Content from this work may be used under the terms of the Creative Commons Attribution 3.0 license. Any further distribution of this work must maintain attribution to the author(s) and the title of the work, journal citation and DOI. Published under license by Materials Research Forum LLC.

Materials Research Proceedings 69 (2026) 885-890 https://doi.org/10.21741/9781644904251-156

$$ {}^{i}X_j := \begin{bmatrix} {}^{i}R_j & 0_3 \\ S({}^{i}p_j){}^{i}R_j & {}^{i}R_j \end{bmatrix} := X({}^{i}R_j, {}^{i}p_j). \tag{1} $$

The Euclidean norm is denoted by $\|\cdot\|$. We use the symbols $\bar{(\cdot)}$ and $\tilde{(\cdot)}$ to indicate errors and desired quantities, respectively. Given a matrix A, $\mathrm{skew}(A) := \frac{A-A^{\mathsf{T}}}{2}$.

The Weighted Moore-Penrose Inverse (WMPI) is compactly written as [6]:

$$ A^{\dagger} = \mathrm{WMPI}(A, W_1, W_2) = R_2^{-1}(R_1 A R_2^{-1})^{\dagger} R_1, \tag{2} $$

with $W_1 = R_1^{\mathsf{T}} R_1$, and $W_2 = R_2^{\mathsf{T}} R_2$ positive-definite weight matrices.

System Configuration

The scenario considered is the same as that presented in [5] and involves a space robot (a spacecraft equipped with an $N = 7$-link robotic manipulator) and a second satellite on which servicing operations are to be performed. The latter is referred to as the *target* and the former as the *chaser* throughout this work.

The system configuration is described using multiple Cartesian reference frames to represent the relative motion of the various bodies involved. Figure 1 provides a visual representation of the frames and the transformations along the kinematic chain. Readers may refer to [5] for a more detailed definition and description of the frames.

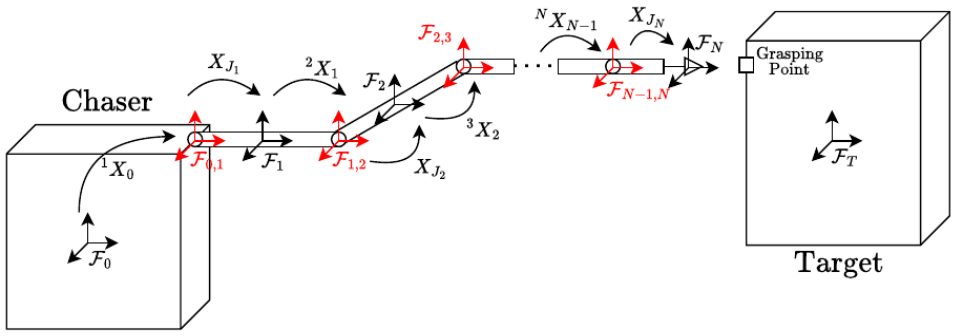

Figure 1: Geometric model of the space robot.

The attitude and position of the space robot base with respect to the target frame $\mathcal{F}_T$ are identified by the rotation matrix $R_0 \in \mathrm{SO}(3)$ and the position vector $p_0 \in \mathbb{R}^3$, respectively. Equivalently, using the spatial notation, the pose of the base frame is denoted $X_0 := X(R_0, p_0) \in \mathrm{SR}(6)$. The manipulator coordinates are described using joint angle variables, namely, as a set of angles collected in a vector $q = (q_1, q_2, \dots, q_N) \in \mathbb{T}^N := \mathbb{S}^1 \times \cdots \times \mathbb{S}^1$, where $\mathbb{S}^1$ is identified with $\mathbb{R}\,\mathrm{mod}(2\pi)$. These angles specify the relative rotation of the i-th joint frame, $\mathcal{F}_i$, with respect to the link frame $\mathcal{F}_{i-1,i}$. Given $n = 6 + N$ the number of total DoFs of the system, the configuration of the space robot is then uniquely and globally specified by the tuple (X_0, q), which is an element of the n-dimensional nonlinear manifold $\mathcal{M} := \mathrm{SR}(6) \times \mathbb{T}^N$.

The following system of nonlinear differential equations describes the kinematics of the multi-body system under consideration:

$$ \begin{cases} \dot{X}_0 = X_0 \nu_0^{\times} \\ \dot{q} = \Omega \end{cases} \tag{3} $$

Materials Research Proceedings 69 (2026) 885-890 https://doi.org/10.21741/9781644904251-156

where $\nu_0 := ({}^0\omega_{T0}, {}^0v_{T0}) \in \mathbb{R}^6$ is the base twist expressed in $\mathcal{F}_0$, while $\Omega \in \mathbb{R}^N$ represents the vector collecting the angular rates of the joints. For ease of notation, let us define $\mathrm{v} := (\nu_0, \Omega) \in \mathbb{R}^n$ as the system velocity.

The space robot dynamics is then given by the compact expression

$$H(q)\dot{\mathrm{v}} + C(\mathrm{v}, q)\mathrm{v} = u, \tag{4}$$

where $u := (\tau_0, f_0, \tau_q) \in \mathbb{R}^n$ collects the base torque, the base force, and the joint motor torque, respectively, while $H \in \mathbb{R}^{n\times n}$ is the generalized mass matrix and $C \in \mathbb{R}^{n\times n}$ is the Coriolis/centrifugal matrix (See, *e.g.*, [9], for a detailed derivation of these terms).

It is worth reporting the kinematics of the end-effector as well:

$$\dot{X}_N = X_N \nu_N^{\times}, \tag{5}$$

with $\nu_N := ({}^N\omega_{TN}, {}^Nv_{TN}) \in \mathbb{R}^6$ being the twist of the end-effector.

Multi-task priority control law design

Given the system (1)-(2), and a predefined number of tasks r, we remove the implicit assumption of [5] that the total task dimension $m = \sum_{k=1}^{r} m_k$, namely the overall number of DoFs requested by the tasks, is at most equal to the number of DoFs of the system n. Instead, we focus in the opposite case: we assume that the total task dimension is not less than the DoFs of the robot, *i.e.*, $m \geq n$, as done in [6].

As remarked in the introduction, the controller developed in this work relies on an inner–outer loop paradigm, where the outer loop commands to the inner one a virtual velocity input.

The commanded virtual velocity is determined based on the following process: a set of tasks is first established, after which the procedure outlined in [6] is applied. For each task, the dynamically consistent Jacobian matrix is computed starting from the actual Jacobian. According to the following routine:

$$\begin{aligned} \hat{J}_k &= J_k P_{k-1} \\ P_k &= P_{k-1}\left(I_N - \hat{J}_k^{\dagger}\hat{J}_k\right) \end{aligned} \tag{6}$$

where $k = 1, \dots, r$ and $\hat{J}_k^{\dagger} = \mathrm{WMPI}\left(\hat{J}_k, W_{1k}, W_2\right)$. The weight $W_{1k} = I_{m_k} \in \mathbb{R}^{m_k \times m_k}$ is chosen as an identity matrix of appropriate dimension, while $W_2 = H(q)$. Moreover, $P_0 = I_n$.

Using this definition, the Jacobian matrix of the first task remains unchanged. The recursive use of nullspace projectors will ensure that tasks are decoupled, since each lower-priority task will be applied only in directions that do not interfere with higher-priority tasks.

The pseudoinverses of the dynamically consistent Jacobian matrices may be compactly collected in a stack as well:

$$\hat{J}^{\dagger} = \begin{bmatrix} \hat{J}_1^{\dagger} & \cdots & \hat{J}_r^{\dagger} \end{bmatrix}. \tag{7}$$

The control law of the outer loop can now be explicitly stated:

$$\mathrm{v}^c = \hat{J}^{\dagger}\zeta. \tag{8}$$

The stack $\zeta = (\zeta_1 \cdots \zeta_r) \in \mathbb{R}^m$ collects the commanded tasks' velocities, which can be designed using different stabilizers, according to specific needs.

Materials Research Proceedings 69 (2026) 885-890 https://doi.org/10.21741/9781644904251-156

Then, the inner-loop controller computes the control input u to track the generalized velocity $\mathrm{v}^c \in \mathbb{R}^n$, provided by the outer loop to achieve the task objectives, according to the following law:

$$u = K_P\tilde{\mathrm{v}} + K_I x_I + H(q)\,\dot{\mathrm{v}}^c + C(q,\dot{q})\mathrm{v}^c, \tag{9}$$

where $\tilde{\mathrm{v}} = \mathrm{v} - \mathrm{v}^c \in \mathbb{R}^n$ is the control error, and $x_I \in \mathbb{R}^n$ is the integral state, defined such that $\dot{x}_I = \tilde{\mathrm{v}}$, which provides integral action on the twist error. The matrices $K_P \in \mathbb{R}^{n\times n}$ and $K_I \in \mathbb{R}^{n\times n}$ are gain matrices tuned using robust control techniques [8].

Numerical Results

In this section, we present the same scenario considered in [5], where a space robot must perform an orbital capture on a tumbling target. The control objectives are translated into two tasks: tracking the pose (position and attitude) of the end-effector and tracking the pose of the base spacecraft. In this work, we have added a third task, representing a safe joint configuration $\bar{q}$ [6]. Such a quantity is a set of joint angles that the arm has to track whenever the upper tasks become singular, *i.e.*, the corresponding Jacobian loses rank.

The three tasks considered can be specified as functions of the system state:

$$\begin{aligned} \xi &= (X_N, X_0, q) \\ \zeta &= (\nu_N^c, \nu_0^c, \Omega^c) \end{aligned} \tag{10}$$

where $\xi \in \mathbb{R}^m$ is the task specification vector.

Table 1: Selected Tasks.

Task #	Description	Jacobian	# of DoFs
1	Tracking EE's pose: X_N	$J_1 = [J_b \quad J_m]$	$m_1 = 6$
2	Tracking base pose: X_0	$J_2 = [I_6 \quad 0_{6\times 7}]$	$m_2 = 6$
3	Safe joint config.: q	$J_3 = [0_{7\times 6} \quad I_7]$	$m_3 = 7$

The three tasks, along with their Jacobians, are reported in Table 1.

The end-effector Jacobian J_1 is defined by

$$\begin{aligned} J_b &:= {}^N X_0 \\ J_m &:= \left[\cdots \; {}^N X_i X_{J_i}(q_i)\, s_r \; \cdots\right] \end{aligned} \tag{11}$$

with $s_r := [0\ 0\ 1\ 0\ 0\ 0]^\mathsf{T} \in \mathbb{R}^6$ being the motion constraint of the revolute joint.

Once the tasks have been specified, the problem may be solved by selecting the following commands:

$$\begin{aligned} \nu_N^c &= \gamma^X\left(\tilde{X}_N\right) + \tilde{X}_N^{-1}\bar{\nu}_N \\ \nu_N^c &= \gamma^0\left(\tilde{X}_0\right) + \tilde{X}_0^{-1}\bar{\nu}_0 \\ \Omega^c &= -K_q\tilde{q} \end{aligned}$$

The outer loop stabilizer is selected as in [5]. For $\kappa = 0, N$:

$$\gamma^\kappa = \left(\tilde{e}_\kappa, -\tilde{R}_\kappa K_\kappa^p \tilde{p}_\kappa\right),$$

where $\tilde{e}_\kappa = -S^{-1}\left(\mathrm{skew}\left(K_\kappa^R \tilde{R}_\kappa\right)\right)$ is the attitude error, and $K_\kappa^p \in \mathbb{R}^{3\times 3} > 0$, $K_\kappa^R \in \mathbb{R}^{3\times 3}$ and $K_q \in \mathbb{R}^{N\times N} > 0$ are symmetric gain matrices.

Materials Research Proceedings 69 (2026) 885-890 https://doi.org/10.21741/9781644904251-156

In the scenario considered, a reference trajectory is commanded to the end-effector to follow the grasping point on the target and perform an orbital capture. The base spacecraft is commanded to follow such a grasping point. The third task is commanded as a safe pose different from the one naturally obtained with the first two tasks active.

Two representative simulations are reported next.

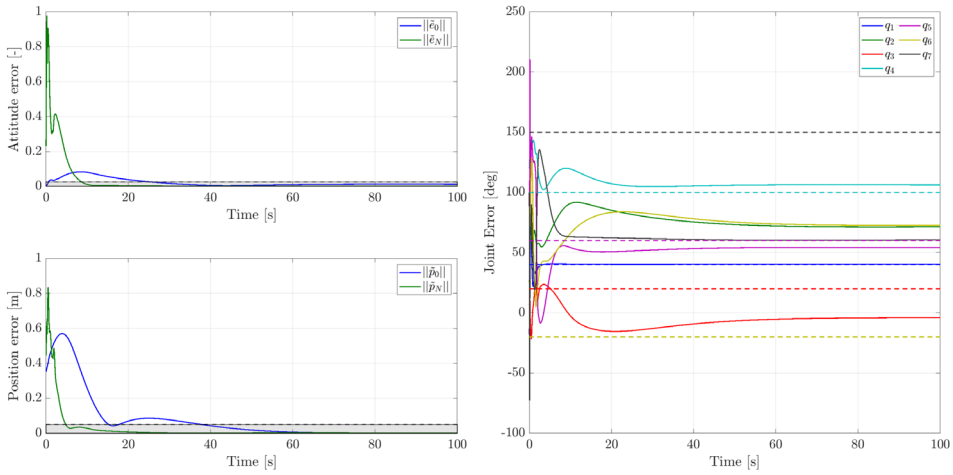

Figure 2: Pose errors of base and end-effector, and joint angles – non-singular ICs.

In the first simulation, the first two tasks are performed, as in both cases the position error norm and the attitude error norm converge below the threshold error (gray area in (Figure 2-left)) while the joint angles do not reach the safe configuration (dashed lines), except for the first joint q_1, that represents the only DoF not used by previous tasks (Figure 2-right).

In the second simulation (Figure 3), the initial conditions (ICs) of the manipulator are modified to make it start the maneuver in a singular configuration. In this way, the third task comes into action and the joints that result in critical positions (q_3 and q_5) reach the safe configuration. Then, the capture is performed nominally, after successfully exiting the singularity. The gray area in the joints plot marks the instant where the capture actually begins.

Conclusions

This paper has extended the hierarchical task-priority algorithm proposed in our previous work [5] to scenarios where the task dimension exceeds the DoFs of the system, while preserving modularity and robustness to kinematic singularities. Simulation results have proven the effectiveness of the proposed control scheme. By leveraging the safe pose at the end of the tasks stack, the system manages to escape from the singularity condition and subsequently performs the capture.

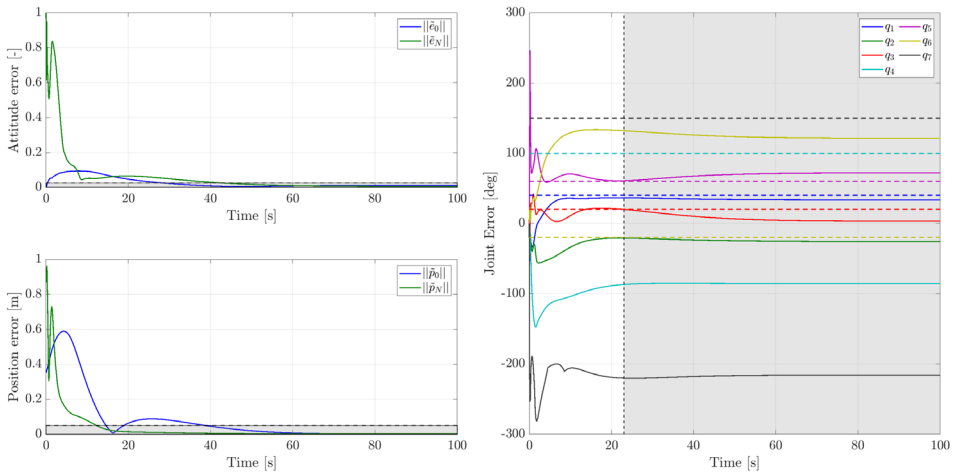

Figure 3: Pose errors of base and end-effector, and joint angles – singular ICs.

Keywords: Angles-Only Relative Navigation, Sliding-Window LSQ, Analytical Batch LSQ

Abstract. Angles-only relative navigation enables autonomous operations with non-cooperative targets such as defunct satellites and orbital debris, which lack the means of communicating with other satellites or ground stations. In fact, this navigation paradigm relies on gathering information about the target only by means of passive cameras mounted on the chaser satellite. The camera provides a pair of bearing angles which are used by the navigation filter to estimate the relative orbit. As of today, sequential filters are typically employed for on-board applications due to their computational efficiency, whereas batch filters are mostly confined to ground-based operations, where their higher computational cost poses no limitation. In this work we revisit the semi-analytic batch least-squares (LSQ) filtering framework with the aim of bringing its on-board implementation closer to practical feasibility. The proposed LSQ filter preserves the analytical propagation required for real-time use while improving accuracy and observability through three key upgrades: (i) a closed-form propagation model including first-order J_2, J_4, J_6 and second-order Keplerian and J_2 effects; (ii) an exact measurement model with improved mean-to-osculating transformation; (iii) an efficient circular-buffer configuration. The proposed filter is tested in a high-fidelity 750 km sun-synchronous orbit simulation with realistic perturbations and is shown to achieve accurate relative state estimation without manoeuvre-induced observability.

Introduction

Angles-only relative navigation is a key technology for autonomous operations with non-cooperative resident space objects such as defunct satellites and debris lacking GNSS receivers, inter-satellite links or cooperative beacons. Missions such as on-orbit inspection, servicing, end-of-life disposal and active debris removal [1, 2, 3] must therefore rely on navigation systems capable of estimating relative states solely from onboard passive optical sensors [4]. Cameras are ideal due to their availability, low power, light weight and wide dynamic range. While sequential filters (extended/unscented Kalman filter) are the standard choice for onboard implementation [5], batch least-squares (LSQ) filtering may offer a robust complementary approach for onboard state estimation. Although traditionally used for precise ground-based orbit determination, an analytical formulation with a sliding observation window might enable computationally efficient onboard use, as suggested (but not demonstrated) by Ardaens [6]. In fact, these filters could serve as: (i) Cross-check mechanisms to reduce/eliminate outliers before they are used by the sequential filter. (ii) Re-initialisation in the event of filter divergence. (iii) Entirely novel hybrid batch-sequential architectures. This work extends the analytical LSQ framework by Gaias et al. [7], which used bearing angles and relative orbital elements (ROE) as states. Their inclusion of J_2 yielded weak observability compared to the completely unobservable Keplerian case studied in [8]. However, their relatively benign scenario characterised by high altitude, negligible differential drag (DD) and simplified propagation and measurement models limits applicability and estimation accuracy.

Materials Research Proceedings 69 (2026) 891-896 https://doi.org/10.21741/9781644904251-157

Specifically, the J_2 model did not include effects induced by non-zero semimajor-axis. Moreover, the first-order mapping from relative orbital elements and line of sight (LoS) omitted the orbital curvature and mean-to-osculating transformations, reducing accuracy and observability. Nonetheless, the fully analytical nature proposed in [7] made the algorithm highly efficient. Here, the manoeuvre-free phase presented in [7] is revisited with the aim of improving estimation accuracy and observability while preserving analytical tractability. The proposed LSQ-based filter introduces the following improvements: (i) Enhanced propagation: analytical model including first-order J_2, J_4, J_6 and second-order Keplerian and J_2 effects [9]. (ii) Improved measurement: exact non-linear LoS transformation coupled with a refined mean-to-osculating transformation [10]. (iii) Circular-buffer implementation: the data batch is implemented as a sliding window, sized according to [11] and managed as a circular buffer to reduce memory operations. The LSQ filter is validated in a model-in-the-loop setup using a high-fidelity orbital simulator that accounts for higher-order gravity, third body effects, solar radiation pressure, and atmospheric drag. Camera noise, illumination, and shadowing are excluded in this first analysis and will be addressed in future work. The test scenario, consistent with [7], is inspired by the PRISMA mission and uses a 750 km sun-synchronous orbit. No manoeuvres is executed to avoid any observability enhancement. Preliminary results demonstrate good filter performance and a notable improvement in estimation accuracy compared to typical TLE-level initialization.

Propagation Model

Quasi-non-singular ROE provide an intuitive parametrisation of the relative motion of the target ("T") with respect to the chaser ("C"). Recalling the classical orbital elements (OE) vector $\boldsymbol{\alpha}=[a, e, i, \Omega, \omega, M]^\top$, the ROE are as a non-linear combination of the of $\boldsymbol{\alpha}_C$ and $\boldsymbol{\alpha}_T$ [9]. In particular, the dimensional (quasi-non-singular) ROE are defined as $a\delta\boldsymbol{\alpha} = a_C[\delta a, \delta\lambda, \delta e_x, \delta e_y, \delta i_x, \delta i_y]^\top$, where the components denote relative semi-major axis, mean relative longitude, eccentricity and inclination vectors. This representation gives a geometrically meaningful description of the motion in the Radial-Transversal-Normal frame (R) and separates the weakly observable range analogue $a\delta\lambda$ from the strongly observable components [7]. The GCL model [9] is selected for the LSQ filter since it accurately propagates $a\delta\boldsymbol{\alpha}(t_0)$ at initial time t_0 to time t, accounting for J_2, J_4, J_6, and second-order Keplerian and J_2 effects (DD is not modelled). The manoeuvre-free, analytical propagation model is:

$$a\delta\boldsymbol{\alpha}(t) = \mathbf{F}_{\mathrm{GCL}}(t_0, t, a\delta\boldsymbol{\alpha}(t_0), \boldsymbol{\alpha}(t_0)). \quad (1)$$

Measurement Model

In angles-only navigation, the chaser perceives the target solely through the bearing angles vector composed by a pair of azimuth (α) and elevation (ϵ) angles measured in the camera frame. In this article we follow the convention used in [5]. The camera frame (C) is oriented in anti-flight direction as in [7]. At time t, the navigation subsystem knows: the current knowledge of the ROE (from the filter), the chaser absolute OE (from external sources, e.g., GNSS) and the orientation of the inertial frame (I) relative to the camera ${}^{\mathrm{C}}\mathbf{R}_{\mathrm{I}}(t)$. The LoS vector is thus obtained using the exact fully non-linear transformation reported in [10]. By then the applying the definition of bearing angles, the resulting complete non-linear sequence of operations defines the modelled measurement:

$$\mathbf{y}(t) = [\alpha(t), \epsilon(t)]^\top = \mathbf{h}_{\mathrm{NL}}(a\delta\boldsymbol{\alpha}(t), \boldsymbol{\alpha}_C(t), {}^{\mathrm{C}}\mathbf{R}_{\mathrm{I}}(t)). \quad (2)$$

Circular Buffer Batch LSQ

In this work we implement an updated version of batch LSQ filter proposed in [7]. In fact, we use the more accurate [11] GCL analytical propagation model and, instead of relying on the

Materials Research Proceedings 69 (2026) 891-896 https://doi.org/10.21741/9781644904251-157

inaccurate ROE-to-LoS mapping presented in [7], we compute it numerically by taking the Jacobian of Eq. (2) with respect to $a\delta\boldsymbol{\alpha}(t)$. This results in a slightly higher computational cost which is however offset by the much higher accuracy [11]. The LSQ filter operates on a data structure composed of B data-points. The "batch size" B corresponds to the number of data-points available to the filter where the latter are *synchronous* collections of measurement time t_{meas} and corresponding observed bearing angles pair $\mathbf{z}(t_{\text{meas}})$, chaser absolute orbit $\boldsymbol{\alpha}_C(t_{\text{meas}})$ and camera attitude ${}^{\text{C}}\mathbf{R}_{\text{I}}(t_{\text{meas}})$. When a new measurement arrives, it is stored in a fixed, preallocated memory block together with the corresponding timestamp and the chaser absolute OE and camera attitude at that same instant. This operation effectively adds a new data point to the batch. This memory acts as a sliding window managed as a circular buffer, where the write position advances with each new entry and wraps around once the buffer is full, overwriting the oldest data to maintain a constant batch size (defined according to the guidelines of our previous work [11]). This strategy avoids physically shifting data in memory. Instead, only the read position is updated. When this index exceeds the buffer size, it is reset to the initial position. The process repeats, overwriting old data with a first-in, first-out logic. Once the buffer is fully updated, corresponding to a complete non-overlapping shift of the sliding window, the LSQ algorithm is executed using the current buffer contents as input. The selected algorithm also requires an *a priori* estimate of the $a\delta\boldsymbol{\alpha}$ and its associated uncertainty. During the first execution, this information is provided by external sources (e.g., NORAD TLE). For subsequent executions, the *a priori* information is derived from the previous estimate, propagated to the new estimation epoch. Additionally, the LSQ requires specifying the time instant at which the estimate is computed. In this work, it corresponds to the earliest measurement time within the buffer.

Preliminary Results

The LSQ filter undergoes model-in-the-loop validation by means of a high-fidelity simulation tool. The ground-truth simulation is obtained over 20 chaser orbital periods using a Dormand-Prince 5th-order integrator with a fixed step of 10 (s). The dynamical model includes the GGM03S gravity field up to degree and order 30, a cannonball drag model and atmospheric density computed from NRLMSISE-00. Camera noise, illumination and shadowing are excluded in this first analysis and will be addressed in future work. No manoeuvres are simulated to avoid artificial observability enhancement. Coherently with [7], the simulated case study is inspired by the PRISMA mission and uses a 750 km sun-synchronous orbit with LTAN = 9.5 hours for the chaser absolute orbit, whose spacecraft physical parameters can be found in [6]. The ground-truth initial conditions for the relative orbit are taken from Table 6 of [7] which also provide the initial guess for the batch LSQ filter with an error consistent with NORAD TLE accuracy, representing typical knowledge for debris or non-cooperative targets. The same level of uncertainty is the one used by the filter for the first call, in particular we assume that the *a priori* standard deviation vector $\boldsymbol{\sigma}_{a\delta\boldsymbol{\alpha}} = [20, 1000, 100, 100, 100, 100]^{\intercal}$. Moreover, for the successive calls, a minimum uncertainty is always enforced on the propagated uncertainty as suggested by [7]: $\boldsymbol{\sigma}_{a\delta\boldsymbol{\alpha}}{}^{\text{min}} = [3, 50, 10, 10, 10, 10]^{\intercal}$. Each time the circular buffer completes a full update, the LSQ algorithm receives the 120 data-points batch of data and performs the estimate. In this paper, the camera is assumed to output a valid measurement every 250 (s). Thus, with a circular buffer of 120 data-points, the measurements are uniformly spread over almost 5 full chaser orbit periods, as suggested in [11]. The results of the periodic estimation outcome are reported in Fig. 1 for the first run of the least square in Fig. 2 for the last run.

Materials Research Proceedings 69 (2026) 891-896 https://doi.org/10.21741/9781644904251-157

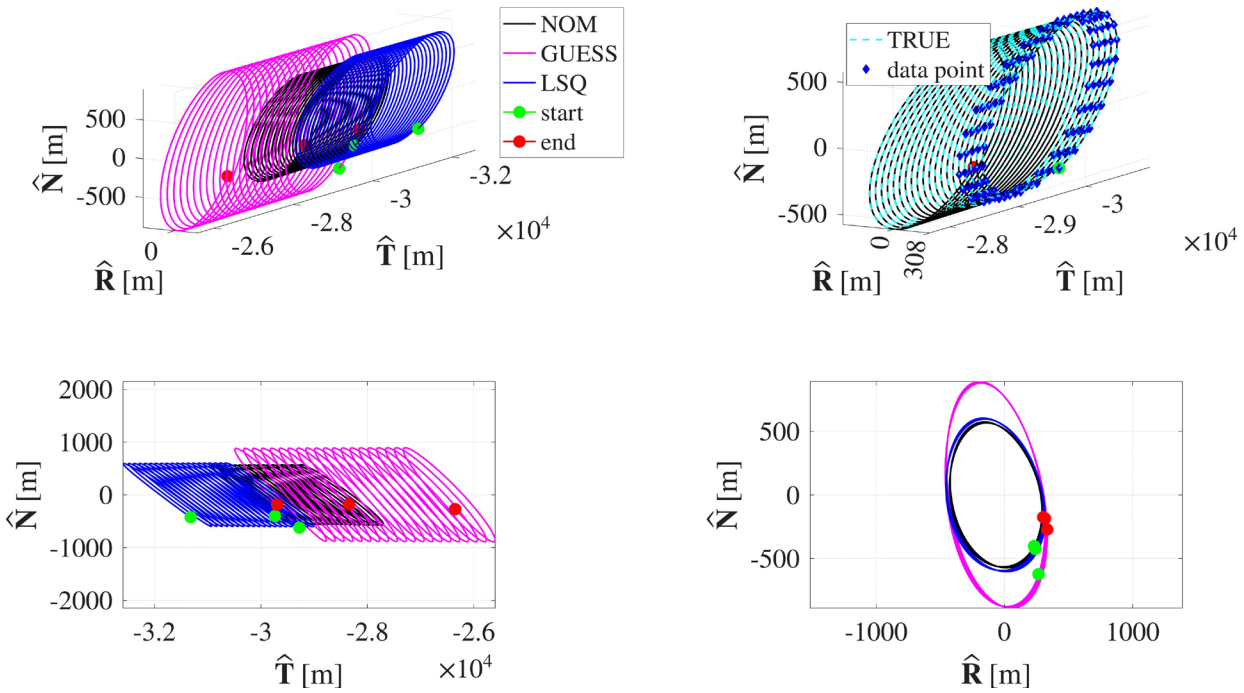

Figure 1: Results of the estimation procedure. Data collected over orbits 1 to 5.

Each figure consists of four plots. The top-left panel shows a 3D view of three relative orbits in the *R* frame, centred on the chaser spacecraft. The nominal (NOM) orbit, in solid black, is obtained by propagating the *true* initial conditions with the analytical model $\mathbf{F}_{\mathrm{GCL}}$. The initial guess (GUESS) orbit, in solid magenta, is propagated from the filter *a priori* guess, while the post-estimation (LSQ) orbit, in solid blue, uses the converged LSQ output. All orbits are propagated with the analytical model of Eq. 1, thus neglecting DD. The green and red markers indicate the start and end points, respectively. The second row presents the TN- and RN-plane projections (bottom-left and bottom-right plots). The top-right panel shows an additional 3D view, where the true (TRUE) orbit, obtained from the high-fidelity simulator, is superimposed on the nominal one with a dashed cyan line. The case study is inspired from PRISMA mission, where the high altitude orbit and almost equivalent ballistic coefficients of the two spacecraft [6] make DD effects negligible. Thus, given the high accuracy of the GCL model, NOM and TRUE orbits are practically equivalent. From the first figure, it is evident that the initial guess (derived from TLE) is significantly improved by the LSQ, despite the large uncertainty on $a\delta\lambda$. Recall that the authors of [7] had to impose an unrealistically small range uncertainty in the LSQ to ensure convergence, which in turn prevented meaningful updates of $a\delta\lambda$. The enhanced observability provided by the improved models allows this component to be accurately estimated.

Materials Research Proceedings 69 (2026) 891-896 https://doi.org/10.21741/9781644904251-157

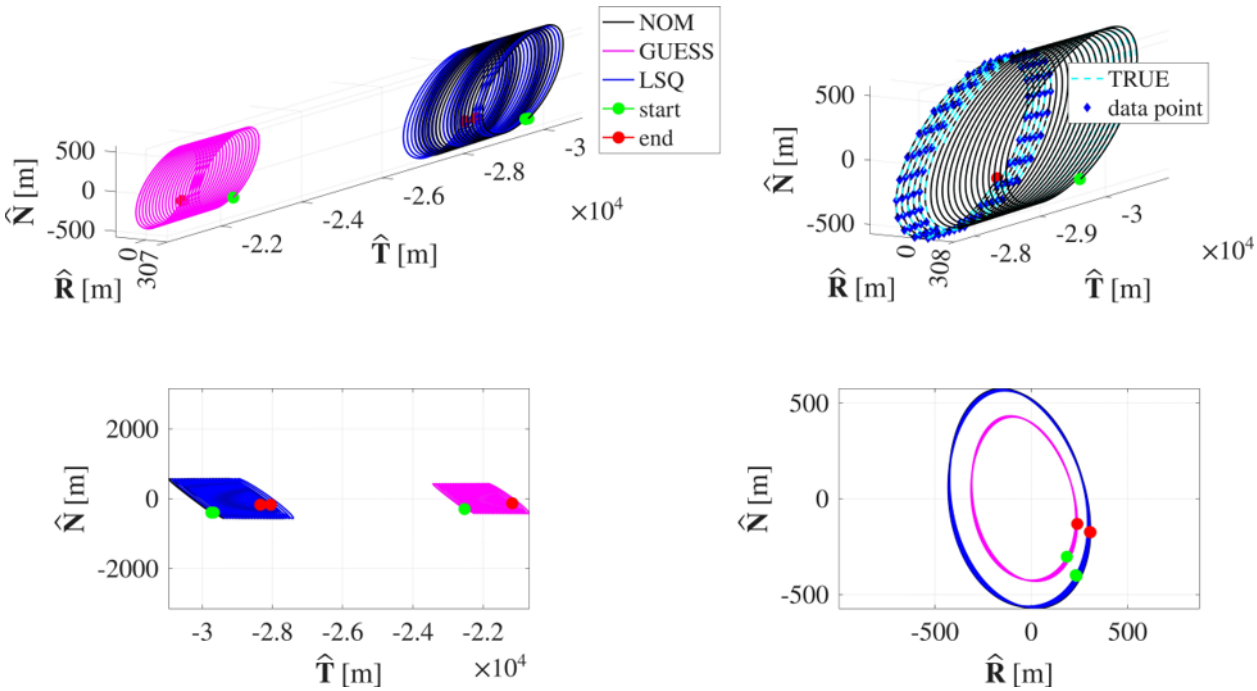

Figure 2: Results of the estimation procedure. Data collected over orbits 16 to 20.

The second figure illustrates two key aspects: first, that the previous LSQ runs degraded the estimate due to weak observability and the necessity to impose $\boldsymbol{\sigma}_{a\delta\boldsymbol{\alpha}}^{\min}$ to prevent filter stagnation [7]. Secondly, the filter successfully recovers and achieves an even more accurate relative orbit estimate. In general, it is observed that progressively running the LSQ as described in this work results in estimates oscillating around the true orbit. This behaviour arises partly from the weak observability of the problem and partly from the need to impose a minimum uncertainty to prevent filter stagnation [7]. In conclusion, this work enhances the batch LSQ framework of [7]. The refined analytical propagation and exact non-linear ROE-to-LoS transformation improve accuracy and observability in manoeuvre-free scenarios, enabling estimation of the weakly observable $a\delta\lambda$. The circular-buffer sliding window further advances the framework toward onboard implementation.

Abstract. In this work the implementation and hardware-in-the-loop testing of a boresight stabilization algorithm, based on the use of magnetorquers as actuators, is presented. The proportional-derivative controller, previously validated by numerical simulations, is here adapted to fixed-point arithmetic and discrete time, and implemented on a Field Programmable Gate Array. Optimal control gains are determined through particle swarm optimization and the resulting algorithm is tested hardware-in-the-loop, with the spacecraft attitude dynamics being simulated using Matlab/Simulink, through a Monte Carlo campaign. The results of this study confirm the suitability and performance of the boresight stabilization algorithm, even within limitations set by real flight hardware. The demonstrated hardware implementation bridges the gap between theoretical control design and embedded execution, offering a robust, low-cost solution for precise satellite pointing using minimal sensors and computational resources.

Introduction

Boresight stabilization represents a fundamental task of attitude control and it consists in pointing the bore axis of an onboard device (i.e. antenna, camera, etc.) towards a prescribed direction. Because the interest is related to the alignment of only one axis of the satellite, reduced attitude control techniques, with the pointing axis corresponding the boresight one, can be preferred to three-axis attitude control, leading to lower computational and energy requirements [1, 2, 3].

For satellites equipped with only magnetorquers as actuators, boresight stabilization towards an inertially-fixed reference direction has been developed and verified through numerical simulations [4, 5]. The resulting algorithm shows a proportional-derivative behavior, ensures stabilization without spinning around the boresight axis, and requires the measurements of the reference direction, the magnetic field induction, and the satellite angular rates, obtained by common on-board devices such as star-trackers, three-axis magnetometer and rate gyro. The result has been later extended to nadir pointing, that also requires determination of the full attitude [7].

In this paper, the effectiveness of the boresight stabilization algorithm developed in Refs [5,6] is verified after implementation on flight-proven hardware, a Artix-7 Field Programmable Gate Array (FPGA). The translation of the control algorithm from Matlab syntax to the Hardware Description Language (HDL) compatible with the use of finite-resolution sensors (i.e. star-tracker, three-axis MEMS magnetometer and gyroscope) requires two major adjustments: the transition from double-precision to fixed-point arithmetic and from variable-step to fixed-step. Indeed, this process produces a loss of accuracy of the attitude control algorithm, resulting in a larger pointing error and oscillation of the steady-state angular rates.

To mitigate accuracy loss, adequate scale factors for the input measurements are identified, which guarantee the input never exceed the maximum representable value while maximizing the accuracy associated to the chosen fixed-point representation. Inasmuch, optimal gains are identified through particle swarm optimization (PSO) performed on Hardware-in-the-Loop (HiL) simulations, where the attitude dynamics is simulated on a host PC and the control algorithm is run onto the FPGA.

Finally, the performance of the algorithm is verified from a HiL Monte Carlo campaign, in which the initial attitude and angular rates are selected randomly within closed intervals. The results show good agreement with those obtained from numerical simulations and suggest the solution is effective to be used on real flight hardware.

Magnetic Boresight Stabilization Algorithm

The magnetic boresight stabilization algorithm can be described as follows. The spacecraft is modeled as a rigid body, and the body-fixed boresight axis is expressed by the constant column matrix of its body coordinates $\boldsymbol{a} \in S = \{\boldsymbol{v} \in R^3 : \boldsymbol{v}^T\boldsymbol{v} = 1\}$. The inertially-fixed reference axis is expressed by the constant column matrix $\boldsymbol{a}_r^i \in S$ of its coordinates along the standard Earth-Centered Inertial (ECI) frame. Let $\boldsymbol{R}$ be the rotation matrix that transforms a column matrix of ECI coordinates into the corresponding column matrix of body coordinates. Thus, the reference axis expressed in body-coordinates is given by $\boldsymbol{a}_r = \boldsymbol{R}\boldsymbol{a}_r^i$. The attitude kinematics is given by $\dot{\boldsymbol{R}} = -\boldsymbol{\omega}^{\times}\boldsymbol{R}$ where $\boldsymbol{\omega}^{\times}$ is a 3×3 skew-symmetric matrix that fulfills $\boldsymbol{\omega}^{\times}\boldsymbol{v} = \boldsymbol{\omega} \times \boldsymbol{v}$ for all $\boldsymbol{v} \in R^3$. The spacecraft attitude dynamics are given by $\boldsymbol{J}\dot{\boldsymbol{\omega}} + \boldsymbol{\omega} \times (\boldsymbol{J}\boldsymbol{\omega}) = \boldsymbol{T}_c$ where $\boldsymbol{J}$ is the spacecraft inertia matrix, $\boldsymbol{T}_c$ is the column matrix of body coordinates of the control torque. Disturbance torques are neglected throughout this work. The control torque is generated by three magnetorquers aligned with three orthogonal axes. Thus, it is given by $\boldsymbol{T}_c = \boldsymbol{m}_c \times \boldsymbol{b}$ where $\boldsymbol{m}_c$ is the column matrix of the body coordinates of the control magnetic dipole moment, and $\boldsymbol{b}$ is the column matrix of body coordinates of the geomagnetic induction at the spacecraft. The boresight stabilization law employed in this work is of the Proportional-Derivative (PD) type [5] and is given by

$$\boldsymbol{m}_c = \boldsymbol{b} \times \left[k_p(\boldsymbol{a} \times \boldsymbol{a}_r) - k_d\boldsymbol{\omega}\right] \tag{1}$$

where k_p and k_d are positive scalar gains. Its effectiveness is first validated by running numerical simulations employing a double precision variable-step solver. Tables 1 and 2 report the values of the parameters used in the simulations.

Table 1: Spacecraft parameters

$\boldsymbol{J}$ [kg m^2]	$m_{cx_{max}}$ [A m^2]	$m_{cy_{max}} = m_{cz_{max}}$ [A m^2]
diag ($9.2\cdot10^{-3}$ $4.44\cdot10^{-2}$ $4.486\cdot10^{-2}$)	0.097	0.151

Table 2: Orbital and boresight stabilization parameters

a [km]	e	i [deg]	Ω [deg]	$\boldsymbol{a} = \boldsymbol{a}_{ri}$	k_p	k_d
6971	0	98	235	[1 0 0]^T	218	$1.88\cdot10^5$

The spacecraft initial attitude, its initial argument of latitude, the initial angle of rotation of the Earth are all selected randomly with a uniform distribution over all of their possible values. The initial angular velocity is selected randomly with a uniform distribution over $\|\boldsymbol{\omega}(0)\| \leq 3$ deg/s. The IGRF model [8] is adopted for geomagnetic induction. A Monte Carlo (MC) campaign is carried out by running 30 simulations. The 30 time behaviors of the pointing error and of the norm

Materials Research Proceedings 69 (2026) 897-901 https://doi.org/10.21741/9781644904251-158

of the angular velocity are displayed in Fig. 1. They show that in all 30 simulation runs the law in Eq. (1) achieves boresight stabilization without spinning with very good accuracy.

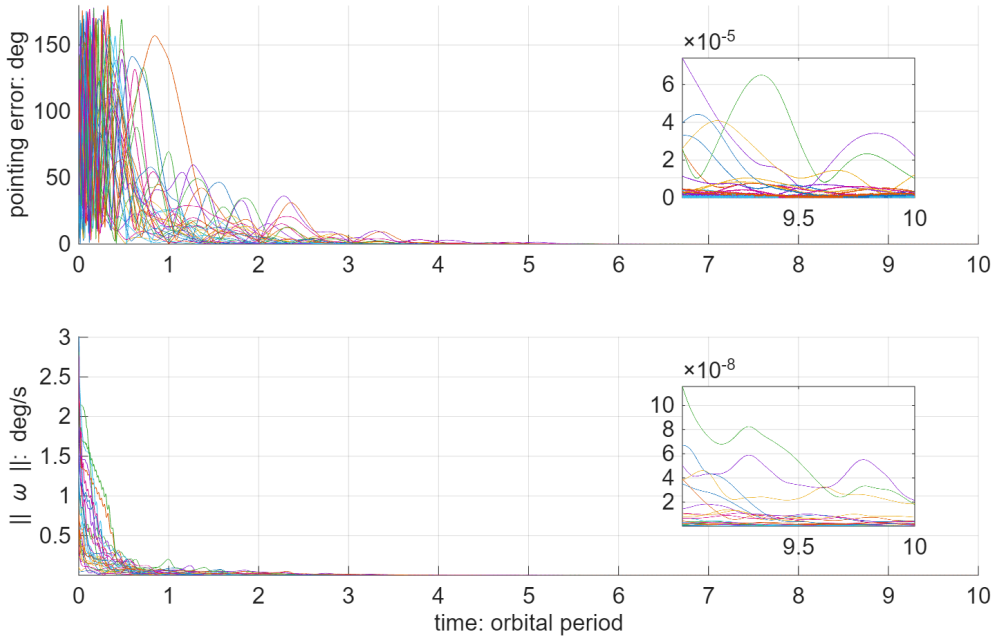

Figure 1: Time behaviors of pointing error and norm of angular velocity from the MC numerical campaign with double-precision variable-step solver.

Hardware-in-the-Loop Implementation and Testing

To validate the practical feasibility of the control law, the algorithm described in Eq. 1 was implemented on an AMD Artyx-7 FPGA and tested in a HiL configuration. This translation from the double-precision variable-step environment used for numerical simulation to a fixed-step fixed-point hardware implementation introduces several challenges that must be addressed.

First, the controller must operate at a fixed sample time T_s, which is chosen as 1 s for the HiL implementation. Additionally, the optimal behavior of FPGAs occurs under fixed-point operations, rather than floating-point operations. This conversion introduces quantization errors and carries the risk of numerical overflow or underflow. To overcome this, the input measurements (reference direction in body coordinates a_r, geomagnetic induction b, and angular velocity ω) and all intermediate variables were carefully scaled. The selection of these scale factors is a trade-off between maximizing the numerical precision (using the full fractional part of the fixed-point number) and maintaining sufficient integer part to prevent saturation during orbital variations or attitude maneuvers. To find the optimal gains for the controller, a PSO campaign has been conducted. The optimal parameters for the controller are indicated in Table 2.

Using the optimal control parameters as the reference, the fixed-point controller was designed. It was decided to use a 20-bit signed fixed-point arithmetic, with a fraction length of 16-bit to get the best accuracy as well as preventing the overflow. The units of the controller input parameters are subsequently arranged according to this fixed-point representation. Table 3 shows the unit conversions that are conducted to get the optimal controller input representation.

Materials Research Proceedings 69 (2026) 897-901 https://doi.org/10.21741/9781644904251-158

Table 3: Controller input ranges and conversions for fixed-point implementation

Variable	Numerical simulations	HiL simulations
Angular velocity $\boldsymbol{\omega}$	[-0.052, 0.052] rad/s	[-3 3] deg/s
Geomagnetic Induction	$[-5\ 5]\cdot 10^{-5}$ T	[-0.05, 0.05] mT

To validate the performance of the final fixed-point controller, the same Monte Carlo campaign was repeated using the HiL setup. The initial conditions for attitude and angular velocity were randomized identically to the double-precision variable-step numerical campaign. The results are presented in Fig. 2.

As shown in Fig. 2, the HiL results demonstrate the successful boresight stabilization in all 30 cases, showing strong agreement with the double-precision simulations in Fig. 1. A closer look to the steady-state performance (inset plots in Fig. 2) shows the expected effects of the fixed-point arithmetic. The pointing error stays in a bounded ``bouncing" region, with an amplitude of approximately 2 deg. Similarly, the norm of the angular velocity stays in a region with an amplitude of approximately $3\cdot 10^{-3}$ deg/s, indicating a minimal steady-state spin. This behavior is a direct and acceptable consequence of the quantization of sensor inputs and control outputs, and the performance remains well within acceptable limits for many nanosatellite missions.

To compare the pointing accuracy achieved in numerical simulations with HiL simulations, Table 4 reports the statistics of the maximum pointing error Θ_{max} and of the maximum norm of the angular velocity $|\omega|_{max}$ both in steady-state.

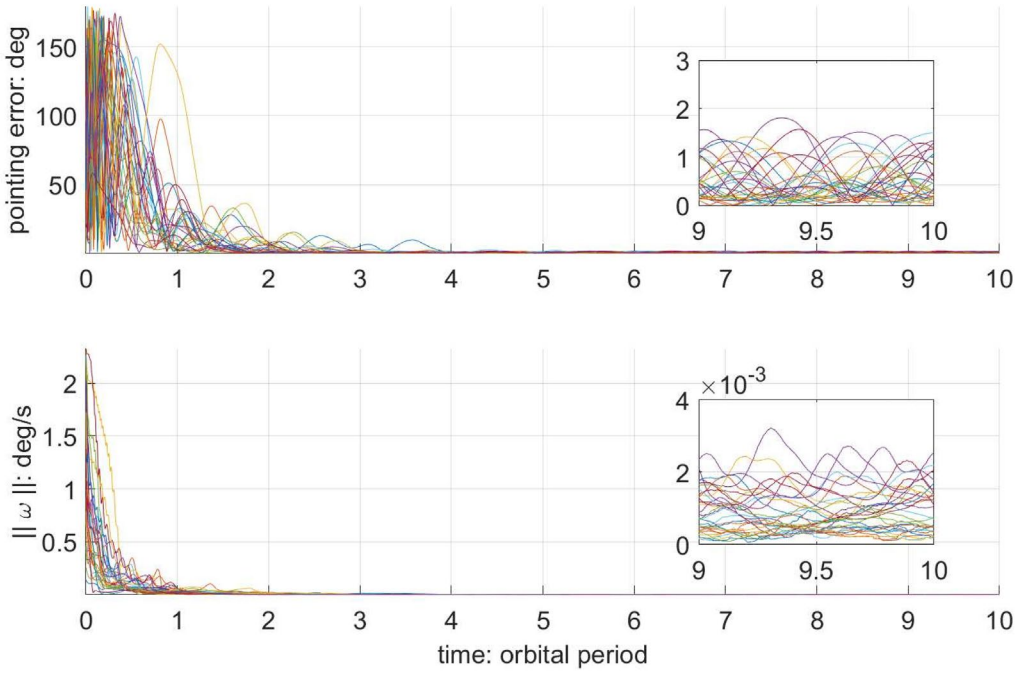

Figure 2: Time behaviors of pointing error and norm of angular velocity from the HiL MC campaign with 20-bit wordlength and 16-bit decimal resolution with fixed 1s time step.

Table 4: Statistics from the two MC campaigns ($\boldsymbol{\mu}(\boldsymbol{v})$ and $\boldsymbol{\sigma}(\boldsymbol{v})$ denote the mean and standard deviation of $\boldsymbol{v}$ respectively).

	Numerical	HiL	Unit
$\mu(\Theta_{max})$	$1.24 \cdot 10^{-5}$	0.94	deg
$\sigma(\Theta_{max})$	$1.95 \cdot 10^{-5}$	0.46	deg
$\mu(\|\omega\|_{max})$	$1.55 \cdot 10^{-8}$	$1.45 \cdot 10^{-3}$	deg/s
$\sigma(\|\omega\|_{max})$	$2.63 \cdot 10^{-8}$	$0.77 \cdot 10^{-3}$	deg/s

Discussion of the Results and Conclusions

The HiL experiments successfully demonstrated the capability of the proposed attitude control architecture to operate under realistic timing and quantization effects. The implemented fixed-point design maintained stable and accurate control performance within the expected operation, showing the suitability of the chosen numerical representation and scaling strategy. The results confirmed that the effects of fixed-step and fixed-point constraints remained acceptable for the test cases. Monte Carlo simulations performed in the HiL environment strengthened the controller's robustness against variations in initial conditions.

Overall, the obtained results verify the practical feasibility of the developed controller for real-time implementation on embedded hardware. The study emphasizes the importance of the fixed-point methodology, ensuring that the transition from simulation to hardware remains reliable. Future work will focus on extending the current HiL setup toward a full hardware-based validation environment. This will involve integrating a real magnetorquer and magnetometer within a Helmholtz cage to to test the behavior under controlled magnetic field, while the spacecraft simulator will be mounted on an air-bearing platform to emulate the friction-free rotational motion.

Keywords: On-Orbit Inspection, Reinforcement Learning, Task Scheduling

Abstract. The increasing demand for autonomous space operations motivates lightweight AI-based approaches to Resident Space Objects (RSO) inspection, where spacecraft must balance trajectory optimization with strict onboard resource limitations in real-time. This paper presents a Deep Q-Network (DQN) for single-agent RSO inspection, combining fuel-efficient orbital exploration with battery management and data down-linking in a unified control policy. The environment features a discrete set of relative orbits, stochastic resource dynamics, and a closed-loop transfer method based on Relative Orbital Elements (ROEs). Results show how, across multiple training runs, the agent learns to accomplish the mission with a low number of transfers while efficiently handling battery and data processes.

Introduction

Inspection missions—particularly those targeting high altitude orbits—require spacecraft to autonomously manage multiple mission phases over extended durations. These missions involve coordinating several, competing objectives: maximizing information gain through optimal orbital path planning while preserving onboard resources for future operations. Resource management is crucial to prevent premature satellite failures and the resulting increase in space debris. This work specifically focuses on three critical constraints: fuel for orbital transfers, battery energy for sustaining operations and communications, and data storage capacity, which must be periodically cleared to enable near real-time data availability for ground stakeholders. Balancing these demands from ground stations in real-time is evidently unfeasible. In this paper, we do not address the problem of selecting the optimal set of orbits for inspection; instead, we assume a precomputed set. Unlike existing state-of-the-art approaches for on-orbit inspection [1-3], our primary focus is on the task allocation formulation rather than on optimizing the path to maximize information gain.

The main challenge in implementing scheduling methods on a spacecraft lies in computational complexity [4]. Being an NP-hard problem, classical optimization is impractical in high-variance, large-scale scenarios [5]. Therefore, this paper investigates AI-based approaches, focusing on Reinforcement Learning (RL) for real-time inspection mission planning. RL has shown promise in space applications such as Earth observation [6] and rendezvous [7], demonstrating its ability to learn complex, multi-objective policies without explicit mathematical models. This positions RL as a lightweight, onboard-deployable decision-making framework that can match the performance of traditional methods.

Follows a description of the system software architecture, comprehending the inspection environment simulator, the neural network acting on it, and the RL training algorithm. Then, we show the numerical results obtained in our training campaign and an exemplary simulation of the

trained system. At the end of the manuscript, we draw summary conclusions based on our research work.

Reinforcement Learning Framework

We assume the close-distance inspection of a target orbiting circularly around the Earth, to meet the conditions imposed by the Hill-Clohessy-Wiltshire (HCW) relative frame [8] and thus relying on a well-established physical plant. We consider a fixed set of N orbits, assuming they were previously selected as suitable candidates for collecting image data around the target (see, for instance, [1]). The proposed single-agent inspection framework is formulated as a Markov Decision Process (MDP) and optimized via maximization of a *Reward* signal. An MDP can be interpreted as a sequential control loop running at fixed frequency, where an *agent* takes *decisions* based on feedback from the *environment*. The environment simulates the evolution of the surroundings and the agent's internal status (battery and data buffer) in response to actions.

Agent: The neural network is a Multi-Layer Perceptron (MLP) with four layers. The input layer matches the dimension of the observed state, followed by two hidden layers of 256 neurons each with ReLU activations. The output layer contains one neuron per action. Since the agent aims to explore the target from multiple viewing angles, it must perform an orbital transfer once the current relative orbit has been sufficiently explored. Moreover, to preserve the battery and data buffer states, the satellite can enter *Recharge* and *Downlink* modes, which are modeled here at a high level as a reset of the memory state and a fixed amount of battery recharged within a single timestep. We decided to keep a discrete action space by considering M fixed anomalies on each relative orbit as possible landing points of a transfer action. This way, we use an integer action set $\mathcal{A}$ that encloses both *inspection* and *transfer* actions as:

$$\mathcal{A} = \left\{ \underbrace{1, \dots,}_{\text{transfer}} \underbrace{(i-1) \times M + 1, \dots, i \times M,}_{\text{inspection arc}} \underbrace{i \times M + 1, \dots,}_{\text{transfer}} \underbrace{N \times M + 1,}_{\text{recharge}} \underbrace{N \times M + 2}_{\text{down-link}} \right\} \tag{1}$$

where $i \in \{1, \dots, N\}$ is the index of the currently visited orbit, passed as input to the agent.

Environment. Given the current anomaly ν on the current orbit i, the state space is composed of:

$$\mathcal{S} = \left\{ \underbrace{i, \nu}_{\text{Position onto current orbit}}, \underbrace{b, d}_{\text{Battery and Data level} \in [0,1]}, \underbrace{g_1, \dots, g_N}_{\text{Inspection Level} \in [0,1]} \right\} \tag{2}$$

with g the inspection level, namely the fraction of an orbit that has been explored. The objective of the mission is to maximize the inspection level, ideally $g_j = 1 \; \forall j \in \{1, \dots, N\}$. The action (1) taken by the agent modify the system's state (2) differently. While the transfer action moves the satellite to the given relative orbit at the given anomaly, the inspection arc results in a simple on-orbit propagation regardless of the chosen anomaly. The inspection level of the visited orbit is increased by a quantity μ, here modeled as a Gaussian variable to account for orbit and target heterogeneity. The data buffer is increased accordingly. The battery decay also follows a gaussian dynamics with a mean parameter $\beta_{a \in \mathcal{A}}$, whose value depends on the action taken. Both battery and data state are clipped to the interval [0,1].

Reward. The designed reward function (Table 1) seeks to achieve the full inspection of the relative orbits while minimizing the fuel expenditure Δv and ensuring the energy and data maintenance.

Materials Research Proceedings 69 (2026) 902-907 https://doi.org/10.21741/9781644904251-159

Table 1: Reward Function

Description	Value
Maneuver cost proportional to Δv	$-500 \cdot \Delta v$
Battery penalties	$\begin{cases} -5 & b < b_{th} \rightarrow \text{(battery threshold)} \\ -1 & a = N \times M + 1 \text{ (recharge)} \end{cases}$
Positive feedback for inspection	0.5
Full Inspection	$100 \quad \text{if } g_j = 1 \; \forall j \in \{1, \dots, N\}$

When a transfer occurs, the consumption Δv is computed through a closed-loop Artificial Potential Field (APF) controller [9], which stands on the Relative Orbital Elements (ROEs) theory [10].

Training Algorithm. We opted for the Deep Q-Network (DQN) [11] for its suitability to discrete action spaces. DQN approximates the cumulative discounted reward function for each action in a given state. Actions are selected using an ϵ-greedy policy, where ϵ decays from 1.0 to 0.01 over 4 million training epochs, trading off exploitation of learned strategies vs exploration of novel ones. Agent-environment interactions are stored in a replay buffer of size 100,000, and mini-batches of 256 samples are drawn to compute the loss, which is optimized with Adam (learning rate 10^{-4}). Training stability is ensured by maintaining a target network, updated every 3,000 steps.

Numerical Results

The architecture was tested for a target in a circular orbit around Earth with a mean motion of $n = 5 \times 10^{-4}$ s^{-1} (corresponding to a period of $T \simeq 200$ min and a semi-major axis of 11,600 km), considering the passive relative orbits shown on the left-hand side of Fig.1. The training results are also depicted on the right-hand side of Fig.1. Fig. 2 presents four different timestamps of the simulation, showing the trajectory of the satellite tasked with observing the debris from each orbit. Recharge and downlink operations are also indicated, along with the inspection level on the left and the amount of information gathered from each orbit. Fig. 3 shows the remaining battery and data storage levels throughout the inspection, as well as the ΔV expenditure. During the complete simulation, which lasts approximately 20 hours, the satellite performs three recharging operations and three data downlinks. It successfully avoids critical battery conditions, with the minimum battery level reaching around 30%, while the maximum data storage utilization reaches 94%.

Summary

This study represents an initial step toward developing energy-aware strategies for autonomous on-orbit inspection. In this preliminary scenario, the satellite successfully manages its resources while performing inspection tasks. Future work will focus on refining the modeling of resource dynamics and improving the inspection framework.

Abstract. Close-range inspection of non-cooperative satellites is essential to assess their condition and support potential servicing or removal operations. This work considers targets with fixed attitude in the Local-Vertical Local-Horizontal frame, leveraging relative Clohessy-Wiltshire dynamics and six Relative Orbital Elements (ROEs). The best candidate orbits were found by means of a density-based clustering approach and assigned using a distributed best-response scheme balancing information gain and maneuver cost.

Introduction

The growing population of inactive satellites and orbital debris has made On-Orbit Servicing (OOS) and Space Situational Awareness (SSA) key priorities in modern space operations [1,2]. OOS aims to extend satellite lifetimes and support debris mitigation through actions such as refueling, repairing, or controlled disposal, while SSA focuses on monitoring and characterizing Resident Space Objects (RSOs). In both contexts, close-range inspection plays a fundamental role, enabling detailed observation and assessment of an RSO's condition to support servicing or removal activities. Both single- and multi-agent inspection strategies have been explored, with the latter offering improved efficiency, coverage, and robustness, though at the cost of greater coordination complexity. Multi-agent inspection can be approached through fixed formations, where each spacecraft maintains a predefined geometry, or via optimization-based frameworks that maximize information gain. In [3], optimal trajectories are obtained through continuous-time optimal control solved with pseudospectral methods, while [4] adopts a hierarchical scheme combining offline orbit selection with distributed onboard attitude planning. Similarly, in [5], satellites transition between intersecting orbits for more efficient target coverage. To enable real-time execution, such guidance strategies must remain computationally lightweight. This work addresses this need by considering the case of a target with a fixed attitude in the Hill frame. Exploiting natural relative dynamics, the inspection problem is reformulated geometrically using Relative Orbital Elements (ROEs) [6], and best orbits are identified through Density-based Spatial Clustering of Applications with Noise (DBSCAN) [7].

Problem Formulation

We consider an RSO orbiting the Earth and a group of N satellites assigned to perform its on-orbit inspection. The motion of an inspector satellite relative to the target is expressed in the Hill frame centered at the target's center of mass. Under the assumption of a circular reference orbit, the relative dynamics follow the well-known Clohessy–Wiltshire equations:

$$\ddot{x} - 3n^2x - 2n\dot{y} = 0, \quad \ddot{y} + 2n\dot{x} = 0, \quad \ddot{z} + n^2z = 0 \tag{1}$$

Content from this work may be used under the terms of the Creative Commons Attribution 3.0 license. Any further distribution of this work must maintain attribution to the author(s) and the title of the work, journal citation and DOI. Published under license by Materials Research Forum LLC.

Materials Research Proceedings 69 (2026) 908-912 https://doi.org/10.21741/9781644904251-160

where n is the mean motion of the target, and the relative position and velocity of the inspector are given by the vectors $[x, y, z]^T$ and $[\dot{x}, \dot{y}, \dot{z}]^T$ respectively. The free solutions of these linear dynamics can be written as:

$$x(t) = x_r - \frac{1}{2}a_r \cos E_r(t), \quad y(t) = y_r + a_r \sin E_r(t), \quad z(t) = A_z \sin(E_r(t) + \gamma) \tag{2}$$

where the ROE vector $\rho = [x_r, y_r, a_r, E_r, A_z, \gamma]$ uniquely defines the geometry and phase of the relative orbit, and provides a direct mapping between orbital parameters and Cartesian coordinates. The target's surface is discretized into M Points Of interest (POIs), each associated with a normal vector $\mathbf{n}_j$. Each POI has an inspection level $I_j \in 0,1$, where $I_j = 1$ if the point has been successfully observed and $I_j = 0$ otherwise. The global inspection level is defined as the fraction of observed points over the total number of POIs:

$$I = \frac{1}{M}\sum_{j=1}^{M} I_j \tag{3}$$

The inspection problem then consists of planning the motion of the inspecting satellites, selecting the most suitable relative orbits to maximize I, aiming to achieve complete coverage ($I = 1$) in the shortest possible time, while minimizing the propellant required for maneuvering.

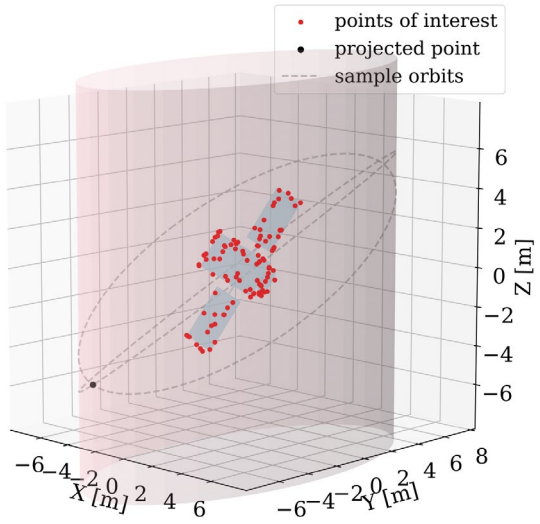

Figure 1: An illustrative satellite is selected as the inspection target. The red surface represents the space of all orbits, with two example orbits passing through a POI projected onto it.

In order to reach a geometric formulation of the problem, we restrict the set of admissible orbits to concentric ones with a fixed radial amplitude a_r. The family of all such trajectories spans a three-dimensional region $S \subset \mathbb{R}^3$, which corresponds to the lateral surface of a prism with elliptical base, as illustrated in Fig. 1. To evaluate which orbits provide the most information gain, each POI on the target surface is projected onto S along the direction of its surface normal $\mathbf{n}_j$. The intersection of this ray with the surface S defines the projected point $p_j \in S$. The resulting set of projected points makes it possible to identify candidate orbits from which the visibility of the largest number of POIs can be achieved. The remaining ROEs of the orbits passing through a projected point $p_j = (x_p, y_p, z_p)$ can be expressed as functions of its coordinates. In particular, the in-plane anomaly and the out-of-plane amplitude are given by:

$$E_r = \arctan\left(\frac{y_p}{-2x_p}\right), \quad A_z = \frac{z_p}{\sin(E_r+\gamma)} \tag{4}$$

Materials Research Proceedings 69 (2026) 908-912 https://doi.org/10.21741/9781644904251-160

Each projected POI thus defines a curve in the (A_z, γ) parameter space. The intersections of these curves correspond to orbits from which multiple POIs can be simultaneously observed. To identify the most informative orbits, i.e., those that enable the observation of the largest number of target points, we need to identidy the most dense regions in the (A_z, γ) space while discarding isolated or sparsely distributed points, with a density-based cluster algorithm. This allows us to extract a reduced set containing only the most effective orbits. The output of the clustering method is a set of K candidate orbits, each associated with m_k observable points, with $k = 1, \dots, K$, providing a guaranteed level of coverage. Then the orbit assignment is performed, taking into account the propellant required to reach the desired orbit, assuming a point-to-orbit ΔV-optimal bang-bang maneuver. This allocation problem can be modeled as a non-cooperative game, where each satellite independently selects an orbit from the available set based on its own knowledge. The decision process is governed by an individual utility function that balances inspection performance and fuel expenditure:

$$u_i = m_k - \lambda \Delta V_{ik}, \quad i = 1, \dots, N \tag{5}$$

where m_k is the number of observable points from orbit k, ΔV_{ik} is the required transfer cost for agent i, and λ is a weighting factor defining their trade-off. Each satellite updates its choice via Best Response Dynamics [8] to maximize its utility given the others' decisions. The process iterates until a Nash equilibrium is reached, where no agent can further improve its utility. Afterward, each satellite moves to its assigned orbit, performs the inspection, and broadcasts its observations to update the shared global map once all observable points have been covered.

Results

We now present the results of the proposed method. The algorithm was implemented in Python and tested in a realistic inspection scenario using an illustrative spacecraft model. The STL file was imported with a random attitude, and $M = 100$ surface POIs were uniformly sampled, as shown in Fig. 1.

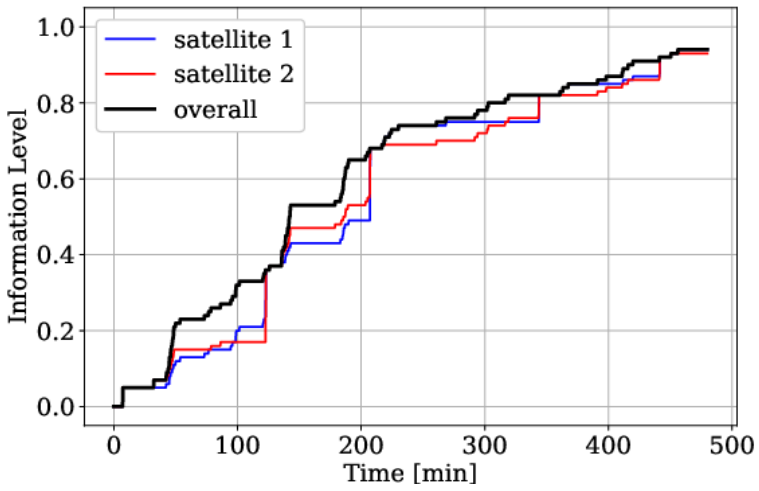

Figure 2: Inspection Level over time of both satellites and the overall level.

The algorithm was validated with $N = 2$ agents over a simulation time of $T_{sim} = 540$ min. As shown in Fig. 2, the system achieves 95% surface coverage. The two satellites inspect distinct POIs and update their information four times (at approximately 120, 200, 350, and 450 min), changing orbit after completing the observation of their current targets.

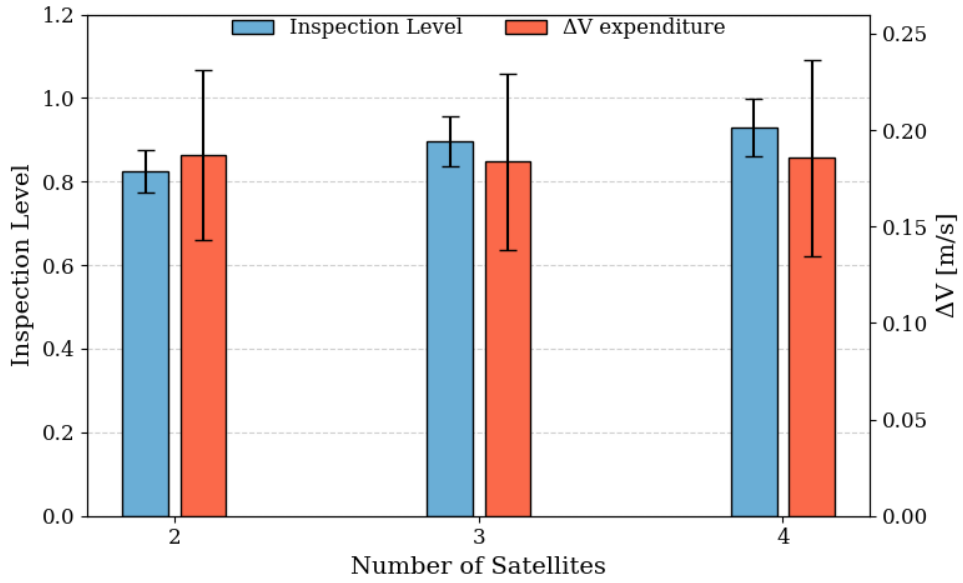

Figure 3: Mean and standard deviation of final inspection level reached and total ΔV expenditure for each configuration with 2, 3, and 4 satellites.

The algorithm was further validated through a Monte Carlo simulation with 2, 3, and 4 agents, demonstrating its scalability. For each case, 100 runs were performed with random initial agent states, spacecraft attitudes, and surface sampling. Each simulation lasted $T_{sim} = 360$ min. Fig. 3 reports the mean and standard deviation of the final overall inspection level and total ΔV expenditure. As expected, the inspection level increases with the number of agents, reaching nearly complete coverage with 4 satellites, while the ΔV remains approximately constant since each agent inspects a similar number of orbits within the same time window.

Summary

This work presents an initial framework for multi-agent satellite inspection that exploits clustering in the ROEs space to identify and select the most informative orbits. The resulting set of orbits effectively guides the agents toward configurations that ensure high levels of inspection coverage of the target. Future extensions will focus on refining the information gain function to account for attitude dynamics and on integrating a closed-loop controller.

Keywords: Flight Dynamics, Terminal Phases, Simulation, Crosswind, Landing Gear, Nonlinear Aerodynamics, Ground Effect

Abstract. Due to ground proximity and limited time to react to possible issues, take-off and landing maneuvers represent the most critical conditions within the envelope of any airplane. In this context, accurate modeling of terminal maneuvers is essential to evaluate performance, identify possible issues, and assess the safety integrity of a design solution. This work focuses on the development of a nonlinear flight simulator capable of handling terminal maneuvers, including the impact of wind and ground effect on the aerodynamic characteristics of the aircraft. The proposed simulator is employed in different landing scenarios including crosswind conditions for evaluating the maximum wing-tip clearance.

Introduction

Terminal maneuvers represent the most critical conditions within an aircraft flight envelope. In the event of unexpected occurrences, pilots are given only a few seconds to assess the situation and respond appropriately, because of ground proximity [1, 2]. For this reason, accurate modeling of take-off, landing, and the associated airborne phases is essential to analyze the aircraft behavior in these conditions and identify potential safety concerns. This work focuses on the development of a nonlinear flight simulator tailored to terminal maneuvers, capable of handling both take-off and landing, as well as all airborne flight conditions. The simulator also accounts for the impact of wind and ground effect on the aerodynamic characteristics of the aircraft.

Although simple simulation methods relying on lumped elements are sufficient for many preliminary aircraft design applications to provide a general understanding of aircraft behavior during take-off and landing [3, 4, 5], a more sophisticated modeling approach is necessary when analyzing realistic terminal maneuvers, especially under windy conditions. Several factors must be considered. First, the airplane may touch down or lift off asymmetrically, such as one leg making contact first, so the kinematics of the aircraft movement must be accurately reproduced. Second, the contact between each leg and the ground requires consideration of the nonlinear dynamics of the landing gear and tires, including their interaction with the ground. Third, airplane aerodynamics are highly complex and must account for the variation in aerodynamic properties due to ground effects, affecting lift, drag, and moment coefficients.

This work focuses on the development of a nonlinear flight simulator tailored to terminal maneuvers, capable of handling both take-off and landing, as well as all airborne flight conditions. This simulator is an evolution of the one described in Ref. [6], utilizing standard rigid-body dynamics equations to model the aircraft motion, with its orientation parameterized using Cardan angles. The rigid-body dynamics is supplemented by the dynamics of the tires and landing gear, along with a specialized function to detect which leg, if any, has made contact with the ground. The aerodynamic angles are calculated while taking into account the presence of wind of generic magnitude and direction.

Additionally, the simulator includes a dedicated tool to model the aircraft aerodynamic characteristics, partially based on Digital Datcom [7], providing steady-state data and stability and

control derivatives across the entire flight envelope, including the impact of ground effects on these characteristics. Due to certain limitations of the Datcom software, e.g. only one movable surface can be analyzed at a time, the derivation of the aerodynamic model is performed through multiple analyses in a prescribed process, which can also be applied to unusual configurations [8].

The paper is organized according to the following plan. In the section *Methodology*, the simulator will be described putting emphasis on the procedure based on Datcom to estimate the overall aerodynamic characteristic of a given airplane so as to create a large database which considers both longitudinal and lateral directional models and the impact of ground effect on both stability and control derivatives. Some examples of the possible use of the simulator will be reported in the section *Results*. This includes a comparison between landing performed with static aerodynamic model in which stability and control derivatives do not change as the airplane approaches the ground, and an evaluation of minimum wing-tip clearance and maximum lateral gear load during landing as functions of landing speed and crosswind velocity. Finally, section *Conclusions and outlook* concludes the paper by summarizing the main findings and the possible extension of this work.

Methodology

The simulator tailored to terminal maneuvers, which is the focus of this paper, is an evolution of the one described in Ref. [6]. It first relies on the standard rigid-body dynamics equations to model the aircraft motion, while Cardan angles are used for parameterizing the orientation of the airframe with respect to the navigational frame. The aerodynamic angles are calculated while taking into account the presence of wind with a specified magnitude and direction.

The rigid-body dynamics is supplemented by the dynamics of the tires and landing gear, along with a specialized function to detect which leg, if any, has made contact with the ground. In particular, a simplified tricycle landing gear geometry is implemented in which each gear leg consists of a tire and an oleo-pneumatic shock absorber. Tire behavior is rendered through a point-contact model, represented by a linear spring-damper system. The values of the equivalent tire spring and damper characteristics are chosen from literature to yield realistic deformations during simulations. Friction between tires and ground are formulated according to [9], which provides expressions for computing longitudinal and lateral friction coefficients. Braking is also simulated as an additional friction force.

The shock absorbers are modeled using basic physical nonlinear equations linking the elastic force to the stroke and the pressure inside the gas chamber, whereas the dissipative component is rendered through the usual damping arising from flow of the oil through an equivalent orifice. The forces generated at each landing gear contact point are integrated into the aircraft overall equations of motion. The landing gear dynamics is considered only when tire-ground contact is detected.

Additionally, the simulator includes a dedicated tool to model the aircraft aerodynamic characteristics, partially based on Digital Datcom [7], providing steady-state data and stability and control derivatives across the entire flight envelope, including the impact of ground effects on these characteristics.

Due to certain limitations of the Datcom software, and in particular that only one movable surface can be analyzed at a time, the derivation of the aerodynamic model is performed by simulating multiple analyses in a prescribed process.

First, the nominal aircraft is modeled in Datcom including flaps. The outcome of the analysis is the aerodynamic model of the airplane parameterized for different Mach numbers and different flap deflections. The model comprises steady characteristics (e.g. polar and steady moment coefficient) and dynamic stability derivatives.

The same analysis performed at point 1, is repeated including the deflection of the elevator. The outcome of this analysis consists in the variation of the lift $\Delta C_L(\alpha, M)$, drag $\Delta C_D(\alpha, M)$ and moment $\Delta C_{\mathcal{M}}(\alpha, M)$ coefficients entailed by the elevator deflectionδ_E as function of the elevator

Materials Research Proceedings 69 (2026) 913-918 https://doi.org/10.21741/9781644904251-161

deflection itself, the angle of attack α and Mach number M.Finally, $\Delta C_L(\alpha, M)$, $\Delta C_D(\alpha, M)$ and $\Delta C_{\mathcal{M}}(\alpha, M)$ should be then added to the polar obtained at point 1.

This analysis considers the ground effect. Since it is possible to analyze only one control surface at a time, the ground effect analysis is done in conjunction with multiple flap deflections, neglecting in this way the mutual impact of ground effect and elevator deflection. Datcom allows for the study of up to 9 deflections and 10 ground heights. Since the ground effect becomes essentially negligible for ground heights greater than the wingspan, the analyzed ground heights, normalized by the wingspan, range from a minimum value of 0.1 to a maximum value of 1. Digital Datcom performs the analysis for every combination of flap deflection and ground height. Additionally, no impact on the lateral-directional stability derivatives is considered.

In the fourth analysis, the ailerons are included in the Datcom model to estimate the aileron-related control derivatives, $C_{\mathcal{L}_{\delta A}}$ and $C_{\mathcal{N}_{\delta A}}$, which are given as functions of the aileron deflection δ_A and Mach, M.

The fifth analysis considers a model of the isolated fuselage to estimate the increment in the related drag caused by side-slip angle β. Since Digital Datcom does not support analyses varying with β, the approach is to rotate the fuselage by 90 degrees around the x-body axis. This way, when Datcom performs its standard analysis varying α on the rotated fuselage, it effectively analyzes the fuselage aerodynamic characteristics as a function of β.

This step considers the estimation of the control derivatives with respect to the rudder deflection and the increase in the drag entailed by the gears. Both tasks are accomplished using the approach described in [10]. The simulator is implemented in Matlab, and, for the discontinuity management, the model from Ref. [11] was used: as several discontinuous events occur during landings (contact with ground, rebounds, shock absorber motion), the simulation had to be segmented in between the events to avoid numerical problems due to integration of stiff systems.

Results

To demonstrate the capabilities of the simulator, a model of the Ryan Navion (a single-engine, propeller driven, four-seat aircraft) is considered. The digital Datcom was employed to characterize the aerodynamic modeling of the airplane as described in the Methodology section.

In the first scenario, we considered landing in calm air without the flare maneuver. In particular, the airplane was trimmed at a descending angle equal to 1 deg and the controls (deflection of control surfaces and throttle) are maintained fixed throughout the entire simulation. In order to show the importance to have a good characterization of the ground effect, two cases were simulated: one including the variation of the ground effect as function of the distance between the airplane center of gravity and the ground, and the other considering constant aerodynamic coefficients no matter the ground proximity.

Fig.1 shows the output of these simulations, respectively in terms of the airplane trajectory and flight angles as functions of the horizontal distance. The plots also compare two cases: one where the ground effect is considered (solid lines) and one where it is not (dashed lines).

In the considered scenario, due to the ground effect, resulting from the combined modification of the aerodynamics of the wing and tail, the aerodynamic pitch moment increases in magnitude while the airplane descends, causing a tendency to pitch the nose downward. This increase in pitching moment depends on many factors, including the location of the center of gravity and wing aerodynamic center, and is airplane-specific. This behavior is not new, as it was also observed in a paper by O'Leary on a de Havilland DH.106 Comet [12].

From the obtained outputs, although the approach angle is 1 deg, the airplane touches the ground at nearly 3 deg. Notably, this result would not have been obtained if the impact of the ground effect on the moment coefficient had not been considered.

Materials Research Proceedings 69 (2026) 913-918 https://doi.org/10.21741/9781644904251-161

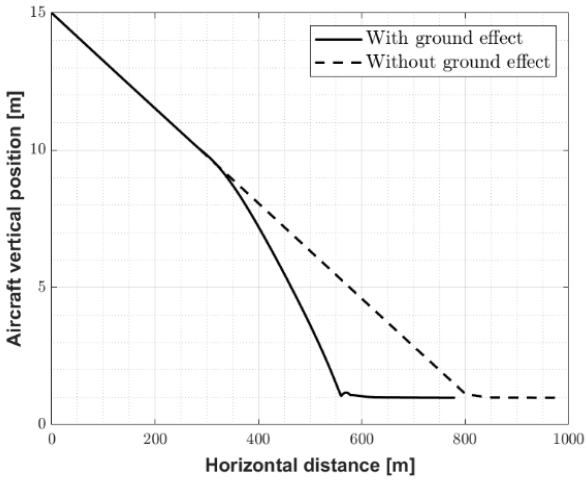

Figure 1: Example of the effect of ground effect on a landing simulation in calm air. Left plot: aircraft trajectory. Right plot: pitch angle (green line), climb angle (red line) and angle of attack (blue line). Solid lines: including ground effect; dashed lines: without ground effect.

In a second scenario, a crosswind is included in the simulations, as well as a dedicated automated control that models pilot's actions. Specifically, the pilot performs the flare before touching the terrain and, once the nose leg has touched the terrain, it also steers the nose wheel to align the trajectory of the airplane with the runway. A crosswind of 8 m/s blows from the left of the airplane, perpendicular to the runway direction. The landing simulation begins with the flapped aircraft in a trimmed configuration, with the nose aligned with the runway, yielding a sideslip approach, where the heading angle matches the flight path angle. Due to the crosswind, both the sideslip and roll angles are non-zero and touchdown occurs asymmetrically, with the left leg touching the ground first, followed by the right leg and, finally, by the nose leg. Fig. 2 shows the trajectory of the aircraft center of gravity during a landing with crosswind of 8 m/s coming from the left of the airplane. In the same plot, it is also possible to visualize the airplane trajectory on the runway after touchdown that follows the runway direction thanks to the nose wheel steering.

The same analysis was repeated multiple times for different values for the approach speed and the crosswind velocity in order to evaluate the impact of these quantities on minimum wing tip clearance. The maximum crosswind considered is 14 m/s, a value that is 50% higher than the maximum crosswind demonstrated in field for Navion aircraft. Fig. 4 shows the minimum wing tip clearance as a function of both approach and crosswind speed. It is possible to show that the worst case, referring to the approach speed equal to 45 m/s and crosswind equal to 15 m/s is associated with a minimum clearance of about 0.7 m. This value, although lower than the clearance for null crosswind, is still significantly positive, demonstrating the landing is still safe even in the presence of crosswind with severity significantly higher than that tested for certification.

Conclusions

A flight dynamics simulator has been developed, coupled with landing gear dynamics, capable of simulating any flight phase, including terminal maneuvers. The aerodynamic characteristics of the airplane are nonlinear and are obtained through a dedicated set of Datcom analyses to generate the aerodynamic dataset which also accounts for ground effect. The use of nonlinear aerodynamics, unlike linearized models, avoids introducing additional errors related to the deviation from the equilibrium point around which the linear model is built. A terminal phase control system has been also designed, to model the presence of the pilot acting on all control surfaces, throttle and nose wheel steer. The tool is effective in simulating terminal maneuvers also in presence of crosswind, without introducing significant simplifications to the dynamics and aerodynamics modeling. A

parametric study has been also performed to quantify the impact of crosswind on the minimum wingtip clearance to verify possible wingtip strikes. The analyses show that the reference aircraft can safely land even at crosswind speeds 50% higher than the maximum one demonstrated in field, without issues related to wingtip strikes.

Keywords: raPPPid, Precise Orbit Determination, GNSS, Nanosatellites, Single frequency, Extended Kalman Filter

Abstract. Nanosatellites, particularly CubeSats, are being extensively used for Earth observation, scientific experimentation, atmospheric research, communication, and emerging LEO-based PNT (Positioning, Navigation, and Timing) missions. Hence, precise knowledge of satellite position and velocity is crucial to support both standalone CubeSat missions and large constellations. In this work, we present enhancements to the open source raPPPid software package to perform Precise Orbit Determination (POD) for LEO platforms using an Extended Kalman Filter (EKF). The state prediction is performed by incorporating the satellite's dynamical model, and observation correction is implemented by pseudo-range and carrier-phase measurements. Group and Phase Ionospheric Correction (GRAPHIC) Linear Combination (LC) method is implemented to mitigate the ionospheric delay, and Doppler measurements are used for robust cycle-slip detection to accurately estimate float ambiguities, in low-cost, single-frequency receivers. Observation weighting and exclusion are governed by elevation angle and boresight angle criteria. Boresight angle criterion improves orbit accuracy and performs efficient observation handling, especially, for satellites with rear-facing antennas. Validation is conducted on the Astrocast nanosatellite constellation, where low-cost receiver results yield a 3-D root mean square error (RMSE) of the post-fit residuals on the order of a few decimeters. As for high-quality geodetic receivers, such as the GNSS receiver onboard the Sentinel-3A satellite, the RMSE reduces to a few centimeters. The resulting ephemerids archive, formatted in SP3c, supports future space-based applications, e.g. measuring the dynamics of composition and density of Earth's upper atmosphere, and holds promise for real-time onboard application, e.g. by incorporating the Galileo High Accuracy Service (HAS) into orbit determination approach. These developments open the door for more autonomous, effective, and scalable navigation systems in future space missions, and highlight the possibility of low-cost GNSS-based POD for nanosatellites.

Introduction

Precise Orbit Determination (POD) is essential for modern satellite missions to provide positioning, navigation, and timing accuracy needed for both scientific and operational use. With the rise of nanosatellite constellations and CubeSats in low Earth orbit (LEO), achieving high-precision orbits using compact and cost-effective receivers has become a major challenge. Traditional differential techniques such as Real-Time Kinematics (RTK) provide high accuracy, but depend on dense ground networks and continuous communication links. In contrast, Precise Point Positioning (PPP) achieves comparable position accuracy using precise GNSS satellite orbit, clock and bias products, making it more suitable for autonomous space-borne applications.

raPPPid [1], an open-source MATLAB-based PPP software developed at TU Wien, provides a robust platform for PPP processing. For high quality receivers onboard geodetic missions, e.g. GRACE [2] and SWARM [3] etc., post processed results show enhanced accuracy and reliability of orbit determination solutions on the order of several millimeters to centimeters. Previous EKF-

Materials Research Proceedings 69 (2026) 919-924 https://doi.org/10.21741/9781644904251-162

based POD studies have achieved sub-meter accuracy using single-frequency GRAPHIC combinations. For example, K.S. et al. [4] demonstrated 1 meter accuracy for missions such as GRACE and COSMIC, while the APOD nanosatellite [5] improved orbit precision from 67 cm to 31 cm by correcting for Code Residual Corrections (CRC). Real-time onboard POD remains challenging due to ionospheric effects, limited GNSS product accuracy, and receiver noise. Müller et al. [6] demonstrated 5–16 m real-time accuracy for low-cost receivers on the Astrocast satellites by NAVSOL.

Hence, it is observed that the performance of such low-cost receivers is often limited by poor observation handling. This work addresses these limitations by extending raPPPid, the PPP module of the Vienna VLBI and Satellite Software (VieVS PPP), for EKF-based POD of satellites with several novel processing strategies: (1) Boresight angle-based observation weighting and exclusion, which improves data handling for satellites with non-nadir or rear-facing antennas. (2) A Doppler-based cycle slip detection algorithm augmented with an acceleration term for high dynamic receivers. (3) An adaptive error covariance matrix tuning scheme for newly introduced ambiguities, maintaining solution continuity and improving filter stability for low-cost receivers. The raPPPid framework supports both low-cost and geodetic receivers, enabling comparative analysis under identical processing conditions.

The structure of this paper is organized as follows: Section 1 introduces the background, motivation, and related work. Section 2 describes the proposed POD methodology and EKF implementation within raPPPid. Section 3 presents the setup and results for the Astrocast and Sentinel-3A satellites. Section 4 concludes the paper with key findings, future recommendations and prospects for real-time onboard POD.

POD Methodology

Satellite Dynamical Model. A satellite's dynamical model is the mathematical representation of its motion, accounting for the dominant perturbing accelerations acting along its orbit. The model integrates the satellite's velocity and acceleration by summing the gravitational and non-gravitational forces acting on it, given in [7].

While gravitational accelerations such as Earth's central gravity and harmonics can be modeled with high precision, non-gravitational forces, such as atmospheric drag and solar radiation pressure, are more difficult to predict accurately. For example, the drag and solar coefficient may have to be estimated once per every orbit to account for varying environmental disturbances. For this research, they have been taken as constants. As a result, purely model-based orbit propagation gradually deviates from the true orbit over time. Hence, a GNSS receiver onboard nanosatellites offers a reliable and efficient way for POD, and helps correct modeling errors in the dynamical model.

Observation Handling. The quality of the GNSS observations plays a significant role in achieving accurate POD results. Hence, dedicated strategies for observation handling are implemented, including adequate cycle slip detection, observation weighting, and exclusion.

A Doppler-based cycle slip detection method is employed to ensure the continuity of carrier-phase measurements, tailored for high-dynamic receivers onboard satellites. Rapid motion can cause large phase variations, which is mitigated by including the acceleration term. The predicted phase measurement $L_{pred,k}$ based on Doppler measurements is given as:

$$L_{pred,k} = L_{k-1} - D_k dt + 0.5\left(\frac{D_k - D_{k-1}}{dt}\right) dt^2 \quad (1)$$

Here, L and D denote the phase and Doppler measurements, respectively, at time epoch k and $k-1$. dt is the time interval between the consecutive epochs. A cycle slip is flagged when the difference between $L_{pred,k}$ and the current measurement L_k exceeds a certain threshold.

Materials Research Proceedings 69 (2026) 919-924 https://doi.org/10.21741/9781644904251-162

Observation weighting and exclusion based on elevation and boresight angles, improve robustness by reducing the influence of low-quality or geometrically unfavorable measurements. In this research, we particularly mention boresight angle, which is the angle between the receiver antenna's pointing direction (antenna boresight) and the line of sight vector to the GNSS satellite, given as [8]:

$$\theta_{boresight} = \cos^{-1}\left(\frac{los_b \cdot r_{ant}}{\|los_b\| \, \|r_{ant}\|}\right) \quad (2)$$

Here, los_b is the line of sight vector between the GNSS satellite and the receiver in the body frame, while r_{ant} is the pointing vector of the antenna boresight. The boresight angle varies between [0, 180°]. For example, a cut-off value of 90° would mean that all the measurements outside of this 90° angular cone are assumed to be weaker and noisier, and will be excluded. Similarly, measurements with higher boresight angles can be given a lower weighting factor, and vice versa. A simple weighting function is given as:

$$W = 0.5\left(1 + \cos\left((\theta_{boresight}\right)\right) \quad (3)$$

Measurement Model: The measurement model is computed with the predicted states, accounting for receiver and satellite clock errors, atmospheric delays, and other measurement perturbations. The ionosphere is a major source of error in GNSS positioning. For single-frequency measurements, the first-order ionospheric effect can be mitigated using the GRAPHIC method, which utilizes the fact that the ionosphere affects code and phase measurements in opposite ways [9]. The combination G_1 is formed using single frequency pseudorange P_1 and carrier phase L_1 measurements as:

$$G_1 = \frac{P_1 + L_1}{2} \quad (4)$$

The combined GRAPHIC measurement G_1, after removal of the ionospheric effect d_{Iono}, is given as:

$$G_1 = \rho - c.dt^S - dt_{rel} + c.dt_R^{GPS} + \delta\rho_{PCO,PCV}^S - \frac{\delta\rho_R^{PCO,PCV}}{2} - \frac{\delta\rho_R^{CCO,CCV}}{2} + \frac{\delta\rho_{Wind-Up}}{2} + \frac{\lambda N}{2} \quad (5)$$

Here, ρ denotes the geometric distance between the receiver and GNSS satellite, which corresponds to the norm of los. $c.dt^S$ is the GNSS satellite clock offset correction, dt_{rel} is the relativistic correction, and $c.dt_R^{GPS}$ is the receiver clock error, with respect to GPS time. $\delta\rho_{PCO,PCV}^S$ is the correction for GNSS satellite antenna phase center offset and variation. $\delta\rho_R^{PCO,PCV}$ and $\delta\rho_R^{CCO,CCV}$ denote the corrections for receiver antenna phase center offset and variation, and code center offset and variation, respectively. $\delta\rho_{Wind-Up}$ represents the correction for the phase wind-up effect (phase rotation due to relative movement between the transmitter and receiver antenna), and λN is the carrier phase integer ambiguity term.

Extended Kalman Filter Tuning. The EKF framework is adopted for state estimation through prediction and correction steps, as commonly used in GNSS-based Precise Orbit Determination (POD) [4]. In this research, the focus is on its adaptive tuning to improve stability for low-cost receivers. To mitigate abrupt jumps in estimated states, and optimal handling of the observations when new satellites appear, an adaptive error covariance inflation strategy is applied on float ambiguities. The initial variance of a newly introduced ambiguity, $\sigma_{amb,0}^2$ is scaled according to its satellite "age" counter n as:

Materials Research Proceedings 69 (2026) 919-924 https://doi.org/10.21741/9781644904251-162

$$\sigma^2_{amb,0}(n) = max(1, f_0 - \alpha(n-1))\sigma^2_{amb,0} \quad (6)$$

Here, f_0 is the initial inflation factor and α is the decay rate. This gradual reduction of covariance smooths the transition when satellites enter or reappear. Hence, it improves filter stability and orbit solution for low-cost, single-frequency receivers which are subject to frequent constellation changes.

Results

Validation of satellite POD in raPPPid software was performed using GNSS data (GPS L1) from Astrocast satellite P03S04 and Sentinel-3A, to evaluate its performance for both CubeSat-class and high-quality geodetic receivers. These implementations are part of the public raPPPid Github repository. IGS Final precise orbit and clock products were used, and the ionospheric delay was corrected with the GRAPHIC-LC applied to GPS L1 measurements. An elevation cut-off of −15° was set, as the GRAPHIC combination mitigates most low-elevation ionospheric effects, while a boresight cut-off of 90° was applied. Boresight angle weighting was implemented for Astrocast P03S04 measurements due to its rear-facing antenna, whereas Sentinel-3A measurements employed an elevation angle weighting corresponding to its zenith-facing antenna.

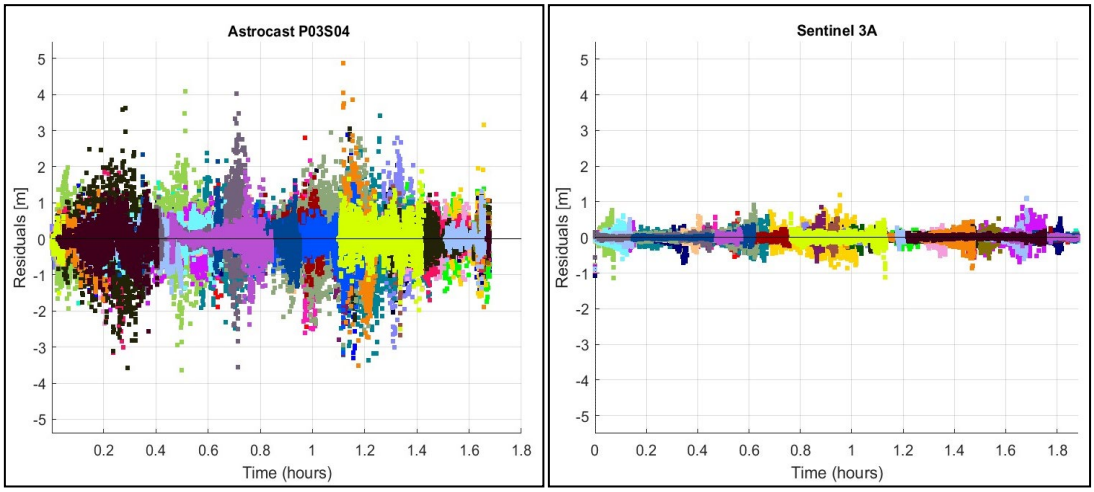

Figure 1: GRAPHIC post-fit residuals for Astrocast P03S04 and Sentinel-3A (GPS L1)

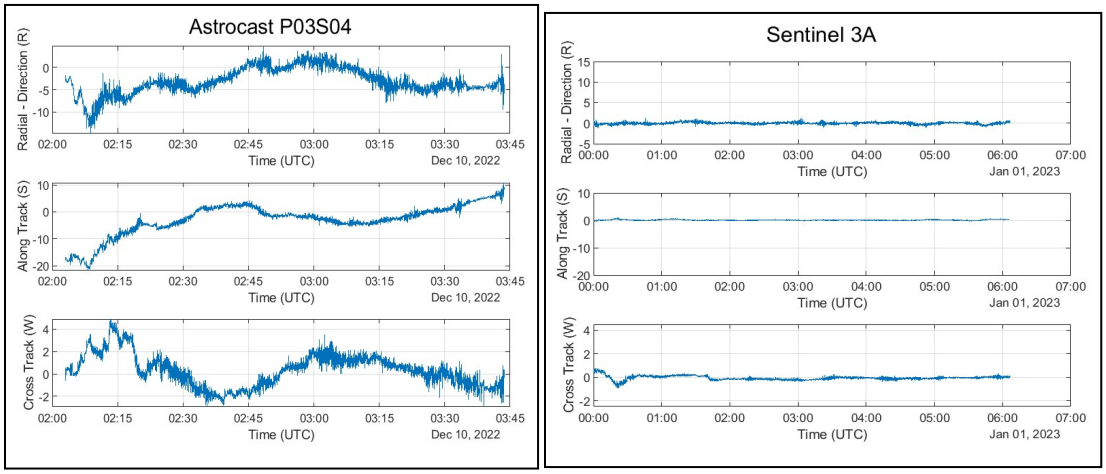

Figure 2: Difference in position for Astrocast P03S04 and Sentinel-3A (meters)

Fig. 1 shows the post-fit residuals between the observed and computed measurements for both satellites. The standard deviation of these residuals is 39 cm for the Astrocast P03S04 satellite and

9 cm for Sentinel-3A. Fig. 2 illustrates the differences in orbital positions for both satellites. For Astrocast P03S04, adaptive error covariance scaling was applied to newly introduced phase ambiguities, along with boresight angle weighting for observations. The improved solution, compared with the NAVSOL orbit [6], yields a 3D RMSE of 7.9 m, reduced from 8.7 m obtained without weighting and inflation. For Sentinel-3A, an elevation angle weighting was applied, increasing the influence of high-elevation measurements. As a result, the 3D RMSE improved from 52.5 cm to 47 cm, compared to its final SP3 orbit solution. These adaptive weighting strategies demonstrate a clear enhancement in orbit determination accuracy for both low-cost and high-quality GNSS receivers.

Conclusions

This work extends the open-source raPPPid software to perform Precise Orbit Determination (POD) for satellites using an Extended Kalman Filter with a dynamical model and GNSS observations. The GRAPHIC linear combination mitigates ionospheric delay, while an improved Doppler method effectively detects cycle slips. Adaptive error covariance tuning, and measurement weighting by elevation and boresight angle improve observation quality.

The achieved post-fit residuals are on the order of decimeters for low-cost receivers (e.g., Astrocast P03S04) and centimeters for geodetic receivers (e.g., Sentinel-3A), using L1 GPS measurements. The NAVSOL orbit is computed only with code measurements and without ionospheric correction, suggesting that our raPPPid solution may be more accurate. However, the results also highlight certain limitations of the GRAPHIC approach arising from code noise and unmodeled hardware effects. In the case of Sentinel-3A, multipath effects and unmodeled antenna code center corrections still remain present, whereas for Astrocast, both phase center and code center corrections are unknown, and therefore not applied.

Because raPPPid supports multiple precise orbit and clock products, it can also be used for near real-time POD by integrating correction streams such as the Galileo High Accuracy Service (HAS). All resulting orbits are stored in SP3-c format, enabling further applications such as atmospheric modeling etc. These findings demonstrate the potential of low-cost GNSS-based POD for autonomous and scalable nanosatellite missions.

Keywords: CubeSat, Piggyback, Interplanetary, Exploration, Architecture

Abstract. Deep-space exploration is rapidly evolving toward agile, distributed mission architectures that leverage miniaturized platforms to increase scientific return while reducing cost. GeoScout is a proposed 12-U CubeSat architecture designed to deploy as a piggyback payload on interplanetary motherships and perform short, very low-altitude flybys for high-resolution geological imaging. Building on heritage from pioneering interplanetary CubeSats and recent asteroid flyby demonstrators, GeoScout accepts higher mission risk in exchange for low cost and high scientific payoff. Key innovations include a battery-first operational mode for critical flyby phases, a compact cold-gas propulsion thrust system optimised for precision ΔV manoeuvres in deep space, and a mothership-relayed high-bandwidth short-range link that eliminates on-board high-gain radios. This paper introduces the architecture, subsystem choices, mission profile, and a comparative analysis with past small-sat demonstrations, highlighting the unique capability of GeoScout to acquire high-resolution surface observation data from very low-altitude encounters.

1. Introduction

Since the launch of the Soviet Venerea program [1], interplanetary exploration has been mostly performed with large, highly capable spacecraft. Data from NASA interplanetary missions [2] show that for a total of 35 spacecraft the average launch mass was above 1500 kg and the average cost (adjusted to fiscal Year 2022 equivalent dollars) well above 1 billion dollars.

The recent rise of CubeSats has changed this paradigm: small platforms have demonstrated viability beyond Low Earth Orbit, performing communications relays, targeted observations, and technology demonstrations. Among them, the Mars Cube One (MarCO) pair were the first CubeSats to operate successfully at interplanetary distances, relaying data during the InSight Mars landing and validating deep-space communication systems [3]. More recently, LICIACube achieved the first-ever asteroid flyby by a CubeSat, imaging the DART impact on Dimorphos and proving that compact imaging systems and autonomous operations can return valuable science despite the distance of tens of millions of kilometres from Earth [4,5]. In addition, cis-lunar (ArgoMoon [6]) and Hera mission (Juventas and Milani [7]) CubeSats are further demonstrating that deploying small satellites as secondary payloads on major missions is a viable opportunity to acquire additional scientifically relevant data.

In this context, GeoScout is a 12-U CubeSat architecture proposed to further extend the capabilities of piggyback CubeSats, enabling very low-altitude flybys for high resolution imaging.

2. Mission concept and operations

GeoScout is conceived as a 12-U CubeSat (size of about $10\times20\times60$ cm^3), designed for deployment from a mothership probe during cruise (e.g. for secondary targets investigation) or near-encounter phases to perform low-altitude fly-bys of the mission's primary target. The CubeSat design balances miniaturization with the minimum subsystem capability required for controlled, low-

altitude flybys: a Cold-Gas propulsion system to provide the ΔV for at least a trajectory correction, enough power budget to perform the fly-by, a telecommunication system to relay data to the mothership, and a high-resolution imaging payload. This architecture trades a high margin of mission risk for low cost and simplicity: primary operations for the critical encounter phase are battery-powered, and communication relies on a short-range link instead of direct transmission to Earth. Among the critical subsystems, GeoScout will be also provided with a full 3-DoF attitude control system to satisfy pointing requirements.

A mission profile for GeoScout would be divided into three main phases:

1. Deployment from mothership and trajectory acquisition. In this phase, GeoScout will execute the necessary manoeuvres and corrections to enter the fly-by trajectory. This phase can be performed autonomously or with support from the mothership.
2. Low-altitude fly-by and scientific data acquisition. In this phase, GeoScout will acquire the images with its high-resolution payload and save it in its on-board memory. No data relay is expected in this phase, as the CubeSat will be pointed to the target body and all on-board resources will be dedicated to data acquisition.
3. Data relay and decommissioning. After the fly-by, GeoScout will relay the scientific data to the mothership. Post-encounter, the spacecraft may continue secondary science operations. Once the communication link will be lost, the CubeSat will deactivate all on-board systems entering in its decommissioned state.

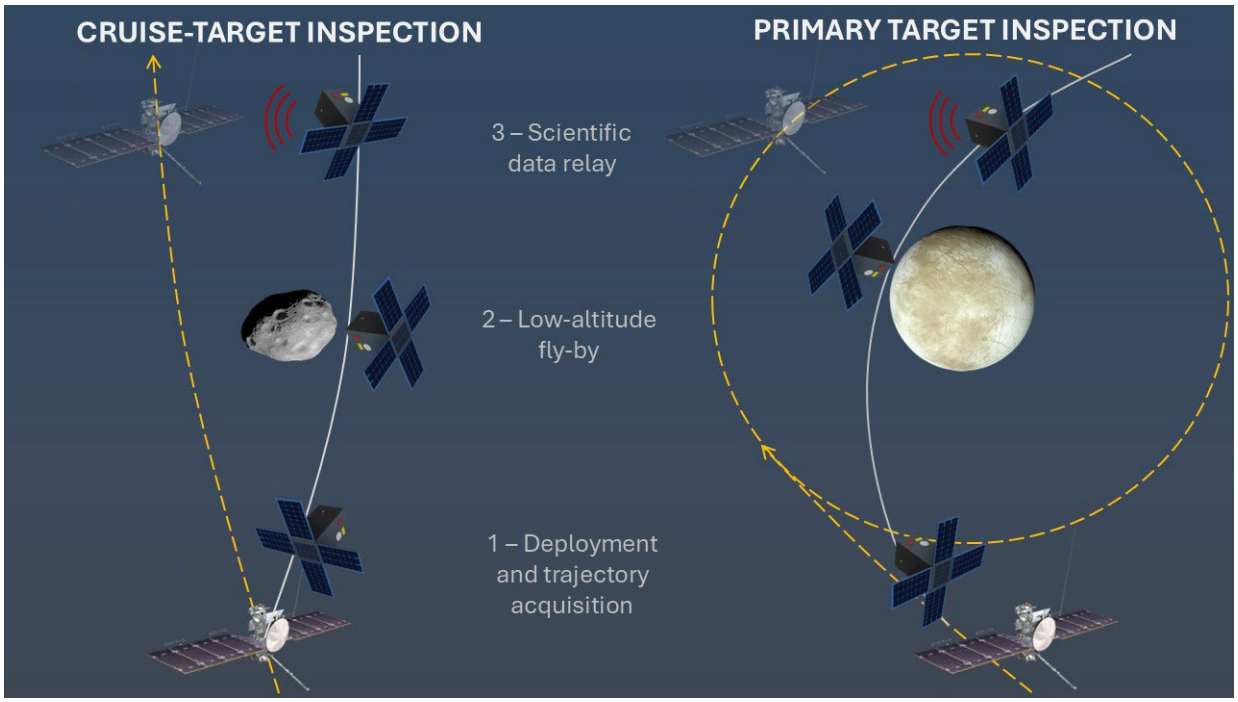

Figure 1: mission phases for targets fly-by during cruise (left) or for the primary target inspection (right)

3. Main systems design

In this section a first iteration of GeoScout design is presented, with details for the main CubeSat subsystem.

3.1 Propulsion

Achieving very low-altitude flybys requires a compact propulsion system capable of very precise thrust control. For GeoScout a Cold-Gas system has been selected as a trade-off between heritage,

Materials Research Proceedings 69 (2026) 926-929 https://doi.org/10.21741/9781644904251-163

safety, and system simplicity. In addition, the cold-gas choice mitigates propellant handling risks during launch and integration with a host spacecraft.

Such systems have been demonstrated in several small satellite missions and were installed on board of deep-space CubeSats; Table 1 shows a partial list of such missions, with reported CubeSat size, propellant, and estimated ΔV. It can be observed that for 6U CubeSat the average ΔV is about 40 m/s.

For a first iteration of the 12U GeoScout design, a scaled tank and thruster arrangement, as well as careful mass allocation, can provide ΔV budgets comparable to or exceeding those achieved by these missions.

Table 1: summary of Cold-Gas thrusters employed in deep-space CubeSat missions

Spacecraft	Size	Propellant	Estimated ΔV (m/s)	Reference
MarCO A / B	6U	R-236fa	~ 60 m/s	[8]
LICIACube	6U	R-236fa	~37–40 m/s	[9]
NEA Scout	6U	R-236fa	~37 m/s	[10]
ArgoMoon*	6U	R-236fa	~56 m/s	[6]
Juventas	6U	Butane	14 m/s	[11]
Milani	6U	Butane	~40 m/s	[12]

* equipped also with a monopropellant thruster

3.2 Power management and communications

GeoScout adopts a battery-first approach for the encounter phase: the spacecraft relies on rechargeable batteries charged during cruise (via body-mounted or deployable solar arrays when practical) but performs the short-duration, high-energy flyby and high-rate data transmission using the batteries alone. This approach was partially validated by CubeSats in previous deep-space operations that operated on battery during short critical phases when solar pointing was suboptimal [13].

To reduce mass and complexity, GeoScout uses a short-range high-bandwidth link to the mothership, rather than a large on-board high-gain antenna and DSN-class transmitter. This approach allows reducing the telecommunication system mass, allowing more volume for the other subsystems and the payload.

3.3 Scientific payload and data handling

GeoScout's primary payload is a high-resolution imager, capable of achieving resolutions below the meter from very low altitudes; its optical design will be based on state-of-the-art telescopes and off-the-shelf cameras. With this targeted resolution, GeoScout can resolve boulder distributions, stratigraphic layering, small-scale faulting, , pits accessing to underground voids, small landslides and granular flows, volcanic vents, rilles and small craters (including fresh and artificial ones) and candidate resource deposits. As reference, LICIACube achieved about 1.38 m/pixel imaging at about 60 km altitude during a flyby of Dimorphos, demonstrating that CubeSat optics can return valuable planetary imagery [9]; GeoScout aims to improve this by an order of magnitude in resolution through closer approach and larger aperture optics.

Supporting subsystems include an onboard data buffer sized to retain full-resolution data until transfer windows with the mothership, and a compact processing unit for compression and limited pre-processing.

Science return will depend on encounter geometry, surface slopes and photometric conditions, but even partial success provides datasets complementary to the broader, lower-resolution surveys of mothership instruments, and is particularly suitable for landing site reconnaissance and

characterization, geological and geomorphological investigations, and small-body surface process studies.

Conclusions

GeoScout represents a low-cost, high-gain architecture for piggyback interplanetary CubeSats focused on very low-altitude geological flybys. By combining a 12-U form factor, safe and validated cold-gas propulsion, battery-first encounter operations, and mothership-relayed communications, GeoScout enables high-resolution surface imaging at low incremental cost to host missions. Future work includes detailed trade studies of propellant sizing, cold-gas thruster arrangements, imaging system designs optimised for motion blur at close approach, and demonstration missions in cis-lunar or small-body contexts.

Abstract. BOREALIS – Biofilm Onboard Radiation Exposure Assessment Lab In Space – is a 6U CubeSat mission developed under the Italian Space Agency's ALCOR program. It introduces a dual-phase orbital profile enabling biological experimentation in both Low Earth Orbit (LEO) and Medium Earth Orbit (MEO), making BOREALIS one of the first CubeSat missions to attempt a LEO-to-MEO orbital transfer. This paper focuses on the mission's engineering innovations that make this transfer feasible, particularly the propulsion subsystem based on a water-fueled pulsed plasma thruster and the Attitude Determination and Control System (ADCS), validated through numerical and Hardware-in-the-Loop (HIL) experiments. Conducted in collaboration between the School of Aerospace Engineering of Rome and the University of Arizona, the tests demonstrated that a commercial ADCS can maintain sub-degree pointing during long-duration thrust operations when integrated within a closed-loop Simulink environment.

Introduction

BOREALIS (Biofilm Onboard Radiation Exposure Assessment Lab In Space) is a 6U CubeSat mission developed under the Italian Space Agency's ALCOR program through a consortium including the School of Aerospace Engineering (SIA) at Sapienza University of Rome, the Interdepartmental Centre for Industrial Aerospace Research (CIRI-Aerospace) of the University of Bologna, and Kayser Italia S.r.l. The mission pioneers a dual-phase orbital profile that enables biological experimentation in both Low Earth Orbit (LEO) and Medium Earth Orbit (MEO), representing one of the first CubeSats to attempt an autonomous orbit transfer between these regimes. The payload, a miniaturized lab-on-chip integrated with a fluorescence microscope, allows *in-situ* monitoring of microbial biofilms to study their survival, adaptation, and gene

expression response to ionizing radiation, including the effects of a purpose-designed radiation shield.

The orbital architecture consists of an initial 650 km circular LEO phase dedicated to biological experiment activation and baseline environmental data collection, followed by a transfer to a 2050 km MEO orbit for exposure to an enhanced radiation environment. This profile enables comparative biological analysis across two distinct radiation regimes using a single payload, an uncommon capability within the CubeSat class. To achieve this ambitious goal, BOREALIS integrates two enabling technologies: a water-fed Pulsed Plasma Thruster (PPT) providing specific impulse around 4800 s and thrust of 37.5 mN, and a commercial Attitude Determination and Control System (ADCS) capable of maintaining sub-degree pointing during extended thrust operations.

The spacecraft design required a deep tradeoff between propulsion, power, and attitude control architectures. The adopted PPT allows incremental burns ranging from 600 to 3000 seconds, while the ADCS ensures stable boresight (i.e. thrust axis) stabilization and robust detumbling performance through quaternion-based feedback control and magnetorquer-assisted desaturation. The mission development followed a model-based systems engineering approach supported by MATLAB/Simulink simulations and GMAT trajectory analyses, incorporating higher order gravitational perturbations. This paper focuses on the engineering innovations behind the orbit-raising maneuver, highlighting the integrated propulsion-ADCS design and the test campaign performed using the HIL testbed developed at the School of Aerospace Engineering, accessed remotely from the University of Arizona.

Mission architecture and propulsion design

A model-based trade study was conducted to evaluate candidate propulsion architectures: cold-gas, monopropellant, and electric systems [1]. The selected water-based PPT provides ~37.5 mN thrust, specific impulse of ~4800 s, and total $\Delta v \approx 150$ m/s, enabling the orbit transfer in several burns of increasing duration (from 600 s to 3000 s). Orbit propagation and thermal analyses were performed using GMAT and MATLAB, including gravitational perturbations and aerodynamic drag. Table 1 summarizes the propulsion options.

Table 1. BOREALIS propulsion options during trade-off analysis [2].

Type	Thrust	Specific impulse	Max cont. firing time
Monopropellant thruster	1000 mN	215 s	600 s
Hall-effect thruster	5 mN	1000 s	900 s
RF ion-thruster	0.4 mN	2200 s	2500 s

ADCS architecture and simulation model

The BOREALIS ADCS is based on the CubeSpace CubeADCS 3-Axis unit [3], integrating three orthogonal reaction wheels (maximum torque 3.0 mN·m, inertia 1.3×10^{-6} kg·m², and maximum speed 6000 rpm) and three magnetorquers with dipole moments up to 0.2 A·m². The sensor suite includes fine and coarse sun sensors, a Nadir sensor, double-redundancy three-axis magnetometers, and a MEMS gyroscope, providing attitude estimation accuracy down to 0.1°. The ADCS can be accessed via UART interface. A HIL testbed, developed using Simulink and connected to the ADCS, was developed at the School of Aerospace Engineering and allows remote access from the University of Arizona for HIL testing. In this setup, Simulink runs on a host PC and it simulates the satellite attitude and orbital dynamics and commands the ADCS setup, that is monitored in real-time to provide a feedback on the actual torque produced over time, injected into

Materials Research Proceedings 69 (2026) 930-935 https://doi.org/10.21741/9781644904251-164

the Simulink model to close the loop. In the experiments discussed in this paper, telemetry and command exchange were achieved via a TCP/IP bridge from the University of Arizona, allowing real-time supervision from the U.S. laboratory during SIA-led control experiments.The attitude kinematics follow the quaternion differential equation [4]:

$$\dot{q} = ½\ \Omega(\omega)\ q$$

where q is the spacecraft quaternion and $\Omega(\omega)$ is the skew-symmetric angular rate matrix.

The control law is formulated using the quaternion error vector, which directly expresses the attitude error between the current spacecraft quaternion q_s and the target quaternion q_t. The quaternion error is defined as: [5]:

$$q_e = q_t^* \otimes q_s$$

where q_t^* is the conjugate of the target quaternion and $\otimes$ denotes quaternion multiplication.

Let $q_e = [\ q_{e4}\ \ q_{e1}\ \ q_{e2}\ \ q_{e3}\ ]^T = [\ s\ \ e^T\ ]^T$ where $s = q_{e4}$ is the scalar part and $e = [q_{e1} q_{e2}\ q_{e3}]^T$ is the vector part.
To ensure the shortest rotation path, the vector error is defined as:

$$\hat{e} = sign(s)\ \ e$$

The quaternion-based PD control torque can then be written as:

$$T_{cx} = 2K_p q_{e1} q_{e4} + K_d\ \omega_x$$

$$T_{cy} = 2K_p q_{e2} q_{e4} + K_d\ \omega_y$$

$$T_{cz} = 2K_p q_{e3} q_{e4} + K_d\ \omega_z$$

or, in compact vector form:

$$\tau_c = 2K_p\ \hat{e} - K_d\ \omega$$

with gain matrices K_p=0.12 $I_{3\times3}$ and K_d=0.015 $I_{3\times3}$. These values were tuned accounting for ±15% inertia uncertainty and disturbance torques below 2×10^{-6} N·m. The controller ensures robust pointing during thrusting maneuvers and stable detumbling following deployment.

Reaction wheel dynamics are modeled as first-order systems with a time constant of τ = 0.05 s, consistent with analytical formulations in REF [6]:

$$J_w\ \dot{\omega}_w = T_c - T_f$$

where T_f includes viscous and Coulomb friction terms. A continuous latent desaturation algorithm modulates the magnetic dipole mm to unload reaction wheel momentum via the cross-product interaction with the geomagnetic field [7]:

$$m = k_d\ (H_w \times B)$$

where H_w is the total wheel momentum and B the geomagnetic field vector. This approach follows the continuous momentum-dumping framework by Hogan and Schaub [8], enabling autonomous control without discrete unloading events.

The simulator uses ephemerides from GMAT, propagating position, velocity, and local field vectors along the orbit. Under nominal conditions, the model achieves <1° steady-state pointing error for detumbling, thrust-alignment modes, and maintains wheel momentum within ±5% during simulated PPT burns. Figure 1 illustrates the integrated Simulink–hardware communication and feedback loop scheme.

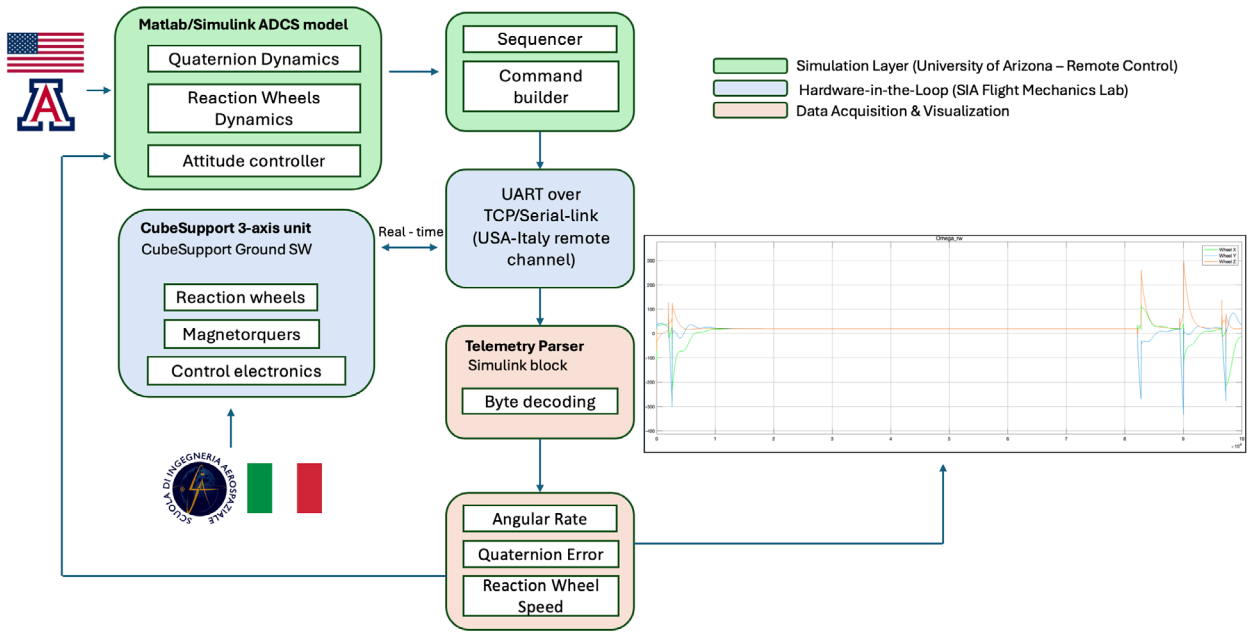

Figure 1. Integrated Simulink–hardware communication and feedback loop. The ADCS simulator developed at the University of Arizona exchanges real-time telecommands and telemetry with the ADCS testbed hosted at SIA Flight Mechanics Laboratory.

Hardware-in-the-loop experimental setup

The HIL campaign was performed collaboratively between the School of Aerospace Engineering (hardware site) and the University of Arizona (control and data processing). Using the remotely-controlled testbed discussed in a previous section the ADCS testbed located in Rome was commanded in real time from Tucson, ensuring data latency <100 ms via UART. Telemetry was parsed with a custom Simulink function compliant with the CubeSpace ICD, automatically updating wheel speed, torque, and magnetorquer current. Polling frequency was 2 Hz, and real-time command packets were generated every 0.5 s. The control loop managed mode transitions (enable, set-speed, poll, off) via a deterministic sequencer with time-indexed states. During thrust-mode simulation (3000 s equivalent burn), the reaction wheels reached ~4200 rpm while maintaining a pointing error below 2°. The magnetic desaturation loop executed every 250 s without oscillations. The revised telemetry parser with time-based watchdog successfully forced rpm reset within 1 s of wheel stop.

Materials Research Proceedings 69 (2026) 930-935 https://doi.org/10.21741/9781644904251-164

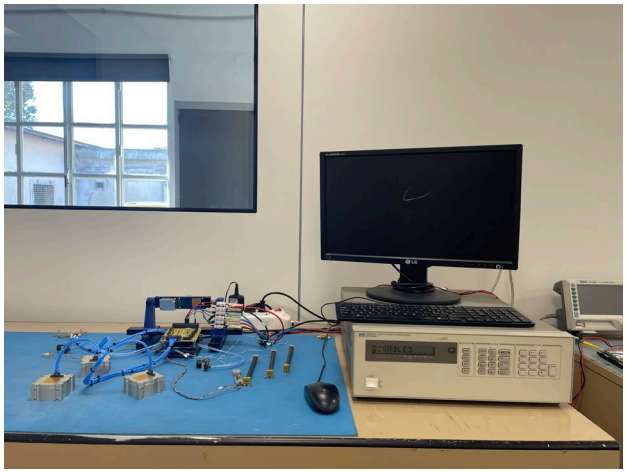

Figure 2. ADCS testbed and Host PC at SIA Flight Mechanics Lab connected to the control terminal at University of Arizona

Results and discussion

Simulink and HIL results exhibited good consistency, with less than 5% deviation in angular velocity profiles and torque command tracking. Table 2 summarizes key performance metrics. The experiment validated the stability of the attitude control algorithm under long-duration torque commands representative of low-thrust maneuvers.

Table 2 – ADCS performance metrics for preliminary tests.

Parameter	Simulation	HIL Test	Requirement
Pointing Error [max]	1.1	1.8	<2.0
Wheel Speed Max [rpm]	4300	4200	6000
Desaturation Period [s]	240	250	<300
Telemetry Latency [s]	0.5	0.6	<1.0

All parameters meet mission requirements with consistent margins between simulation and HIL results for the attitude control up to the burn moment (2000s into the simulation). Minor differences are due to hardware latency, sensor noise, and friction losses in the ADCS testbed unit. The pointing error refers to the maximum attitude deviation during thrust-pointing, and telemetry latency to the command–feedback delay. Overall, results confirm stable control and communication performance under representative LEO conditions. These findings confirm that a small-satellite-class ADCS can support orbit-raising maneuvers when tightly coupled with precise modeling and continuous ground verification. The combination of real-time telemetry, quaternion-based control, and remote HIL capability sets a precedent for distributed academic collaboration in spacecraft testing.

Conclusions

The BOREALIS CubeSat demonstrates how advanced ADCS and propulsion subsystems can extend the scientific reach of small spacecraft to inter-orbital research. Through the joint effort between the School of Aerospace Engineering of Sapienza University of Rome and the University of Arizona, the HIL testbed for BOREALIS ADCS and orbit control system was modeled, integrated, and validated in a cross-continental HIL campaign. Results confirm sub-degree pointing performance during simulated thrust operations and efficient desaturation management.

Keywords: Anomaly Detection, Maneuver Detection, Pattern of Life, Space Situational Awareness, Space Surveillance & Tracking

Abstract. The proliferation of Resident Space Objects (RSOs) within the near-Earth orbital regime presents serious challenges for the sustainability and safety of space operations. Accurate tracking and cataloguing of RSOs are critical for Space Situational Awareness (SSA) and Space Traffic Management (STM). These tasks are hindered by unknown maneuvers of active satellites, which can lead to difficulties in correlating new observations with existing catalogued data. To address this issue, the study proposes a novel algorithm to detect satellite orbital anomalies based on a statistical analysis of its operational behaviour. Specifically, the algorithm is designed to detect anomalous or non-nominal satellite activities through the comparison of its most recent Pattern of Life with its current behaviour. The integration of statistical behavioural models into SSA pipelines provides a scalable solution for maintaining catalogue integrity in the increasingly congested orbital environment, by identifying satellite orbital anomalies.

Introduction

The proliferation of Resident Space Objects (RSOs) within the near-Earth orbital regime introduces substantial challenges to the long-term sustainability of space operations. As reported in the ESA Space Environment Report 2025 [1], population of debris larger than 1 cm exceeds one million, while only approximately 40000 objects are currently catalogued, including around 11000 active payloads. Tracking and cataloguing RSOs are crucial tasks for monitoring the space environment, understanding object behaviour, preventing collisions, predicting re-entries, and updating orbital states. Unknown maneuvers by active satellites introduce additional complexity to these activities. The correlation between new observations and catalogue objects can fail due to events such as fragmentations creating new unknown candidates, unknown maneuvers of catalogued objects, or the discovery of a new RSO. The detection and the estimation of maneuvers can cope with the second source of correlation errors, thus avoiding the duplication of objects and gaining a better understanding of their behaviour. Establishing a recurrent operational behaviour of satellites, called Pattern of Life (PoL), can help in predicting their maneuvers and facilitating their tracking, and enables the detection of anomalous or non-nominal activities. This work focuses on the development of an algorithm to detect anomalies in satellite behaviour through the comparison of the most recent PoL with the current satellite behaviour. The Pattern of Life provides a detailed characterization of a space object by capturing its typical behavioural patterns over time. Most applications in literature rely on Machine Learning techniques to generate PoL and detect maneuvers, but this requires a given amount of data that is not always available [2,3]. The alternative solution proposed in this study adopts a statistical approach to identify both maneuver and orbital parameter anomalies, enhancing scalability and broadening applicability. The remainder of the paper is structured as follows. Section 2 describes the architecture and the

Materials Research Proceedings 69 (2026) 936-941 https://doi.org/10.21741/9781644904251-165

logic of the anomaly detection algorithm. Section 3 presents and discusses the achieved results. Final remarks and future works are reported in Section 4.

Methodology

The top-level architecture of the anomaly detection algorithm is reported in Fig. 1.

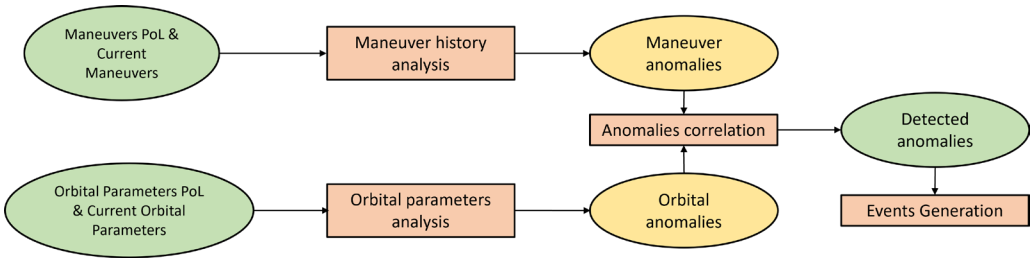

Fig. 1. Anomaly detection algorithm top-level architecture.

In order to identify deviations from the PoL that indicate an anomalous behaviour and avoid false anomalies, consistency between the PoL generation and the satellite behaviour analysis is required. To this end, the satellite behaviour subject to anomaly detection is organized in the same structure as the PoL to facilitate comparison and analysis, and the same logic to identify maneuvers is used for both PoL and anomaly detection. The PoL is constructed through the methodology introduced in [4], which is based on a statistical analysis of both the detected maneuvers [5,6] and the satellite orbital parameters. It includes the time history of the Keplerian orbital parameters of the satellite and information about the typical maneuvers, divided in four bins based on the intensity and distinguished according to the affected orbital parameter (Semi-Major Axis, Inclination, Right Ascension of Ascending Node, Argument of Latitude). The structure is represented in Fig. 2.

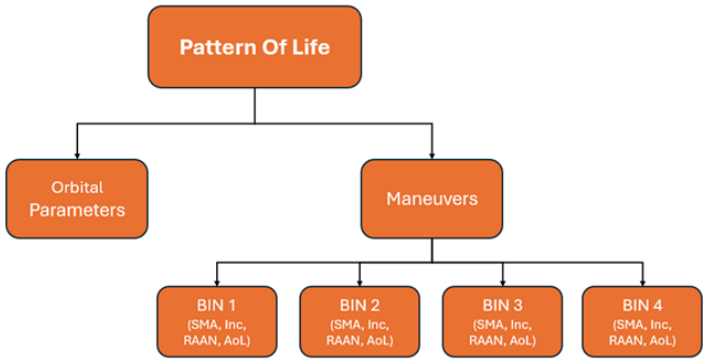

Fig. 2. Pattern of Life architecture.

The anomaly detection algorithm takes as input the list of maneuvers and the orbital state history of the object in the time interval of analysis *T*, organizes the input data in the same structure as the PoL and compares the object behaviour with its most recent Pattern of Life. Three main types of anomalies are defined:

- *orbital parameters anomaly*, which occurs when deviations in Semi-Major Axis and/or inclination exceed the admissible bounds defined by the nominal PoL variation envelope by more than the specified tolerance (*SMA tolerance* and *Inclination tolerance*). This kind of anomaly is the result of the orbital parameters analysis.
- *missed maneuvers anomaly*, that is caused by the absence of a maneuver within the expected time window. At each time instant, the time to last maneuver (TTLM) is computed in each bin of each parameter. If the TTLM is larger than the maximum time

Materials Research Proceedings 69 (2026) 936-941 https://doi.org/10.21741/9781644904251-165

between maneuvers reported in the PoL with a given tolerance (*Time-To-Last-Maneuver tolerance*), a missed maneuver anomaly occurs in that bin of that parameter for the entire time interval characterised by the absence of the expected maneuver.

- *out-of-scheme maneuver anomaly*, which is caused by an unexpected maneuver, because of intensity, if the maneuver magnitude exceeds the nominal bounds, or because of time, if it occurs with a significant temporal offset from the predicted time window. The algorithm analyses each maneuver detected in *T*. If the PoL does not contain any maneuver in the same bin of the same parameter as the detected maneuver, it is classified as an out-of-scheme maneuver of intensity. If the PoL contains maneuvers in the same bin of the same parameter as the detected maneuver, a temporal analysis is performed: the TTLM is computed and if it is smaller or larger than the minimum or maximum time between maneuvers with a given tolerance (*Time-Between-Maneuvers tolerance*), the maneuver is classified as an out-of-scheme maneuver of time.

Results

To evaluate the performance of the anomaly detection algorithm, three satellites were analysed: WorldView-1, COSMO-SkyMed-4, and Starlink-5481. For each of them, a long-term orbit maintenance simulation was carried out with the NASA open-source software General Mission Analysis Tool (GMAT). During the first six months, the nominal behaviour was simulated, after which artificial anomalies were randomly generated. The configuration parameters of the algorithm were the same for all the cases and are reported in Table 1.

Table 1. Anomaly detection algorithm configuration parameters.

Configuration Parameters	Value
SMA tolerance	± 0.1 [km]
Inclination tolerance	± 0.1 [°]
Time-To-Last-Maneuver tolerance	86400 $[sec]$
Time-Between-Maneuvers tolerance	± 86400 $[sec]$

Table 2 presents the four bins used for the PoL and to organize the maneuvers detected in the time interval of analysis *T*.

Table 2. Maneuvers bins intensity.

Maneuvers bins	
Bin 1	$[0, 0.1]$ $[m/s]$
Bin 2	$[0.1, 0.3]$ $[m/s]$
Bin 3	$[0.3, 50]$ $[m/s]$
Bin 4	> 50 $[m/s]$

WorldView-1. WorldView-1 is a commercial satellite for Earth observation operating on a Sun-Synchronous Orbit at about 500 km of altitude. During the 12 months following the nominal maintenance, 23 anomalies of different types were randomly introduced: 2 SMA anomalies; 8 missed maneuvers in the second bin of SMA; 8 out-of-scheme maneuvers of time in the second bin of SMA; 5 out-of-scheme maneuvers of intensity in the third bin of SMA. The SMA anomalies are clearly visible in Fig. 3, where SMA exceeds the PoL bounds twice.

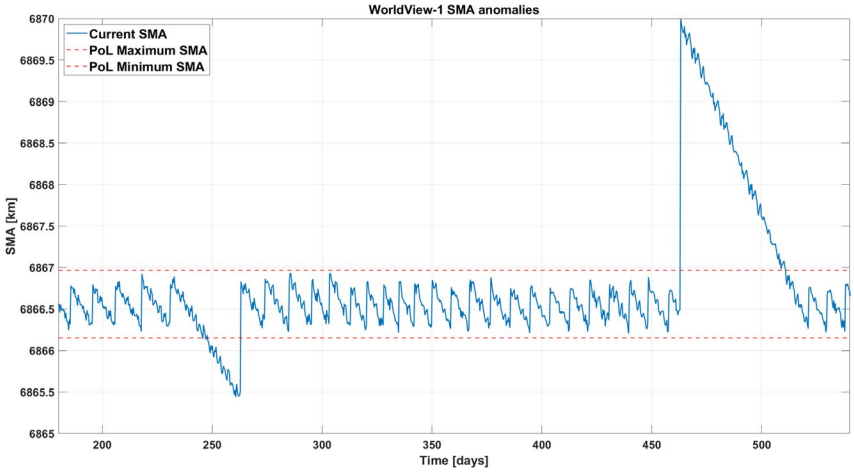

Fig. 3. WorldView-1 SMA anomalous behaviour.

The results of the anomaly detection algorithm are reported in Table 3. Following the comparison of the WorldView-1 behaviour in the time interval of analysis *T* with its most recent PoL, all the anomalies were correctly detected.

Table 3. WorldView-1 anomaly detection algorithm results.

WorldView-1 anomalies detected	
SMA anomaly	2/2
Missed Maneuer – SMA bin2	8/8
Time Out-Of-Scheme Maneuver – SMA bin2	8/8
Intensity Out-Of-Scheme Maneuver – SMA bin3	5/5

COSMO-SkyMed-4. CSK-4 is the unit of a constellation of four Earth observation satellites operated by the Italian Space Agency (ASI). It is placed on a Sun-Synchronous Orbit at an altitude of approximately 620 km. After six months of nominal maintenance, 10 anomalies were randomly generated: 1 SMA anomaly; 1 inclination anomaly; 2 missed maneuvers in the second bin of SMA; 2 missed maneuvers in the third bin of SMA; 2 out-of-scheme maneuvers of time in the second bin of SMA; 1 out-of-scheme maneuver of time in the third bin of SMA; 1 out-of-scheme maneuver of intensity in the third bin of inclination. Fig. 4 represents the anomalous behaviour of inclination with a sudden jump corresponding to the intensity out-of-scheme maneuver.

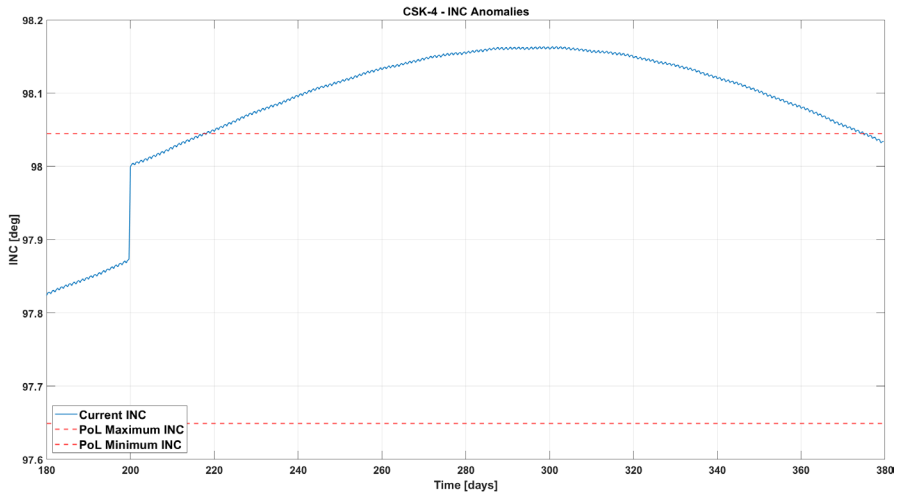

Fig. 4. CSK-4 inclination anomalous behaviour.

The results of the anomaly detection algorithm reported in Table 4 show that also in this case all the anomalies were correctly detected.

Table 4. CSK-4 anomaly detection algorithm results.

CSK-4 anomalies detected

Intensity Out-Of-Scheme Maneuver – Inclination bin3	1/1

Starlink-5481. Starlink-5481 is part of a mega-constellation providing internet services. Its orbit is quasi-circular, with an altitude of about 566 km and an inclination of 43°. Following a nominal maintenance of six months, 10 anomalies were randomly introduced: 2 SMA anomaly; 2 inclination anomalies; 2 missed maneuvers in the third bin of SMA; 1 out-of-scheme manuever of time in the second bin of SMA; 2 out-of-scheme maneuvers of time in the third bin of SMA; 1 out-of-scheme maneuver of intensity in the third bin of inclination. As it is reported in Table 5, all the anomalies were correctly detected.

Table 5. Starlink-5481 anomaly detection algorithm results.

Intensity Out-Of-Scheme Maneuver – Inclination bin3	1/1

Conclusion and Future Works

The tool developed in this work aims to automate and speed up the anomaly detection process, generating an alert each time the satellite exhibits an anomalous behaviour, based on the statistical data derived from its Pattern of Life, which characterizes its nominal operations. Results demonstrate that this approach effectively detects anomalies in both orbital parameters and maneuvers in different scenarios. This functionality not only enhances situational awareness but also reduces the risk of errors in cataloguing activities and improves the reliability of space traffic management operations. In the framework of cooperative SSA, it is particularly relevant for uncooperative or non-collaborative objects, where external maneuver intent disclosures are unavailable. By integrating statistical behavioural models into SSA pipelines, the method provides a scalable solution for maintaining catalogue integrity in the increasingly congested orbital environment. Future work will focus on testing the methodology in a real operational environment.

Keywords: Orbital Robotics, Failure Management, Deep Reinforcement Learning

Abstract. This study develops a data-driven motion planning framework for a 7-DoF robotic manipulator to enhance fault tolerance against joint failures during the pre-capture phase of In-Orbit Servicing missions. The system is trained using meta-Reinforcement Learning (meta-RL), exposing the agent to a wide range of randomized scenarios, including stochastic joint-locking. This process achieves two main goals: it equips the agent with strong generalization capabilities for conditions beyond its training domain, and it bypasses traditional inverse kinematics by learning a direct mapping from sensor data to joint-space commands. The meta-learning framework is shown to significantly improve the system's ability to autonomously manage unforeseen failure events. In non-critical scenarios, the agent successfully learns to repurpose redundant joints to complete its task. However, the system cannot recover from failures that cause an unrecoverable reduction of the manipulator's workspace. The results demonstrate that this approach leads to more predictable autonomous behavior during failures and, most importantly, shows how some unexpected anomalies may be overcome by simply reframing them as an operational constraint, before critical operations begin.

Introduction

In-Orbit Servicing (IOS) activities represent a transformative shift in space operations, demanding highly autonomous robotic systems for critical close-proximity tasks like satellite capture, maintenance, and disposal under strict safety constraints [1, 2]. Increasing the autonomy of Guidance, Navigation, and Control (GNC) pipelines for these missions remains challenging, as traditional methods struggle to adapt in real-time to environmental variability or unexpected system anomalies. Deep Reinforcement Learning (DRL) has emerged as a promising approach to enhance these GNC architectures [3], offering the ability to learn complex dynamics through simulated interactions with the environment [4, 5, 6].

Overview. This study, carried out within the ASTRA Lab at Politecnico di Milano, presents a DRL-based guidance framework for a 7-DoF space manipulator mounted on a free-flying satellite. Its specific goal is to synchronize the end-effector with a fixed point on a tumbling, uncooperative target object (Fig. 1) during the pre-capture operations. To achieve this, the proposed framework employs a meta-learning approach [7, 8, 9]. The agent is trained across a wide range of randomized nominal and off-nominal scenarios, including varied initial poses, target tumbling rates, and potential joint failures. This work specifically explores the agent's ability to leverage the system's kinematic redundancy to maintain performance under degraded conditions. The proposed guidance agent receives information from ideal sensors in the task space and directly produces joint-space trajectory references, and demonstrates that a learning-driven manipulator guidance architecture can inherently adapt to failures on-the-go under specific conditions.

Space Robot Dynamics and GNC implementation

The robotic system is modeled through the open-source SPART toolkit [10], assuming a free-flying space robot model. The coupled equations of motion between base and manipulator are expressed in the compact form $\mathbf{H}(\mathbf{q})\ddot{\mathbf{q}} + \mathbf{C}(\mathbf{q}, \dot{\mathbf{q}})\dot{\mathbf{q}} = \boldsymbol{\tau}$ where $\mathbf{q}$ is the state variable (comprising the full state of the base and manipulator joints), and $\mathbf{H}$, $\mathbf{C}$ are the generalized inertia and convective inertia matrices. The implemented GNC system (Fig. 2) operates under the assumption of ideal navigation sensor outputs. These sensors feed information to the DRL-based guidance system, which in turn provides the desired manipulator trajectory.

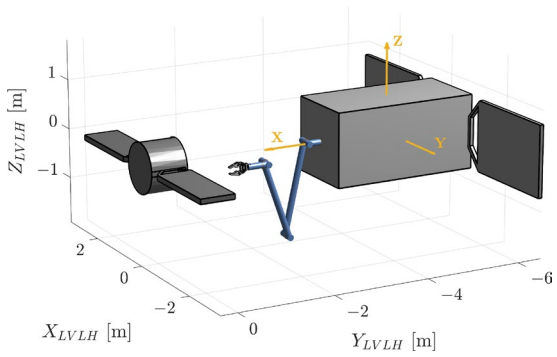

Figure 1: Satellite capture scenario.

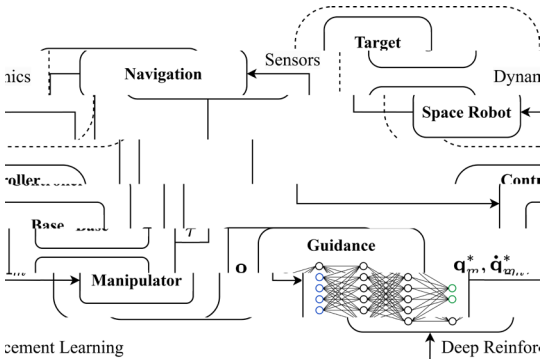

Figure 2: Space robot GNC architecture.

DRL agent guidance system. The core of the work regards the autonomous trajectory generation of the space manipulator, that is produced in real-time as each simulation progresses, based on the environmental perception of the agent at each instant. The inputs received by the agent correspond to the current state of the manipulator, and the errors between the current and target end-effector poses; the latter is ideally assumed as a known quantity for the scope of this work. The agent, implemented through a feedforward neural network, produces the desired joint angles and rates of the manipulator at each instant, bypassing the need for online optimization or inverse kinematics to produce a trajectory reference. A stochastic policy is applied during training to improve exploration of the action space, and consequently actions applied during training are sampled from a Gaussian distribution individually for each joint, encouraging the agent to avoid local minima during network optimization. The selected DRL algorithm is Proximal Policy Optimization [11], applying a reward function based on an Artificial Potential Field (Eq. 1), adapted from [12]. The value of U at each timestep k increases when the pose error of the end-effector decreases over time, such that the agent learns to guide the end-effector towards the desired pose. This goal-oriented reward is the core element of this formulation: the agent is motivated to move towards the desired goal, without directly prescribing how it should use the joint angles to achieve that. This is the crucial detail that makes the resulting trained policy adaptive, allowing it to autonomously decide how to exploit each of the joint angles, such that the final goal can be reached.

$$U_{\mathrm{k}} = -\tilde{r} + \frac{10}{(1+\tilde{r}_{ax})} + \frac{10}{(1+\tilde{r}_{tx})} + \frac{10}{(1+\tilde{\theta})} \qquad (1)$$

Training and results in nominal environment

As defined through the reward function, the goal is for the agent to synchronize the end-effector with a target pose, that is taken fixed to a target spacecraft, that follows a free tumbling dynamics. In the nominal training phase, the tumbling only happens around a single axis, without any failures encountered. In these conditions, each simulation starts with a different distance between chaser and target satellites, initial manipulator configuration, tumbling rate of the target, as well as final

Materials Research Proceedings 69 (2026) 942-947 https://doi.org/10.21741/9781644904251-166

end-effector goal on the circular face of the target (Fig. 1). Fig. 3 shows that the network optimization process in the randomized environment, under nominal (non-failure) conditions, converges in approximately 8000 episodes. To compute an episode's outcome, the time that the end-effector can reliably stay below specific thresholds $\bar{\boldsymbol{r}}$ and $\bar{\theta}$ is considered.

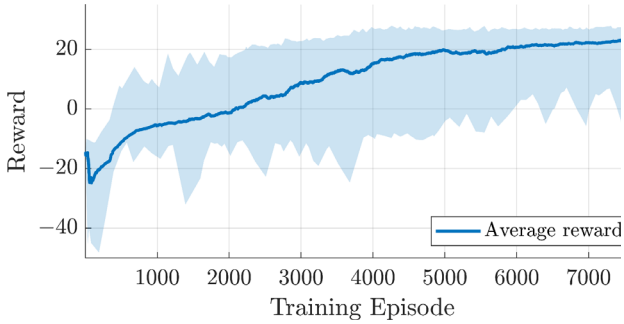

Figure 3: Training reward curve.

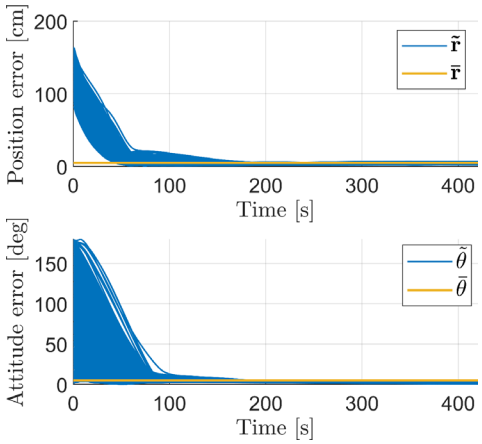

Figure 4: Montecarlo results.

A Monte Carlo analysis (Fig. 4) confirms the agent's ability to reliably synchronize its end-effector with a desired pose fixed to the tumbling target. In all simulations, the agent maintained a pose error below $\bar{r}$ = 1.5 cm and $\bar{\theta}$= 1° for at least 30 consecutive seconds, regardless of the randomized end-effector goal. This performance constitutes a 100% success rate, establishing the baseline used for comparison against non-nominal simulation scenarios.

Agent behavior under joint failures

This section explores how the agent manages the kinematic redundancy of the system, to maintain performance in degraded conditions where one of the joints is assumed failed, and is locked from the beginning of the simulation. The specific joint that is locked is chosen randomly at the beginning of each simulation: the joints are assumed ordered from 1 to 7, from base of the manipulator to end-effector. To evaluate the potential of the meta-reinforcement learning approach, three testing scenarios are considered: i) the baseline agent from the previous section is directly tested under degraded conditions, ii) additional training is conducted starting from the baseline agent, exposing it to a failure of any of the 7 joints, and iii) additional training is conducted with the baseline agent, exposing it to failures of only the joints deemed non-critical in terms of workspace reduction, i.e. joints 1, 5, 6, 7, based on the results from ii). The results in terms of synchronization success percentage are reported in Tab. 1. Despite the large performance decrease with respect to the nominal behavior of 100% synchronization success rate, it is clear that the failure of some specific joints is more critical than others. Through a deeper examination of the results, the unsatisfactory performance of the agent found consequently to the locking of joints 2-4, is due to the drastic reduction of the workspace and dexterity of the manipulator, that is unrecoverable.

Table 1: Testing results with failed joints for cases i), ii), iii).

Joint	1	2	3	4	5	6	7
Case i)	64%	5%	11%	0%	46%	54%	52%
Case ii)	57%	1%	9%	0%	35%	68%	65%
Case iii)	69%	N/A	N/A	N/A	40%	77%	51%

Materials Research Proceedings 69 (2026) 942-947 https://doi.org/10.21741/9781644904251-166

Regarding the non-critical joints, focusing specifically on iii), the performance with respect to nominal conditions is heavily impacted, with a percent reduction in the order of 23%-60%. Despite this, further analysis of the failure locations for each test case demonstrate that the proposed method leads to some important insight on the agent's behavior under failed conditions. An example is provided for joint 1 (Fig. 5), overlaying the randomized end-effector targets, together with the success/failure of each episode, on top of the target's circular face. While only the results from joint 1 are shown, the same behavior is found for the others deemed non-critical (5-7). While the percentage of failures itself does not improve through additional training that subjects the agent to joint failures, it can be seen in the results from case iii) (Fig. 5) that the region where failures are encountered becomes more predictable; in cases i) and ii), this region almost overlaps the whole surface of the target, demonstrating that the agent fails unpredictably. The greater predictability of failures in test case iii) is the primary benefit of the meta-training approach, demonstrating that for each joint there exist relative configurations between the servicer spacecraft and target, such that the agent can reliably provide a successful synchronization of the end-effector to the desired pose after encountering a manipulator failure.

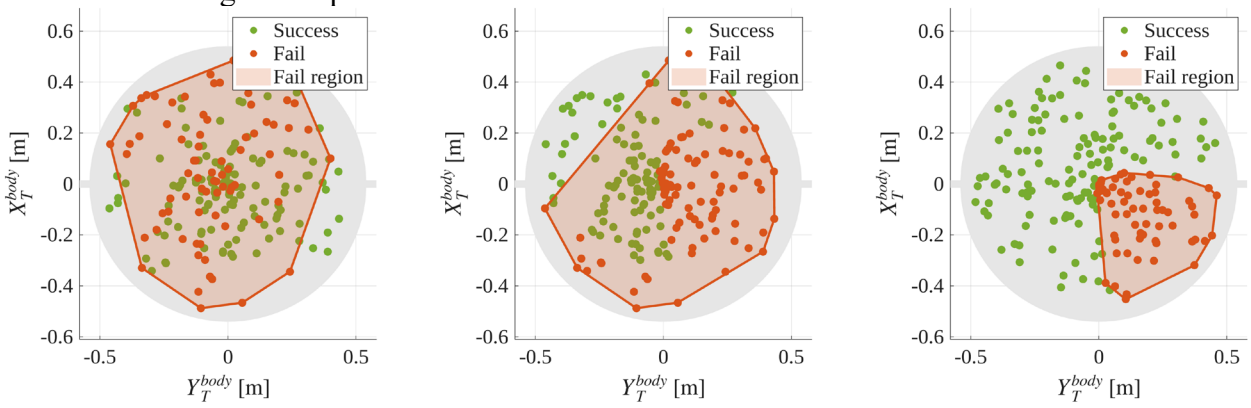

Figure 5: Joint 1 results for each testing case, i), ii), iii) (from left to right).

Overlaying the results from each of the non-critical joints (Figs. 6-7), it is clear that there are certain configurations between servicer spacecraft and target that allow the synchronization to be completed successfully, regardless of whether a non-critical joint is stuck in place at the beginning of the manipulator's motion. Indeed, by opportunely constraining the initial relative configuration between chaser and target, and maintaining it such that the grasping position falls outside of the failed-episode envelope, the 100% success rate of the agent can be fully retained even under failed conditions; this is achieved by autonomously repurposing the redundant joints. While a large reduction in success percent is obtained with respect to nominal conditions, the results show that a DRL-based manipulator guidance law trained through a meta-learning approach successfully improves the adaptability of the agent to unforeseen joint locks in the manipulator. This is a fundamental characteristic in safety-critical applications, and could be one of the main reasons to look into similar systems despite their novelty for space applications. By selecting an optimal relative configuration between chaser and target prior to the start of operations, together with an agent that can adapt to unforeseen failure events, the probability of a successful target capture can be increased even if a failure were to be encountered during operations.

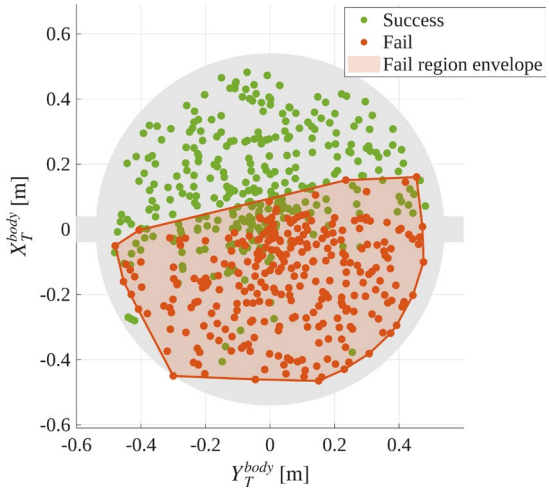

Figure 6: Fail region envelope.

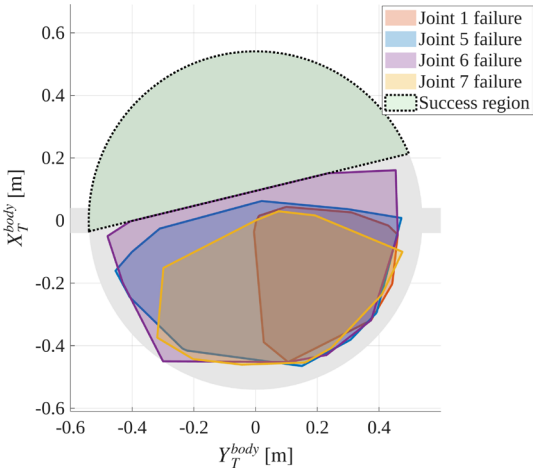

Figure 7: Fail regions overlayed.

Conclusion

This study demonstrates that meta-DRL approaches can significantly boost fault-tolerance capabilities of the space robot GNC system, that can be achieved by exposing the agent to targeted failures during the training phase. While overall performance still lags behind nominal conditions, the main outcome of the approach is the agent's ability to exploit the manipulator's kinematic redundancy to achieve its objective even under failed joint conditions, together with a much greater predictability of the agent's behavior during critical operations. Having similar knowledge of the agent's predictability consequently to failures is operationally invaluable, as it turns critical anomaly events into operational constraints.

Keywords: Probability Estimation, Conjunction Assessment (CA), Monte Carlo Simulation, Line Sampling (LS), Subset Simulation (SS)

Abstract. Advanced Monte Carlo-based approaches are investigated for conjunction assessment with a breakup event, namely Line Sampling and Subset Simulation, which enable to detect the same extent of probability with fewer samples. The proposed approaches are applied to a hypothetical fragmentation and compared with the standard Monte Carlo approach.

1. Introduction

Probability estimation of Close Approaches (CAs) caused by a fragmentation is one of the key components for orbital neighbourhood awareness conjunction assessment. While the distribution of the fragments is often derived from the NASA Standard Breakup Model, a Monte Carlo simulation with large number of samples is required from such a model for a conjunction risk assessment, especially when the probability is small.

On the other hand, advanced Monte Carlo methods, namely line sampling and subset simulation can be used. Both approaches were originally developed to estimate structural failure [1,2], similar to the CA assessment, the system failure probability is the fraction of the number of samples which lead to the failure region. From its nature, a large number of samples are required for standard MC method to guarantee the accuracy of the estimated probability, which causes high computational cost. Both line sampling and subset simulation reduce this problem, by transforming it to a one-dimensional problem in the standard normal space, or by reformulating it as a combination of multiple conditional probabilities. Smaller number of samples will be required as a result, to achieve the same level of accuracy. The same approaches were applied later to the conjunction analysis of near-Earth objects for planetary projection as well [3].

In this work, we propose a line sampling and subset simulation approach to estimate the probability of close approach against debris fragments, to reduce the number of required samples and enhance computational efficiency and improve accuracy in the estimation of the collision probability. Instead of the uncertainty covariance of the initial condition, the probability distribution function from the breakup model can be treated in the same manner. The sample fragmentations are numerically propagated using high-fidelity gravity model implemented in ESA GODOT [4]. The performance of the proposed approaches is compared with the standard Monte Carlo simulation under the same condition, and the feasibility and the limitations of the proposed approaches are addressed by numerical simulations.

2. Advanced Monte Carlo-Based Approaches

Line Sampling

The line sampling (LS) method is a Monte Carlo-based approach for the estimation of small probabilities. It was originally developed for the reliability analysis of failure in complex structural systems [5,6], and later applied to risk estimation for orbital conjunction analysis in combination with differential algebra [3,7]. Both problems have very low probability (generally in the range of

Materials Research Proceedings 69 (2026) 948-953 https://doi.org/10.21741/9781644904251-167

10^{-7} to 10^{-6}) and therefore require a large number of samples for probability estimation. The main feature of the Line Sampling method is the analytical estimation of the probability, obtained by reducing the multi-dimensional integration problem across the uncertainty domain to many one-dimensional integrals along lines following a reference direction that are used to sample the initial distribution; this direction is determined so that it points toward an impact region of the domain, and, if this is properly chosen, the method can considerably increase the accuracy of the solution or reduce the number of required system simulations with respect to a standard MC. It consists of four steps: 1) the mapping of random samples from the physical coordinate space into a normalized standard space; 2) the determination of the reference direction $\boldsymbol{\alpha}$; 3) the probing of the impact region along the lines following the reference direction; 4) the estimation of the impact probability [8].

The first step of the LS procedure is to map the physical coordinates $\mathbf{x} \in R^n$ onto the standard normal space $\boldsymbol{\theta} \in R^n$, whose components are all associated with a unit Gaussian distribution. The components of the vector $\boldsymbol{\theta}$ have the property of being independent and identically distributed random variables. In other words, each component has the same probability distribution as the others and all are mutually independent. Therefore, the joint PDF ϕ of these random parameters is equal to the product of all the single PDFs.

$$\phi(\boldsymbol{\theta}) = \prod_{j=1}^{n} \phi_j(\theta_j) \tag{1}$$

Thanks to this property, this transformation grants efficiency to the method, especially with high dimensions. It reduces the problem to a series of one-dimensional analytical evaluations, thus enabling a simplification of the computation of the probability. The direct and the inverse transformation, from the physical domain to the normalized one and vice versa, which preserve the joint cumulative distribution function (CDF) between the two spaces, are defined as below.

$$\begin{aligned} &\Phi(\boldsymbol{\theta}) = F(\mathbf{x}) \\ &\boldsymbol{\theta} = \Phi^{-1}\left[F(\mathbf{x})\right] \\ &\mathbf{x} = F^{-1}\left[\Phi(\boldsymbol{\theta})\right] \end{aligned} \tag{2}$$

Then the reference direction $\boldsymbol{\alpha}$ is determined, as the direction of a normalized “centre of mass” of the impact region in [3,8].

$$\boldsymbol{\alpha} = \frac{1}{N_s} \sum_{u=0}^{N_s} \frac{\boldsymbol{\theta}^u}{\left\|\boldsymbol{\theta}^u\right\|} \tag{3}$$

This region is approximated by applying the Metropolis-Hastings algorithm [9,10] as below, to generate a Markov Chain Monte Carlo (MCMC) lying entirely in the impact subdomain starting from an initial condition within it.

a. from the current element $\mathbf{x}_u$, $\boldsymbol{\xi}$ is generated by randomly sampling a user-defined "proposal" pdf $p^*(x_u)$;
b. compute the ratio $r = p(\boldsymbol{\xi}) / p(\mathbf{x}_u)$;
c. set $\tilde{\mathbf{x}} = \boldsymbol{\xi}$ with probability $\min(1, r)$ and set $\tilde{\mathbf{x}} = \mathbf{x}_u$ with the remaining probability $1 - \min(1, r)$, where $\tilde{\mathbf{x}}$ is the candidate for the next element of the chain;

Materials Research Proceedings 69 (2026) 948-953 https://doi.org/10.21741/9781644904251-167

d. check whether the candidate $\tilde{\mathbf{x}}$ lies in the region of interest I or not: if $\tilde{\mathbf{x}} \in I$, accept it as the next sample $\mathbf{x}_{u+1} = \tilde{\mathbf{x}}$; else, reject it and take the current sample as the next sample $\mathbf{x}_{u+1} = \mathbf{x}_u$.

After determining the reference sampling direction, N_T initial conditions $\mathbf{x}^k$ are randomly drawn from the nominal uncertainty distribution and then mapped to standard normal coordinates as $\boldsymbol{\theta}^k$ using the transformation above. For each sample in the standard normal space, a line starting from $\boldsymbol{\theta}^k$ and parallel to $\boldsymbol{\alpha}$ is defined according to the parameter c^k, such that

$$\begin{aligned} \boldsymbol{\theta}^k &= c^k \boldsymbol{\alpha} + \boldsymbol{\theta}^k{}_{\perp} \\ \boldsymbol{\theta}^k{}_{\perp} &= \boldsymbol{\theta}^k - \left\langle \boldsymbol{\alpha}, \boldsymbol{\theta}^k \right\rangle \boldsymbol{\alpha} \end{aligned} \tag{4}$$

where $\left\langle \boldsymbol{\alpha}, \boldsymbol{\theta}^k \right\rangle$ is the scalar product. In this way, the problem is reduced to a series of one-dimensional evaluations associated with each sample, with c^k also normally distributed in the standard space.

The standard domain is then explored along each line with the aim of identifying the impact region of an uncertainty set. For the problem under study, the occurrence of the events is expressed by the value of the non-dimensional performance function

$$g_\theta(\boldsymbol{\theta}(c)) = Y(c) \big/ R_{imp} - 1 \tag{5}$$

where Y is a function that maps the value of the parameter c to a performance index, an R_{imp} is the selected critical distance. By setting Y as the minimum distance from the body of interest in the given time of window, while R_{imp} as the radius around the body to define an impact, the performance can be written as

$$g_\theta(\boldsymbol{\theta}(c)) \begin{cases} < 0 \rightarrow & \text{Impact} \\ = 0 \rightarrow & \text{Limit condition} \\ > 0 \rightarrow & \text{No impact} \end{cases} \tag{6}$$

There will be a maximum of two intersections between each line and the impact region, meaning that two values of c^k exist for each standard normal random sample $\boldsymbol{\theta}^k$. Once the value $(\bar{c}_1^{\,k}, \bar{c}_2^{\,k})$ are known for all the sampling lines, the unit Gaussian CDF provides each random initial condition $\boldsymbol{\theta}^k$ with the conditional impact probability $\hat{P}^k(I)$, which can be computed as a one-dimensional integrals based on the properties of the normalized coordinate space.

$$\hat{P}^k(I) = \hat{P}\left[\bar{c}_1^{\,k} < N(0,1) < \bar{c}_2^{\,k} \right] = \int_{\bar{c}_1^{\,k}}^{\bar{c}_2^{\,k}} \phi(u) du = \Phi(\bar{c}_2^{\,k}) - \Phi(\bar{c}_1^{\,k}) \tag{7}$$

The total probability of the event $\hat{P}(I)$ can be approximated as follows.

$$\hat{P}(I) = \frac{1}{N_T} \sum_{j=1}^{N_T} \hat{P}^k(I) \tag{8}$$

Materials Research Proceedings 69 (2026) 948-953 https://doi.org/10.21741/9781644904251-167

Subset Simulation

The subset simulation (SS) method is an adaptive stochastic simulation method to compute efficiently small failure probabilities [3,7]. The approach was originally developed to address structural failure, but it was also used in different research areas in reliability, e.g. to address the failure probability of thermal-hydraulic passive system [5]. The basis of the method is to compute the probability as a product of larger conditional probabilities. Given a sequence of intermediate failure regions $F_1 \supset F_2 \supset \cdots \supset F_m = F$, the failure probability becomes

$$P(F) = P(F_m) = P(F_1)\prod_{l=1}^{m-1} P(F_{l+1}|F_l) \tag{9}$$

where $P(F_{l+1}|F_l)$ indicates the probability of F_{l+1} conditional to F_l. The method is initialized using a standard MC simulation to generate samples at conditional level 0. Once the failure region F_1 is determined and the probability $P(F_1)$ computed, a Monte Carlo Markov Chain (MCMC) algorithm is used to generate samples conditional to the failure region F_1. The next intermediate failure region F_2 is then located and other samples are generated with MCMC. The process can be repeated till the failure region corresponding to objects collision is identified. Similar to the LS method, the MCMC Metropolis-Hastings algorithm is to generate conditional samples in the new region [10]. The resulting SS algorithm can be performed through the following steps [7].

a. set $l = 0$ and generate N sample vectors $\mathbf{x}_0^{0,k}$ by standard MC simulation.
b. propagate each sample for the selected time window, and a list of possible target events is obtained. And compute the values of the performance function $g_x^{\,l}(\mathbf{x}_0)$ for the N samples $\mathbf{x}_0^{l,k}$.
c. sort the N samples in ascending order, according to their values of the performance function $g_x^{\,l}$. The samples closer to the failure region will be at the bottom of the list.
d. identify the intermediate threshold value D_{l+1} from the $(1-p_0)N$ th value of the sorted list. Define the $(l+1)$ th conditional level as $F_{l+1} = \left\{ d_{\Delta t_e} < D_{i+1} \right\}$. Considering how the threshold is defined, the associated conditional probability $P(F_{l+1}|F_l) = p_0$
e. if $D_{l+1} < D_{\lim}$, where $D_{\lim}$ is the target threshold distance, go to the last step. Otherwise select the last $p_0 N$ samples of the list. By definition, these samples belong to the $(l+1)$ th conditional level.
f. using MCMC, generate $(1-p_0)N$ additional condition samples starting from the previously selected seeds belonging to F_{l+1}. A sample is set to belong to F_{l+1} according to the following performance function.
g. set $l = l+1$ and return to step b.
h. stop the algorithm.

The total number of generates samples is

$$N_T = N + (m-1)(1-p_0)N \tag{10}$$

where n is the overall number of conditional levels required to reach the impact region. Since the conditional probability is equal to p_0 for each level, the impact probability becomes

Materials Research Proceedings 69 (2026) 948-953 https://doi.org/10.21741/9781644904251-167

$$\widehat{P}(F) = \widehat{P}(F_m) = P(F_m \left| F_{m-1} \right) p_0^{\,m-1} = p_0^{\,m-1} N_F / N \tag{11}$$

where N is the total number of samples at each conditional level and N_F is the number of samples at conditional level m, whose distance from the target is lower than D_{lim}.

3. Simulation Studies

The proposed LS and SS approaches are applied to a breakup scenario in Table 1, together with the standard Monte Carlo, for both explosion and non-catastrophic collision cases.

Table 1 Breakup simulation scenario

Parent orbit @ 2025-01-01 00:00:00					
SMA [km]	Ecc	Inc [deg]	RAAN [deg]	AoP [deg]	TA [deg]
8000.8008	0.0001	98.0	50.0	0.0	180.0
Target orbit @ 2025-01-01 00:00:00					
SMA [km]	Ecc	Inc [deg]	RAAN [deg]	AoP [deg]	TA [deg]
8248.307	0.03	80.0	50.0	0.0	188.0408

Conjunction assessment results after 2 hours from the breakup are summarized in Table 2. Taking into account the fact that each Monte Carlo simulation is different, it is noticeable that LS gives the same order of probability with a one hundredth of samples. If the standard deviations of the computed probabilities are considered, advanced Monte Carlo-based approaches provide smaller error covariances, meaning the LS is more reliable than the standard Monte Carlo when the number of samples is the same, or even smaller.

Table 2 Probability of close approach < 5 [km]

	Explosion	Collision
Standard MC ($N = 100,000$)	6.3282e-4	3e-5
LS ($N = 1000$)	2.5442e-4	2.7482e-5

A couple of points shall be added. First, the essential idea of the LS is based on the Gaussian distribution of the samples, which is the assumption used in the domain transformation. The distribution of the fragments from the breakup model, on the other hand, is not Gaussian, which explains the difference between two probabilities. Moreover, we suspect that this distribution becomes even less Gaussian along the propagation. It is expected the LS cannot find the $(\bar{c}_1^{\,k}, \bar{c}_2^{\,k})$ at a certain point. Second, we decided to discard the SS at the moment, not because it is not able to calculate the probability, but the value is strongly dependent on the distribution used in the MCMC, and it is not clearly figured out yet which distribution shall be used. The SS is still a considerable approach when the objective of the application is to detect possible close approaches, however the proposed distribution part should be investigated further for probability estimation.

4. Conclusion

Line sampling (LS) and subset simulation (SS) are applied to the conjunction assessment with a breakup event, which are alternatives to calculate a small probability with less random samples. While the approaches detect 1e-4 to 1e-5 probability of close approaches, we also notice some limitations, which are worth investigating further. One possible future work is the sensitivity analysis of the LS with respect to propagation time, to check when it starts not finding the roots in the standard normal domain. Another idea is to think of a way to keep the samples distribution Gaussian as possible, e.g. by introducing Gaussian mixture model. Last but not least, Markov

Chain in the SS could be examined further, to decide which proposed distribution provides the most realistic probability.

Keywords: Multistage Suborbital Vehicles, Conceptual Design, Parametric Study

Abstract. Suborbital vehicles, which have the potential to drastically reduce the flight time of medium- and long-range missions to durations below one hour, are attracting increasing attention from the scientific community. The iConDeS (Integrated Conceptual Design Tools for Suborbital Vehicles) research project aims to develop advanced methodologies for the conceptual design and optimization of this class of vehicles. In this context, the present work investigates the influence of thrust-to-weight ratios on the design characteristics of a fully reusable two-stage launcher, with the objective of minimizing its liftoff mass.

Introduction

This work presents a multidisciplinary framework for the conceptual design and optimization of suborbital transatmospheric vehicles intended for space tourism and rapid global transportation of people and goods. The possibility of covering distances comparable to half of Earth's circumference in exceptionally short flight times would be a dramatic improvement for human society, and significant attention and investments have been drawn to this application. In recent years, private companies have developed suborbital vehicles for commercial use, notably in space tourism. Examples include Blue Origin's vertically launched New Shepard, Virgin Galactic's air-launched SpaceShipOne and SpaceShipTwo, and XCOR's Lynx, a rocket plane with conventional takeoff and landing. In parallel, major aerospace firms and research centers have focused on technology demonstrators for suborbital and hypersonic missions, such as Boeing X-37, Dream Chaser, CIRA's USV, and ESA's IXV. Research into fully reusable hypersonic aircraft continues, with key projects including SKYLON [1], LAPCAT A2, ZEHST, SpaceLiner [2], and HYPLANE [3]. The EU-funded STRATOFLY project further explores high-speed stratospheric flight [4]. Despite progress, integrated tools for efficient and safe suborbital vehicle design remain an active research need. This paper is based on the outcomes of the research program iConDeS (Integrated Conceptual Design Tools for Suborbital Vehicles) funded by the European Union through Next Generation EU (Project Identification Number P202272HBN). In this frame, a suborbital vehicle with a mission profile divided into four phases is considered: (i) an acceleration that brings the vehicle out of the atmosphere; (ii) a ballistic transfer covering most of the travel distance; (iii) an atmospheric re-entry close to the destination; (iv) a glide to the landing site. The methodology integrates sizing, aerodynamics, and trajectory analysis to design a minimum mass, fully reusable, two-stage vehicle tailored to specific mission scenarios. As a result, a multi-disciplinary technique

Materials Research Proceedings 69 (2026) 954-959 https://doi.org/10.21741/9781644904251-168

is obtained that integrates all analysis tools [5, 6]. Building upon previous results, this study investigates the influence of the thrust-to weight ratios of both stages of the vehicle on its design characteristics at launch and on the overall mission profile, with the ultimate goal of analyzing and characterizing the design space to simplify and enhance the efficiency of the launcher's optimization process, which represents the final objective of the research project. The theoretical framework is complemented by numerical analysis to support the findings and ensure their validity.

Methodology

The conceptual design process, as shown in Fig. 1, follows a structured, iterative sequence of disciplinary modules. The design process begins with the definition of the Top-Level Requirements (TLR), which specify a fully reusable two-stage vehicle capable of transporting 50 passengers to the desired destination using liquid oxygen (LOX) and liquid methane (LCH4) as propellants. During the mission, the maximum acceleration must not exceed 4.5 g in either the ascent or descent of the flight, as higher values are considered hazardous for humans [5]. Initial data is generated using a statistical database and heuristic strategies (to estimate design velocity). The Weight and Sizing module, comprising HASA [7] for hypersonic orbiter and MARYLAND [8] for booster, iterates until mass convergence is reached. An embedded optimization minimizes fuel split while meeting acceleration limits. The design is then simulated in the Trajectory module, allowing the sizing of the Thermal Protection System (TPS), whose feedback refines velocity and mass. After convergence, the mass balance, the inertial properties, and the visual output are finalized. A detailed description of each disciplinary module and their integration within the design framework can be found in Ref. [6], where both stages were assumed to operate with fixed thrust-to-weight ratios, and the gross liftoff mass together with the optimal propellant distribution was determined to meet the mission objectives. In the present work, building on the results of previous studies, a design of experiments on the thrust-to-weight ratios for both stages is addressed. The goal is to identify the configuration that minimizes the total liftoff mass for a given mission, while fully complying with the Top-Level Requirements and the associated operational constraints.

Results

A design matrix was set up to assess the effects of varying the thrust-to-weight ratios of the booster ($(T/W)_1$) and the aircraft ($(T/W)_2$), ranging from 1.15 to 1.6 and from 0.9 to 1.2, respectively. The ranges of variation of the two ratios were selected to enable a comprehensive analysis of the strong relationships between these parameters and the characteristics of the vehicle at launch (gross mass, length, TPS ratio), as well as the trajectory flown to reach the target destination (acceleration, deceleration, heat flux profiles). Although no feasibility assessment of propulsion technologies was performed, the selected ranges still represent realistic scenarios for possible vehicle configurations. As a further remark, based on practical and technological considerations, the analysis was limited to configurations where the thrust-to-weight ratio of the first stag$(T/W)_1$) is always greater or, at most, equal to that of the second stage ($(T/W)_2$).

Materials Research Proceedings 69 (2026) 954-959 https://doi.org/10.21741/9781644904251-168

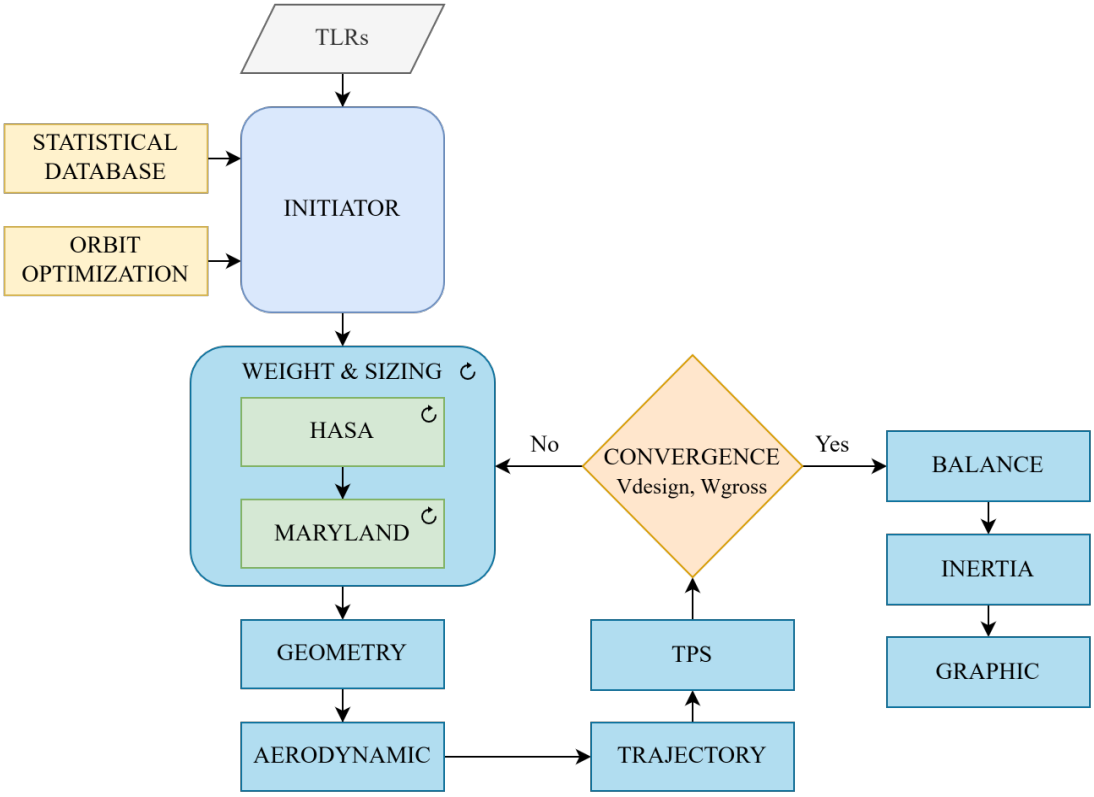

Figure 1: Workflow of the vehicle design methodology.

Fig. 2 shows a scatter plot of the results in terms of the gross mass of the entire vehicle at liftoff. Note that the graph includes some points that marginally exceed the maximum acceleration constraint (by less than 5%), and these points are marked with crosses. From this plot, it immediately emerges that the acceleration constraint poses an upper limit to the thrust-to-weight ratios, as excessive values of these parameters would bring the identified configuration to the bottom right corner of this plot, where all the crosses are distributed. The results shown in Figure 2 clearly indicate that the behavior of the gross mass at liftoff as a function of the two ratios is non-trivial, as it presents several local minima within the analyzed region. The global minimum can be identified at $(T/W)_1 = (T/W)_2 = 1.155$, corresponding to a total mass of 827.1 t. This point lies on the boundary delimiting the region of acceptable configurations and, importantly, the gradient of the gross mass is very steep in the vicinity of this minimum: a variation of only 4% in either parameter results in a change of approximately 10% in the gross mass.

Another region of interest can be observed around $(T/W)_1 = 1.25$ and $(T/W)_2 = 1.10$, corresponding to a total mass of 840.1 t. Unlike the previous case, the mass gradient in this region is milder with more gradual variations of the mass for the same variation in either parameter. Considering this region instead of that near the global minimum could therefore yield a more robust and less sensitive design solution.

Materials Research Proceedings 69 (2026) 954-959 https://doi.org/10.21741/9781644904251-168

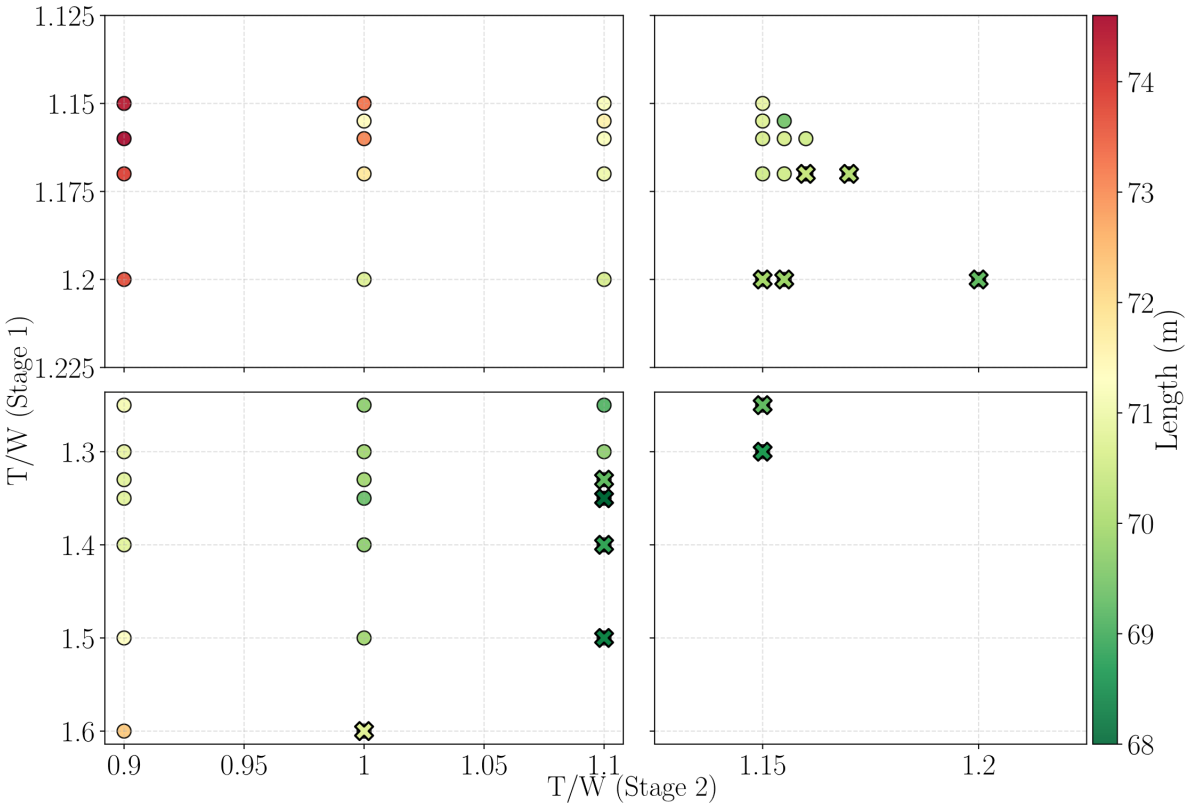

Figure 2: Scatter plot of considered points colored by gross mass. Circles represent configurations that comply with the maximum acceleration constraint, while crosses those that marginally exceed it. Axes are split and rescaled for clarity.

It is worth noting that, when including the solutions slightly violating the acceleration constraint, the global minimum corresponds to the configuration with $(T/W)_1$ = 1.35 and $(T/W)_2$ = 1.10, yielding a total mass of 812.5 t. This case achieves the mission with nearly 20 t less propellant compared to the configuration at $(T/W)_1 = (T/W)_2$ = 1.155, thus representing a significant design improvement while exceeding the acceleration limit by less than 1%. This small acceleration difference could be absorbed by considering control techniques of thrust and angle of attack in the launch and reentry phases, respectively, making this configuration fully acceptable.

Fig. 3 shows a scatter plot similar to that in Fig. 2 but with the points colored according to the total length of the vehicle instead of the gross mass. This quantity appears to qualitatively follow the same trend as the gross mass described previously. However, its variation with respect to the ratios is smaller, with a peak deviation of about 5% at $(T/W)_1$ = 1.15 and $(T/W)_2$ = 0.9 relative to the mean value across all configurations. This result indicates that variations in the thrust-to-weight ratios of the two stages have only a minor influence on the vehicle geometry, whose configuration at the acceptable global minimum is shown in Fig. 4 - 5.

Summary

A preliminary design of a suborbital vehicle capable of transporting 50 passengers from Naples to Port Moresby has been developed while satisfying, among other requirements, the acceleration constraints on the payload. The design optimization was conducted through a systematic design of experiments, varying the thrust-to-weight ratios of the two stages. The analysis revealed a nonlinear dependence of the vehicle gross mass on these parameters, with several local minima identified. Interestingly, the vehicle length remains nearly constant across all these minima, indicating a robust geometric configuration and suggesting that operational performance could be further optimized even after the vehicle's construction.

Abstract. Planetary exploration increasingly relies on autonomous robotic systems, yet the rigorous validation of end-to-end system behavior remains a significant bottleneck, par ticularly for small, multidisciplinary teams lacking the resources of large space agencies. This work addresses this challenge by tailoring established aerospace testing principles into a modular, scalable framework that balances thoroughness with agility. We demonstrate its application on the ARDITO rover, a platform developed by the DIANA student team at Po litecnico di Torino. Our approach provides a lean yet structured validation pathway, bridging the gap between ad-hoc laboratory tests and full-scale qualification campaigns governed by ECSS or NASA standards. The framework defines four distinct, interconnected testing layers: Design Validation (DEV), which focuses on component-level verification (e.g., finite-element analysis, bread board testing, test-driven development) within individual technical departments; Reduced Functional Tests (RFT), used as rapid control points to validate integrated subsystems after major events like transport or configuration changes; Full Functional Tests (FFT), which comprehensively evaluate the fully integrated rover under controlled laboratory conditions; and Mission Tests (MST), which simulate realistic task scenarios in environments like AL TEC Martian Terrain Simulator to evaluate performance under mission constraints. This hybrid agile-lean approach offers a clear academic and practical contribution for research groups and early-stage projects, ensuring reliable, mission-ready performance.

Introduction

Robotic systems with full or partial autonomy are becoming increasingly vital for planetary exploration. They are deployed to execute scientific, scouting, and support functions in remote, hazardous, poorly characterized locations (B. Hussain, 2025) (Ishigami, 2024). In the unforgiving space domain, where post-launch repair is impossible, Verification and Validation (V&V) are fundamental (R. C. Cardoso, 2021). Verification ensures a system is built according to its specifications, building the system right, while validation confirms it fulfills its intended purpose in its operational environ ment, building the right system. The state-of-the-art in V&V is polarized into two distinct paradigms based on mission scale and risk. The heavyweight standard, used for large-scale rovers, is exhaustive and requirements driven. Governed by NASA (Kapurch, 2010) and ECSS standards (ECSS, 2018), this multi-year process uses tiered f idelity testing, from simulations to hardware testbeds, consuming up to 80% of project timelines and creating a validation gap as system complexity outpaces testing capabilities. Conversely, the lightweight agile V&V for CubeSats is constraints-driven, prioritizing rapid schedules and fixed budgets. It relies on standardized tests and Commercial-Off-The Shelf (COTS) components. This polarization

Materials Research Proceedings 69 (2026) 960-965 https://doi.org/10.21741/9781644904251-169

presents a significant challenge, particularly for the small, multidisciplinary teams in university and startup environments, which lack the resources for the heavyweight approach but cannot always afford the high risk of the lightweight model. The case study for this work is the rover ARDITO (Caraccio, 2025) (N. di Gruttola Giardino, 2024).

Layered Validation Framework

To bridge the gap between ad-hoc laboratory tests and full-scale qualification campaigns, we developed a modular, scalable validation framework tailored for resource-constrained robotic projects developed in an educational environment **(Corpino, IFAC Workshop on Aerospace Control Education WACE 2021)**. This framework is built on a progressive philosophy, systematically escalating the scope and complexity of testing from individual components to the fully integrated system operating under mission-like conditions. It provides a structured pathway to retire risk incrementally, ensuring that foundational elements are robust before they are integrate into more complex assemblies. The work starts with the system's functions prioritization coming from the European Rover Challenge (ERC) rules and some key core requirements identified in parallel by the team's board of directors. Aspecific functional analysis identifies which requirements and functions are relevant for the test plan, and consequently they are organized and divided by subsystems.

The framework is composed of four distinct yet interconnected layers: Design Validation (DEV), Reduced Functional Tests (RFT), Full Functional Tests (FFT), and Mission Tests (MST). Each layer serves a specific purpose, building confidence in the system's reliability and performance at critical stages of the development and operational lifecycle.

Layer 1: Design Validation (DEV). The foundational layer, Design Validation (DEV), focuses on component-level verification before any system integration occurs. This phase is executed internally by each technical departments, from mechanical subsystems designs **(Trentini, 2024)** to software autonomy modules creation **(Mustich, 2023)**. This allows for focused, discipline-specific analysis **(Festa L. M., 2022)** and testing. The primary goal of DEV is to confirm that each component meets its design requirements and specifications in isolation, preventing fundamental flaws from propagating to higher levels of assembly where they become more difficult and costly to diagnose and fix.

Layer 2: Reduced Functional Tests (RFT). RFTs serve as a crucial ”health check” on integrated subsystems. These are rapid, targeted tests designed to be executed after major events such as

Materials Research Proceedings 69 (2026) 960-965 https://doi.org/10.21741/9781644904251-169

hardware configuration changes, software updates, or transportation. The purpose of an RFT is to quickly validate essential functions with minimal external depen dencies, providing prompt feedback on the system's baseline health. This allows the team to confirm that a recent change has not introduced a critical failure before proceeding with more time-consuming tests. For example, a typical RFT, performed after transporting the rover to a test site, is a 10-minute procedure that involves powering on the main computer and drive system, commanding each wheel to spin for five seconds, and confirming a teleme try is received from all critical sensors. This simple test quickly verifies the integrity of the power system, drivetrain, and core communication pathways.

Layer 3: Full Functional Tests (FFT). FFTs are designed to comprehensively evaluate the fully integrated rover and its payloads under controlled laboratory conditions. Unlike RFTs, which are narrow in scope, FFTs execute pre-programmed, end-to-end mission routines to stress-test every operational mode and verify complex software logic and inter-system interactions. These tests are performed on a flat, predictable surface to isolate the system's performance from environmental challenges, focusing purely on functional correctness and integration stability. An example FFT for the ARDITO rover involved a 1-hour autonomous sequence that executed a full mission profile to validate the entire chain of operations from navigation to payload deployment, ensuring that all subsystems work cohesively as intended.

Layer 4: Mission Tests (MST). The final layer, Mission Tests (MST), evaluates the sys tem's end-to-end performance under realistic task scenarios and environmental constraints that closely recreate actual mission parameters. For this critical phase, we had the oppor tunity to perform tests in ALTEC S.p.A Martian Terrain Simulator (MTS Facility**) (Bramante, et al., 2019)** in Turin, Italy. ALTEC, a center of excellence for space logistics and engineering, operates the Rover Operations Control Centre (ROCC) for the ESA ExoMars mission, and its MTS provides a high-fidelity Martian analogue terrain for testing and verification activities. The MTS hosts a ground test model of the ExoMars rover and is designed to rehearse surface operations in a terrain with Mars-like morphology. Within this facility, the ARDITO rover was subjected to mission scenarios derived from the rules of the European Rover Challenge, including navigating uneven terrain with slopes and obstacles, and operating under simu lated communication constraints, such as limited bandwidth and command delays. These tests were essential for validating the rover's performance and robustness in conditions that could not be replicated in a standard laboratory.

To manage this campaign within tight schedules and with limited personnel, we integrated lean operational practices, using physical Kanban boards **(Bacea, Ciupe, & Meza, 2017)** for real-time task prioritization and checklist-based reports to ensure traceability and facilitate anomaly tracking.

Methodology: Agile & Lean Process Management in the ARDITO project

To manage our complex four-layered validation campaign within a resource-constrained stu dent team, we adopted an agile-inspired approach. Our hybrid agile-lean methodology **(Festa G. P., 2025)** for the ARDITO project combines a high-level annual timeline with a dual-layered system built around major integration milestones called ”stable points” and two-week development cycles known as ”sprints.” The sprints were the engine of the project, where the low-level continuous work of the Design Validation (DEV) layer occurred. Within each sprint, techni cal groups focused on designing, building, and verifying their individual components through FEA, breadboarding, and test-driven development, ensuring quality was built in from the very beginning. The focus then shifted from the DEV layer to system-level verification, primarily using the Reduced Functional Test (RFT) and Full Functional Test (FFT) layers. This incremental approach was transformative for the project lifecycle; instead of a single, high-stakes integration event at the end of the year, we had multiple, lower-risk checkpoints. Each stable point provided a validated, reliable fallback

configuration, systematically miti gating risk and ensuring we always had a functional rover baseline. This structure creates a powerful feedback loop DEV − > RFT/FFT − > DEV. System-level failures found at a stable point are documented and feedback into the agile backlog to be resolved at the component level in the next sprint. This makes validation a continuous, iterative process, allowing us to manage complexity by progressively and thoroughly validating the system at every stage.

Conclusions

The novelty of our work lies in structuring these established methods into a tailored frame work guided by three core principles: modularity, scalability and feedback-driven iteration. By decoupling validation layers, defining adaptable templates and embedding agile feedback loops, the framework can be adopted or modified based on project scale and constraints. We have already begun applying this paradigm to other DIANA demonstrators, such as aerial companions, to further test its generalizability. In conclusion, this work presents a reproducible multi-layered testing framework that enables robust and resource-efficient validation of complex robotic systems. Its successful deployment on the ARDITO rover underscores its potential for broader adoption across academic and small-scale industrial contexts. Future work will formalise quantitative met rics, integrate software tools to replace physical boards and conduct cross-project studies to benchmark efficacy

Ackowledgments

The authors express their gratitude to the STAR Lab team and DIANA's students for their passion and continuous work, making this kind of work possible.

Abstract. This work proposes a hybrid tilt–twist fin configuration for CubeSat attitude control in Very Low Earth Orbit (VLEO), combining passive stability with potential control authority through two geometric parameters: tilt and twist angles. The aerodynamic forces and torques have been evaluated through a panel method in free molecular flow, across a parametric design space. Results demonstrate that hybrid configurations achieve lower drag than shuttlecock designs while providing superior control authority compared to feather configurations, establishing a crucial step for future dynamic deflection-based control laws in VLEO missions.

Introduction

The Very Low Earth Orbits (VLEOs), typically defined below 450 km, offers unique opportunities for future spacecraft missions by improving optical resolution, communication latency, and overall mission efficiency through lower-altitude operations. The denser atmosphere at these altitudes, however, introduces substantial aerodynamic forces and torques, which not only accelerate orbital decay but also dominate the disturbance environment affecting attitude dynamics. While traditional actuators, such as reaction wheels or magnetic torquers, may suffer from frequent saturation and limited lifetime under these conditions, the persistent aerodynamic environment can be exploited as a control resource rather than merely a disturbance [1]. The concept of aerodynamic attitude stabilization was initially formalized through analytical models linking geometrical parameters with stability derivatives, enabling the design of configurations that naturally keep the spacecraft's attitude around its aerodynamic equilibrium positions [2]. Subsequent studies demonstrated the feasibility of using deployable, fixed or multi-degree-of- freedom aerodynamic surfaces to achieve passive or active stabilization and control in VLEO [3,4]. Nonetheless, the integration of flexible elements can lead to complex nonlinear phenomena, including chaotic motion and coupled aero-elastic effects, which must be carefully modeled to ensure robust performance [5]. In this framework, the present work focuses on the aerodynamic characterization of fin-based configurations for CubeSats operating in VLEO, introducing a parametric design methodology that integrates geometric flexibility, with an aerodynamic analysis based on a panel method in free-molecular flow. The objective is to identify configurations that guarantee passive stabilization while preserving control authority and compatibility with CubeSat constraints, and to compare performances against shuttlecock and feather architectures. The paper is organized as

follows: the Methodology section introduces the aerodynamic modeling approach and the parametric fin generation tool; the Results section presents the numerical outcomes and discusses the stability trends as a function of fin geometry; and the Conclusions section reports key findings and prospects for the integration of hybrid aerodynamic control architectures in future VLEO missions.

Methodology

This paper uses the following convention on aerodynamic angles, according to the defined Body Reference Frame (BRF) (Fig. 1): angle of attack (α, angle between X_{BRF} and the projection of the freestream vector on the XZ_{BRF} plane, positive in case of clockwise rotation about Y_{BRF}) and sideslip angle (β, angle between X_{BRF} and the projection of the freestream vector on the XY_{BRF} plane, positive in case of counterclockwise rotation about Z_{BRF}).

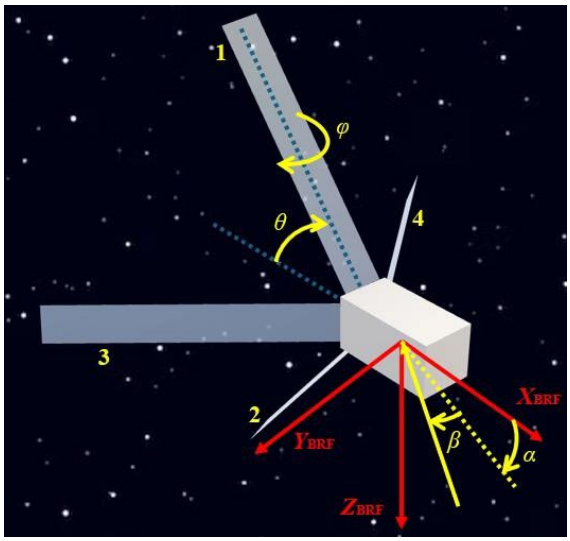

Fig. 1 Illustration of a 16U CubeSat with four deployable fins, the fin's geometric parameters (tilt angle θ and the twist angle φ) and the associated fin ID number, BRF and the aerodynamic angles (α, β).

The baseline spacecraft is a 16U CubeSat with four deployable fins attached to longitudinal edges (Table 1).

Table 1 Dimensions, mass, and material properties of the 16U CubeSat body and the deployable fins used for aerodynamic characterization.

Component	Parameter	Value
Body	Dimensions [mm]	400×200×200
	Mass[kg]	24
Fin	Dimensions [mm]	1000×130×0.5
	Mass [kg]	0.182

Each fin is characterized by two independent angular parameters: tilt angle θ (rotation about attachment edge, positive outward from X_{BRF}) and twist angle φ (rotation about spanwise axis, negative following right-hand rule) (Fig. 1), yielding an eight-dimensional design space $S = [\theta_1, \theta_2, \theta_3, \theta_4, \varphi_1, \varphi_2, \varphi_3, \varphi_4]$. Both parameters are discretized into $\theta \in [0°, 90°]$ and $\varphi \in [-90°, 90°]$, with

Materials Research Proceedings 69 (2026) 966-971 https://doi.org/10.21741/9781644904251-170

a 10-degree step each. For computational efficiency, the design space was subsequently reduced by imposing an axial symmetry with respect to X_{BRF} axis, coupling the parameters of opposing fin pairs ($\theta_1=\theta_2=\theta_3=\theta_4$; $\varphi_1=\varphi_2$; $\varphi 3=\varphi 4$). All configurations undergo geometric feasibility screening using intersection detection. The aerodynamic characterization employs the ADBSat computational framework for rarefied flow environments [6]. Aerodynamic forces and moments are computed using DRIA Gas Surface Interaction (GSI) with flight conditions specified in Table 2. Each configuration is evaluated under different wind conditions relative to the spacecraft. Specifically, α and β are varied within the range [−15°, 15°] with 3-degree increments, yielding 121 wind scenarios.

Table 2 Flight conditions and atmospheric parameters for aerodynamic characterization at 250 km altitude. The accommodation coefficient is computed according to [7].

Parameter	Value	Parameter	Value
Altitude [km]	250 km	Orbital velocity [km/s]	7.8
Latitude/Longitude [°]	40 N, 20 W	Atmospheric density [kg/m³]	~10^{-11}
Solar flux ($F_{10.7}$) [SFU]	140	Surface temperature [K]	300
Geomagnetic index (Ap)	14	Accommodation coef.	0.99
Knudsen number (Kn)	>> 10	Atm. Model	NRLMSISE-00

Among the 190 generated configurations, one optimal hybrid design is selected for comparison; this spacecraft architecture was derived from a Pareto optimization using the following objective weighting scheme: 0.2 for drag, 0.25 for torque magnitude, and 0.15 for each stability derivative.

Results

The aerodynamic characterization of this configuration demonstrates balanced performance in stability, controllability, and drag magnitude among the 190 candidate hybrid configurations. The optimal hybrid configuration, derived from Pareto analysis, features four fins with 10-degree tilt angle and asymmetric twist: $\varphi_1=\varphi_2=-20°$ and $\varphi 3=\varphi 4=+20°$. As shown in Fig. 2, the moment coefficients C_l, C_m, and C_n are close to zero at $\alpha=\beta=0$ (equilibrium), confirming trim conditions when the freestream aligns with -X_{BRF}. In this region, C_m and C_n are assumed to vary linearly with α and β, allowing the identification of static stability derivatives, according to [2].

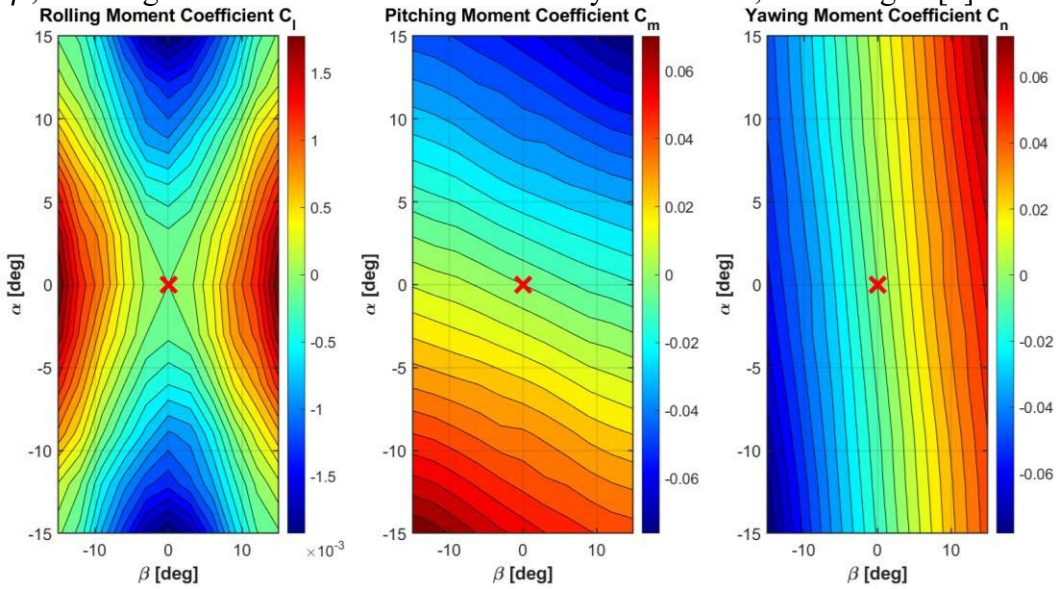

Fig. 2 Contour maps of the momentum coefficients as functions of the angle of attack and sideslip angle for the optimal hybrid fin configuration.

Materials Research Proceedings 69 (2026) 966-971 https://doi.org/10.21741/9781644904251-170

Fig. 3 indicates that $C_{m,\alpha}<0$ produces a restoring pitching moment as α increases, confirming pitch stability, while $C_{n,\beta}>0$ denotes yaw stability as β increases. In near-equilibrium region, the small magnitudes of $C_{l,\alpha}$ and $C_{l,\beta}$ suggest weak cross-axis coupling, ensuring nearly roll-independent pitch–yaw dynamics. The alternating sign of $C_{l,\alpha}$ reveals marginal roll stability, typical of symmetric aerodynamic layouts, yet acceptable for hybrid aerodynamic control schemes.

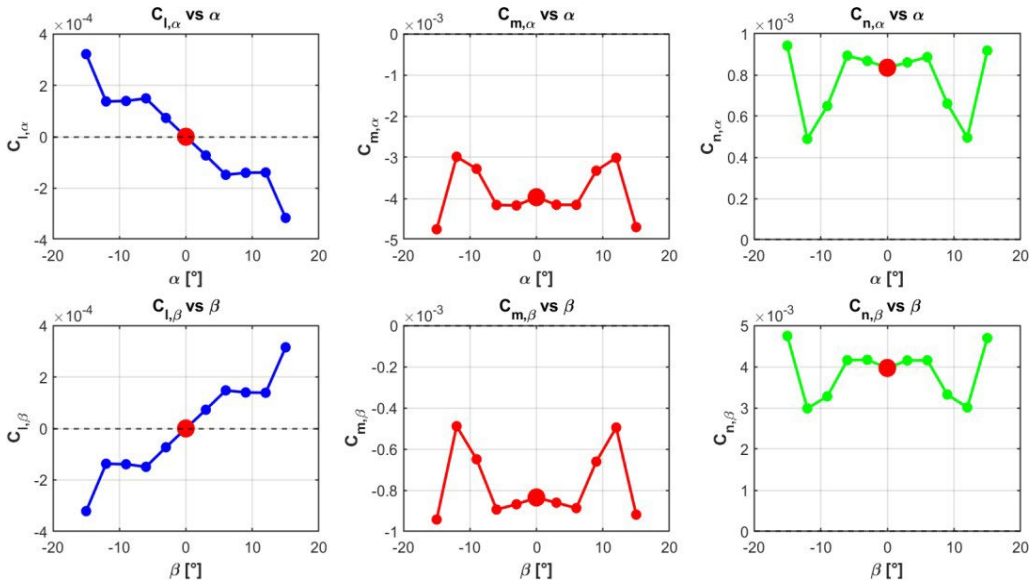

Fig. 3 Static aerodynamic derivatives as a function of incidence angles for the hybrid fin configuration.

For larger incidence angles, nonlinear variations of C_l, C_m, and C_n indicate increased torque generation, corresponding to reduced passive stability but improved control authority, especially along X_{BRF}. To validate the preliminary static performance of the hybrid configuration, a comparative analysis was conducted. In this study, the shuttlecock has 30-degree tilted fins with zero twist, promoting passive aerodynamic stabilization along the velocity vector, while the feather has 90-degree tilted and 90-degree twisted fins, minimizing drag and restoring torque [2]. Comparative results (Fig. 4) show that the shuttlecock offers stronger passive damping but with drag two orders of magnitude higher, while the feather minimizes drag but provides limited torque. The hybrid configuration effectively merges both behaviors, ensuring low drag and sufficient aerodynamic torque. The outperformance and trade-offs are further quantified in Table 3 by simulated semi-major axis decay over a single circular-orbit period using Gaussian Variation of Parameter (VOP) equations [8], where the shuttlecock's high drag leads to the highest decay, contrasting with the feather's minimal drag and lowest decay. The hybrid represents an optimized compromise, reducing the decay by approximately 83% compared to the shuttlecock.

Materials Research Proceedings 69 (2026) 966-971 https://doi.org/10.21741/9781644904251-170

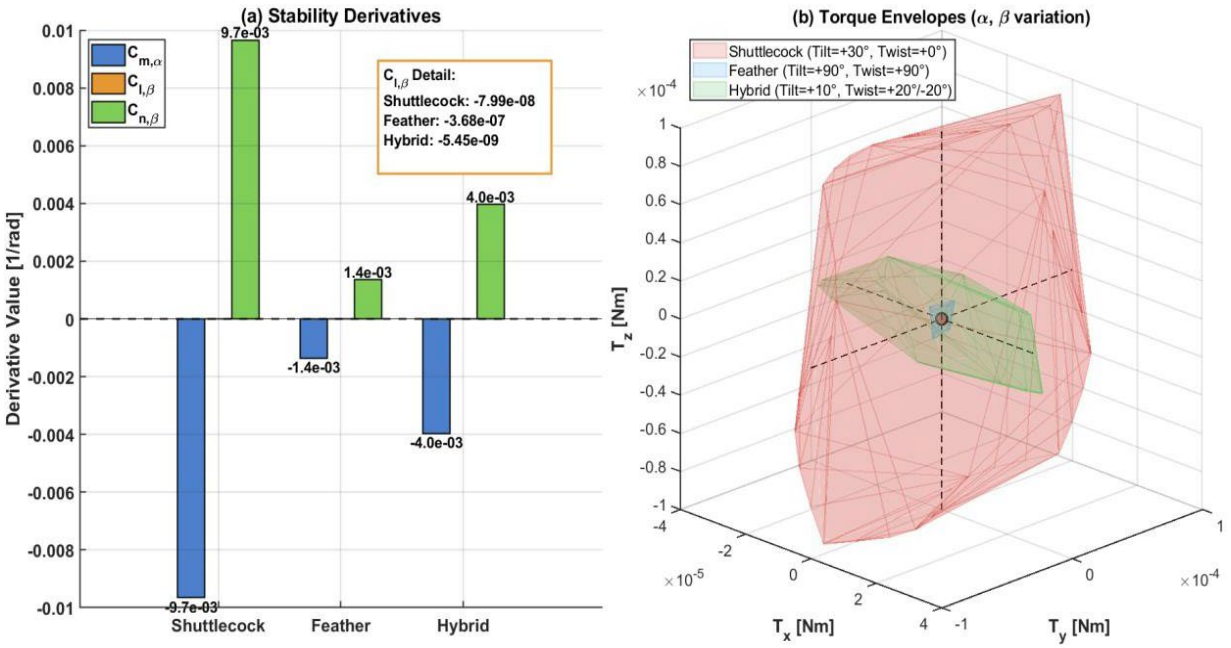

Fig. 4 Comparative analysis of the shuttlecock, feather, and hybrid fin configurations, showing (a) the stability derivatives at zero incidence, and (b) the resulting aerodynamic torque envelopes as a function of the aerodynamic angles.

Table 3 Comparative drag analysis and orbital decay for shuttlecock, feather, and hybrid fin configurations over one orbital period at 250 km altitude.

	Shuttlecock	Feather	Hybrid
Drag magnitude [N]	4.94×10^{-4}	1.45×10^{-5}	8.58×10^{-5}
1-orbit decay [m]	188	5.5	32.8

Conclusions

This work presents a parametric aerodynamic characterization of hybrid tilt–twist fin configurations for CubeSat attitude stabilization and control in VLEO. Panel-method free molecular flow simulations demonstrate that the selected optimal hybrid configuration achieves synergistic balance between passive damping and active control authority. The hybrid design exhibits negative pitch stability derivative and positive yaw stability derivative, confirming three-axis passive stability at trim conditions. Comparative analysis shows 83% reduction in orbital decay relative to the shuttlecock (32.8 m vs. 188 m per orbit) while maintaining superior control authority compared to the feather design.

Future work will extend this static aerodynamic characterization to dynamic attitude motion, validating the stability predictions through coupled rotational dynamics simulations. The parametric database established herein provides the foundation for developing control laws based on time-varying fin deflections. Control allocation algorithms will regulate fin deflections to achieve commanded torques while minimizing drag penalties.

Keywords: Orbital Forces Modelling, Orbital Torques Modelling, GPU-Powered Approach, In-Parallel Computation, SRP, Drag

Abstract. Precise orbit determination (POD) is essential for Earth observation missions and geodetic satellites operations. While current POD systems achieve centimetre-level accuracy, occasional residual discrepancies result from simplified spacecraft geometry models. Considering the true shape of the object, rather than relying on the typical box-wings approximation, can further increase the accuracy of the computation. Moreover, SST applications, such as collision risk assessment or re-entry predictions, can be enhanced by considering the real shape and attitude of space objects. In this regard, tools for attitude propagation and determination of tumbling objects are crucial, and require precise modelling of the torques affecting the satellite. This work presents GMV's GRIAL, a GPU-powered library for high-fidelity computation of force and torque perturbations acting on the surfaces of space objects of any complex shape in any attitude motion. In particular, the library models perturbations arising from solar radiation pressure (SRP), atmospheric drag, and Earth's albedo and infrared (IR) radiation. Utilizing the GPU enables highly efficient and precise calculations, allowing the forces and torques to be computed simultaneously at numerous points on the object's surface, and then summed using the CPU. Moreover, the incorporation of an OpenGL layer in the tool enables shadow casting, that efficiently accounts for the self-shadowing that occurs between different parts of the object, which is particularly significant for convex shaped features or protrusions such as dish antennas or solar arrays.

Introduction

The number of objects orbiting Earth has seen a rapid increase, particularly in the last decade. With the launch of mega-constellations and the advent of more affordable and accessible space technology, even for smaller entities, the density of satellites and debris in Low Earth Orbit (LEO) has significantly increased. Consequently, space traffic management has become a critical area of interest for satellite operations. Collision avoidance manoeuvres are becoming more and more essential, and their cost and effectiveness depend primarily on the precision of collision risk assessment. This precision relies mainly on accurate orbit prediction but can be further improved when the shape and attitude of the objects at the moment of closest approach are known. The same principle applies to other space applications, including re-entry predictions, Active Debris Removal (ADR) and In-Orbit Servicing (IOS), which rely on the real attitude of the object.

Consequently, a key step toward improving these applications is the ability to propagate the attitude motion of tumbling objects, which in turn requires accurate modelling of orbital torques acting upon them. It is important to highlight that determining the shape and surface properties of tumbling objects can represent a challenging task; the present work assumes that such information is available.

The accurate modelling of non-gravitational perturbations is a fundamental requirement for precise orbit and attitude prediction. Perturbations like SRP, atmospheric drag, and the Earth's albedo and infrared radiation can affect both orbital and rotational dynamics.

Content from this work may be used under the terms of the Creative Commons Attribution 3.0 license. Any further distribution of this work must maintain attribution to the author(s) and the title of the work, journal citation and DOI. Published under license by Materials Research Forum LLC.

Traditional POD tools typically rely on simplified geometries, such as box-wing or equivalent-area macromodels, in which more complex structures are reduced to a number of flat panels. While computationally efficient, these approximations neglect local variations in surface orientation and fail to capture self-shadowing effects that can arise between spacecraft components. As a result, the computed forces and torques may deviate from the true values, leading to systematic errors in orbit and attitude prediction.

Considering the actual three-dimensional geometry of a spacecraft allows a much finer description of the distribution of orbital forces and torques acting on its surfaces. However, computing sequentially the individual contributions of infinitesimal surface elements for complex geometries, while simultaneously considering self-shadowing effects, is computationally unfeasible.

This paper proposes a methodology for tackling these challenges by developing a high-fidelity, GPU-powered orbital forces and torques simulator, designed to handle complex-shaped objects in tumbling motion. The tool takes advantages of GPU-parallelization and OpenGL shadow-casting capabilities to increase its efficiency and the accuracy of the results.

For this purpose, the paper is organized as follows. First, the State-of-the-art Section presents current state-of-the-art POD software tools and GPU-based applications for orbital perturbations modelling. The Methodology Section illustrates the concept of GPU-based computation and presents the mathematical models used for orbital forces and torques of interest. The Results Section focuses on the validation of the work and on the discussion of the obtained results. Finally, all the results achieved are summarized in the Conclusions and Future Work Section and the possible focus points for future work are listed.

State-of-the-art

The state-of-the-art in POD software has seen significant advancements, driven by the growing complexity of space missions and the increasing need for high-precision satellite tracking. GEORB, an open-source software released in 2022, specializes in POD of Low Earth Orbiters and satellite gravity missions, supporting missions such as GRACE and GOCE [1]. It uses estimation techniques such as Kalman filtering and supports high-fidelity models for perturbation forces, including atmospheric drag, SRP, and third-body interactions.

On the other hand, OCEAN (Orbit/Covariance Estimation and ANalysis) is a comprehensive software suite for orbit determination and ephemeris propagation, employing high-fidelity models and classical estimation techniques such as least squares adjustment [2]. Its detailed covariance analysis is particularly useful for mission planning, satellite conjunction analysis, and risk assessment.

GMV employs its own POD software for satellite control of the ESA Copernicus constellation, called FocusPOD [3]. FocusPOD is powered by MAORI, a GMV Flight Dynamics and Geodesy library written in C++ and Python [3], highly efficient and accurate for box-wing-shaped satellites, whose attitude is controlled and known at all times. With extremely high-fidelity models for orbital perturbations, MAORI is capable of ensuring an accuracy on the order of centimetres for the satellite's estimated position.

However, all the aforementioned POD software tools rely on simplified macromodels of the satellite that do not account for its actual complex geometry or the self-shadowing effects between different components. To address these limitations, several studies have proposed higher-fidelity modelling of orbital perturbations, particularly SRP and atmospheric drag, through the explicit consideration of the object’s true three-dimensional shape. The advantages of GPU-based approaches have been explored by Zardaín [4] and, previously, by Tanygin [5]. Specifically, the first study [4] employs more traditional ray-casting and ray-tracing algorithms and it focuses exclusively on SRP. On the other hand, Tanygin [5] proposes in his study a similar OpenGL-based approach as the one used in this work, which relies on the GPU's native capabilities to perform

Materials Research Proceedings 69 (2026) 972-993 https://doi.org/10.21741/9781644904251-171

projections of a three-dimensional scene. The current research however expands the modelled perturbations, accounting for IR and albedo radiation (in addition to SRP and atmospheric drag), and it performs an extensive validation analysis against existing highly accurate POD tools.

Methodology

This section outlines the steps, methods and techniques used in the development of the GRIAL software for high-fidelity orbital forces and torques modeling. As previously mentioned, the work relies on GPU-powered computation to increase the performance and the accuracy of the software. The GPU-Powered Approach Section details the procedure behind this approach, explaining each step of the computation action both on the CPU and GPU sides.

Moreover, the Modelling Section details the equations and physics underlying the disturbance forces acting on the satellite. Each subsection will focus on a specific force, with the explanation of each individual model.

Finally, in the Torques Section the focus shifts towards GRIAL's torque computation capability, a feature critical for attitude propagation of tumbling objects.

GPU-Powered Approach. GPUs are designed to handle multiple operations concurrently, making them ideal for tasks that require parallel processing. In the context of orbital forces and torques simulation, this feature can be employed to perform simultaneous computations of vectorial forces and torques across numerous points on a satellite's surface. Traditional CPU-based methods for modelling orbital disturbances often involve sequential processing, which can be time consuming and computationally intensive, particularly for complex satellite shapes.

In the development of the GRIAL software, the parallel processing capabilities of GPUs were utilized through OpenGL to take advantage of its inherent automatic shadow-casting capability. The process begins with the definition of a detailed wavefront *.obj* file of the satellite using some open source 3D creation suite. This file describes the satellite's geometry. Alongside, a *mtl* file is created, which includes essential properties like optical characteristics (for radiation-related calculations, like SRP, albedo and IR), material temperature and air-interactions properties (for drag force computations, see the Atmospheric Drag Section).

Fig. 1 contains example snippets of a *.obj* and a *.mt* file. In summary, the *.obj* file defines:

- *Objects* (line starts with *o*). Object's parts are defined by their name and are composed of multiple triangular surface elements (facets).
- *Vertices* (line starts with *v*). Facets' vertices are defined by their position vectors in metres.
- *Normal Directions* (line starts with *vn*). Unit vectors defining the outwards normals to the facets of the part.
- *Textures* (line starts with *vt*). They are not used in the force and torque simulations.
- *Facets* (line starts with *f*). Each triangular facet of the part is defined by three triplets, each defining the index of the position vector, the index of the texture and the index of the outward normal direction at a vertex. They are grouped by materials.

The materials used by the facets of the *obj* file are defined in the *mtl* one. Each material is identified by a name and associated with the following data:

- Its specular and diffuse coefficients for visible light K_s and K_d necessary for SRP and albedo forces computation, as in the Solar Radiation Pressure and Albedo Reflected Radiation Sections.
- A wall temperature T_W used for drag force computation as will be explained in the Atmospheric Drag Section.
- Surface-air interactions parameters for drag computation σ_N and σ_T, as explained in the Atmospheric Drag Section.

Materials Research Proceedings 69 (2026) 972-993 https://doi.org/10.21741/9781644904251-171

- A reradiation index for visible light R_r, employed in the Solar Radiation Pressure and the Albedo Reflected Radiation Sections.
- Its specular and diffuse coefficients for IR radiation K_s^{ir} and K_d^{ir}, used for IR force computation, as in the Earth IR Radiation Section.
- A reradiation index for IR radiation R_r^{ir}, used in the Earth IR Radiation Section.

Fig. 1 Examples of obj and mtl files

Once the *obj* file is loaded, an OpenGL scene is created each time a computation is executed. Depending on the force being calculated, the scene is projected in a specific direction (i.e. towards the Sun for SRP, along the velocity vector for atmospheric drag etc.). This projection simulates the casting of shadows on the model, ensuring that forces are computed only on the vertices directly exposed to the flow. This method represents a significant innovation and advantage over traditional approaches: without the need to perform any simplification or approximation of the satellite's shape, the software is capable of retrieving efficiently the set of "visible" points of the object.

The next step involves retrieving the material properties on the CPU side and passing them to the *vertex shader* as uniforms, which allows for dynamical modification of the properties if required. On the GPU side, the *vertex shader* executes the requested computations for each vertex exposed to the flow. The results of these calculations are stored as 3-dimensional force vectors in

Materials Research Proceedings 69 (2026) 972-993 https://doi.org/10.21741/9781644904251-171

an array of floats. The values are then normalized with a constant computed on the CPU, making each element fall between -1 and 1, and then passed as uniforms to the *fragment shader*.

Before reaching the *fragment shader*, OpenGL computes the interpolated normalized force vector on each visible pixel of the object, derived from the normalized forces of the vertices belonging to the facets where the pixel belongs. Then, in the customized *fragment shader*, each component of this normalized force vector is written to the red channel of a separate colour buffer (resulting in three buffers returned to the CPU), each stored as a 32-bit floating-point value. Since colour channels can only represent values between 0 and 1, a conversion of the form 0.5×(value+1) is applied prior to storage. Pixels that are not visible by the flux do not pass through the *fragment shader* and are directly assigned a zero value.

Finally, the CPU retrieves the three buffers and extracts the encoded normalized components of the force acting on each pixel. Pixels with a value exactly equal to zero are disregarded, as they correspond to areas not exposed to the incoming flux. After decoding and applying the inverse of the normalization factor, the forces from all pixels are summed, and the resulting vector is multiplied by the incident flux (e.g. radiation pressure or aerodynamic pressure) to obtain the total force acting on the object.

Traditional methods often rely on simplified satellite geometries, which can lead to inaccuracies in force and torque calculations. GRIAL can instead compute forces for detailed 3D models without approximation, even accounting for solar panel orientation. Specifically, the software is capable of continuously orientating the solar arrays of the satellite towards the Sun direction, optimizing at each instant the solar power generated and reflecting the behaviour of real-world satellites.

In the *mtl* file, the user can define solar panels and the Sun-lit face by naming the corresponding materials appropriately (name starting with "*SA_*"). This allows the software to recognize them as part of a moving solar array and autonomously rotate them in the optimal direction. To do so, the user has to define the rotation axis of the panel and its position in the body-fixed reference frame when loading the object model. Then, for every calculation, the software creates a rotation matrix $\underline{R}$, computed from the normal direction of the Sun-facing side of the panel, identified through the material name *SA_TO_SUN* in the *mtl* file. The matrix is then applied on the GPU side to the normal and the vertices of the panel, to account for its correct orientation. Let $\hat{n}_p$ be the projection of the panel normal vector $\hat{n}$ on the plane orthogonal to the rotation axis $\hat{r}$, defined as:

$$\hat{n}_p = \hat{r} \times (\hat{n} \times \hat{r}) \tag{1}$$

And $\hat{s}_p$ be the projection of the Sun direction in the satellite reference frame $\hat{s}$ on the same plane:

$$\hat{s}_p = \hat{r} \times (\hat{s} \times \hat{r}) \tag{2}$$

Then, $\underline{R}$ is defined as the rotation matrix that when applied to $\hat{n}_p$ returns s $\hat{s}_p$ with the smallest associated rotation angle around the $\hat{r}$ axis, as:

$$\hat{s}_p = \underline{R} \cdot \hat{n}_p \tag{3}$$

Modelling

The following Sections detail the characteristics of the mathematical models selected and implemented in GRIAL. The fidelity and the accuracy of the models is proved by their wide employment in POD applications.

Materials Research Proceedings 69 (2026) 972-993 https://doi.org/10.21741/9781644904251-171

Solar Radiation Pressure. SRP is a major perturbation factor for satellites in all orbital regimes. GRIAL makes use of a widely employed mathematical model for computing the force applied to the satellite by the solar radiation, defined and used by Zardaín [6] and Rodriguez [7]. The model, which corresponds to the one employed by MAORI, defines the SRP force $\vec{F}_{srp}$ on a flat surface to be a linear combination of the forces produced by the specular $\vec{F}_s$, absorbed $\vec{F}_a$ and diffuse $\vec{F}_d$ reflections, as:

$$\vec{F}_{srp} = K_s\vec{F}_s + K_a\vec{F}_a + K_d\vec{F}_d \tag{4}$$

Each force is defined as:

$$\vec{F}_a = P_{srp}A\cos\theta\,\vec{r}_s \tag{5}$$

$$\vec{F}_s = 2P_{srp}A\cos^2\theta\,\vec{n} \tag{6}$$

$$\vec{F}_d = P_{srp}A\cos\theta\left(\vec{r}_s + \frac{2}{3}\vec{n}\right) \tag{7}$$

Where:

- K_s, K_a, K_d are the material optical properties of the flat surface. Each coefficient is bounded between 0 and 1 and $K_s + K_a + K_d = 1$.
- A is the area of the flat surface.
- $\vec{n}$ is the unit vector normal to the surface.
- $\vec{r}_s$ is the unit vector that lies in the Sun-to-spacecraft direction.
- θ is the angle between incoming radiation and surface normal direction.
- P_{srp} is the solar radiation pressure at a given distance R from the Sun, computed as:

$$P_{srp} = P_{1AU}\left(\frac{\mathrm{AU}}{R}\right)^2 \tag{8}$$

Where $P_{1AU} = 4.57 \times 10^{-6}\ \mathrm{N/m^2}$ is the solar pressure at 1 Astronomical Unit (AU).

The total SRP force acting on the i-th surface element of a satellite is then defined by the sum of the three contributions as:

$$\vec{F}^i_{srp} = P_{srp}A_i\cos\theta_i\left[\left(1 - K_s^i\right)\vec{r}_s + 2\left(K_s^i\cos\theta_i + \frac{K_d^i}{3}\right)\vec{n}_i\right] \tag{9}$$

Finally, the model also allows for the user to require specific panels of the objects to re-radiate, as:

$$\vec{F}^i_{srp} = P_{srp}A_i\cos\theta_i\left[\left(1 - K_s^i\right)\vec{r}_s + 2\left(K_s^i\cos\theta_i + \frac{1-K_s^i}{3}\right)\vec{n}_i\right] \tag{10}$$

Atmospheric Drag. Aerodynamic drag is a significant force acting on satellites in LEO, where the residual atmosphere creates a drag effect that gradually reduces the satellite's altitude and affects its trajectory. This force arises from the interaction between the satellite's surface and the flow of atmospheric particles, leading to a deceleration that must be accurately modelled to predict the satellite's orbit over time.

Materials Research Proceedings 69 (2026) 972-993 https://doi.org/10.21741/9781644904251-171

The aerodynamic model selected for GRIAL is the one defined by Carná and Bevilacqua [8] in free molecular regime. The model uses the geometrical properties of the object and the atmospheric data to compute the aerodynamic coefficients. Breaking the spacecraft structure down into a series of panels, it is possible to express a pressure and a shear stress coefficient for each panel, as functions of the local inclination angle between the surface normal and the incoming flow direction. The coefficients, c_{P_i} and c_{τ_i} respectively, associated to the i-th surface of the body are expressed as:

$$c_{P_i} = \frac{1}{s^2}\left[\left(\frac{2-\sigma_N^i}{\sqrt{\pi}} s\cos\theta_i + \frac{\sigma_N^i}{2}\sqrt{\frac{T_w^i}{T_\infty}}\right) e^{-s^2\cos^2\theta_i} + \left(\left(2-\sigma_N^i\right)\left(\frac{1}{2}+s^2\cos^2\theta_i\right) + \frac{\sigma_N^i}{2}\sqrt{\frac{T_w^i}{T_\infty}}\sqrt{\pi}\, s\cos\theta_i\right)\right]\left(1+\mathrm{erf}(s\cos\theta_i)\right) \quad (11)$$

$$c_{\tau_i} = \frac{\sigma_T \sin\theta_i}{s\sqrt{\pi}}\left[e^{-s^2\cos^2\theta_i} + \sqrt{\pi}\, s\cos\theta_i\left(1+\mathrm{erf}(s\cos\theta_i)\right)\right] \quad (12)$$

Where θ_i is the angle between the incoming air flow direction and the panel surface normal ($\vec{n}_i$), σ_N and σ_T are the normal and the tangential momentum accommodation coefficients, dependent on the material of the body and on the incoming flow properties. These two parameters can be subject to parametric analysis to determine their optimal values for specific applications. A good agreement with experimental data is mentioned by Carná and Bevilacqua [8], considering $\sigma_N = \sigma_T = 0.9$ for aluminium-air interactions.

Also, s is the freestream molecular speed ratio:

$$s = \frac{V_\infty}{\sqrt{2RT_\infty}} \quad (13)$$

Where R=287 $\frac{\mathrm{J}}{\mathrm{kg}}$K is the ideal gas constant for air, T_∞ is the air temperature, T_w is the wall temperature of the panel.

Finally, the aerodynamic drag force acting on the i-th panel on the surface of the satellite is expressed as:

$$\vec{F}_{drag}^{\,i} = -\frac{1}{2}\rho v_i^2 A_i\left(c_{P_i}\vec{n}_i + c_{\tau_i}\vec{\tau}_i\right) \quad (14)$$

Where:

- ρ is the atmospheric density.
- v_i is the velocity of the panel with respect to the atmosphere.
- $\vec{n}_i$ is the unit vector in the direction normal to the surface.
- $\vec{\tau}_i$ is the unit vector tangent to the panel's surface and co-planar with respect to the velocity direction $\hat{v}_i$ and the normal $\vec{n}_i$, as:

$$\vec{\tau} = \frac{(\hat{v}\times\vec{n})\times\vec{n}}{\|(\hat{v}\times\vec{n})\times\vec{n}\|} \quad (15)$$

The minus sign is used so that the vector is opposed to the force direction, which is then accounted for with the other minus sign in front of the force definition.

Materials Research Proceedings 69 (2026) 972-993 https://doi.org/10.21741/9781644904251-171

It is important to observe that the angular velocity of the object also plays a role in the computation. Indeed, if the object is in tumbling motion, the incoming direction of the flow cannot be considered the same for all the surface points, as a relative air velocity vector $\vec{v}_{rel}$ must be added to the overall flow velocity in the body-fixed reference frame $\vec{v}_{air}$, as:

$$\vec{v}_i = \vec{\omega} \times \vec{r}_i + \vec{v}_{air} \tag{16}$$

where $\vec{\omega}$ is the object's angular velocity in the body-fixed reference frame, $\vec{r}_i$ is the considered vertex position with respect to the centre of mass. The flow velocity $\vec{v}_{air}$ is computed as the vectorial combination of the satellite velocity and the atmosphere velocity, assumed fixed to the Earth. Since GRIAL is designed to tackle uncontrolled tumbling satellites, this phenomenon has to be taken into account, as it affects the computation, in particular the drag-induced torque.

For its aerodynamic drag computation, MAORI employs a similar but slightly different model. In particular, MAORI takes into account all the elements in the atmosphere individually and computes their individual contribution to the total drag, taking into account each element's molar mass and its concentration, whereas GRIAL considers air as a unique mean. Moreover, while GRIAL employs the hypothesis of a free molecular regime and hyper-thermal flow, which means that any portion of the object not directly exposed to air flow does not contribute to the overall drag force computation, MAORI employs the front-back model developed by Smith [9].

As the first step in graphic computation of GRIAL is the projection and a shadow casting in the flow direction, the parts of the satellite which are not visible must be neglected, meaning that the assumption of hyperthermal flow is necessary for its implementation.

Albedo Reflected Radiation. Originating from the reflection of a fraction of the solar radiation on the Earth's surface, the albedo force mostly affects satellites in LEO. The albedo force is modeled exactly as the SRP one. As the radiation remains within the visible spectrum, the optical parameters K_s and K_d are the same as the ones employed for the SRP computation. The key difference between the two forces is the source of the radiation: unlike the SRP where the radiation arrives from the Sun, considered as a distant point, the albedo force comes from the radiation's reflection on Earth's surface. From the satellite's perspective, the Earth is a large entity and cannot be simplified to a point source as the Sun is in SRP calculations. To address this issue, the Earth's surface is divided into smaller areas, all of which contribute to the total computed force. Each surface element is associated to:

- The coordinates of its centre point (in *ITRF*).
- The area of the surface.
- An albedo coefficient. The albedo coefficient indicates how much of the incoming radiation is reflected towards the object. This value is not homogeneous across Earth's surface and is not constant over time. NASA's Space Weather website [10] provides data for surface elements of the Earth, subdivided into longitude–latitude grids and available for each month of the year.

As a result, a single force computation requires iterating over each visible portion of Earth's surface, performing a graphical computation for each element. Once computed, all the contributions are summed together to compute the total force. This process increases drastically the computation time compared to the SRP and atmospheric drag cases, which only require one graphical computation for each point.

The albedo force contribution produced by the i-th surface element is modelled similarly to the SRP case, described in Eq. 9 and Eq. 10, with the incoming flux direction being the Earth surface vector-satellite direction, instead of Sun-satellite, and the radiation pressure coming from the surface element, computed as:

Materials Research Proceedings 69 (2026) 972-993 https://doi.org/10.21741/9781644904251-171

$$P_{arp} = a_i \frac{L_\odot}{4\pi R^2} A_i \cos\alpha \frac{\cos\beta}{\pi} \frac{1}{d^2} \frac{1}{c} \quad (17)$$

Where:

- a_i is the albedo coefficient associated to the Earth's surface element.
- $L_\odot = 3.828 \times 10^{26}$W is the luminosity of the Sun.
- R is the distance of the Sun to the Earth's surface element.
- A_i is the area of the Earth's surface element.
- α is the angle of the Sun direction with respect to the normal to Earth's surface element. If $\alpha \leq 0$ the Sun is not visible from the surface element, thus the incoming radiation is zero.
- B is the angle of the satellite direction with respect to the normal to Earth's surface element.
- d is the distance between the satellite and the Earth's surface element.
- c is the speed of light.

Finally, the sum of each contribution results in the total albedo force acting on the satellite.

Earth IR Radiation. IR force is generated by the emission of thermal energy from Earth's surface, which impacts satellites in orbit. While typically weaker than solar radiation pressure, the IR force is still significant, especially for satellites in LEO. Unlike SRP and albedo, which become null during the eclipse phases, IR radiation applies a continuous force on satellites throughout the entire orbit.

As they are both Earth-emitted radiations, the IR force is modelled following the same approach as the albedo case, detailed in the previous section, with the only difference being in the use of the infra-red optical properties of the satellite, instead of visible light. Indeed, being an Earth-emitted radiation as well, the total force is the result of the sum of a set of individual contributions derived from all visible Earth's surface elements. The formulation for the force due to a single Earth surface element is identical to the expression for the SRP force (Eq. 9 and Eq. 10), with the direction of the Earth's surface element replacing the Sun direction, and the solar radiation pressure being replaced by the IR radiation pressure coming from the element, which is computed as:

$$P_{irp} = I_i A_i \frac{\cos\beta}{\pi} \frac{1}{d^2} \frac{1}{c} \quad (18)$$

Where:

- I_i is the irradiance of the Earth's surface element.
- A_i is the area of the Earth's surface element.
- β is the angle of the satellite direction with respect to the normal to Earth's surface element.
- d is the distance between the satellite and the Earth's surface element.
- c is the speed of light.

Finally, the sum of all the contributions results in the total IR pressure force.

Torques. Torque computation largely depends on the object shape and orientation. For example, satellites equipped with solar arrays that extend far from the centre of inertia of the object can be subject to non-neglectable torques, caused by forces acting on the surface of the panel (which can behave like a sail). Traditional algorithms are not capable of performing these point-wise computations efficiently and experimental data is limited.

In contrast, GRIAL represents a viable tool in this regard: its graphical, pixel-wise computation enables the calculation of the torque generated by any mentioned orbital disturbance. In OpenGL, the position of each pixel relative to the satellite's centre of mass (as defined in the *obj* model) is

Materials Research Proceedings 69 (2026) 972-993 https://doi.org/10.21741/9781644904251-171

known, allowing the torque around the centre of mass to be computed for any of the modelled forces presented in previous sections.

Moreover, using the OpenGL graphical approach (detailed in the *GPU-Powered Approach* subsection), the data transferred between the GPU and the CPU is not necessarily bounded to the three components of a 3-dimensional vector. Indeed, it is possible to transfer up to n colour buffers, where n varies depending on the hardware, with a typical value of n = 8. This means that the GPU can simultaneously compute up to two 3-dimensional vectors, which can be employed to evaluate each force and the corresponding torque by means of a single execution of the OpenGL computation.

In the vertex shader, for each vertex, the selected disturbance force is computed and stored. Then, from the knowledge of the position vector $\vec{r}_i$ of the vertex with respect to the center of mass of the object, the torque is computed as $\vec{T} = \vec{r}_i \times \vec{F}$. Finally, $\vec{F}$ and $\vec{T}$ are passed on to the vertex shader, where they are encrypted and transferred to the CPU side of the operations.

In addition to the torques produced by the orbital forces presented in the sections above, there are other common torques that do not depend on the surface of the object and are not computed by GRIAL: the gravity gradient torque, which directly depends on the inertia matrix (as described by Kasiri [11]) and the eddy currents torque, which depends on the eddy currents tensor (whose relevance is presented by Lin [12], and a mathematical model is presented by Gomez [13]). These two torques will however be considered in the analysis of orbital torques presented in the Torques Section for a relative comparison against the torques implemented by GRIAL and their mathematical models are presented in the Eddy Currents Torque and the Gravity Gradient Torque Sections.

Results

This section presents the results obtained from the implementation and testing of the GRIAL software for forces and torque simulation. The primary goal of this work was to evaluate the performance of GRIAL's GPU-powered orbital force computation against traditional CPU-based methods. The software chosen to perform the comparative analysis is MAORI.

The case study selected for the analysis is represented by the Sentinel-3A satellite. Sentinel-3A is the third satellite to be launched for Europe's Copernicus environmental monitoring program [14]. It is a 1200 kg satellite in a 800 km altitude Sun-synchronous orbit [15], whose shape is easily approximated to a box-wing structure. Given that MAORI is highly accurate in handling such geometries, it serves as an ideal benchmark to compare the results obtained from GRIAL.

Fig. 2 shows a comparison between the real Sentinel-3A satellite and its geometrical model from its *obj* file.

Fig. 2 Sentinel 3A satellite (left) and its geometrical model (right)

As mentioned, GRIAL is designed to handle both controlled and tumbling objects, both with simple and complex geometries. However, the lack of available data on disturbances acting on

Materials Research Proceedings 69 (2026) 972-993 https://doi.org/10.21741/9781644904251-171

uncontrolled objects limits the scope of this analysis to controlled targets. Therefore, the full range of GRIAL's capabilities, particularly for tumbling objects, cannot be fully explored in this study.

Forces. Sentinel-3A orbits Earth approximately every 90 minutes, completing around eight revolutions during the 12 hour long simulation period selected for the SRP and drag computation. The satellite orbit is a near-polar, sun-synchronous orbit, with 10:00h Mean Local Solar time [16].

Fig. 3 shows the comparison between the SRP and the drag forces acting on the Sentinel-3A satellite, as calculated by GRIAL and MAORI. The graph clearly shows the periodic repetition of illuminated and eclipse phases, corresponding to one complete orbital period. Notably, both tools account for the penumbra phase, during which only part of the Sun is visible, resulting in a partial but non-zero amount of radiation reaching the satellite. This phase has a short duration relative to the entire simulation, which is why it appears on the graph as a quasi-vertical line.

The accuracy of the results is also proven by the graph of Fig. 4, which shows the element-wise difference between the force vectors computed by both propagators. The graph allows to observe that that GRIAL has a margin of error relative to MAORI on the order of 10^{-7} N (approximately three orders of magnitude smaller than the force itself).

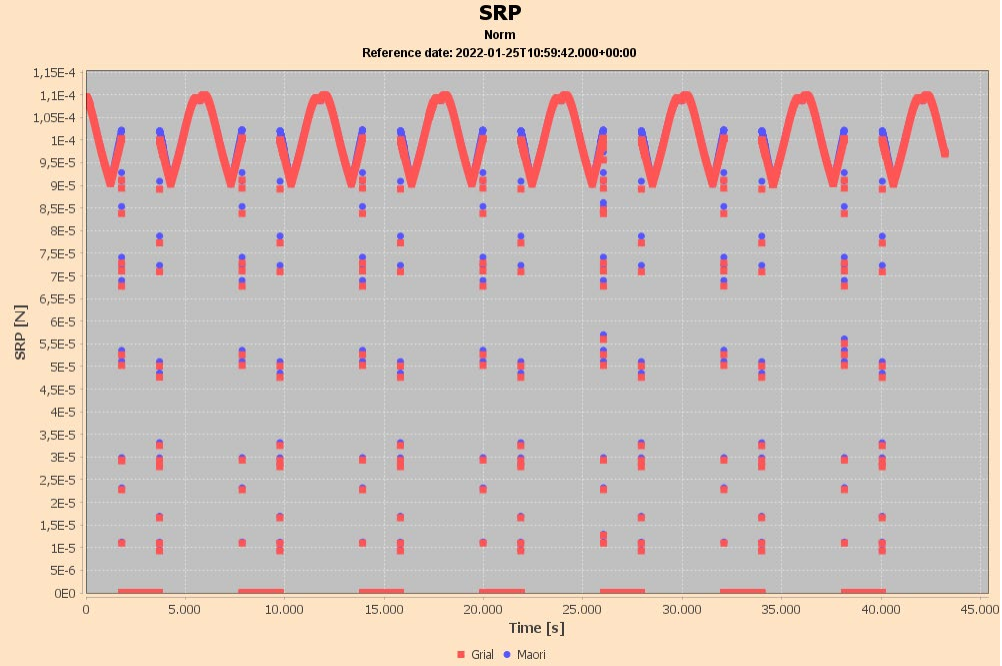

Fig. 3 SRP magnitude comparison between GRIAL and MAORI

Materials Research Proceedings 69 (2026) 972-993 https://doi.org/10.21741/9781644904251-171

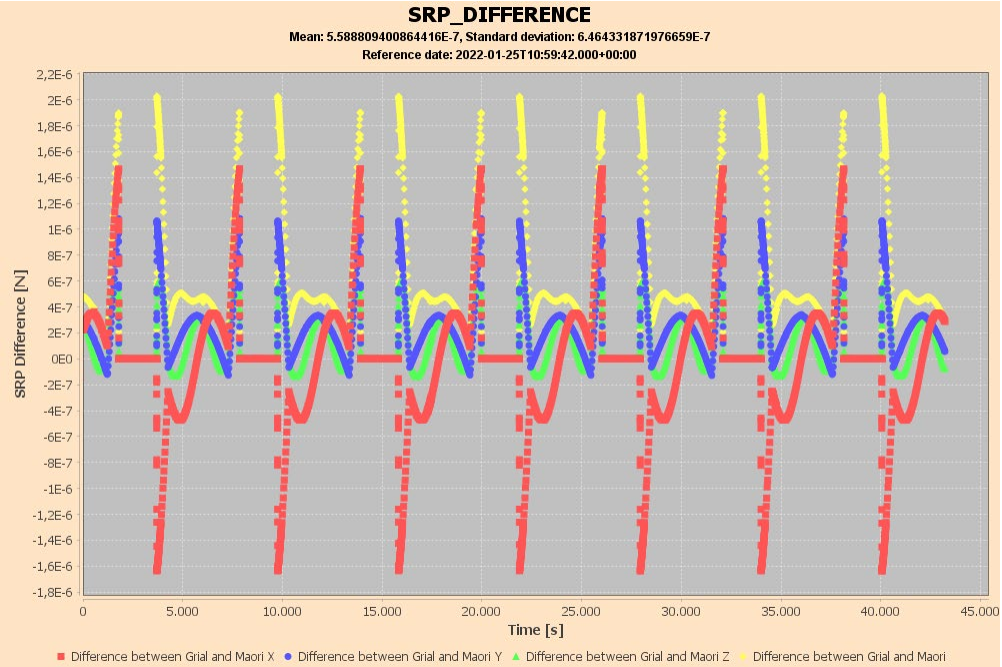

Fig. 4 SRP vector element-wise difference between GRIAL and MAORI

Similarly, Fig. 5 shows the magnitude of the drag force acting on the Sentinel-3A computed by GRIAL and MAORI. As the altitude of the satellite is not constant throughout the orbit (ranging between 811 km and 794 km), the drag force magnitude oscillates between 6.5×10^{-6} N and 10^{-6} N or below, with the peaks corresponding to the lower-altitudes instances (where the velocity and the air density are bigger).

Unlike the SRP case, the mathematical methods employed by GRIAL and MAORI for the computation of the aerodynamic drag are not the same, as explained in the *Atmospheric Drag* subsection. Nonetheless the simulations produce once again extremely similar results, as shown in Fig. 6, which illustrates the component-wise difference of the GRIAL and MAORI force vectors in the body-fixed reference frame.

The mean relative difference is once again in the order of 10^{-7} N, one order of magnitude below the force itself, despite the different models employed by the two tools, successfully validating GRIAL's method.

Materials Research Proceedings 69 (2026) 972-993 https://doi.org/10.21741/9781644904251-171

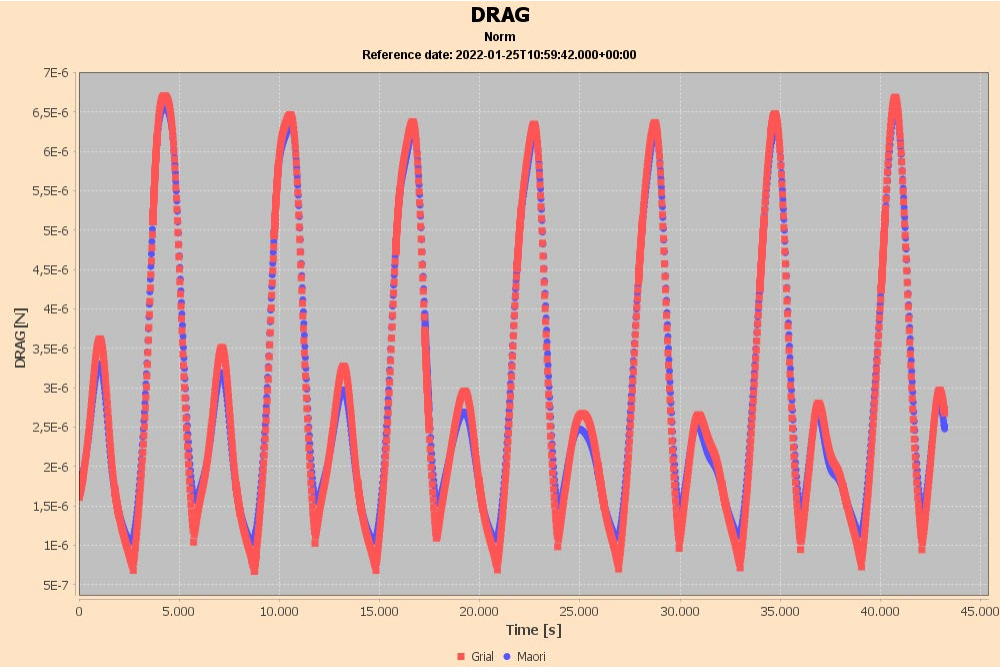

Fig. 5 Drag magnitude comparison between GRIAL and MAORI

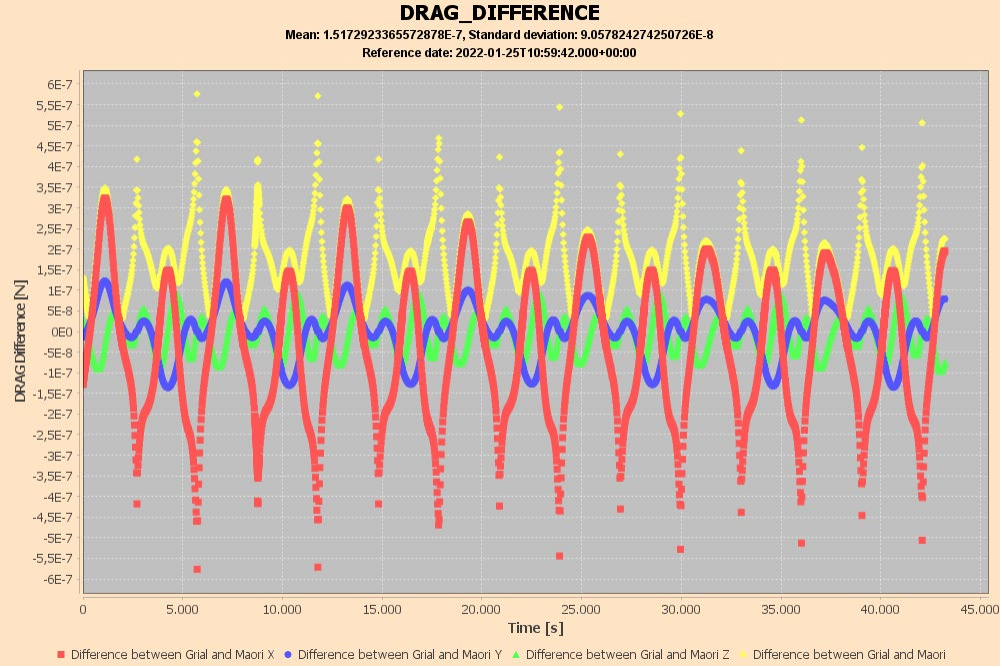

Fig. 6 Drag vector element-wise difference GRIAL and MAORI

Before performing the same analysis for the albedo and IR cases, it is necessary to make the following remark: the amount of radiation (reflected or emitted) is not constant around the surface of the Earth. For the albedo case, oceans and glaciers reflect more of the incoming solar radiation compared to trees and ground. Likewise, the IR radiation emitted varies depending on the temperature and radiative properties of the ground. With the seasonal changes in water levels, ice quantity and clouds presence, the amount of radiation reflected and emitted by any point of the surface is not quantifiable with absolute precision at every moment.

To tackle this issue, to each surface element of the 5°×5° longitude-latitude discretization of the Earth is assigned one reflective coefficient for each month of the year, for a total of 12 coefficients

Materials Research Proceedings 69 (2026) 972-993 https://doi.org/10.21741/9781644904251-171

per element. These grids have been generated for MAORI using monthly data from July 2002 to June 2020 from NASA's space weather website [10], and calculating the monthly average.

GRIAL follows exactly the same approach and it employs exactly the same coefficient as MAORI, allowing for a fair comparative analysis of the results. While the coefficients selected represent an accurate estimation of the real values, surface discretization introduces complexity and computational time problems for the algorithm. Being written on a pre-compiled language and performing all its computations on the CPU, MAORI is not expensively affected by this, whereas for GRIAL it represents an important performance limitation issue.

As mentioned in the *Albedo Radiation* and the *Infrared Radiation* subsections, the albedo and IR force calculation require to execute multiple times the graphic computation, one for each surface element into which the Earth has been divided visible from the satellite. Dividing the Earth's surface into a 72×36 grid across longitude and latitude (totaling to 2592 smaller surfaces), the Sentinel-3A satellite is visible from up to 400 of these surfaces at the time, with an average of around 250 surface elements per measurement. This means that to compute the Earth-radiation force in a single point of the orbit, hundreds of graphical computations must be performed (instead of just one, like in the SRP and drag cases). This heavy computational effort results in an exponential increase of computation time required to perform the calculation.

For computational time-related reasons, the results presented are computed over a reduced time interval of one single satellite orbital period, which corresponds to around 7500 seconds. This time span allows to fully observe the evolution and the behaviour of the forces over time, eclipse phases and most importantly the validity and accuracy of the results.

The comparison of Fig. 7 shows that the magnitude of the albedo force computed by GRIAL accurately matches the one computed by MAORI. Because of the resemblance to the SRP model, the accuracy of the results for the albedo calculation was expected. Moreover, both tools employ the same discretization of the Earth surface into smaller surfaces and the same albedo coefficients.

Fig. 8 shows the element-wise difference between the two solutions, with a mean difference between the results in the order of 10^{-7} N, which is two orders of magnitude below the force values. A possible source of discrepancy between the results are self-shadowing events that occur throughout the orbit caused by the solar panel, which MAORI cannot simulate.

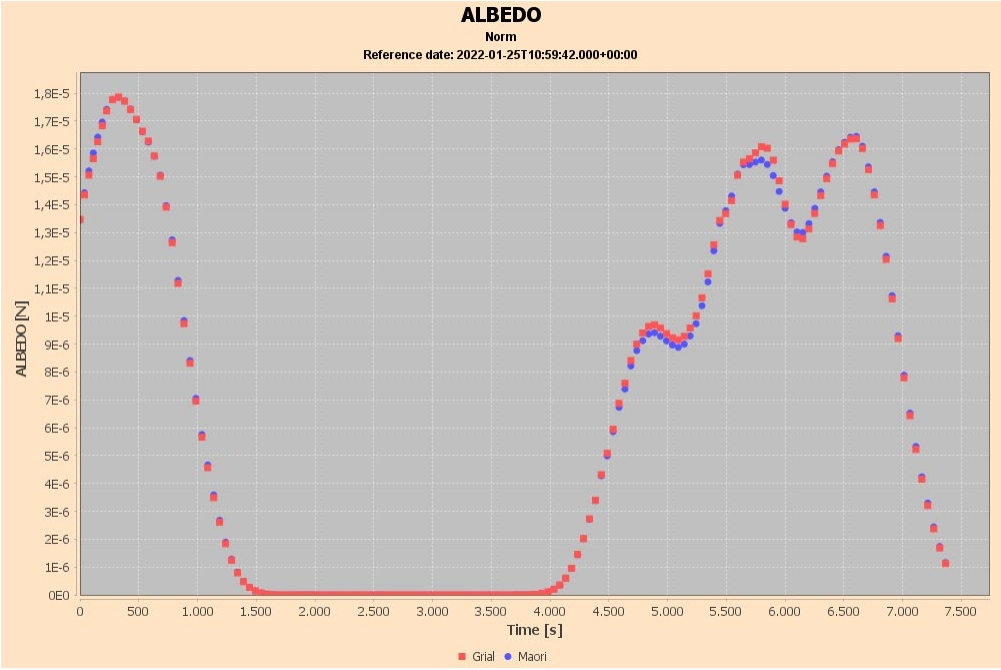

Fig. 7 Albedo force magnitude comparison between GRIAL and MAORI

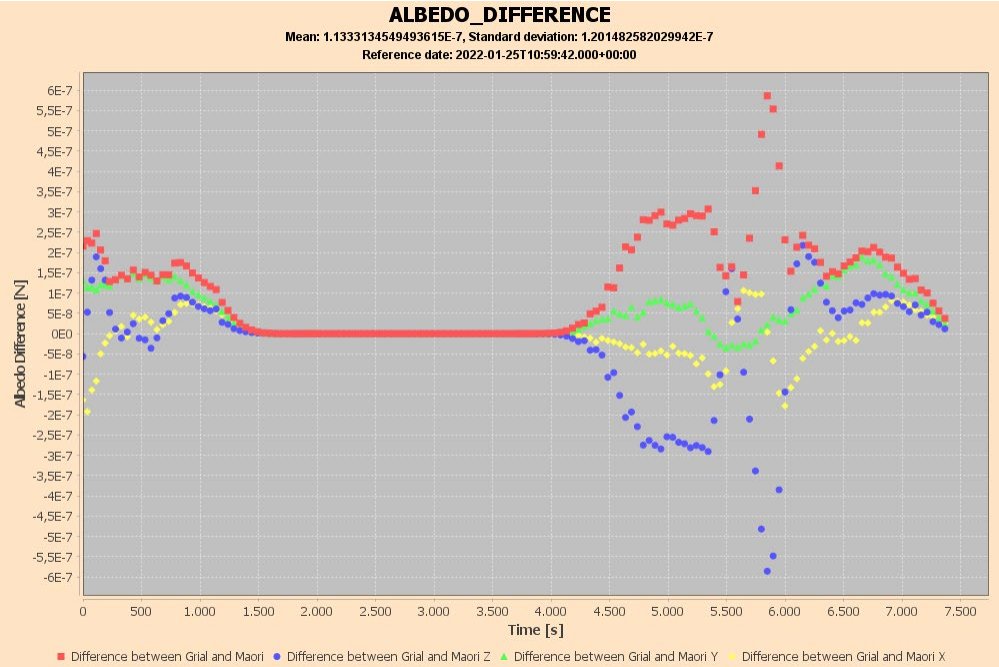

Fig. 8 Albedo force vector element-wise difference between GRIAL and MAORI

Finally, Fig. 9 shows the results of the same analysis applied to the IR radiation force case. The accuracy of the results was expected, given the similarity to the albedo radiation case, and it is further proved by the element-wise difference graph of Fig. 10. In particular, the mean difference between the two tools is found to be in the order of 10^{-8} N, which is three orders of magnitude lower than the force itself.

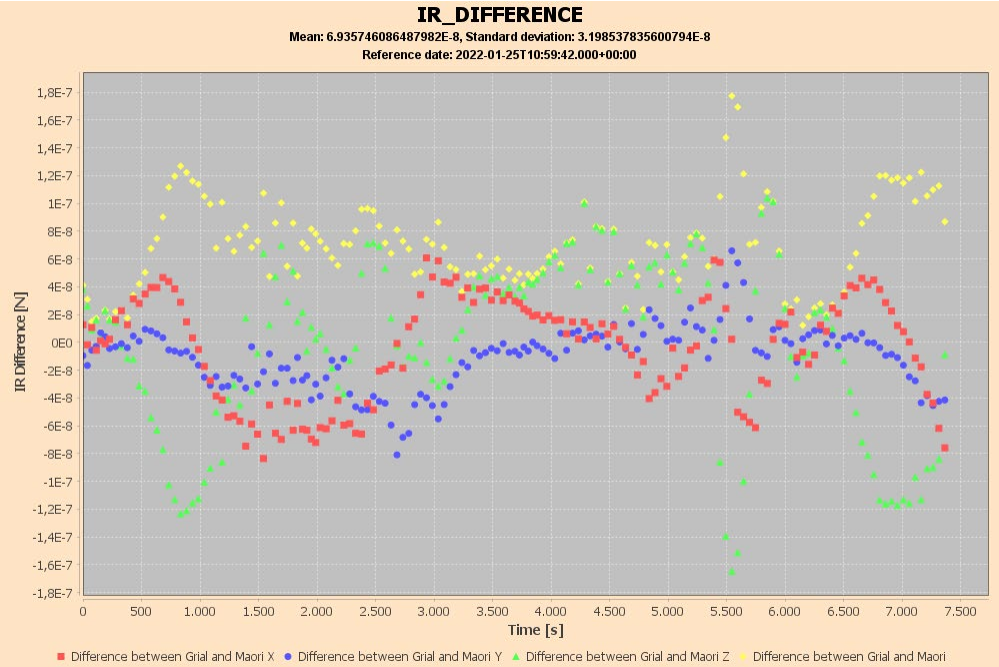

Fig. 10 IR force vector element-wise difference between GRIAL and MAORI

Computational Time. This section showcases GRIAL's computational efficiency for each of the force computations presented so far. As mentioned in the document, performance is a key driver for GRIAL. The graphic approach and the in-parallel computation enabled by the GPU aim at achieving high levels of accuracy without the need to compromise efficiency, even in the most complex scenarios. However, this method also introduces delays. Specifically, transferring data between processing units is the most time-costly operation of the algorithm. As this operation is performed once for every graphical computation, the number of times the GPU-powered methods are called directly affects the computational time of the entire operation. Table 1 shows the average time required to compute each force for different window resolutions.

The values in the table show that GRIAL is capable of efficiently performing complex calculations in acceptable durations. The main outtakes to retain from the table are:

- SRP and drag forces are computed fast because they only require executing the graphical computation once and they only perform one transfer of data between the GPU and the CPU.
- On the other hand, Earth radiation forces (albedo and IR) require much more time. This is due to the iteration over the visible smaller surfaces into which the Earth has been discretized (explained in the Albedo Reflected Radiation subsection). This repetition is particularly costly for GRIAL, as an asynchronous data transfer between the GPU and the CPU is performed for each graphical computation, which significantly increases computational time. The number of graphical computations is represented by the number of Earth surface elements visible from the satellite.
- GRIAL computes the albedo and IR forces simultaneously, optimizing a process which is time inefficient. The time required to compute them one at the time is the same as computing them together, as they can be transferred simultaneously to the CPU.
- The values do not depend on the satellite shape, but only on the desired resolution. Any geometry, regardless of its complexity, requires the same computational time, thanks to the graphical approach (GPU-Powered Approach subsection).

Materials Research Proceedings 69 (2026) 972-993 https://doi.org/10.21741/9781644904251-171

Table 1 Computational time (in ms) for each force computed over different window resolutions

	1000×1000 pixels per window	2000×2000 pixels per window
SRP	≈13 [ms]	≈90 [ms]
Drag	≈13 [ms]	≈90 [ms]
Albedo + IR	≈4000 [ms]	≈27000 [ms]

Torques. In addition to the torques implemented by GRIAL, there are two other main torques acting on space objects that do not depend on the surface geometry of the object: the gravity gradient torque and the eddy currents torque. These torques can directly be computed in the CPU and will be used in the analysis presented in this section to show the relative impact of all different torques in the case of Sentinel-3A.

Eddy Currents Torque. The electromagnetic interaction between a tumbling conductive satellite and Earth's magnetic field generates surface currents, known as eddy currents. These currents create a magnetic moment, which interacts with the magnetic field to produce a torque that alters the satellite's attitude. The eddy current torque mathematical model used is derived by Lin [12] and it is described by the following equation:

$$\vec{M}_{ec} = \vec{B} \times \left(\underline{L} \cdot \left(\vec{\omega} \times \vec{B} \right) \right) \tag{19}$$

Where:

- $\vec{M}_{ec}$ is the eddy current torque in the body-fixed reference frame.
- $\vec{B}$ is the geomagnetic field vector in body-fixed reference frame.
- $\vec{\omega}$ is the angular velocity of the object in the body-fixed reference frame.
- $\underline{L}$ is the eddy current tensor, defined in its general representation as:

$$\underline{L} = \begin{pmatrix} M_1 & -M_4 & -M_5 \\ -M_4 & M_2 & -M_6 \\ -M_5 & -M_6 & M_3 \end{pmatrix} \tag{20}$$

The coefficients M_1 to M_6 are constants which are determined by the geometry, conductivity, and material properties of the satellite. When the body-fixed reference frame is aligned with the eddy tensor eigenspace, the tensor reduces to a diagonal form, where $M_4=M_5=M_6=0$. Closed-form analytical solutions for the values of the parameters M_1 to M_3 exist only for simple geometries, such as a thin spherical shell. For general shapes, the coefficients must be experimentally determined or approximated. As the model indicates, eddy current torques act in opposition to the angular velocity of a tumbling object, thereby inducing rotational damping.

Gravity Gradient Torque. The gravity gradient torque arises from the gravitational potential acting on an extended rigid body in orbit, due to the difference in gravitational force acting on various parts of the satellite. For elongated or asymmetric spacecraft, this effect generates a restoring torque that tends to align the satellite's major axis with the local vertical (toward the Earth). This torque is particularly relevant in LEO, where the gravity gradient is strongest. The formulation used is extracted from Vallado [17]:

$$\vec{M}_{gg} = \frac{3|\vec{g}|}{|\vec{r}|} \hat{g} \times \left(\underline{I} \cdot \hat{g} \right) \tag{21}$$

Where:

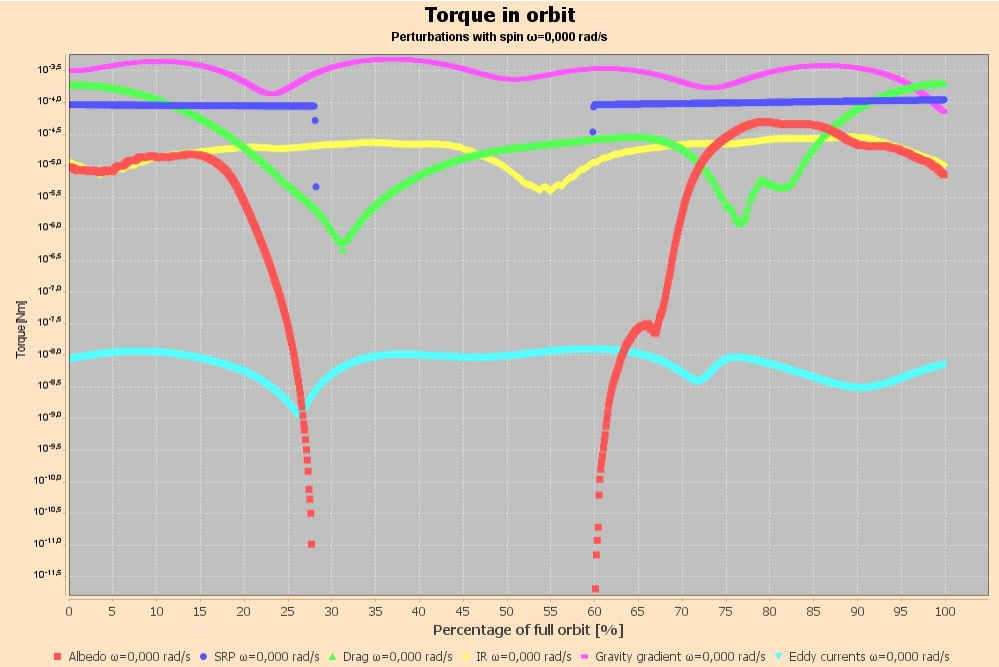
- M_{gg} is the gravity gradient torque in the body-fixed reference frame.
- $\vec{r}$ is the satellite centre-of-mass (CoM) position vector relative to Earth attraction centre.

Materials Research Proceedings 69 (2026) 972-993 https://doi.org/10.21741/9781644904251-171

- $\vec{g}$ is the total gravity acceleration acting on the CoM of the object expressed in the body-fixed reference frame frame, with $\vec{g} = |\vec{g}|\hat{g}$.
- $\underline{I}$ is the inertia matrix of the spacecraft in the CoM of the object in body-fixed frame.

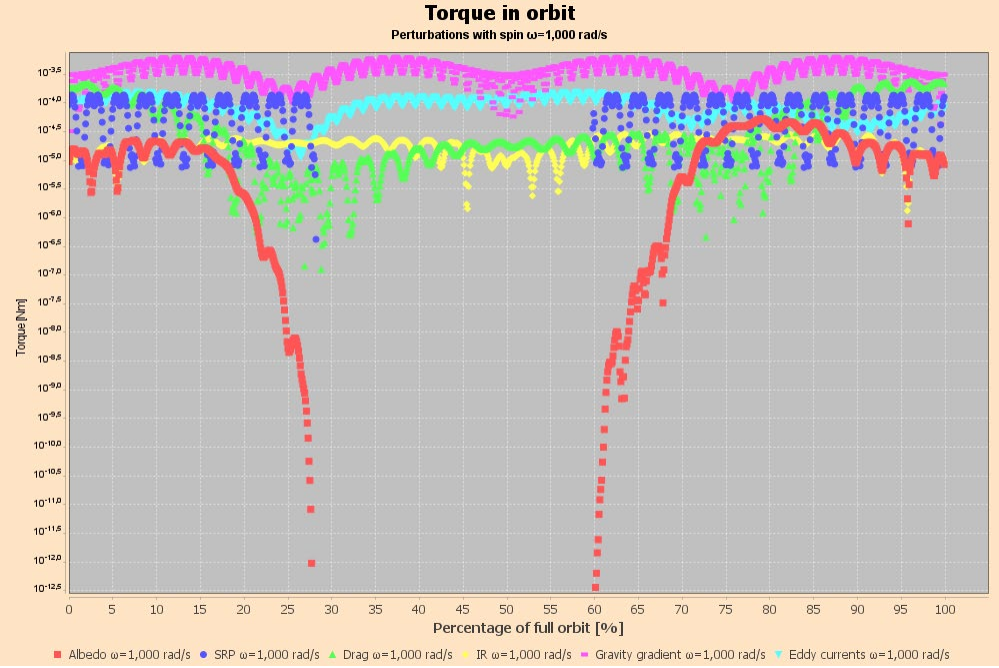
Magnitude of Torque Sources in Nominal Orbit. The external torques acting on a spacecraft are highly dependent on both the orbital environment and the rotational state of the satellite. For the Sentinel-3A satellite in a reference Sun-synchronous orbit (see Table 2), the sources considered in this study are albedo, atmospheric drag, eddy currents, gravity gradient, IR radiation and SRP. These torques are evaluated for the two (lower and upper) limits of analysed spin rates in the stable Z axis: Fig. 11a showcases an example with 0 rad/s while Fig. 11b shows a high-spin example at 1 rad/s.

Table 2 Orbital Information for Sentinel-3A



Altitude	Inclination	Period	Cycle	Ground-track deviation	Local time at descending node
814.5 km	98.65°	100.99 mins	27 days	±1 km	10:00 hours

Several phenomena that validate the implementation can be observed in Fig. 11, which simulates one orbital period of Sentinel-3A:



- During the eclipse (from around 28% to 60% of the orbit) there is no albedo or SRP torque on the object. Moreover, the transition for SRP takes place between less than two plotted points (each point represents 0.1% of the orbit) signalling a fast but not instantaneous transition to zero, coherent with the body's fast entrance to or exit from Earth's shade in the limits of the eclipse. In comparison, albedo diminishes at a lower rate, which is coherent with the progressive reduction of visible Sun-illuminated Earth tiles and their angle of reflection as the body approaches penumbra. All other perturbations are, as expected, not affected by Earth's shade.
- The spin rate barely affects the magnitude of the torques induced by Albedo, SRP, drag, IR or gravity gradient directly: instead, each rotational regime induces some level of oscillations around the same values which means that the attitude is the main driver for the change, not its derivative.
- For Eddy currents, the magnitude of the torque changes noticeably between the spin regimes: around $10^{-8.25}$ for 0 rad/s and around $10^{-4.25}$ for 1 rad/s, which is coherent with the proposed model. The eddy current tensor used for these simulations is:

$$\underline{L} = \begin{pmatrix} -1.8e5 & -2.0e4 & 1.5e4 \\ -2.0e4 & -2.5e5 & -1.8e4 \\ 1.5e4 & -1.8e4 & -3.5e5 \end{pmatrix}$$

A study by ESA [18] describes how for LEO objects the main torque-inducing disturbances are the gravity gradient, eddy currents (especially for fast rotating satellites) and SRP, in accordance with the results seen in Fig. 11, although atmospheric drag does reach their orders of magnitude for some configurations.

a) ω = 0 rad/s

b) ω = 1 rad/s

Fig. 11 Torques on Sentinel 3A during one orbital period.

When representing the average magnitude of each perturbation's torque over one orbit as a function of altitude (Fig. 12), using the shape of Sentinel-3A and a rotation period of 0.01 rad/s, the following conclusions can be drawn:

- The order of magnitude of the torques whose sources also provide a perturbation force evolve like the latter when varying altitude, that is: SRP stays constant and drives evolution at higher altitudes, drag decreases the fastest (it is not modelled after 1000 km with the atmospheric model employed in the work) and is the main perturbation at the lowest altitudes and IR and albedo decrease at the same ratio with altitude.

Materials Research Proceedings 69 (2026) 972-993 https://doi.org/10.21741/9781644904251-171

- Gravity gradient dominates the attitude from around 800 km to about 5500 km, and then follows an evolution like that of IR and albedo torques.
- Eddy current effects decrease at the highest rate when altitude increases due to the diminishing magnetic field ($\propto 1/r^3$) making the torque effect proportional to $1/r^6$. The plot was generated for a low spin case.
- The initial increase of SRP and albedo at low altitudes is due to the increase of Sun visibility, not an effect of higher order of magnitude per se. This effect depends on the mission orbit, specifically on inclination and local time at descending node, which define visibility and eclipses together with altitude. IR is somewhat indifferent to variables other than altitude.

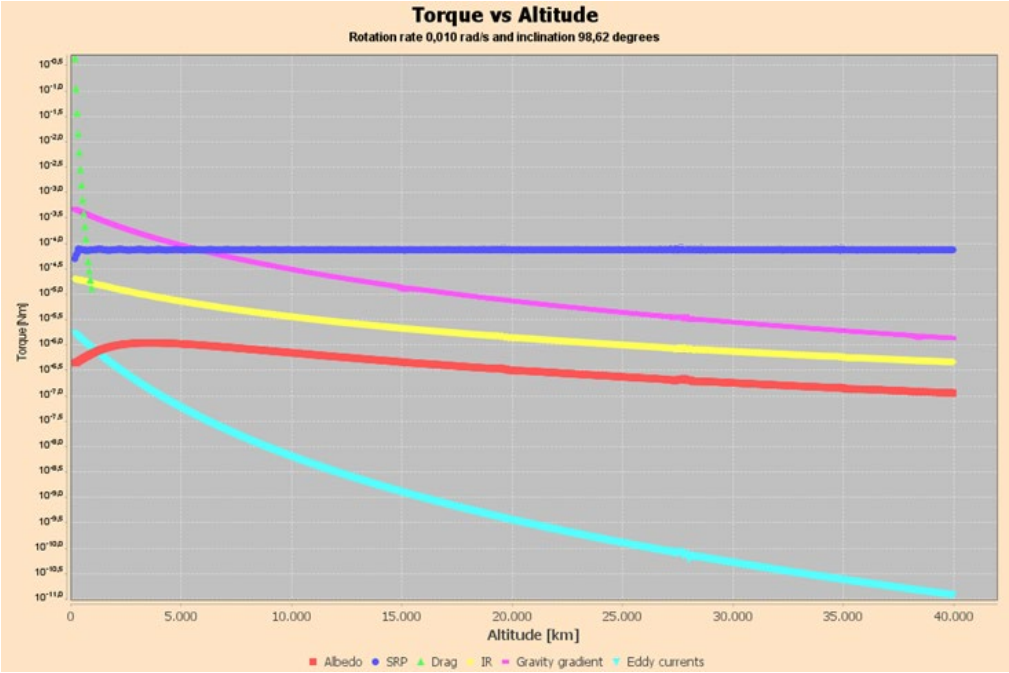


Fig. 12 Mean torque vs altitude at 98.62° inclination.

Conclusions and Future Work

High-fidelity orbital force computation is crucial for attitude propagation of tumbling objects and could improve POD operations on satellites orbiting Earth. High-fidelity mathematical models for the computation of aerodynamic drag, SRP, albedo and IR radiation forces have been successfully integrated into GRIAL for these purposes. Additionally, torque computation methods for these forces, along with gravity gradient and eddy current torques, have been modeled, enabling attitude propagation for tumbling objects.

The Sentinel-3A satellite case study was selected to perform the validation procedure against the forces obtained by the state-of-the-art POD software MAORI. The results were found to match the expected ones, consequently validating GRIAL.

A key aspect that could become the subject of future research is improving computational time. A possible solution to the issue is represented by the creation of grids of values of forces and torques of each orbital disturbance for an extensive number of possible incoming directions of the flux (e.g. solar radiation for the SRP, air flow for drag etc.). This discrete but extensive set of values computed by GRIAL can then be interpolated during the orbit or the attitude propagation procedure, to account for any incoming direction. Other than allowing for quick execution times, this approach would also enable any user to implement these tables in their own programming

language, without the imposition of using Java. Moreover, there is no requirement related to the presence of a GPU on the user's hardware, which GRIAL has.

Another possible improvement to the time-efficiency of the tool could be achieved by grouping together multiple pixels of the same window and summing their values together, instead of passing to the CPU the value associated to each individual pixel. As shown in Table 1, the computational time only depends on the number of pixels of the window, because of the delay in the GPU-CPU transmission. Lowering the number of values transmitted would lower the computational time, without affecting the accuracy.

Additionally, albedo and IR perturbations (which are the most time-consuming computations) could be enhanced by the use of a pool of CPUs, each associated to a copy of the object shape in the GPU.

Moreover, future studies should aim at refining and improving the mathematical models employed by the GRIAL algorithm. In particular, the atmospheric drag model has shown the greatest inaccuracy. A possibility of improvement could be represented by the use of a front-back model, which only requires the assumption of free molecular regime and accounts for forces acting on both the directly exposed surfaces and the rear-facing ones.

Further work also involves applying the software to other case-studies, to find out if it is possible to improve the efficiency of the POD analysis. In fact, the Sentinel-3A case study was selected because the satellite's structure can be easily approximated to a box-wing object, which is the structure usually employed by other tools to approximate satellites. GRIAL is instead capable of higher graphic computational capabilities, which allow to consider the real satellite shape. GRIAL is also capable of handling shapes of any complexity with the same efficiency, thanks to its GPU-powered parallel computation. Indeed, the real strength and novelty of GRIAL lies in scenarios with more complex satellite shapes, which cannot be approximated to simple box wing models, like the Sentinel-6, which represents the following trial ground for the software.

In conclusion, GRIAL proofs the efficiency and the potential of graphical approaches for orbital disturbances computation. The mathematical models it employs and its computational capabilities have been successfully validated against accurate results. The good performance and quality of the results highlight the software's potential for orbital and attitude propagation applications. Future analysis will demonstrate the tool's capabilities when employed in case studies with increasingly more complex-shaped satellites.

Keywords: Launch Traffic, Launch Trends, Space Debris Evolution, Machine Learning, Historical Sampling

Abstract This paper provides a step-by-step guide to go from a given future number of launches to a complete picture in terms of orbital region and physical parameters. This paper only describes non-constellation launches. For these non-constellation launches distributions are built using historical data from DISCOS. Here, the orbital parameter distribution is built using Gaussian-Mixture Models. The object class is determined from a simple probability distribution. A special focus is given to the mass of the objects, since this is an important quantity to be considered when talking about the evolution of the space environment. For the mass, an XGBoost algorithm is employed, which uses the other object characteristics as an input. Finally, the area of the object is determined based on the mass.

Introduction

Forecasting the future launch traffic is not only a matter of determining the number of launches per year. To properly assess the effect of these launches on the space debris environment their orbital and physical parameters play a crucial role. Depending on these the orbital lifetime, collision risks and breakup probability differ drastically. This paper aims to develop a complete method to go from a number of launches to building a full picture of each single launch. This includes the distribution in the orbital parameters of the semi-major axis (sma), eccentricity (ecc) and inclination (inc) and the mass and area of each object, as well as their object type (Rocket Body, Payload, Mission-Related-Object (MRO)). The challenge here is that these parameters are all interconnected. Different orbital regions are used by different types of spacecrafts. This influences their area and mass. An earth observation satellite has significantly different characteristics than a GNSS satellite. Hence, the developed method must take this dependency of the orbital region into account. This paper only describes non-constellation launches. For the constellations information about the or-bit and physical characteristics are publicly available. Therefore, here it does not need to be determined statistically, but can be directly taken from the available information. This paper will give a step-by-step overview of the process at arriving at a complete picture of future non-constellation launches, starting from a given number of launches per year. To determine the distributions for each of the mentioned categories, the historical data coming from the ESA database DISCOS [1] is used. The available data is pre-processed by filtering out the debris objects. The data is then used to either create a distribution directly or as training data for models.

Object Class

The object class determines whether an object is a Rocket Body, Payload or Mission Related Object (MRO). This classification already exists in the historical data in DISCOS. Furthermore, depending on this category, parameters such as the explosion probability vary [2]. Therefore,

Materials Research Proceedings 69 (2026) 994-999 https://doi.org/10.21741/9781644904251-172

the division of the launches into these categories will have a definite impact on space debris evolution.

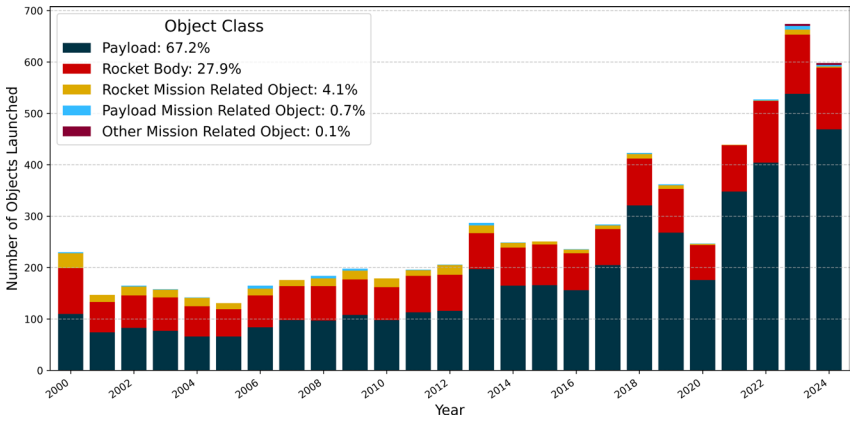

Figure 1: Number of non-constellation launches divided by object class and their total percentages since 2000.

To capture the recent trends in terms of object class distribution the historical data from 2000 to 2024 is considered. As seen in Fig. 1 the majority of launches is determined by Payload objects and Rocket bodies. The total percentages of the object categories in the years between 2000 and 2024 are used to create a categorical distribution. This categorical distribution is then randomly sampled.

Orbital Parameters

The orbital parameters are an important quantity when discussing the evolution of space debris. If the future launches are all concentrated in one orbital region the probability of collisions in that region increase greatly. The orbital parameters of interest are the semi-major axis [km], the eccentricity [-] and the inclination [◦]. To capture the recent trend towards the Low Earth Orbit (LEO), the historical data from 2000 to 2024 is used to create a distribution. The distribution is created by using Gaussian Mixture Models (GMMs). A Gaussian Mixture Model is a probabilistic model, which represents data as a combination of several Gaussian distributions. A more detailed explanation can be found in [3]. It is well suited for creating orbital distributions, since the orbital regions naturally cluster around different combinations of sma, ecc and inc. This method for determining future orbital regions was first presented in Wilson et. al. [4]. To ensure that only Earth related missions are considered, large orbital radius with sma $\geq 60,000$ km are filtered out. Before using the historical data to create the GMM clusters a few transformations are applied. These transformations are to make sure that the data samples stay in a realistic range. The eccentricity should always be between 0 and 1. The inclination between 0° and 180°. In the following the data pre-processing steps are described:

- Log transform the semi-major axis. This helps the model handle large numerical ranges.
- Logit transform the eccentricity to avoid infinites when approaching the bounds of 0 or 1.
- Represent the inclination in terms of sinus and cosinus. This ensures that angles that represent the same orientation such as 0° and 360° are treated in the same manner.
- Scale the entire dataset using the standard scaler which standardizes features by re-moving the mean and scaling to unit variance.

Materials Research Proceedings 69 (2026) 994-999 https://doi.org/10.21741/9781644904251-172

These transformations are only done to ensure a stable fit to the historical data. Before assigning each launch to its orbital parameters they are inverse transformed, so that the final launch data is again represented in the correct units. To determine the number of clusters and therefore the number of orbital regions which best fits the distribution in the historical data, the data from 2000 to 2025 is split into a test and train dataset. Different numbers of components are compared using the Bayesian Information Criterion (BIC) [5]. The best number of components was determined to be 8 orbital regions, with the characteristics represented in Tab. 1. The orbital regions span from Low Earth Orbit (LEO), Sun Synchronous Orbit (SSO) to Medium Earth Orbit (MEO), Highly Eccentric Orbit (HEO), Geostationary Orbit (GEO) and the Geostationary Transfer Orbit (GTO).

Table 1: Cluster orbital characteristics by region.

Region	n	sma_mean [km]	ecc_mean [-]	inc_mean [◦]
LEO (ISS orbit)	798	6762.8	0.0013	51.65
LEO (Mid inclined)	760	6908.8	0.0064	50.72
LEO (SSO)	2060	6951.2	0.0018	97.71
LEO (Polar)	367	7232.6	0.0133	90.19
MEO (Elliptical)	254	19568.5	0.2405	20.38
MEO/HEO (Inclined)	292	24224.7	0.3685	57.01
GTO	350	25099.1	0.7291	17.34
MEO	268	30777.1	0.1162	0.94
GEO	474	42163.4	0.0003	0.02

LEO is a highly populated region. GMMs tend to split dense clusters into multiple components, which is why the LEO clusters vary only slightly in their characteristics. For the future launches for each year the orbital distribution is sampled from these GMMs.

Distribution of Mass and Area

The mass is determined by using an XGBoost algorithm [6]. This is a machine learning algorithm which combines decision trees with gradient boosting. As an input the parameters determined so far are used: the object class, orbital region and type and the launch year. The classification of a satellite based on mass depends on the entity or agency. An overview can be found in A.S. Botelho et. al. [7]. For this work, a very simple classification is adapted. Depending on the mass, the average cross-section area (XSectAvg) also changes. The cross-section area intervals were determined based on the historical data available.

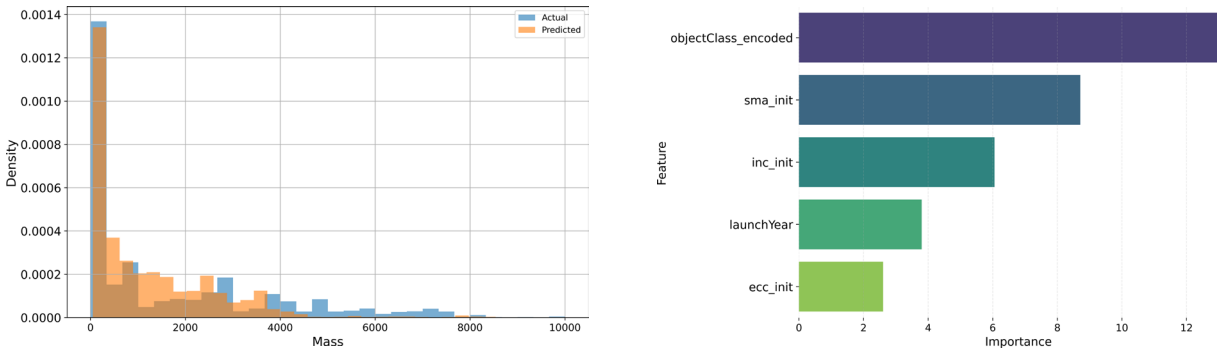

Table 2: Satellite classification by mass and the historical intervals for the average cross-section area.

Classification	Mass [kg]	XSectAvg [m^2]
Nanosatellites	≤10	[0.05, 1.83]
Microsatellites	10-100	[0.59, 13.93]
Minisatellites	100-500	[2.93, 22.10]
Small satellites	500-1000	[9.19, 28.8]
Large satellites	≥1000	[61.40, 1583.48]

When investigating the mass distribution of past launched satellites, it is clear that lower mass satellites are more frequent. In the historical data the biggest recorded mass is from the Discovery (STS-116) space shuttle mission [8]. This mission was launched in 2006 and had a mass of 132931 kg. Just 12 days after launch the shuttle returned to earth. This demonstrates

Materials Research Proceedings 69 (2026) 994-999 https://doi.org/10.21741/9781644904251-172

that the higher mass components in the launch data are more related to human space missions and not satellites that are representative for the space debris evolution. An example of a bigger satellite instead is the Envisat mission [9], launched in 2002, with a mass of 8140 kg. This satellite is characteristic of the mission trends at the time with the launch and operation of large satellites as true space laboratories serving a variety of applications. The XGBoost algorithm is trained for a mass ranging from 0 to 10,000 kg. The results are shown in Fig. 2.

(a) *Mass distribution in training vs. test data* (b) *Feature importance*

Figure 2: The XGBoost model for the mass determination tested against historical data and its feature importance

To train the XGBoost algorithm the full available data from 1957 to 2024 was split into a test and train dataset. The algorithm is validated against the test dataset. This validation can be seen in Fig. 2a. The actual distribution vs. the one predicted by the model is presented. There is good accordance between the two for the lower mass ranges, but the algorithm does not predict many higher mass objects. To correct this difference, in the future a few representative higher mass objects could be added manually. Furthermore, the feature importance can be investigated. Here, as seen in Fig. 2b, the object class drives the assignment of the mass. This is to be expected, since the mass between a Payload object or a Rocket Body might vary significantly. Based on the determined mass the average cross-section area is then assigned by randomly sampling the intervals corresponding to the mass classifications presented in Tab. 2.

Outlook and Conclusions

This paper presented an easy method to go from a given number of future launches to a full picture in terms of object class, orbital region, mass and area. These characteristics are just as important for space debris evolution as the number of launches itself. This method is independent from the model used to predict the future number of launches. The software structure is demonstrated in Fig. 3.

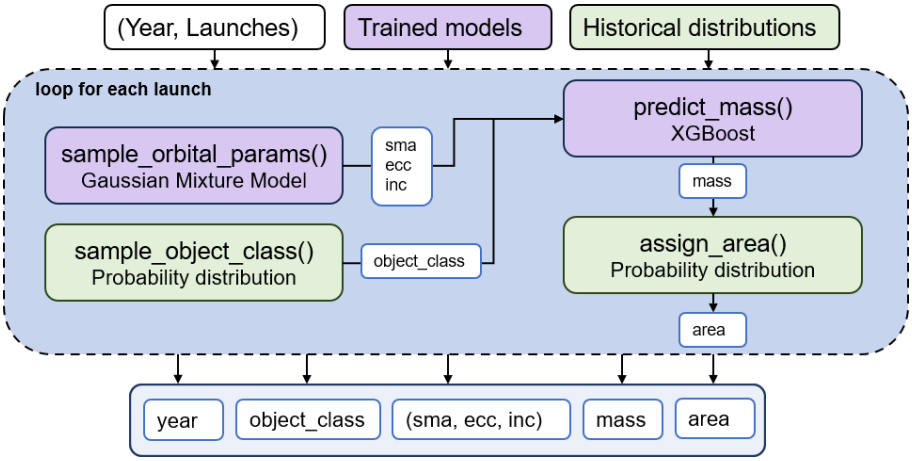

Figure 3: Software architecture to determine a full picture of future launches. The green modules represent historical distributions, and the purple modules describe trained models. The output of each module is marked with a blue border.

The software takes a file representing the future number of launches in the format (Year/Number of launches) and the trained models and distributions based on the historical data as an input. Then, for each launch the different modules are called. Firstly, the orbital parameters are determined using the GMMs, the object class is randomly drawn from the historical categorical distribution. Both of these results are then used as an input into the XGBoost model, to predict a mass based on orbital parameters and object category. The area is then sampled based on the mass classification. The final output file is a file containing the full information for each launch, including the launch year.

This file can then be used as an input into a space debris environment model to further investigate the effects that different launch scenarios can have on the environment as a whole.

Keywords: Space Debris, Space Debris Index, Space Sustainability

Abstract. Fragmentations caused by explosions or collisions contribute a significant share of the growing space debris population. These present a risk to active spacecraft and have caused collisions in the past. Each satellite has the potential to fragment and thereby threaten spacecraft in its vicinity. Politecnico di Milano developed a tool for Tracking health of environment and missions in Space (THEMIS) under a European Space Agency (ESA) project. It quantifies a mission's environmental impact using a space-debris index based on the Environmental Consequences of Orbital Breakups (ECOB) approach. In this approach, the probability and severity of a potential fragmentation are combined. THEMIS is undergoing beta testing and is being upgraded in a follow-up project. Since the approach is new, questions about interpreting the Index values have been raised. In this paper, reference values for selected missions in LEO and MEO, covering Earth observation, telecommunication and navigation applications are investigated. The sensitivities of index changes to orbital parameters, satellite properties and collision avoidance as well as post mission disposal strategies are estimated.

Introduction

The threat posed by space debris is increasingly recognised as a risk to active space missions. The number of objects in space has been rising steadily over the last years, and this trend is projected to continue [1]. Debris objects as small as 1 cm in size can damage or destroy satellites upon impact [2, 3]. The majority of space debris objects, and a large portion of the overall space object population, consists of fragments that originate from explosions or collisions of satellites and rocket stages [1]. Each mission has a risk of fragmentation, potentially increasing the risk for other satellites. Politecnico di Milano developed the Tracking health of environment and missions in Space (THEMIS) tool under an ESA project to quantify a mission's impact on the space environment [4]. Following the Environmental Consequences of Orbital Breakups (ECOB) approach, probability (p_c and p_e) and effect (e_c and e_e) of a potential collision (c) or explosion (e) of the spacecraft are estimated to calculate a space debris index I at a given instance via Eq. 1 [5].

$$I = p_c \cdot e_c + p_e \cdot e_e \tag{1}$$

Indices over all instances of a mission are aggregated to obtain the total Index of a mission. This Index quantifies the impact of the analysed mission on its environment as a measure of the increased risk to other satellites following a fragmentation of another mission. The probability of explosion pe is retrieved from statistical data [4], while the probability of a collision, significant enough to cause a catastrophic event, pc is estimated using ESA's MASTER software [6, 4]. For both explosions and collisions, the effect of the fragmentation (ec and ee) is estimated by propagating the fragment density and calculating the rate of impact on a set of representative

Materials Research Proceedings 69 (2026) 1000-1005 https://doi.org/10.21741/9781644904251-173

targets [4, 7, 8, 12]. With the latest available reference population, only the impact of non-manoeuvrable objects is considered in the analysis. The analysed satellite can be modelled to be disposed at the end of its operational life or to decay naturally. Collision avoidance is modelled by removing a part of the collisions with trackable objects, proportional to the efficacy of the collision avoidance.

The THEMIS tool is now in the beta testing phase [9]. During the presentation of the tool to beta testers, questions on the interpretation of results were raised. Since the use of THEMIS and the underlying ECOB approach is not yet well established, this paper aims to provide reference values for a selected number of representative missions. Alongside those, the sensitivity of the index to certain design parameters, mass, area, orbit, Post-Mission-Disposal (PMD) and Collision Avoidance Manoeuvre (CAM) strategy are estimated.

Reference Objects

THEMIS can currently be used to estimate indices of objects in Low Earth Orbit (LEO), Medium Earth Orbit (MEO), Geostationary Transfer Orbit (GTO) and Geostationary Orbit (GEO). The calculation for GEO is being upgraded in the ongoing THEMIS 2 project and results may change in the near future. Therefore, this paper focuses on presenting results for LEO and MEO regions.

Satellites are selected to cover mission applications with the highest relevance, Earth observation, Telecommunication and Navigation. For LEO Earth observation, satellites similar to the ESA Envisat (OBS1) and Sentinel 1D (OBS2) satellites are selected. For LEO Telecommunication, one satellite similar to the ones of the Starlink constellation (COM1) and one similar to the Oneweb constellation (COM2) are used. In MEO, a satellite similar to the ones of the Galileo constellation (GNSS) and a satellite like the ones of the O3b constellation (COM3) are investigated. For each case, only one satellite is modelled, not the entire constellation. The launch epoch is set to November 2025 for all cases to show the impact of the launch of a new satellite of the given type.

Table 1 lists the reference input values. For all cases the eccentricity is assumed to be close to 0. For the baseline, reliability of both CAM and PMD is set to 90%. For missions representing Starlink, Galileo and O3b the latest satellite models of that constellation are used. Data on mass and area are retrieved from the ESA DISCOS database [11], while orbital data are retrieved from Space-Track [10]. For each case the index is first estimated using the settings described to get a baseline value.

Table 1 Reference settings

Mission	Mass/kg	Area/m²	SMA/km	Inc/°	Mission duration /years	PMD
OBS1	8110.0	74.39	7162	98.5	10	25 year eccentric
OBS2	2185.0	84.40	7064	98.2	12	25 year eccentric
COM1	730.0	33.88	6946	70.0	5	5 year circular
COM2	147.0	3.46	7571	86.4	7	5 year circular
GNSS	733.0	9.22	29601	57.2	15	graveyard disposal
COM3	1700.0	27.340	29601	0.0	15	graveyard disposal

Sensitivity is estimated for changes of: +1 kg mass, +1 m² area, +1 km SMA, +1° inclination and RAAN, +1 year PMD lifetime, and +1 percentage point in CAM/PMD reliability. Changes of this order may be possible during the design phase. The resulting changes are given both as absolute changes as well as percentage change with relation to the baseline value of the given mission $100 \cdot \frac{I_{sensitivity} - I_{baseline}}{I_baseline}$. For the relative values, the change in Index is given relative to a

Materials Research Proceedings 69 (2026) 1000-1005 https://doi.org/10.21741/9781644904251-173

1% change for mass, area and remaining lifetime. This is done to stay consistent across the varying masses, areas and lifetimes of the reference missions.

Results

The reference values for the evaluated missions are presented in Table 2. The heat maps in Figure 2 show both absolute changes (left) and relative percentage changes (right) in the index for design parameter modifications.

For the baseline values, Indices can vary by multiple orders of magnitude (8.84×10^{-5} to 3.43×10^{-8}), even in the same orbital region and the same application. The highest absolute value can be found for the first LEO observation mission. This is also the heaviest satellite placed in one of the most densely populated regions. The MEO communications constellation has the second highest value, only slightly lower. This is due to the fact that multiple satellites of the same constellation are placed in a narrow inclination band. The fragmentation of one of them would have a significant effect on the other satellites of the constellation. The second LEO Earth observation mission has a value around one order of magnitude lower than the first. The two communications satellites have similar values, around 2 orders of magnitude lower than that of OBS2. For COM1 this is due to the fast decay of satellites from low orbits, while for COM2 it is due to low mass, area and low density of objects at the altitude of the satellite. The lowest value overall is that of the GNSS mission, around half the value of that of the LEO communications satellites.

The sensitivity of the index to changes of the parameters varies between orbital regions and mission definitions. Regarding relative values, an increase in mass consistently increases the index. A 1% increase in mass increases the index by between 0.7 and 10%. An increase in area on the other hand increases the index by 0.6 to 2% for each percent of area change for the communications constellations in LEO and the first LEO observations satellite. It decreases the index significantly for the 2nd observation satellite. The reason for this is that, while the collision cross section is increased, the orbital decay is significantly sped up due to the higher area to mass ratio, reducing the impact over the satellite's lifetime. Similarly, increasing the SMA can either increase or decrease the index significantly depending on the orbit. In MEO changes to SMA or area have only little effect. Increasing the inclination by just one degree significantly lowers the index, in some cases by more than 20% for both Earth observation satellites and the constellation in MEO. It has little effect on the other missions though. Increasing PMD reliability and reducing PMD lifetime can significantly improve the index value for missions that are in densely populated regions and do not decay naturally. Increasing the reliability of the disposal by 1 percent point has an effect that is around 10 times larger than reducing the lifetime by 1%. For regions that are sparsely populated or where atmospheric drag is significant, changes in PMD have no effect. Increasing the reliability of CAM has a significant effect on objects in LEO but the effect is close to 0 in MEO.

Table 2 Baseline Index results

Mission	Index baseline value	Orbital Region
OBS1	8.84×10^{-5}	LEO
OBS2	7.84×10^{-6}	LEO
COM1	9.24×10^{-8}	LEO
COM2	7.03×10^{-8}	LEO
GNSS	3.43×10^{-8}	MEO
COM3	6.01×10^{-5}	MEO

Materials Research Proceedings 69 (2026) 1000-1005 https://doi.org/10.21741/9781644904251-173

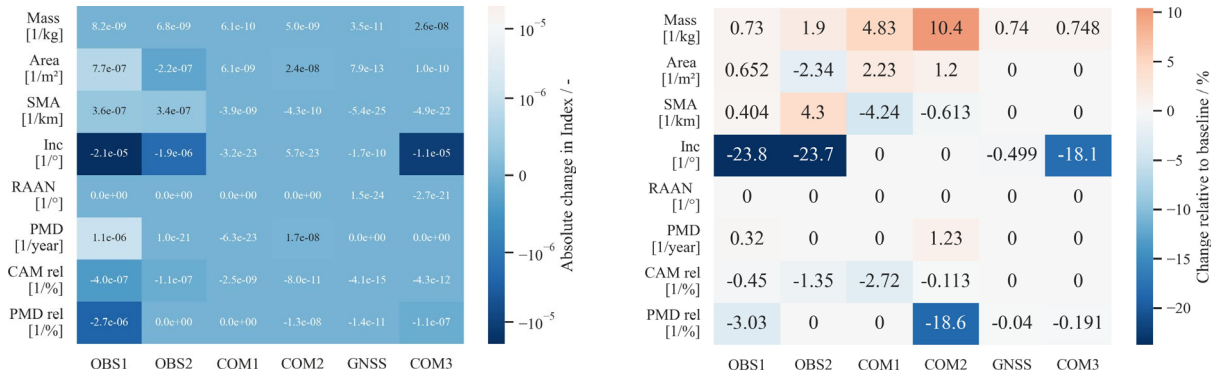

Figure 1: Absolute (left) and relative (right) sensitivity of index to changes in design parameters.

For a given mission, the sensitivity to mass, area, PMD and CAM parameters remain constant across values. For parameters related to the orbital region like SMA, inclination and RAAN however, the dependencies are more complex. Figure 2 shows the Index for an Envisat-like mission across different altitudes and inclinations. Multiple local maxima and minima can be identified. Depending on the location, the direction in which the index decreases switches. The exact location of extrema depends on other mission parameters like mass, area and PMD strategy. The index typically decreases with decreasing altitude below 800 km and with increasing altitude above 1500 km. The specific sensitivities have to be estimated individually for each case.

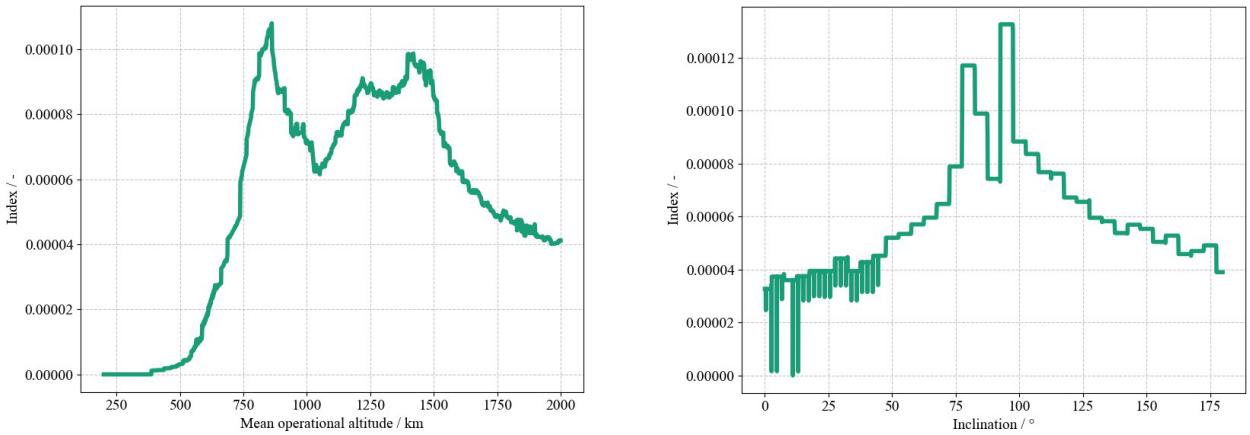

Figure 2: Sensitivity of relative index to changes in orbital altitude (left) and inclination (right) for Envisat-like mission.

Conclusion

Results of the Space Debris Index calculated with THEMIS were presented. The values can vary by multiple orders of magnitude depending on the orbit and spacecraft characteristics. Large satellites in densely populated Sun Synchronous Orbit (SSO) regions are found to have the highest index values but satellites in certain equatorial orbits can have similar values. The lowest indices are found in very low or very high LEO at the location of large communications constellations and for GNSS satellites.

The sensitivity of the index to design parameters also varies across missions. The most impactful changes to the index can be achieved via varying inclination or PMD reliability. Significant changes can also be made by changing mass, area, CAM reliability and SMA for some missions. Changes in RAAN and duration of PMD are small.

These results can be used as reference values to interpret the THEMIS index. The sensitivities can furthermore help to identify ways to effectively reduce the index of a mission during the design phase. In general, densely populated regions should be avoided when possible. If placed at an

altitude where orbital decay due to drag is slow, a high post-mission disposal reliability can decrease the index.

The results presented were obtained using a version of THEMIS that is currently under development. Changes in the implementation or the space environment like the deployment of a large constellation or significant space debris producing events can change those results.

Keywords: Formation Flying, DSAR, Small Satellites

Abstract. Formation flying techniques have enabled advanced interferometric and radar imaging capabilities for Earth observation missions in low Earth orbit (LEO). At one end of the possible geometries lies the safe ellipse configuration, widely adopted for its intrinsic passive safety. However, the continuously varying baseline complicates SAR data processing and may degrade image quality. At the opposite end, the train-like formation features a constant along-track geometry that simplifies SAR imaging and processing, with the downside of perturbations induced along-track drift. Although these performance versus stability trade-offs are well documented for large formation flying missions, their implications for small satellite constellations and distributed SAR (DSAR) realizations remain unexplored. This paper compares safe ellipse and train-like DSAR formations through orbital dynamics simulations, assessing relative motion stability, passive safety, and formation-keeping requirements to identify optimal and cost-effective architectures for small-satellite DSAR missions.

Introduction

The use of coordinated multi-satellite formations has become a recurring aspect of radar-based Earth observation missions, supporting increasingly demanding interferometric applications. For instance, the TanDEM-X [1] mission has demonstrated the potential of multi-satellite radar constellations for generating high-resolution and multi-baseline products. More recently, RODiO mission concept has explored the use of compact clusters of small satellites for distributed radar sensing [2, 3]. DSAR systems exploit the cooperation of multiple satellites flying in formation to synthesize a larger virtual aperture [4]. This approach enables platform miniaturization. Instead of a single large and complex spacecraft, a constellation of smaller and less expensive units, such as microsatellites, nanosatellites, and CubeSats, can achieve comparable imaging performance [5]. The achievable imaging quality depends on the spatial and temporal sampling of the received signals, governed by the satellites' relative geometry and motion [6, 7]. Ideally, the receivers should be displaced purely in the along-track direction, realizing uniform linear sampling of the equivalent phase centres [8]. In practice, perturbations and design constraints lead to non-uniform or even three-dimensional sampling distributions [7]. To represent these two scenarios, two configurations are analysed: the train-like formation, modelling the ideal linear case, and the safe ellipse formation, representing a more realistic three-dimensional geometry. The extension of these architectures to small satellites is still an open topic of research, particularly for DSAR missions. These systems are subject to severe resource limitations in terms of control effort [9], and the need to maintain precise relative geometry to preserve phase coherence further tightens the platform design margins. Therefore, understanding the dynamical behaviour of such formations is a necessary step toward the design of future small satellite DSAR missions. In this perspective, the present work focuses on formation stability and control effort, providing a quantitative assessment of the ΔV required to maintain both configurations under realistic orbital perturbations.

Formation Design and Control

The design and control of satellite formations can be formulated either in terms of differential orbital elements or in Cartesian coordinates within the Hill Reference Frame (HRF) [10], reported in Fig. 1. Commonly, the former are adopted for formation design, while the latter are preferred for control applications. In this study, however, Cartesian coordinates are used as the starting point to derive the corresponding orbital element differences, ensuring a consistent link between geometry and control parameters. Subsequently, the formation keeping strategy, carried out in NASA's General Mission Analysis Tool (GMAT) [11], acts on the orbital elements to restore the desired separations defined in the Cartesian control framework.

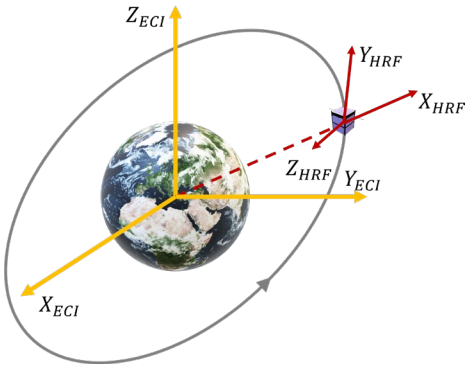

Fig. 1 HRF (in red) centred in the satellite with respect to Earth Centred Inertial reference frame (in yellow)

In the train-like formation satellites are placed along the same orbital path with along-track offsets from the chief, typically generated through variations in argument of perigee (AOP), δω, and mean anomaly, δM [10]. The adopted modelling approach introduces δM so as to produce the along-track offsets y_{off}, as per Eq. (1), while keeping all other orbital elements identical to chief.

$$y_{off} = a(\delta M_0). \tag{1}$$

The safe-ellipse configuration exploits the three-dimensional relative dynamics by introducing controlled differences to both in-plane and out-of-plane orbital elements: eccentricity, δe, δω, semi-major axis (SMA), δa, δM, inclination, δi, and right ascension of the ascending node, δΩ. The methodology detailed in [12] has been adopted for formation design. By tuning the differences in orbital elements, the deputies are placed on elliptical trajectories around the chief, with amplitude of radial oscillations A_x, minimum radial/cross-track separation $d_{xz,min}$, and cross-track separation at zero along-track $\tilde{z}$. The conditions described in Eq. (2) are imposed to ensure a slow variation of the radial/cross-track separations during the motion along the orbit and to suppress the secular drift induced by perigee precession.

$$A_x = d_{xz,min}, \quad \tilde{z} = 0, \quad x_{off} = \delta a = 0, \quad \delta i = 0. \tag{2}$$

For the following discussion, a case study has been considered as representative of a compact, LEO, DSAR mission, i.e., the RODiO cluster. The cluster comprises four 16U CubeSats equipped with an X-band antenna, one chief – RD_1 – and three deputies – RD_2, RD_3, RD_4 –. RD_1 shares the orbital parameters of PLT-1 [2]. The inter-satellite distance between chief and deputies is defined by separations of 0.18 km, 0.36 km, and 0.55 km in the along-track direction, with corresponding radial and cross-track offsets according to the chosen formation. The obtained configurations are reported in Fig. 2.

Materials Research Proceedings 69 (2026) 1006-1011 https://doi.org/10.21741/9781644904251-174

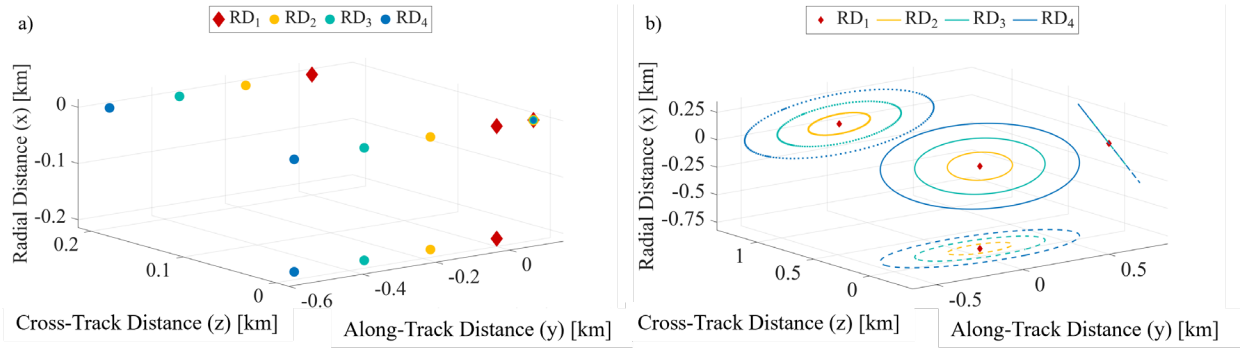

Fig. 2 RODiO cluster in a) Train-like formation and b) Safe ellipse formation

The conceived formation keeping strategy relies on the definition of a control volume, that is the allowable region of motion for each deputy around the chief. When a deputy reaches the boundary of its control volume, a corrective manoeuvre sequence is triggered to restore the nominal configuration. The geometry and size of this control volume depend on the characteristics of each formation. For the safe ellipse formation, the control concept is based on the definition of a safety tube within which the relative motion in all three directions is bound. The maximum along-track and cross-track/radial dimensions of the tube derive from DSAR performance requirements. Specifically, they are set as fractions (~5 to 10%) of the corresponding along-track and orthogonal critical values, following the relations in [5]. The resulting safety tube is characterised by maximum allowable separations of 0.6 km in along-track and 0.4 km in cross-track/radial directions. The same upper bounds are applied to the train-like formation. Additionally, since in this case the relative motion develops almost entirely in the along-track direction and is positive towards the chief, a minimum allowable distance needs to be defined to avoid undesired proximity among the deputies during the natural along-track drift. To this end, two alternative approaches have been considered. The first approach introduces a safe distance corresponding to the radius of the keep out zone sphere, which is defined in [13] as the worst-case sum of the physical radii of two neighbouring satellites with a 50% safety margin. For RODiO's cluster this distance equals to approximately 2 m and represents the minimum admissible separation among any two spacecraft, including the chief. The second approach defines a control window within which each deputy is allowed to drift up to a fixed fraction of its nominal separation from the chief. Since no strict requirement is imposed by the mission on the minimum along-track baseline, it is set to 90%. Until this threshold is reached, each deputy drifts freely. Then, when the first deputy violates this boundary, the entire cluster performs a correction manoeuvre sequence. This choice ensures that, even at the minimum limit of the control window, the residual inter-satellite distance is comparable with the control accuracy (~ 10 m).

Manoeuvring Strategy for Formation Keeping

The formation keeping logic differs between the two configurations. Concerning the safe ellipse, each deputy operates an independent (asynchronous) control, performing its manoeuvres individually as soon as its separation violates the control volume. In contrast, the train-like configuration adopts a coordinated and synchronised approach. Since the only existing separation is one-dimensional, the deputies' cluster performs the corrections once any satellite exceeds its boundary. Based on this operational logic, the manoeuvring strategy has been designed to restore the nominal along-track separations with a four-step sequence of impulsive in-plane burns. These manoeuvres act tangentially to the direction of motion and are carried out at the periapsis, apoapsis, and orbital nodes. The first two burns ΔV_1 and ΔV_2 constitute the phasing manoeuvre [14]. Subsequently, a third burn, ΔV_3, is applied at one of the orbital nodes to correct the rotation of the eccentricity vector using equinoctial elements H and K, whose formulation is detailed in [11]. This

Materials Research Proceedings 69 (2026) 1006-1011 https://doi.org/10.21741/9781644904251-174

manoeuvre restores the designed difference in the AOP between deputy and chief. Finally, two further burns, ΔV_4 and ΔV_5, are executed at the orbit apoapsis: the first compensates for the residual difference in eccentricity with respect to the chief's instantaneous state, and the second re-establishes the SMA. The complete sequence of manoeuvres is executed over a duration of three orbital periods, ensuring convergence of each deputy to its nominal along-track position and restoration of the designed in-plane formation geometry.

Simulation Setup and Results

The formation keeping logic has been simulated through GMAT [11]. The EarthMJ2000 reference frame and BrouwerMeanShort elements have been used to define and propagate the S/C's orbit. The initial simulation epoch is 01 January 2026 05:45:00 UTC. The perturbations included in the analysis are: i) Earth's gravitational potential series expanded up to degree and order 100; ii) the Moon and Sun's third body effect; iii) a reflectivity coefficient Cr = 1.8 for the solar radiation pressure modelling; iv) the Jacchia-Roberts atmospheric model. A chief-centred coordinate system is used to monitor and control the relative motion in the HRF and to evaluate violations of the control volume boundaries. This enables the derivation of the deputies' along-track coordinate behaviour with respect to the chief for both formations, as shown in Fig. 3. Here, the red lines identify the times at which a violation of the control volume occur, determining the scheduling of formation keeping manoeuvres. The corrections happen with a cadence that is in the order of days for the safe ellipse configuration and in the order of four-to-five months for the train-like formation. Consequently, the safe ellipse manoeuvring frequence is higher than the train-like one. As for the radial and cross-track coordinates, results from extended propagation periods, i.e., up to six months, indicate no violation of the control volume upper boundaries. Therefore, no out-of-plane manoeuvre is deemed necessary in this timeframe, and only in-plane manoeuvres are executed to restore the nominal along-track separations.

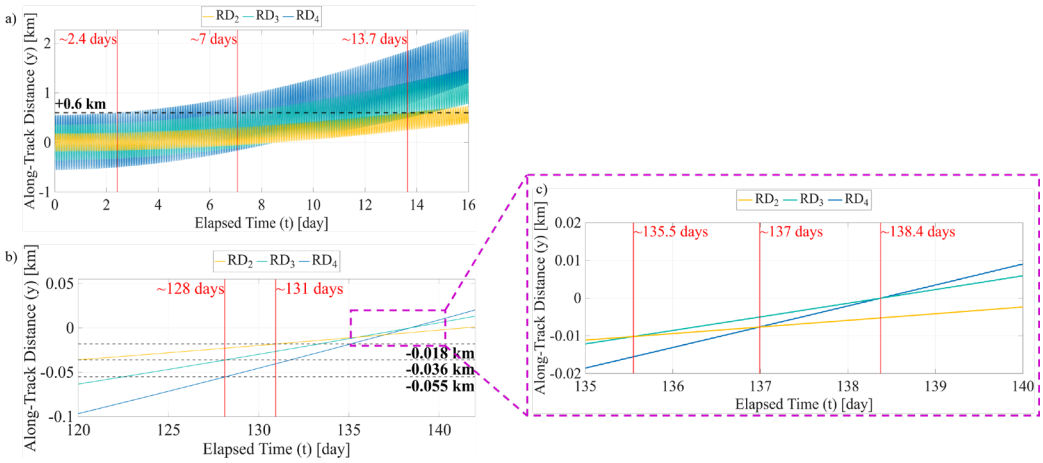

Fig. 3 Evolution of the deputies' along-track distances from the chief. a) safe ellipse formation, maximum along-track boundary of the control volume (black dashed line); b) train-like formation approach #2, minimum along-track boundaries of the control volume for each deputy (black dashed lines); c) zoomed view of Fig.3b) approach#1, collision times (red lines)

By applying the proposed manoeuvring strategy, the required ΔV budget for the safe ellipse and train-like configurations is computed and reported in Table 1. Given the difference in manoeuvring cadence, and to provide a common reference for comparison with the train-like configuration, the ΔV values reported in Table 1 for the safe ellipse formation are also expressed on a monthly basis, considering the violation times of each deputy from Fig. 3 a), b) and c). A first conclusion derivable from Table 1 concerns the comparison between the two approaches

considered for maintaining the train-like formation. The safe distance based approach results in a higher ΔV expenditure compared to control window one. This outcome is primarily due to the slight delay in violation times, which leads to longer drift times and thus larger corrective manoeuvres. Nevertheless, when comparing the two, the second approach proves to be more efficient and operationally preferable. As for the formations' comparison, a consistent trend is confirmed. The deputy with the largest relative orbit, RD_4, requires the highest ΔV for formation keeping, while control costs for RD_2 and RD_3 are smaller. Furthermore, despite the difference in manoeuvre frequency, the total ΔV required to maintain the train-like formation is approximately one order of magnitude lower than that of the safe ellipse case. This suggests that the train-like configuration, although less robust to the along-track drift, offers significantly reduced control effort and therefore represents a more cost-effective solution for small satellite DSAR missions.

Table 1 Formation keeping ΔV budget for the deputies of safe ellipse and train-like formations

	Safe ellipse formation			*Train-like formation*	
	ΔV_{tot} [m/s]	Manoeuvres per month	ΔV_{month} [m/s]	ΔV_{tot} [m/s] Approach #1	ΔV_{tot} [m/s] Approach #2
RD_2	1.27×10^{-1}	2.2	2.80×10^{-1}	2.09×10^{-2}	1.91×10^{-2}
RD_3	1.22×10^{-1}	4.3	5.18×10^{-1}	4.38×10^{-2}	3.94×10^{-2}
RD_4	5.96×10^{-2}	12.4	7.39×10^{-1}	6.58×10^{-2}	6.01×10^{-2}

Conclusions

This paper analysed two representative formation flying architectures for small satellite distributed missions: safe ellipse and train-like formations. Both have been modelled analytically in the HRF, linking their relative geometry to the corresponding orbital element differences. Subsequently, a dedicated formation keeping strategy has been implemented to evaluate the ΔV requirements under realistic perturbations, including J_2 effects, atmospheric drag, solar radiation pressure, and third-body interactions. Two control approaches have been tested for the train-like configuration and compared with the safety tube strategy adopted for the safe ellipse formation. As expected, the latter proves advantageous when collision risk mitigation is prioritised, but at the expense of more frequent corrective manoeuvres due to its varying geometry. Conversely, the former formation requires simpler control and lower fuel consumption, while remaining sufficiently stable over several months.

Keywords: Vision-Based Navigation, Spacecraft Pose Estimation, Hardware-In-The-Loop Validation, Proximity Operations

Abstract. Vision-based navigation is a key enabling technology for autonomous in-orbit operations. However, current deep learning-based pose estimation algorithms face a critical sim-to-real gap, where performance degrades significantly when transitioning from synthetic training images to real ones. This has driven the need for ground-based validation facilities to bridge this gap. This paper presents a robotic testbed installed at the Microsatellites and Space Microsystems Laboratory of the University of Bologna for hardware-in-the-loop validation of vision-based spacecraft pose estimation algorithms. The facility features a 7-DoF robotic system, an optical table with a spacecraft mockup, a sun simulator, and an RGB camera, all integrated within a controlled dark room environment. The software architecture is based on ROS 2, with custom nodes enabling coordinated control of all system components. An initial application demonstrates the facility's capability through the development of a dataset generation pipeline for the ALMASat spacecraft mockup. While designed within constrained budget and space requirements, the testbed provides high precision and supports both fundamental research and educational activities in vision-based spacecraft navigation.

Introduction

In-orbit operations are receiving growing attention within the space community due to their significant economic and scientific prospects for future space missions. Vision-based navigation is widely considered one of the most promising technologies to support autonomous navigation in this framework. Recent advances in deep learning have enabled significant progress in spacecraft pose estimation (i.e. relative chaser-target position and attitude) from images. Despite these advances, current methods face a critical challenge: the sim-to-real gap, where algorithms trained on rendered images achieve high accuracy on synthetic data but show degraded performance on real images [1]. This has led to two key developments: fundamental research at the intersection between space engineering and computer vision, and the establishment of ground-based validation as an essential step in the development pipeline.

This paper presents an ongoing research project at the University of Bologna developing a compact robotic testbed for validating vision-based navigation algorithms (see Fig. 1). While smaller in scale compared to large institutional facilities, the system is designed to provide high precision within a constrained footprint and budget, supporting both research activities and teaching in this field. The following sections first review the main educational facilities that inspired this work, then describe the system components and the design and control approach, briefly present a dataset generation pipeline, and finally discuss the final hardware integration currently underway to complete the testbed.

Robotic Testbeds in Academic Institutions

Ground-based testbed facilities for hardware-in-the-loop validation can be broadly classified into two categories: robotic-arm systems and floating platforms. The former typically offer 6-Degrees-of-Freedom (DoF) motion control, though they are limited by the manipulator's reach. On the other hand, floating platforms provide more realistic free-floating dynamics but generally with fewer controllable DoF.

Among university-operated robotic facilities, Stanford's Robotic Testbed for Rendezvous and Optical Navigation [2] is specifically designed for validating vision-based navigation algorithms. It features two KUKA robotic arms: one mounted to a ceiling linear rail and one ground-based. The testbed includes Vicon motion-tracking cameras and light sources that emulate Earth albedo and sunlight.

Similarly, the Zero-G Lab [3] at the University of Luxembourg features two collaborative robots (UR10e) mounted on linear rails, designed to emulate proximity operations in orbit. The facility includes a sun simulator and a motion-tracking system within a 5×3 m workspace.

Other examples include Politecnico di Milano [4] operating a 7-DoF robotic arm, though primarily focused on planetary landing scenarios, the University of Würzburg [5] with two KUKA manipulators, and the Research Center of the Polish Academy of Sciences [6] with a compact 2-DoF robotic arm.

Overview of the Robotic Testbed

These facilities have inspired the design of the testbed presented in this paper, which also results from trade-offs accounting for available budget and space constraints.

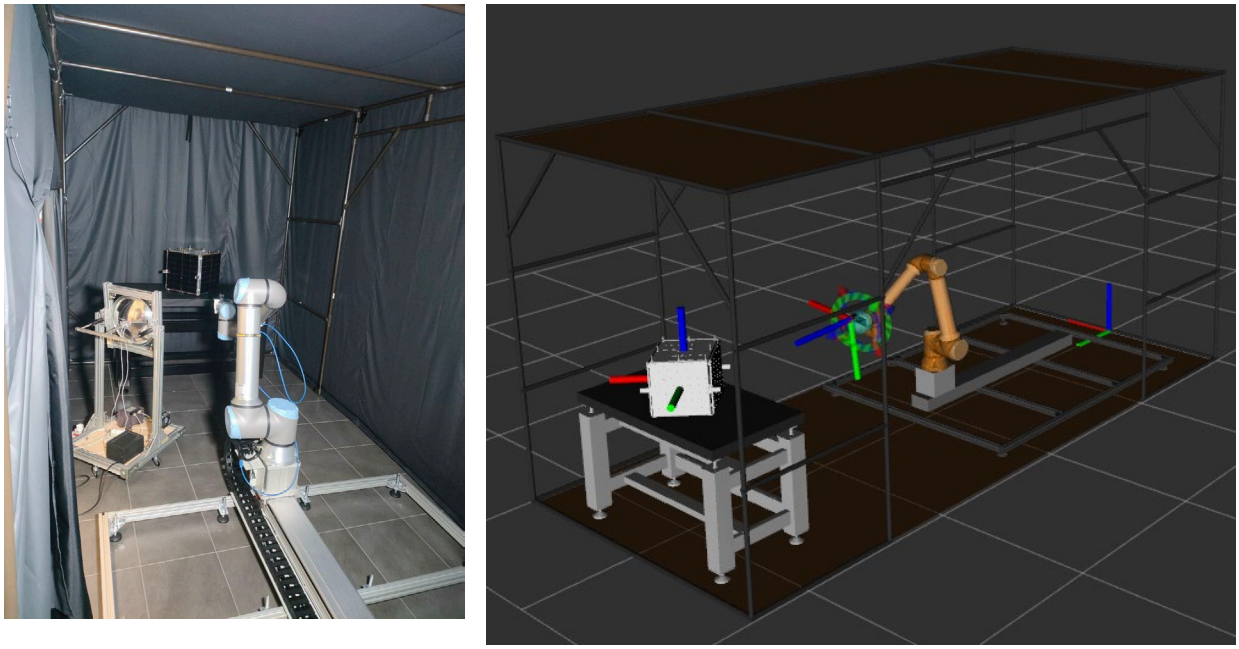

Figure 1: Overview of the robotic testbed: physical setup showing the UR10e cobot on linear rail, optical table with spacecraft mockup, and sun simulator within the dark room (left); RViz visualization displaying the main reference frames including camera frame, target body axes, and world frame (right)

The facility (see Fig. 1) features a 7-DoF robotic system, an optical table, a spacecraft mockup, a sun simulator, and an RGB camera, all integrated within a 4.4 × 2.0 m dark room. The room is enclosed by polyester blackout curtains, allowing fine control over lighting conditions, providing

Materials Research Proceedings 69 (2026) 1012-1017 https://doi.org/10.21741/9781644904251-175

a uniform background, and reducing secondary reflections to simplify image post-processing. A complete list of the current hardware is provided in Table 1.

Table 1: Main components of the robotic testbed

Component	Model	Specifications
Robotic arm	UR10e (Universal Robots)	6-DoF, 1.3 m reach, 12.5 kg payload, repeatability ±0.05 mm
7th axis (linear)	Slidekit 2.0 (Ewellix)	Ball screw drive, 1.8 m stroke, repeatability ±0.1 mm
Optical table	PFR60120-7 + B60120AX (Thorlabs)	1.2 × 0.6 × 0.76 m, high rigidity frame with damped optical surface
Mockup	ALMASat eng. model	33 × 33 × 31.5 cm
Sun simulator	Custom	Metal halide lamp (HMI), 400 W, 6200 K CCT
Camera	MER-231-41U3C (Daheng Imaging)	IMX249 CMOS sensor, 1920 × 1200 px
Dark room	Custom (OptoSigma)	4.4 × 2.0 × 2.2 m, polyester blackout curtain with acrylic backing

The sun simulator is a custom assembly of components originally used for characterizing hardware and numerical models for the CubeDyna ADCS testbed facility [7], developed by the Laboratory under ESA contract. The simulator features an HMI bulb and a parabolic reflector for light collimation, achieving an irradiance of 1000 to 1200 W/m^2.

The spacecraft mockup is a repurposed ALMASat engineering model [8]: a box-shaped spacecraft with side of 33 cm. The main bus is made of aluminum, while solar cells were emulated using glossy black vinyl, applied with a 3D-printed positioning mask that replicates the original cell geometry, over a copper backing. The mockup weighs approximately 8.5 kg, remaining within the cobot's payload envelope, and features a compatible mounting pattern, enabling installation on the end effector.

Software Integration and Control

The software stack controlling the robotic system is based on the Robot Operating System (ROS) 2 [9]. A workstation connects to the robotic arm's control box via Ethernet, the camera via USB 3.0, and the linear axis via a CAN-USB adapter. The seven joints are coordinated using MoveIt 2 [10], which handles inverse kinematics and collision-aware motion planning.

While the UR cobot integrates seamlessly into ROS workflows, the linear axis required a custom implementation leveraging the rail motor's support of the CANopen protocol. At the current deployment stage, the CAN connection is split between the workstation and the cobot's control box, as only target positions are currently controlled through ROS. Position control is performed in encoder counts. Dedicated ROS nodes bridge the low-level CAN communication, invoking the *cansend* and *candump* utilities for transmitting commands and reading responses and states, while interfacing with standard ROS and MoveIt interfaces. The software architecture can be conceptually organized into multiple layers:

- User interface and visualization: provides human-machine interface through RViz and live camera streaming, allowing the operator to monitor robot movements and camera view in real-time, as well as execute commands from the graphical interface.

Materials Research Proceedings 69 (2026) 1012-1017 https://doi.org/10.21741/9781644904251-175

- Motion planning and control: includes MoveIt 2 with three planning groups, one for the linear axis alone, one for the cobot alone, and one for joint control of both systems.

- Data integration and coordination: features custom rail nodes and a joint state merger that continuously collects joint states from the cobot and linear axis, republishing them for the 7-DoF MoveIt planning group.

- Drivers and device control: includes ROS nodes for each hardware component, managing device-specific protocols for the cobot, rail, and camera.

The cobot is always operated through ROS in remote mode. At system startup, a shell script powers on the robot, releases brakes, enables the linear axis motor by executing the CANopen state machine sequence, starts driver nodes, the joint state merger, MoveIt components, and finally launches RViz and camera streaming. After this startup sequence, the robotic system can be controlled through MoveIt move groups.

The main testbed components are modeled in the URDF file used by MoveIt for collision checking and kinematic chain reconstruction. However, discrepancies between actual component locations and the digital model are inevitable. Facility calibration is therefore crucial to reduce these drifts, specifically regarding hand-eye calibration (using OpenCV's *calibrateHandEye*), and determination of the mockup spacecraft position and orientation.

The latter is currently addressed by capturing an image of the mockup, setting a known pose for the robotic system, and manually selecting a set of landmarks matched to a CAD model of the spacecraft. The mockup pose relative to the camera is solved through PnP, while its absolute pose in the world frame is obtained through the robot's kinematic chain.

Towards the ALMASat Image Dataset

The first application of the testbed will be the development of a dataset for validating vision-based pose estimation algorithms. The ALMASat mockup, with its near-perfect symmetry, introduces additional complexity compared to existing datasets. To this end, a software pipeline has been developed with two main components. First, it enables the creation of a synthetic dataset using Blender, following a procedure closely aligned with the one illustrated in [11]. Second, it allows the collection of a real image dataset by separating pose planning and image acquisition steps.

The real dataset acquisition follows a multi-stage procedure. Initially, the working volume is discretized into a grid structure. For each cell center, the algorithm computes a look-at pose where the camera optical axis points towards the mockup's center. Using this target pose as reference, random variations are generated by adding small position jitter and randomly sampling rotation axes and angles. The script verifies pose reachability by sending inverse kinematics requests through MoveIt. If a solution is found, the corresponding joint values are exported for execution. A second script then executes the reachable poses, commanding joint positions with tolerances of 0.0046° for the cobot's joints and 0.1 mm for the linear guide. At the moment of image capture, the relative camera-mockup pose is recomputed to account for residual positioning errors arising from the difference between commanded and executed joint positions. The final step involves image post-processing through background removal using a Segment Anything Model [12]. The neural network is guided by a ground truth bounding box obtained by projecting the CAD wireframe model into the image using the known pose. Sample images from the dataset are illustrated in Fig. 2.

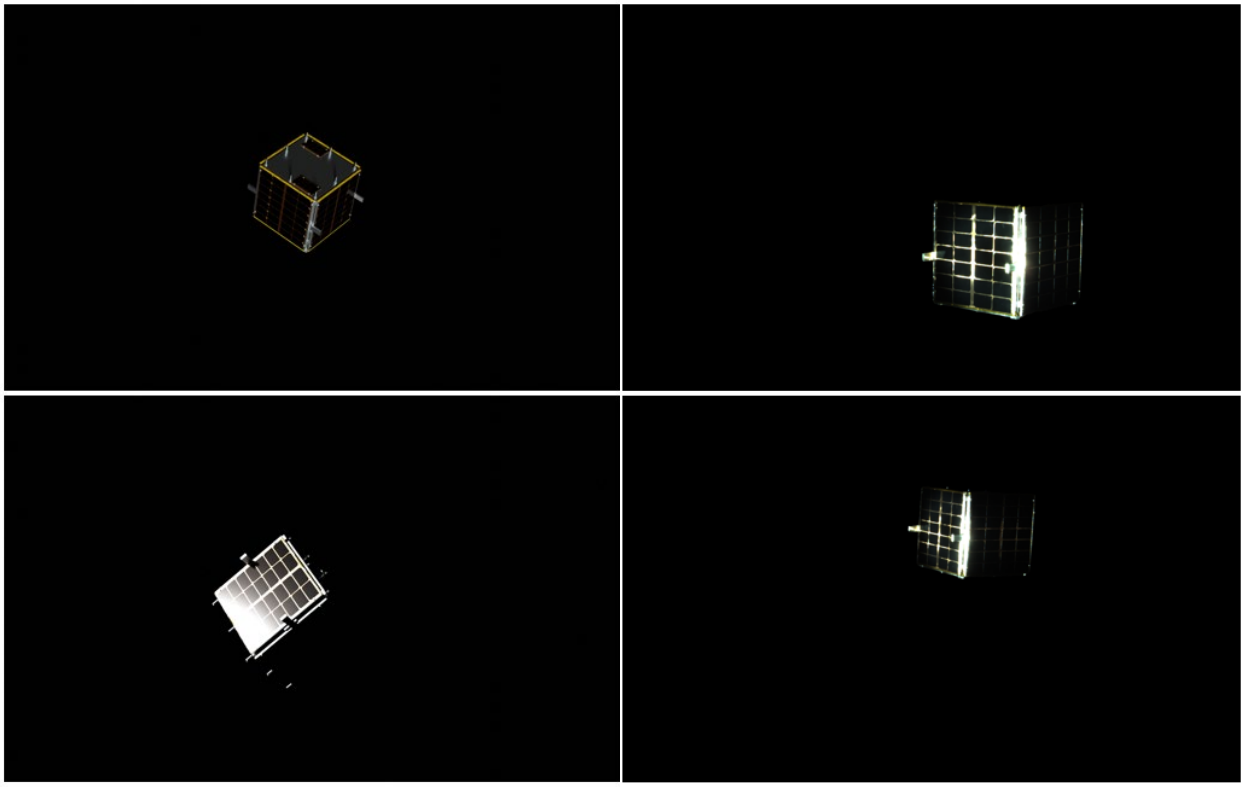

Figure 2: Representative samples from the ALMASat dataset: synthetic rendered images (left) and real images acquired with the testbed (right)

Conclusions and Future Work

This paper presented the development of a robotic testbed facility for hardware-in-the-loop validation of vision-based pose estimation algorithms at the University of Bologna. The main hardware and software components have been integrated and briefly described in the text, along with a dataset generation pipeline and initial samples demonstrating an early application of the facility.

However, the facility development is still ongoing. A set of four OptiTrack cameras has been installed and is being integrated into the ROS framework to provide an external pose reference. Additionally, new cameras and optics have been acquired to improve the depth of field compared to the current setup and to extend the facility with event cameras. These enhancements will further support algorithm validation and facilitate research and teaching activities in vision-based spacecraft navigation.

Keywords: Suborbital vehicles, Emission Estimation, Pollutants Dispersion, Local Air Quality, Environmental Impact

Abstract. As suborbital flights and space tourism move from promise to practice, quantifying their near-ground emissions is essential for responsible deployment and regulatory assessment. This study develops a reproducible, end-to-end methodology to quantify propulsive emissions and near-field plume dispersion for a suborbital carrier aircraft. The methodology is demonstrated on a representative point-to-point mission from the Italian Taranto–Grottaglie spaceport, transporting Virgin Galactic's SpaceShipTwo to approximately 15 km prior to release. Objectives are to generate phase-resolved emission source terms and translate them into site-specific ground concentrations to support early design and regulatory assessment. The methodology integrates high-fidelity mission simulations with the analytical BFFM2 emissions-estimation method to compute chemical source terms in an "idle-to-idle" approach, distinguishing fuel-proportional species (CO_2, H_2O, SOx), from power-dependent species (CO, NO_x, HC, PM). For each Landing and Take-Off (LTO) cycle phase, phase-averaged emission rates are represented as continuous elevated point sources and fed into an analytical Gaussian-plume model to compute spatially resolved concentrations C(x,y,z) of pollutants and greenhouse gases. The methodology is benchmarked against airport dispersion measurements and validated by cross-comparison with high-fidelity pollutant dispersion simulations. The proposed framework provides regulators and designers with a validated, transparent tool for early environmental evaluation of reusable suborbital operations, enabling informed decisions on site selection and operational constraints.

Introduction

Suborbital spaceflight is an emerging segment offering promising scientific and commercial opportunities, yet its environmental impacts remain poorly characterized. As air traffic and space tourism grow, rigorous evaluation of propulsive emissions has become critical, specifically for near-ground air-quality assessments [1,2,3,4]. In this regard, the present paper discloses a conceptual design methodology to quantify aircraft emissions and near-field plume dispersion for a suborbital launch system. In a representative point-to-point (A-to-A) mission from the Taranto-Grottaglie Italian spaceport - currently under evaluation by Italian and European authorities as a potential host site for Virgin Galactic's first European suborbital flights [5], chemical emissions from the WhiteKnightTwo (WK2) carrier aircraft are quantified and ground-level pollutant concentrations are estimated during transport of the SpaceShipTwo (SS2) suborbital vehicle to ~15 km altitude before release [6,7]. High-fidelity mission simulations provided time-resolved fuel flow, thrust and atmospheric data, which are combined with ICAO-certified emission indices [8]

to derive fuel-flow-adjusted emission trends at altitude. Specifically, the BFFM2 [9,10] emissions estimation method is adopted to compute chemical emissions in a "idle-to-idle" approach. Then, local air quality impact assessment is carried out. A simplified Gaussian-plume model estimating NO_x dispersion from the aircraft near the runway is implemented [11,12]. The plume model computes the concentration field C(x,y,z) given emission rate Q and local meteorological conditions [13,14,15,16]. Crucially, this implementation is validated against published airport NO_x measurements and dispersion studies, showing reasonable agreement [17]. The presented conceptual design methodology integrates suborbital mission analysis with environmental assessment techniques, constituting a novel contribution to the field.

Methodology

The adopted methodology establishes a coherent and reproducible protocol that integrates high-fidelity mission simulations with analytical models for emissions estimation and atmospheric dispersion, as illustrated in Figure 1. The objective is to characterize the environmental footprint of the WK2 suborbital carrier aircraft during all operational phases.

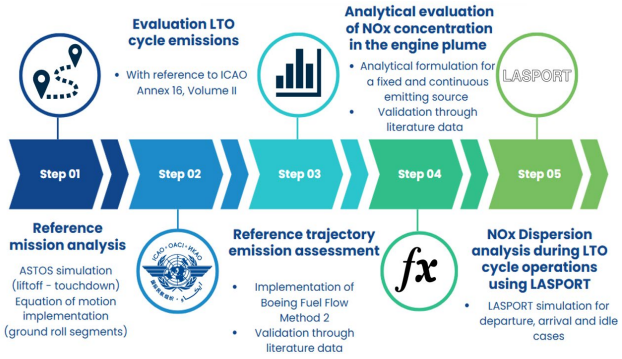

Fig. 1 - Air quality impact assessment methodology

The first step involves the simulation of the reference mission using a high-fidelity trajectory optimization environment. In this case, the authors selected the Analysis, Simulation and Trajectory Optimization Software for Space Applications (ASTOS) [18]. While ASTOS accurately models the airborne phases of flight, it does not explicitly simulate ground operations. To complement this, a dedicated simulation based on the equations of motion and Raymer's semi-empirical formulations was implemented to model the take-off and landing ground rolls, thereby enabling a complete "gate-to-gate" representation of the carrier mission [19]. This approach provides time-resolved outputs of fuel flow, thrust, engine operating conditions, and atmospheric parameters along the overall flight path. These data constitute the dynamic basis for the subsequent emission calculations. Chemical emissions are computed using a dedicated analytical model, namely the Boeing Fuel Flow Method 2 (BFFM2) [10]. This methodology relies on semi-empirical correlations documented in the literature, enabling the estimation of chemical emissions. To derive the Emission Indices (EI) of pollutants and greenhouse gases, expressed as grams of emitted species per kilogram of fuel burned, the BFFM2 procedure is applied as follows: (i) the flight-level fuel flow is corrected to an equivalent sea-level value; (ii) the corrected fuel flow is then used to infer sea-level emission indices through interpolation of tabulated data from the ICAO Engine Emissions Databank [8]; and (iii) the sea-level EIs are subsequently adjusted with altitude-dependent correction factors documented for each chemical species. This procedure yields altitude-corrected emission indices along the entire flight trajectory. For near-field air-quality evaluation, the disclosed methodology employs an analytical Gaussian-plume model to estimate pollutant dispersion and ground-level concentration fields [14,15,16]. Each LTO phase is modeled as a continuous elevated point source emitting a constant phase-averaged mass flow rate Q derived

Materials Research Proceedings 69 (2026) 1018-1023 https://doi.org/10.21741/9781644904251-176

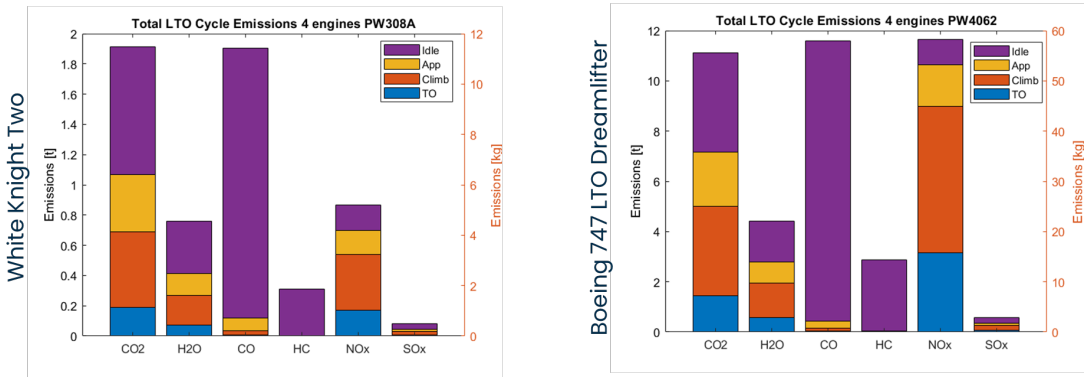
from the emission calculations. The spatio-temporal concentration distribution $C(x, y, z, t)$ at any downwind location is given by the Gaussian-plume simplified formulation reported in Eq.1.

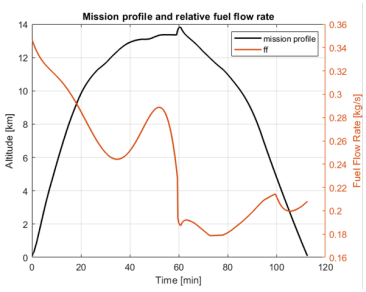
$$C(x,y,z,t) = \frac{Q}{(4\pi t)^{\frac{3}{2}}\sqrt{K_x K_y K_z}} \exp\left(\frac{(x-x')^2}{4K_x t} - \frac{(y-y')^2}{4K_y t} - \frac{(z-z')^2}{4K_z t}\right) \quad (1)$$

Where the K_i are the atmospheric turbulence coefficients calculated from the dispersion parameters obtained using Green's formulations [16]. The atmospheric dispersion model is based on the analytical solution of the advection-diffusion equation under the assumption of constant diffusion coefficients. However, to better reflect atmospheric conditions, the lateral and vertical diffusion parameters were treated as functions of distance, using the Pasquill-Gifford formulations [13]. This approach effectively adapts the Gaussian solution to account for atmospheric turbulence and stability variations. After defining a spatial grid in the vicinity of the emission points representing the LTO cycle phases, it is possible, for each grid node, to (i) calculate the concentration at each time step during the phase, and (ii) determine the mean concentration over the entire phase duration at each grid node. The spatial grid considered is 30 m wide in each direction and centered on the emission source, where the concentration values are the highest. Verification and validation represent the final step of the proposed workflow. Emission and dispersion results are benchmarked against published airport studies and compared with existing assessments of the WK2 aircraft and other large twin-fuselage carriers. Specifically, to validate the concentration results near the spaceport obtained with the simplified Gaussian plume model, high-fidelity dispersion analyses of WK2 NO_x emissions are performed using the commercial software LASPORT [20]. LASPORT represents the standard modeling tool adopted by the German Airport Association and has been applied in several national and international studies (e.g., [21,22]).

Results and Discussion

To address social acceptance concerns among communities surrounding Taranto-Grottaglie Airport, a comparative analysis was performed between the WK2 and the Boeing 747 LCF Dreamlifte, which operates weekly flights from Grottaglie to Charleston to transport fuselage sections of the Boeing 787 Dreamliner. Since LTO emissions and pollutants dispersion are the primary contributors to local air quality impacts, this comparison demonstrates that A-to-A suborbital operations could be integrated into conventional civil aviation without significant effects on nearby populations. Figure 2 compares the total mass of emissions produced by the two aircraft during their LTO cycles.





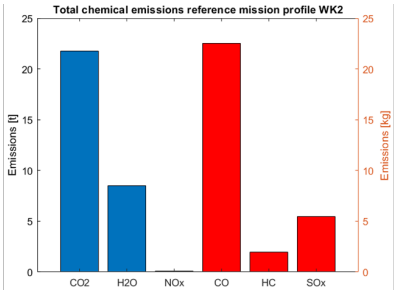


Fig. 2 - Total LTO cycle emissions, WK2 vs Dreamlifter

The Boeing 747 LCF Dreamlifter, equipped with four Pratt & Whitney PW4062 turbofan engines, exhibits similar emission distribution trends but considerably higher total emissions. For

Materials Research Proceedings 69 (2026) 1018-1023 https://doi.org/10.21741/9781644904251-176

both aircraft, CO_2, H_2O, CO, SO_x, and HC emissions are dominant during the idle phase, mainly due to its long duration, whereas NO_x emissions peak during the climb phase as a result of the combination of intermediate phase duration and higher engine power settings. This comparison highlights that suborbital A-to-A operations, such as those performed by WK2, would have a significantly smaller impact on local air quality than existing large transport aircraft activities, thereby supporting their social and environmental acceptability within civil aviation frameworks. Moreover, total aircraft emissions along the reference trajectory were calculated through the BFFM2 method for the WK2. The trajectory, simulated and validated in the ASTOS environment and complemented by analytically modelled ground phases (taxi, take-off, and landing rolls), is shown in Figure 3 together with emission trends compared with documented FAA estimates [17].

Emissions	Estimated Emissions	Documented (FAA) Emissions
CO_2[t]	21.746	22.962
H_2O [t]	8.477	9.12
NO_x [t]	0.088	0.091
CO [kg]	22.54	12.05
SO_x [kg]	5.47	9.43
HC [kg]	1.95	-

*Fig. 3 - Reference trajectory and total emissions comparison for the WK2 [**17**]*

The discrepancy between the two datasets stems from different mission assumptions: the present work considers idle-to-idle operations, including ground phases, and models variable fuel-flow rates during climb and approach instead of assuming constant power settings. Overall, BFFM2 results demonstrate good consistency. Finally, based on the LTO cycle emission results for both the WK2 and the Dreamlifter aircraft, air quality simulations were performed to assess NO_x dispersion in the Taranto-Grottaglie Spaceport area. The first stage of the analysis involved implementing a simplified analytical model to estimate the average NO_x concentration within the engine plume during the take-off phase. This concentration was calculated using the formulation reported in Eq. (1), derived from the simplified Gaussian plume model, assuming a constant emission mass flow rate Q from a single static source over a 1-minute period representing the take-off duration. The resulting concentrations were time-averaged across the defined spatial grid. The maximum point concentrations for both aircraft occur at the emission source, with corresponding values of 9.9 $\mu g/m^3$ for the WK2 and 153.7 $\mu g/m^3$ for the Dreamlifter. Since the LTO cycle emissions of the Dreamlifter are higher than those of WK2, it is expected and has been confirmed that NO_x concentrations are also higher during the take-off phase. The second stage of the air quality assessment validated the WK2 NO_x estimates from the simplified Gaussian plume model through high-fidelity dispersion simulations using the commercial software LASPORT. Three operational cases were simulated (departure, arrival, and idle) considering a headwind of 3 m/s for both departure and arrival. Near-ground concentrations averaged between 0 and 3 m above ground were computed with a 25 m horizontal resolution and recorded as consecutive 10-minute averages. Figure 4 presents NO_x concentration results for three consecutive 10-minute intervals following take-off. According to the EU Ambient Air Quality Directive 2008/50/EC [23], the annual mean NO_2 concentration must not exceed 40 µg/m³, and the hourly mean must remain below 200 µg/m³. The NO_x concentrations resulting from WK2 operations are well below these regulatory thresholds, further validating the simplified plume model results.

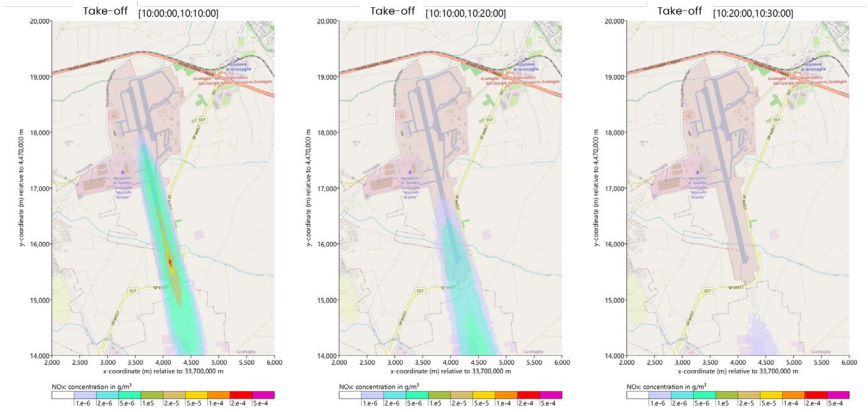

Fig. 4 - LASPORT NO_x concentration results for three consecutive 10-minute intervals following take-off

Conclusions

This work fits within the emerging European context of growing interest in suborbital flight. The study investigated the environmental impact of an A-to-A suborbital mission operating from Taranto-Grottaglie Airport, quantifying chemical emissions of the WK2 carrier enabling SS2's ascent to microgravity and assessing their influence on local air quality at ground level. The air-quality impact was found to be lower than expected, remaining below that of existing operations at the same airport. Consistently with LTO cycle overall emissions comparisons, the maximum NO_x concentration during the WK2 take-off phase is lower than that generated by the Dreamlifter, which performs weekly flights at the reference airport. To validate the concentration results obtained from the simplified Gaussian plume model, a subsequent dispersion analysis of the departure, approach, and idle phases were conducted using the LASPORT tool. The results describe the temporal evolution of NO_x concentrations over 10-minute intervals and constitute an initial step toward broader simulations that account for all airport-related traffic over a representative day at Taranto-Grottaglie Airport. In summary, this integrated workflow translates detailed flight-performance data into quantifiable environmental metrics through a combination of high-fidelity simulation, analytical emissions modelling, and Gaussian dispersion analysis. It provides an adaptable, transparent, and reproducible tool for assessing the atmospheric impact of suborbital carrier operations in mixed-traffic airspace. Beyond its application to the Grottaglie case study and aligned with emerging suborbital regulatory requirements in Italy and Europe, this work delivers a validated methodology for assessing the environmental footprint of reusable launch vehicles in mixed-traffic airspace., bridging the gap between aerospace design and environmental compliance.

Keywords: Space Service Volume (SSV), Galileo, GNSS, Earth Orbit Rising (EOR), Electrical thrust, Spacecraft Manoeuvre, Orbit Determination

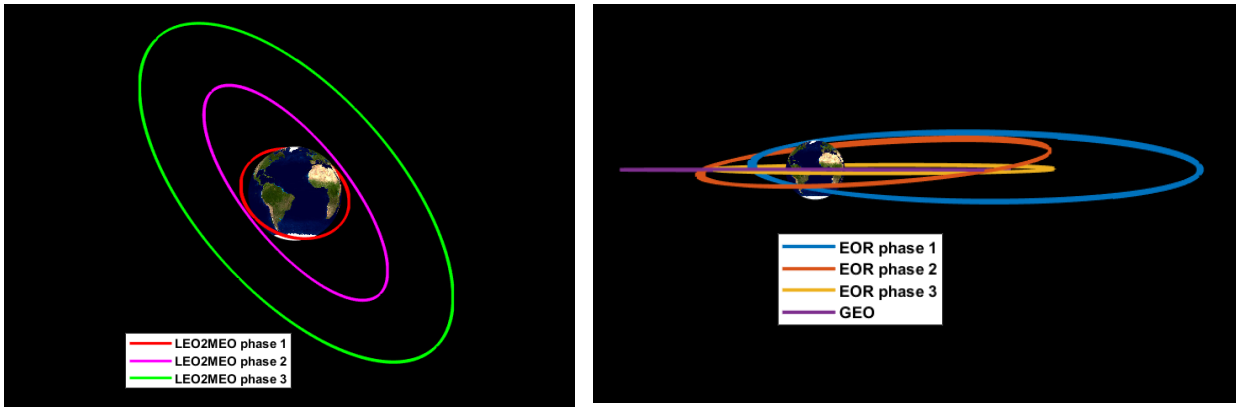
Abstract. Global Navigation Satellite Systems (GNSS) are becoming key enablers for autonomous operations beyond Low Earth Orbit (LEO). The Galileo Space Service Volume (SSV) offers strong potential for Earth Orbit Rising (EOR) missions, where spacecraft ascend from LEO to higher orbits using electric propulsion. This paper evaluates navigation performance achievable within the Galileo SSV for next-generation EOR missions using the JRC Integrated SSV Test Bench, which integrates realistic signal modelling, antenna patterns, and receiver dynamics. Two representative scenarios are analysed: a LEO–MEO transfer for a Galileo Second Generation satellite and a LEO–GEO transfer for a SATCOM platform. Results demonstrate that autonomous orbit determination is feasible with single-antenna configurations and moderate receiver sensitivity, confirming Galileo's readiness, either alone or in conjunction with GPS interoperability to support autonomous orbit raising and guide future receiver design.

Introduction

Global Navigation Satellite Systems (GNSS) has evolved from terrestrial navigation to an essential element of modern space operations. Beyond their widespread use in LEO, systems like Galileo and GPS now extend coverage into Medium Earth Orbit (MEO), Geostationary Orbit (GEO), and even cis-lunar regions. The operational domain supporting this is the Space Service Volume (SSV) [1]. Among emerging applications, Earth Orbit Rising (EOR)—the gradual ascent from LEO to higher orbits via low-thrust electric propulsion—represents a milestone toward fully autonomous space operations [2]. Electric propulsion provides flexibility, efficiency, and cost-effectiveness but also introduces new navigation challenges: weak GNSS visibility, prolonged thrusting, and frequent attitude steering. Autonomous GNSS-based navigation enables real-time manoeuvre planning and reduced ground dependency. While SSV applications have been studied for lunar or deep-space operations, less attention has been given to EOR missions using Galileo alone. Assessing Galileo-only performance within the SSV is essential for designing next-generation spaceborne GNSS receivers. This paper provides an updated Galileo SSV performance analysis using the European Commission's Joint Research Centre (JRC) Integrated SSV Test Bench (JRC-ISSVTB) environment [3], focusing on two reference cases: (i) a LEO to MEO transfer for a Galileo Second Generation satellite [4] , and (ii) a LEO to GEO transfer for a next-generation SATCOM platform [5].

Galileo Scenario Definition and Orbit Profiles

Scenario A – LEO to MEO Transfer (Galileo Second Generation)



This scenario models a possible autonomous transfer of a Galileo Second Generation (G2G) satellite from a 1220 km, 56° circular parking orbit to its nominal MEO altitude of 23,222 km [4]. The spacecraft uses a single ion thruster (thrust 0.180 N, Isp 3829 s) to complete a one-year spiral transfer. The ascent is divided into three representative LEO to MEO (LEO2MEO) phases (Fig. 1a): a low-orbit phase (≈1220 km), an intermediate phase (≈11,860 km), and a high-altitude phase

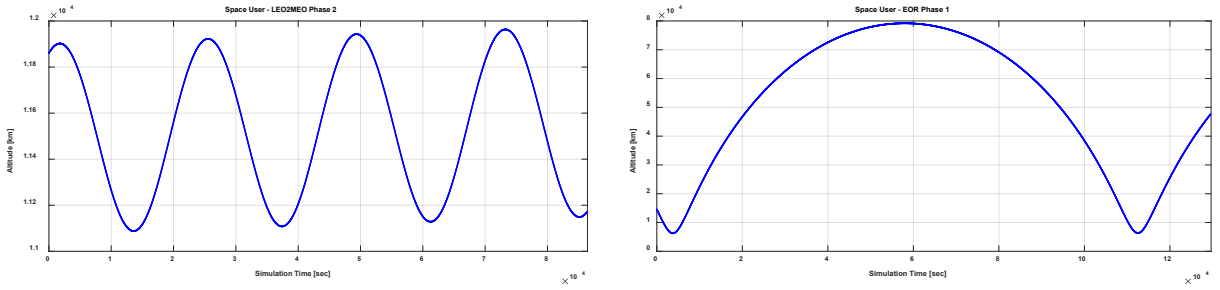
Materials Research Proceedings 69 (2026) 1024-1029 https://doi.org/10.21741/9781644904251-177

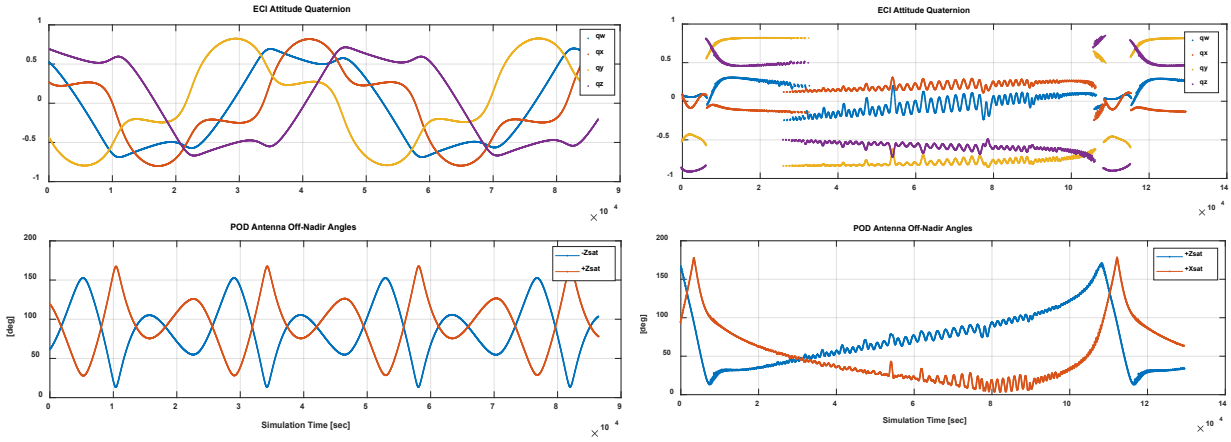
(≈21,813 km). Beyond 10,000 km altitude, GNSS visibility decreases, making spillover on the main lobe reception essential for continuous navigation—an ideal condition for assessing Galileo SSV coverage during orbit-raising operations.

Scenario B – LEO to GEO Transfer for a Next-Generation SATCOM Platform
This case represents an all-electric transfer of a geostationary communications spacecraft [2], [5], from a 700 km, 5° near-equatorial high elliptical Geostationary Transfer Orbit (GTO) to GEO at 35,786 km. The platform employs four Hall-effect thrusters (total thrust 0.35 N, Isp = 1700 s) operated in duty-cycled pairs over about 180-day transfer including eclipses and coasting phases. A sun-tracking attitude induces frequent slews and variable GNSS antenna pointing. Above 25,000 km, only a few Galileo satellites remain visible through side-lobes, yet multi-constellation (e.g. Galileo + GPS) reception and high-sensitivity front ends can sustain navigation continuity. Fig. 1b shows three main LEO to GEO transfer phases, namely EOR Phase 1, 2 and 3, up to the final equatorial GEO orbit.



a) b)

Fig. 1 – Simulated EOR trajectories a) to MEO and b) to GEO



In both EOR scenarios, spacecraft traverse a wide range of altitudes, and the performance of GNSS-based navigation strongly depends on the geometry and visibility of transmitting satellites within the SSV. At LEO altitudes, direct line-of-sight to multiple satellites is ensured, while at MEO and GEO, only a limited number remain visible. The signal environment is characterized by two main reception mechanisms: main-lobe reception, from Earth-facing antennas, and side-lobe reception, from the residual energy radiated outside the nominal beam. As altitude increases beyond the GNSS constellation itself, users gradually move from the "Earth-facing" region (main lobe coverage) into the "above-the-constellation" region (side-lobe and back-lobe coverage). In this work the LEO2MEO phase 2 and EOR Phase 1 shown in Fig. 1 have been considered to evaluate the Galileo SSV performance under different manoeuvre planning, thrust control, and GNSS receiver antenna pointing configurations. The LEO–MEO Phase 2 represents the intermediate ascent segment toward the nominal Galileo MEO altitude, with an initial orbital altitude of approximately 11,860 km (Fig. 2a). The transfer follows a spiralling low-thrust trajectory (Fig. 3a), and both zenith ($-Z_{sat}$) and nadir ($+Z_{sat}$)-facing antennas are considered for signal reception [1]. The EOR Phase 1 case starts from a highly elliptical orbit with perigee and apogee altitudes of about 6,200 km and 79,300 km, respectively (Fig. 3b). A high-gain antenna is mounted on the $+Z_{sat}$ axis, complemented by a secondary along-track ($+X_{sat}$) antenna [5]. The spacecraft attitude is continuously adjusted according to thrust direction and power constraints, as shown in Fig. 3b. Fig. 3 shows the ECI J2000 attitude quaternions and the corresponding precise orbit determination (POD) antenna off-nadir behaviour for both orbital regimes.

Materials Research Proceedings 69 (2026) 1024-1029 https://doi.org/10.21741/9781644904251-177

a) b)

Fig. 2 – Space User Altitude: a) LEO2MEO case, b) EOR case

a) b)

Fig. 3 – Space User Attitude and POD antenna Off-Nadir: a) LEO2MEO case, b) EOR case

The off-nadir angle is monitored throughout the simulation to assess the impact of attitude steering on GNSS signal visibility and received power, a critical factor during electric-thrust phases where vectoring manoeuvres can significantly modify antenna orientation with respect to the GNSS constellation.

Simulation Environment and Configuration

JRC Integrated SSV Test Bench (JRC-ISSVTB)

Developed by the JRC, the JRC-ISSVTB integrates orbit and attitude dynamics, GNSS signal simulation, and receiver-level processing for SSV analysis [3]. It includes orbit propagation, realistic Galileo antenna patterns [6], and receiver modelling under weak-signal conditions. For this work, the software-only configuration was used, employing the same signal and geometry models as the hardware-in-the-loop (HIL) setup. Future work will extend to full hardware validation.

Galileo Constellation and Signal model

Galileo's operational constellation comprises 30 satellites (24 operational and 6 spares) distributed across three orbital planes at an altitude of 23,222 km [7]. This configuration provides stable geometry for terrestrial users and extends navigation service into higher altitudes through antenna side-lobe coverage. The Galileo transmit antennas [6] exhibit secondary lobes, which, although weak, remain detectable at GEO altitudes, supporting signal continuity during extended EOR operations. The simulation includes the Open Service (OS) Galileo Navigation Signals on the three frequency bands—E1, E5a, and E6 [7]. SSV performance is assessed in terms of received carrier-to-noise density ratio (C/N_0), computed from GNSS geometry, spacecraft antenna orientation, and

Materials Research Proceedings 69 (2026) 1024-1029 https://doi.org/10.21741/9781644904251-177

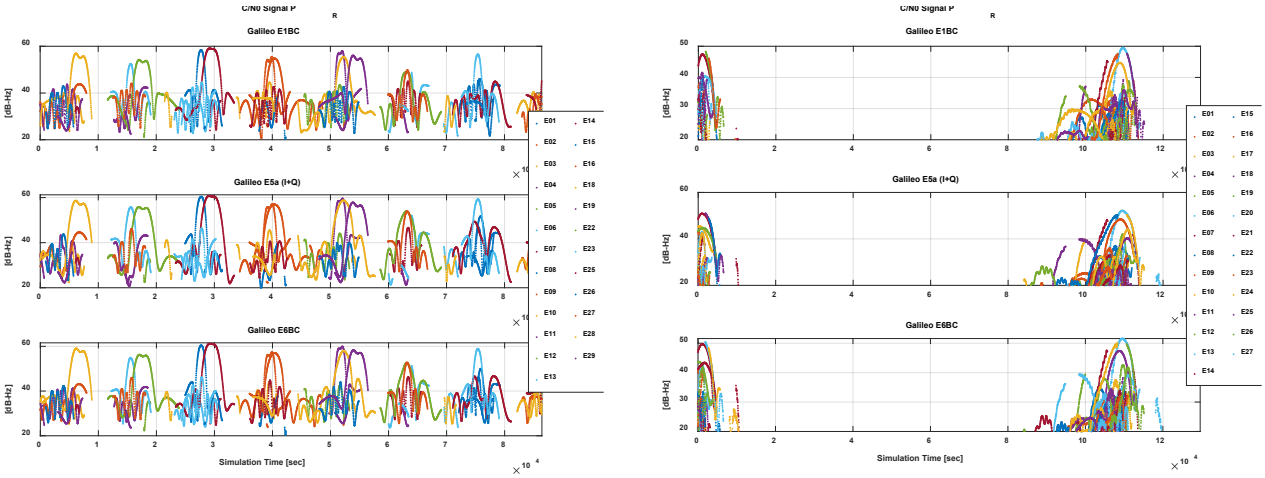
Earth disk obscuration. For each visible satellite, the JRC-ISSVTB simulator computes C/N_0 through a typical link budget model [3]:

$$C/N_0 = P_T + G_{T_x} + G_{R_x} - L_{FS} - L_{SVf} - L_{IL} - I_{IMP} - (K_B + T_{Sys}) \quad (1)$$

where P_T is satellite transmit power, G_{T_x} and G_{R_x} are the transmitting and receiving antenna gains respectively, L_{FS} is the free-space loss, L_{SVf} the filtering and modulation loss, L_{IL} the insertion loss, I_{IMP} the implementation loss, and K_B and T_{Sys} represent Boltzmann's constant and a system noise equivalent temperature, respectively.

Receiver model

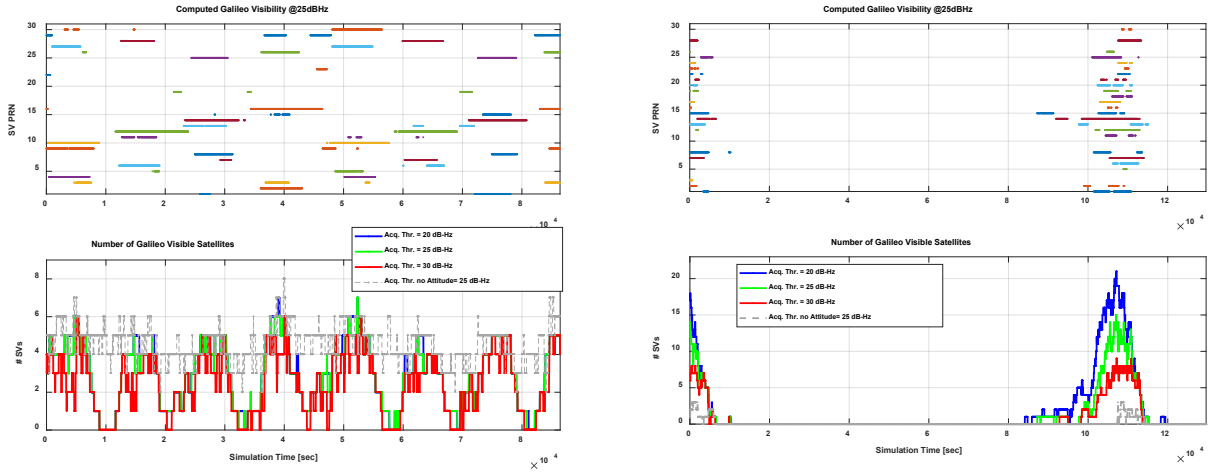
The simulated receiver represents a high-grade spaceborne GNSS unit optimized for weak-signal operations within the SSV. The front-end thermal noise density is set to N_0 = –174 dBm/Hz, consistent with high-sensitivity L-band designs [3]. A C/N_0 acquisition threshold of 20 dB-Hz is used to assess signal availability across different sensitivity levels. Two antenna configurations are modelled [1], [3]: a ~5 dBi Low-Gain (LG) patch antenna, used in LEO to MEO transfers (zenith-pointing), and an 8–9 dBi High-Gain Antenna (HGA), used in MEO to GEO missions (nadir-pointing), where reception depends on spillover and side-lobe signals.



Results

The Galileo SSV performance for orbit transfer operations has been evaluated using Key Performance Indicators (KPIs) quantifying signal reception quality:

- **Received signal power (C/N_0)**: representing the effective carrier-to-noise density ratio at the receiver input, indicative of link margin and tracking robustness under weak-signal conditions [3].
- **Number of visible satellites:** reflecting instantaneous geometry and measurement redundancy, analysed for acquisition thresholds of 20, 25, and 30 dB-Hz.



For the LEO–MEO scenario, a 24-hour simulation period has been analysed, while for the EOR Phase 1 high-eccentricity case, a 36-hour simulation has been performed to cover at least one full orbital period. Fig. 4 shows the simulated Galileo C/N_0 distributions for both scenarios at E1-BC, E5a (I+Q), and E6BC components. The plots highlight the correlation between signal strength and the POD antenna off-nadir angle (see Fig. 3). In the EOR Phase 1 case, extended signal outages—up to ~23 hours—are observed, as expected from mission geometry [5]. Hence, the usage of an Extended Kalman Filter (EKF) supporting signal outages can be a suitable implementation strategy to support autonomous navigation. Conversely, the LEO–MEO Phase 2 case exhibits improved visibility thanks to more favourable satellite geometry and reduced Earth blockage.

Fig. 5 illustrates the corresponding Galileo satellite visibility over time. The top panels show the visibility duration of each PRN (assuming 25 dB-Hz acquisition threshold), while the bottom charts report the total number of visible satellites under the three sensitivity thresholds. The comparison also includes a no-attitude-manoeuvre case at 25 dB-Hz acquisition threshold, highlighting the impact of attitude steering on GNSS signal continuity during orbit-raising. Overall, the simulations confirm that for single-antenna configurations, prolonged measurement gaps—up to 22–24 hours—can occur in high-altitude EOR phases, whereas continuous tracking is more feasible in intermediate MEO altitudes.

a) b)

Fig. 5 – Galileo Visibility: a) LEO2MEO case, b) EOR case

Finally, Table 1 summarizes Galileo signal availability for each frequency band and antenna pattern region (main, secondary, and side lobes) at 25 dB-Hz acquisition threshold. Results show that while LEO–MEO operations primarily rely on secondary-lobe reception, EOR Phase 1 achieves a greater contribution from side-lobe signals, essential for maintaining navigation continuity beyond the Galileo constellation altitude.

Table 1 – Signal Availability vs Pattern lobe , Acq. Thr = 25 dB-Hz

Scenario	**LEO2MEO Phase 2 [%]**			**EOR Phase 1 [%]**		
Signal Component	**E1-BC**	**E5a (I+Q)**	**E6BC**	**E1-BC**	**E5a (I+Q)**	**E6BC**
Main lobe	26.0	26.9	26.9	45.5	58.8	50.5
Secondary lobe	74.0	73.1	73.1	43.9	36.4	37.8

Conclusion and Future Works

This study presented a simulation-based assessment of Galileo SSV performance for electric-propelled orbit transfer missions, focusing on two representative cases: LEO–MEO (Galileo Second Generation) and LEO–GEO (next-generation SATCOM). The analysis characterized

signal availability, geometry, and received power under realistic dynamics and antenna configurations. Results show that Galileo signals can sustain autonomous navigation throughout EOR phases, even beyond the constellation altitude, mainly through side-lobe reception. Although visibility gaps of several hours can occur for single-antenna configurations, the obtained link margins confirm the feasibility of GNSS-based orbit determination for long-duration, low-thrust transfers. Future work will extend this analysis to dual-antenna configurations, multi-constellation (Galileo + GPS) performance, and onboard navigation using an Extended Kalman Filter (EKF). Further validation within the JRC Integrated SSV Test Bench (HIL mode) will support the development of design guidelines for next-generation spaceborne GNSS receivers operating within the Galileo SSV.

Abstract. Satellite scheduling requires balancing dynamic tasking demands, limited resources, and real-time adaptability, conditions under which traditional rule-based and heuristic methods often fall short. This study explores Safe Reinforcement Learning (SRL) as a framework for autonomous, adaptive, and constraint-aware mission planning. We propose a frugal fine-tuning strategy that adapts a Proximal Policy Optimization (PPO) baseline to new operational domains within the BSK-RL simulation environment, leveraging soft constraints modeled through cost signals. Two SRL approaches are evaluated: (i) reward reshaping, which integrates constraint costs into the reward function, yielding stability improvements and an 8% reduction in actions per episode without sacrificing cumulative rewards; and (ii) Lagrangian-based Constrained Policy Optimization (CPO), which separately optimizes rewards and constraint costs, prioritizing constraint satisfaction and reducing actions by 20–28% at the expense of overall reward. Results demonstrate that SRL enhances both efficiency and constraint adherence in scheduling, while the proposed fine-tuning approach enables rapid transfer to new mission scenarios. These findings highlight SRL as a promising pathway toward scalable, safe, and adaptive satellite operations.

Introduction

Optimizing satellite scheduling remains a central challenge in aerospace mission operations, due to dynamic tasking, limited resources, and real-time constraints. Traditional scheduling methods, often based on rule-based logic or (meta)heuristic strategies, frequently lack the flexibility and efficiency required for modern satellite operations.

In recent years, satellite mission planning has seen a shift from traditional heuristic and meta-heuristic approaches, such as Genetic Algorithms (GAs), to modern AI-driven methods. GAs have long been valued for their robustness in solving multi-objective and constraint-rich scheduling problems, including ground station tasking [1,2]. However, their reliance on hand-crafted rules limits their scalability in dynamic, large-scale, and real-time multi-satellite scenarios [3].

In contrast, Deep Reinforcement Learning (DRL) offers a more flexible, learning-based paradigm. Algorithms such as Proximal Policy Optimization (PPO) [4], Deep Q-Networks (DQN) [5], and Shielded PPO (SPPO) [6] enable agents to learn complex scheduling and control strategies through interaction with high-fidelity simulators, such as [7,8]. Recent work has begun to explore hybrid and multi-stage DRL architectures, which combine heuristic or optimization layers with DRL-based policies to improve solution quality and robustness. For example, Rainbow DQN has been employed in a two-stage scheme to first resolve observation conflicts and then optimize task execution [9], while other methods integrate pointer networks or matrix-sorting with DRL agents to decompose sequencing and allocation, achieving higher responsiveness in dynamic scenarios [10,11].

Despite these advancements, most of these recent approaches are not designed with explicit safety guarantees, particularly when operating under hard resource constraints, failures, or unpredictable task injections. While some modular architectures support replanning without retraining [11], and attention-based models improve decision granularity [12,13], they do not account for constraint adherence during learning itself. To address this, our work contributes to the emerging area of Safe Reinforcement Learning (SRL) [14] by integrating a variant of Constrained Policy Optimization (CPO) [15] and a cost-sensitive reward strategy. This promotes constraint-aware behavior during training, without relying on rigid enforcement or manual rule design—advancing the trustworthiness and adaptability of autonomous satellite schedulers in operational conditions.

A core innovation in our approach is its frugality and transferability: rather than retraining agents from scratch, we focus on fine-tuning an existing baseline policy to adapt efficiently to new mission domains or operational conditions. This is achieved within the high-fidelity BSK-RL simulation environment [16], using Proximal Policy Optimization (PPO) as the baseline. We implement soft constraints, which are not enforced through hard limits but modelled through cost signals that influence agent behavior via the learning process. These costs guide policies toward compliance without rigidly restricting exploration or solution space.

Problem formulation

We cast satellite task scheduling as a partially observable Markov decision process in which the full spacecraft–environment state is hidden, and the agent must act from telemetry and mission context. Each observation blends normalized spacecraft status—battery and memory fractions, reaction-wheel speeds, pointing errors, together with environmental cues (eclipse flag, normalized mission time) and planning context: up to thirty-two currently visible imaging opportunities annotated with priority and timing, plus the next ground-station downlink window. At each decision instant, the agent selects one discrete action: capture an image by choosing one of the currently visible targets; initiate a downlink to the next available ground station; switch to solar charging; execute a wheel desaturation; or drift (idle) to conserve resources.

The reward guides two operational goals: acquiring valuable imagery and managing storage through timely downlinks. When an image is successfully captured, the agent receives the target's priority as a positive reward; when a downlink is performed, it receives a utility proportional to the freed storage. Episodes terminate early with a large negative terminal reward if safety limits are violated, specifically, if the battery would drop below zero or reaction-wheel speeds exceed their bounds, so unsafe behavior is both discouraged and truncated. As a learning baseline we employ Proximal Policy Optimization (PPO), which updates a stochastic policy using a clipped surrogate objective with value-function fitting and an entropy bonus to balance exploitation and exploration. To introduce constraint awareness, we build on a common operational cost signal that grows when battery charge falls below a minimum fraction P_{min} or when memory usage exceeds a maximum fraction M_{max} (weights balance power vs. memory).

We study two strategies that use this cost differently. Reward reshaping subtracts the cost from the task reward at every step, yielding a single scalar objective that is simple to optimize but blends task performance and safety into one number. In contrast, a Lagrangian CPO-style variant keeps the original reward untouched and enforces the cost budget through an adaptive penalty: we extend the PPO backbone with a parallel cost-critic head that estimates cost returns, we compute a cost-advantage with cost-specific GAE, and we update a Lagrange multiplier λ online toward a target budget. As λ increases when violations persist and relaxes when behavior is safe, the policy learns to trade reward against constraint systematically without distorting the reward signal itself.

This formulation preserves a clear task objective, exposes resource limits as explicit constraints, and supports both a lightweight penalty (reward reshaping) and a principled safety mechanism (Lagrangian with a cost critic) within the same PPO architecture.

Materials Research Proceedings 69 (2026) 1030-1035 https://doi.org/10.21741/9781644904251-178

Experiment setup

The satellite and scenario configuration were defined through parameters governing data storage, power consumption, attitude control, orbital characteristics, and target generation variables. Several parameters were randomly initialized within realistic ranges to simulate diverse operational conditions, enabling the agent to adapt to varying real-world environments during both training and testing. Other parameters were held constant: data storage capacity of 8 GB, instrument data rate of 0.4 GB/s, transmitter rate of 0.2 GB/s, battery capacity of 720,000 W·s, and mode-dependent power consumption (–10 W·s idle, –30 W·s imaging, –25 W·s downlink, and –80 W·s thruster). The reaction wheels supported rotational speeds up to ±6000 RPM. The satellite operated in a 500 km altitude orbit with a 45° inclination. The scenario included 1000 randomly distributed Earth surface targets and seven predefined ground stations.

The PPO baseline agent was trained using a carefully tuned set of hyperparameters to ensure stable convergence and strong policy performance in the BSK-RL environment. The learning rate was set to 1×10^{-4}, with a discount factor γ of 0.99 and a GAE lambda λ of 0.85. A clipping range of 0.3 was applied to stabilize updates, while an entropy coefficient of 0.01 encouraged exploration. The value function loss was weighted with a coefficient of 1.0. Training used a batch size of 256 and a rollout horizon of 10,000 steps. Each PPO update was optimized over 10 epochs, with a total of 300 training iterations performed. The PPO agent reached stability after approximately 2.3 hours of training, achieving a mean return of about 41 and a mean episode length of around 260 steps.

The reward-reshaped agents, trained from scratch and fine-tuned from PPO, achieved rapid, stable convergence. In contrast, the L-CPO agents trained from scratch initially exhibited slower and less stable learning. However, fine-tuned L-CPO agents with a newly initialized cost head enabled reliable constraint learning and resulted in an approximate 28% reduction in mean episode length.

All training was performed on a virtual machine with 64 CPUs and 64 GB of RAM, leveraging the parallelization capabilities of Ray [17,18], an open-source distributed computing framework that scales Python applications efficiently from a single node to large clusters with minimal code modification.

Results

For a fair comparison, the initial conditions and random seeds were held constant across 100-episode evaluations. Each test began with the battery charged to 50%, data storage filled to 50%, and reaction wheels spinning at 1000 RPM. The orbital parameters—right ascension of the ascending node, argument of perigee, and true anomaly—were all set to zero degrees.

After the training, hyperparameter fine-tuning, and evaluation phases, the best-performing agents are selected: the PPO baseline (PPO), one reward-reshaped agent trained from scratch (RR_S), one reward-reshaped agent fine-tuned from PPO (RR_{FT}), and one Lagrangian agent fine-tuned from PPO ($L\text{-}CPO_{FT}$).

As shown in Fig. 1a, the PPO baseline exhibits higher costs and longer episodes, indicating less efficient operation. In contrast, reward-reshaped agents cluster at lower costs while maintaining longer trajectories, reflecting more cautious storage and power management behavior. The Lagrangian agent achieves the shortest episodes while maintaining costs below 5%, representing a safety-oriented operational regime.

Fig. 1b indicates that the RR variants maintain performance levels comparable to the PPO baseline in terms of cumulative reward, while enhancing policy stability and behavioral consistency. This method integrates constraint costs directly into the reward signal, encouraging a smoother trade-off between objective achievement and resource-aware behavior. Notably, it results in an 8% reduction in the number of actions taken per episode, reflecting more efficient and

Materials Research Proceedings 69 (2026) 1030-1035 https://doi.org/10.21741/9781644904251-178

stable decision-making. In contrast, the L-CPO approach treats the primary reward and constraint cost as separate optimization objectives, enabling a more explicit enforcement of constraint satisfaction. While this yields lower overall rewards compared to PPO and reward reshaping, it significantly emphasizes constraint adherence, resulting in a decrease in the number of actions taken in the episode (reduced by approximately 20–28%) and more conservative agent behavior. This separation of objectives offers greater interpretability and control over constraint tuning, in contrast to the blended reward-cost formulation in reward reshaping.

Fig. 2a (imaged-target distribution) and 2b (episode-length distribution) further characterize these dynamics. The PPO baseline yields higher throughput, but it is inefficient in terms of resource utilisation.

The reward-reshaped agent exhibits steadier and longer operational runs, whereas the Lagrangian agent maintains short, consistent episodes.

In conclusion, the baseline shows the largest variability, the reward-reshaped approach combines low cost with high return, and the Lagrangian method achieves the lowest cost with minimal dispersion but slightly reduced return.

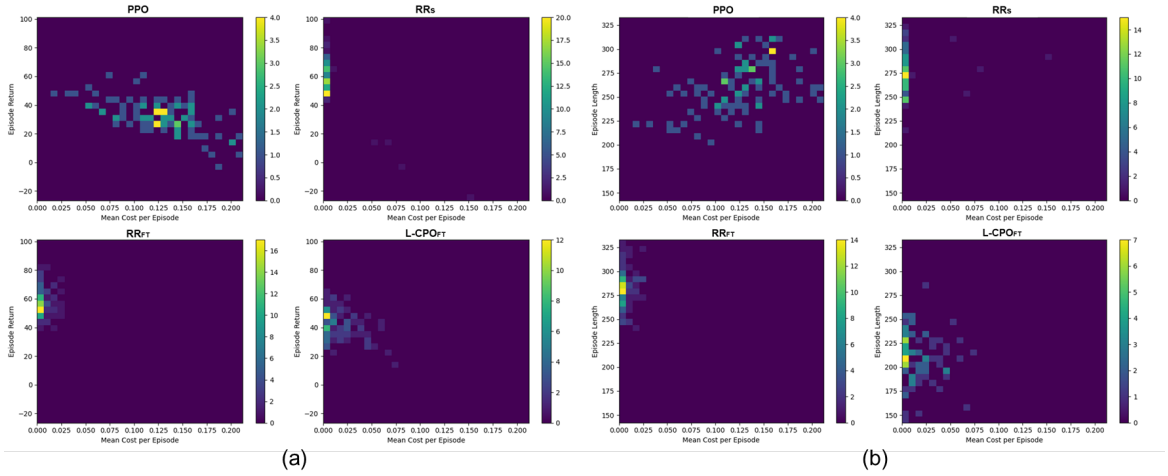

Figure 1. (a) Mean cost vs. episode length and (b) mean cost vs. episode return over 100 test episodes. The PPO baseline shows high-cost variability, often breaching the 10% safety threshold. Reward-reshaped agents (RRS and RRFT) achieve lower costs with longer, more structured episodes, while the Lagrangian-based agent (L-CPO) attains the shortest safe executions (<5% cost).

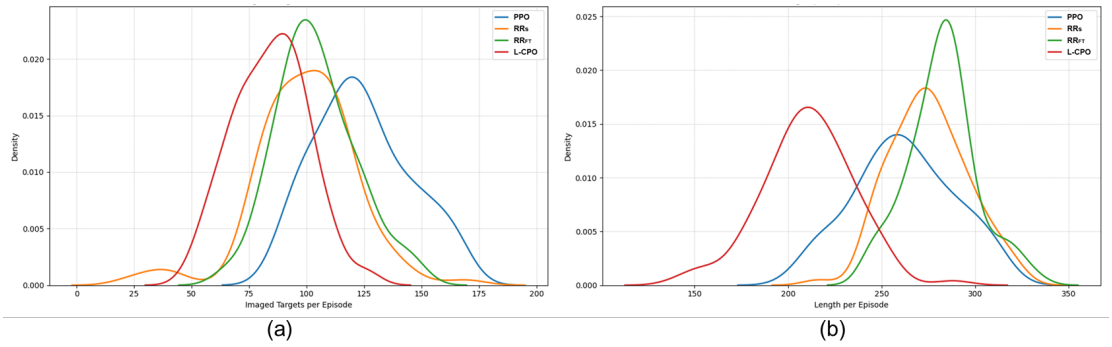

Figure 2. (a) Distribution of imaged targets per episode and (b) episode-length distribution. The PPO baseline achieves the highest throughput, but with inefficient energy and memory use. Reward-reshaped agents (RRS and RRFT) trade minor reductions in target count for longer, more stable operations, while the Lagrangian agent (L-CPO) maintains short, consistent episodes, reflecting efficient and constraint-aware behavior.

Conclusions

We investigated safe reinforcement learning for agile satellite scheduling in the BSK-RL environment, comparing a tuned PPO baseline with two constraint-aware variants: reward reshaping and a Lagrangian CPO-style approach. Our goal was twofold: (i) demonstrate that soft-constraint signals can steer policies toward operationally safe behavior, and (ii) show that frugal fine-tuning of a PPO baseline provides a practical path to rapid adaptation.

The comparative analysis of the PPO baseline, reward-reshaped agents, and the Lagrangian fine-tuned agent demonstrates distinct trade-offs between efficiency, stability, and constraint adherence. The PPO baseline, while achieving high throughput and reward, exhibits higher operational costs, longer and more variable episodes, and less resource-efficient behavior. In contrast, the reward-reshaped approaches—both trained from scratch (RR_S) and fine-tuned from PPO (RR_{FT})—achieve lower costs and enhanced stability without sacrificing overall performance. By embedding constraint information directly into the reward function, these agents demonstrate smoother policy behavior and a more balanced trade-off between performance and safety, reducing unnecessary actions and improving operational consistency. The Lagrangian fine-tuned agent ($L\text{-}CPO_{FT}$) further emphasizes constraint satisfaction, achieving the lowest operational costs and shortest, most consistent episodes. Although this comes with a modest reduction in cumulative reward, the resulting policy reflects a deliberate and safety-oriented operational strategy. Overall, the findings suggest that reward reshaping effectively enhances efficiency and stability while maintaining strong performance, whereas the Lagrangian method provides superior constraint control and interpretability, making it the most suitable approach for safety-critical or resource-constrained environments.

Keywords: Rendezvous, Gateway, Moon Exploration, Low-Thrust, Nonlinear Control

Abstract. This research investigates low-thrust nonlinear control for rendezvous in lunar orbit, in a high-fidelity dynamical model and in the presence of nonnominal conditions. The feedback control law is based on Lyapunov stability theory and is capable of tracking time-varying orbital elements, including the true anomaly. Monte Carlo campaigns are run to assess the performance of the control strategy, with regard to both a controlled and an uncontrolled target vehicle (i.e. subject to free dynamics). Results show that the proposed low-thrust feedback controller is capable of driving the spacecraft to a safe distance from the target vehicle, with minimal residual velocity, without relying on any reference trajectory nor numerical integration, making it suitable for onboard implementation.

Introduction

The Artemis program led by NASA foresees the deployment of the space station Gateway along a Near-Rectilinear-Halo-Orbit around the collinear exterior point of the Earth-Moon system. Establishing a long-term human presence on the Moon will require the development of autonomous and reliable transportation systems between Earth, Moon and Gateway. As part of ESA's Explore 2040 strategy, the Argonaut spacecraft will carry cargo from and to the lunar surface, proving a versatile access to the lunar surface [1]. In this context, the development of efficient and lightweight guidance and control strategies for autonomous rendezvous in Low-Lunar-Orbit (LLO) is an area of doubtless interest among researchers.

The design of optimal trajectories in cislunar space usually leverages dynamical system theory or two-body approximations to generate initial guess solutions, to combine with differential corrections and optimization techniques. In this field, optimal trajectories from Gateway to LLO have been identified through either direct and indirect methods, with both high thrust and low thrust [2, 3]. Instead, other studies focus on guidance and control strategies for rendezvous in cislunar space. However approaches based on direct and indirect optimization methods [4, 5] involve a higher computational load. Recently, the application of machine learning has been investigated for efficient guidance schemes in rendezvous scenarios, though demanding extensive training. In contrast, nonlinear control does not require any offline design process, apart from tuning the control gains. The objective of this research is to assess low-thrust nonlinear control as a viable strategy for rendezvous in lunar orbit, in a high-fidelity dynamical framework and in the presence of nonnominal conditions. Specifically, the study case considers a spacecraft equipped with a low-thrust propulsion system that departs from Gateway and is directed toward a target vehicle in LLO, to rendezvous with minimal residual relative velocity. Modified Equinoctial Elements (MEE) are employed as state variables for dynamics modeling, which includes third-body perturbations from Earth and Sun, as well as the relevant harmonics of the selenopotential. The positions of Sun and Earth are taken from NASA ephemeris, which also provides the state of Gateway at initial time. To drive the spacecraft from Gateway toward the target, a nonlinear controller is being proposed. Specifically, the feedback control law at hand is based on Lyapunov

Materials Research Proceedings 69 (2026) 1036-1041 https://doi.org/10.21741/9781644904251-179

stability theory and is capable of tracking time-varying orbital elements, including the true anomaly, while enjoying quasi-global stability [6]. Two different scenarios are being considered:

a) the target vehicle flies a circular and polar LLO at an altitude of 100 km, with constant orbital elements except for the true anomaly;
b) the target spacecraft is subject to an uncontrolled dynamics; its initial orbit is identical to case (a), but the orbital elements vary under the effect of perturbing accelerations.

Monte Carlo campaigns are intended to assess the performance of the control strategy in the high-fidelity model, in the presence of several nonnominal situations, namely (i) time delays on the departure from Gateway, (ii) thrust misalignment, (iii) temporary thrust unavailability and (iv) noise on the measured perturbing accelerations.

Orbit dynamics

In this research, Modified Equinoctial Elements (MEE) are adopted as state variables since they exhibit no singularities, apart from retrograde equatorial orbits [7], which are rarely encountered. The set of MEEs is denoted as $x = [x_1, x_2, x_3, x_4, x_5, x_6]^T$. Through MEEs, the dynamical equations of a spacecraft orbiting around a primary body (with gravitational parameter μ) can be expressed in a compact form,

$$\dot{\boldsymbol{x}} = \mathbf{G}(\boldsymbol{x})\boldsymbol{a} + \boldsymbol{f}, \tag{1}$$

Where $\boldsymbol{f} = \left[0_{1x5} \quad \sqrt{\mu/x_1^3}(1 + x_2 \cos x_6 + x_3 \sin x_6)^2\right]^T$, while $\mathbf{G}$ is a 6x3 matrix depending on the state $\boldsymbol{x}$. Finally, $\boldsymbol{a}$ collects the components of the vector $\vec{\boldsymbol{a}}$ of non-Keplerian accelerations in the Local-Vertical-Local-Horizontal frame [8]. This vector includes the contribution of (i) the perturbing acceleration $\vec{\boldsymbol{a}}_P$ and (ii) the thrust acceleration $\vec{\boldsymbol{a}}_T$.

Perturbing acceleration. The term $\vec{\boldsymbol{a}}_P$ includes the perturbing acceleration $\vec{\boldsymbol{a}}_g$ due to the harmonics of the gravitational potential (i.e. excluding the Keplerian term) and the gravitational acceleration $\vec{\boldsymbol{a}}_{3B}$ due to the third-body effects of both Earth and Sun. The acceleration $\vec{\boldsymbol{a}}_g$ can be expressed as the gradient of the gravitational potential, conveniently described in terms of multipole series of spherical harmonics functions. In this research, the corresponding coefficients are taken from the Lunar Prospector LP100K model for the lunar gravitational field [9]. However, only the relevant harmonics associated with coefficients $|J_{lm}| > 5 \cdot 10^{-6}$ are retained in the dynamical model. Instead, the gravitational acceleration $\vec{\boldsymbol{a}}_{3B}$ due to a generic third body can be expressed in terms of its gravitational parameter and position vector in the inertial frame [6], taken from NASA ephemeris.

Thrust acceleration. The spacecraft is equipped with a low-thrust engine, which is assumed to be steerable and throttleable, and provides the thrust acceleration $\vec{\boldsymbol{u}}_T = x_7\vec{\boldsymbol{a}}_T$, where x_7 is the mass ratio. The thrust acceleration magnitude $u_T = |\vec{\boldsymbol{u}}_T|$ can be modulated from 0 up to a maximum value u_{Tmax}. Therefore, the dynamical state of the spacecraft includes its mass ratio, whose time derivative is given by $\dot{x}_7(t) = -u_T/c$, where c is the effective exhaust velocity.

Nonlinear orbit control

Rendezvous is achieved through a nonlinear feedback control law, which in a previous work was proven to enjoy global asymptotic stability despite time-variable desired MEEs, including the true anomaly [6]. As a preliminary step, the state of the target vehicle is expressed in terms of MEEs, $\boldsymbol{x}_d = [x_{1d}, x_{2d}, x_{3d}, x_{4d}, x_{5d}, x_{6d}]^T$. Then, the target state is enforced as a nonlinear constraint,

Materials Research Proceedings 69 (2026) 1036-1041 https://doi.org/10.21741/9781644904251-179

$$\boldsymbol{\Psi}(\boldsymbol{x},t)=\begin{bmatrix}(1-\cos(x_6-x_{6d}))x_1\\(x_2-x_{2d})^2+(x_3-x_{3d})^2\\(x_4-x_{4d})^2+(x_5-x_{5d})^2\\(x_1-x_{1d})^2(1+x_2\sin x_6-x_3\cos x_6)\end{bmatrix}. \quad (2)$$

The formulation in Equation (2) allows to track all time-varying orbital elements of the virtual target, including the true anomaly. The instantaneous thrust acceleration is expressed as [6]

$$\boldsymbol{a}_T=-\frac{u_T}{x_7}\frac{\boldsymbol{b}+\boldsymbol{d}}{|\boldsymbol{b}+\boldsymbol{d}|},\qquad u_T=\begin{cases}x_7|\boldsymbol{b}+\boldsymbol{d}|, & \text{if } x_7|\boldsymbol{b}+\boldsymbol{d}|\le u_{Tmax}\\0, & \text{if } x_7|\boldsymbol{b}+\boldsymbol{d}|>u_{Tmax} \text{ and } \boldsymbol{b}^{\boldsymbol{T}}(\boldsymbol{b}+\boldsymbol{d})<0\\u_{Tmax} & \text{if } x_7|\boldsymbol{b}+\boldsymbol{d}|>u_{Tmax} \text{ and } \boldsymbol{b}^{\boldsymbol{T}}(\boldsymbol{b}+\boldsymbol{d})\ge 0\end{cases} \quad (3)$$

with $\boldsymbol{b}$ and $\boldsymbol{d}$ defined as

$$\boldsymbol{b}=\mathbf{A}^{\mathrm{T}}\boldsymbol{\Lambda}\boldsymbol{\Psi},\qquad \boldsymbol{d}=\boldsymbol{a}_P+\ \mathbf{A}^{\mathrm{T}}(\mathbf{A}\mathbf{A}^{\mathrm{T}})^{-1}\left(\frac{\partial\boldsymbol{\Psi}}{\partial\boldsymbol{x}}\boldsymbol{f}+\frac{\partial\boldsymbol{\Psi}}{\partial\boldsymbol{x}_d}\dot{\boldsymbol{x}}_d\right), \quad (4)$$

where $\mathbf{A}=\left(\frac{\partial\boldsymbol{\Psi}}{\partial\boldsymbol{x}}\mathbf{G}\right)$, while $\boldsymbol{\Lambda}$ is a diagonal and positive definite matrix, namely $\boldsymbol{\Lambda}=\mathrm{diag}\{\lambda_1,\lambda_2,\lambda_3,\lambda_4\}$.

Nonlinear orbit control

For each scenario, a Monte Carlo campaign comprising 100 simulations is run to assess the performance of the control strategy at hand in the high-fidelity model. The initial reference epoch is set to 25/05/2025 @14:06:08. The low-thrust propulsion system has effective exhaust velocity c = 30 km/s and maximum thrust acceleration $u_{Tmax}=4.91\cdot10^{-4}$ m/s^2. The control gains are tuned to $\lambda_1=10^2$, $\lambda_2=10^8$, $\lambda_3=10^8$, $\lambda_4=10^5$ and $\lambda_1=10^5$, $\lambda_2=10^{11}$, $\lambda_3=10^{10}$, $\lambda_4=10^{11}$ respectively for scenarios (a) and (b). Furthermore, canonical units are used throughout for numerical convenience: the distance unit (DU) is set to 10000 km, and the time unit (TU) is defined to yield a unit gravitational parameter.

The nonnominal conditions include (i) time delays on the departure from Gateway, (ii) thrust misalignment, (iii) temporary thrust unavailability, and (iv) noise on the measured perturbing accelerations. Further details on the modeling of these effects can be found in [6]. The integration is stopped when the final state corresponds to a safe distance $||\delta\vec{\boldsymbol{r}}||$ < 1.5 km from the target, where close-range rendezvous can be addressed as in recent contributions [10]. The performance of the strategy is analyzed in terms of final mass ratio (m_{Rf}), time of flight (ToF) and dispersions on $||\delta\vec{\boldsymbol{v}}||$, i.e. the magnitude of the spacecraft velocity relative to the target.

Table 1 collects the results of the Monte Carlo campaigns. The analysis of the results shows that the feedback control law drives the chaser to a safety distance from the target vehicle, with limited dispersion on the relative velocity, even when the spacecraft must rendezvous with the uncontrolled target. This is confirmed by inspection of Figure 1, which points out how the relative distance from the target is gradually reduced during each orbit. Rendezvous is achieved within an average of 65 days, with a modest fuel expenditure. Figures 2 and 3 show the time histories of the right ascension of the ascending node Ω, confirming the capability of the control law to track either constant or time-varying orbital elements. In particular, the zoom on the last days highlights the effectiveness of the feedback control law to track time-varying orbit elements induced by perturbations in the LLO environment.

Table 1: Results of the Monte Carlo campaign for scenarios (a) and (b).

Parameter	Scenario (a)		Scenario (b)	
	Mean value	Standard deviation	Mean value	Standard deviation
$\|\|\delta\vec{\boldsymbol{r}}\|\|$ [m]	1477.64	17.00	1471.96	22.03
$\|\|\delta\vec{\boldsymbol{v}}\|\|$ [m/s]	1.17	0.18	1.14	0.36
ToF [days]	65.26	5.37	64.60	0.99
m_{Rf}	0.897	$3.01 \cdot 10^{-3}$	0.912	$1.10 \cdot 10^{-3}$

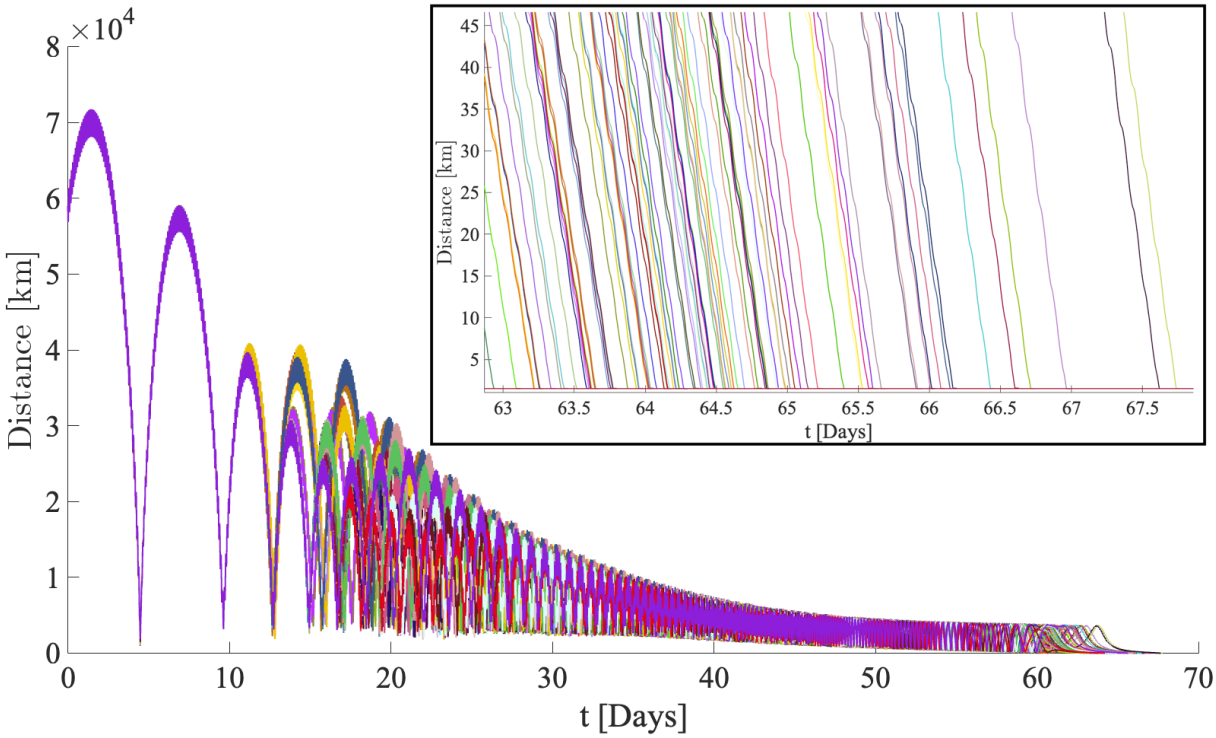

Figure 1: Scenario (b): time histories of the distance from the target across 100 Monte Carlo simulations with nonnominal conditions (in the insets, zoom on the last days).

Concluding remarks

The development of autonomous guidance and control techniques represents a key factor in ensuring the success of future lunar missions. This research addresses low-thrust nonlinear control as an effective guidance strategy for rendezvous from Gateway to LLO. A high-fidelity framework is employed for numerical simulations, including all relevant perturbations and nonnominal conditions associated with delays on the initial injection time, misalignment errors, thrust unavailability, and noise on measured accelerations. Moreover, low-thrust nonlinear control is employed to drive a spacecraft from Gateway toward rendezvous in LLO. The feedback law is capable to achieve rendezvous with either a controlled vehicle flying a Keplerian orbit or an uncontrolled target subject to natural (perturbed) dynamics. Remarkably, this strategy operates without the need for offline data or pre-computed trajectories, nor numerical integration, yielding a significantly lower computational cost compared to solutions based on optimal control theory. The low-thrust feedback controller requires only proper gain tuning, yet it is capable of autonomously generating trajectories online, making it suitable for onboard implementation.

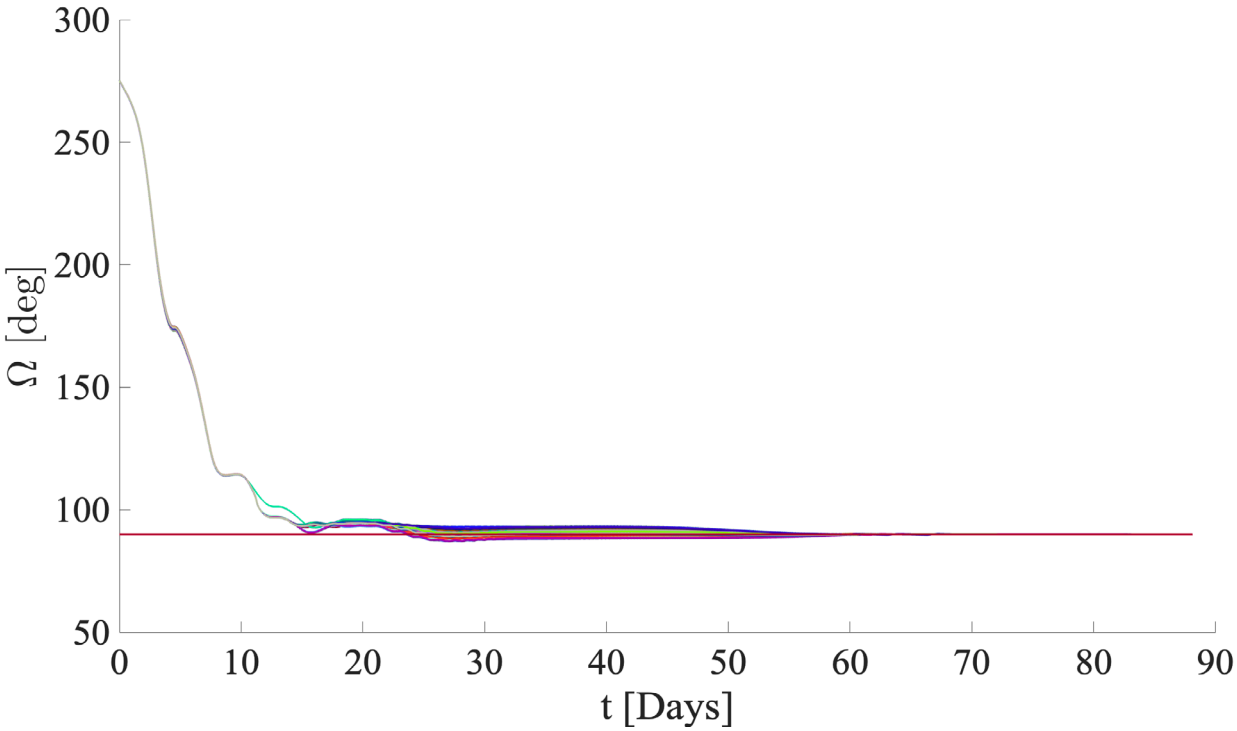

Figure 2: Scenario (a): time histories of Ω across 100 Monte Carlo simulations with non-nominal conditions.

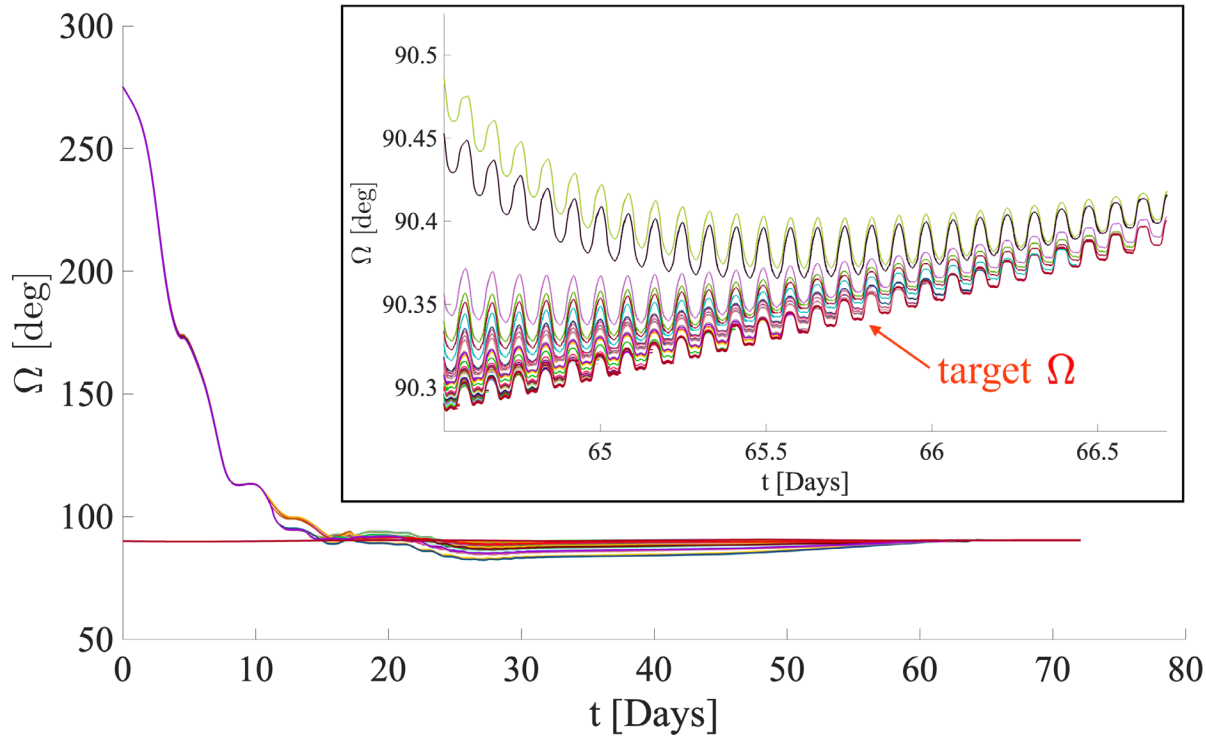

Figure 3: Scenario (b): time histories of Ω across 100 Monte Carlo simulations with non-nominal conditions (in the insets, zoom on the last days).

Abstract. This work explores improving satellite collision prediction through autonomous optical observation and onboard orbit determination on at-risk LEO platforms. Potentially colliding objects pass near each other multiple times in the last orbits before a potential collision, allowing onboard sensors to collect especially timely data on secondary targets. A simulation framework combining multiple tools models these encounters, generating synthetic imagery and extracting astrometric measurements with uncertainties, which are then processed through sequential estimation filters. Results show how observation timing, sensor performance, and initial position/velocity uncertainty affect final accuracy. For debris at current uncertainty levels, most simulated sensors improve OD if detections succeed, while for accurately tracked satellites, achieving <15 arcsec total uncertainty is needed for noticeable gains.

Introduction

In Low Earth Orbit (LEO), potentially colliding objects generally pass close together multiple times during the orbits before the Time of the Closest Approach (TCA). These encounters, currently unexploited, present valuable opportunities for satellites equipped with optical sensors (including star trackers) to collect data on secondary objects. By processing this data onboard together with orbital estimates uplinked from the ground before TCA, meaningful refinement in positional knowledge of secondary objects can be achieved, enabling more informed manoeuvre decisions and reduced false alarm rates.

In previous studies, we established the feasibility of this approach from both orbital dynamics [1] and sensor detection performance perspectives [2]. In this work, we further implement an image-processing and orbit determination (OD) pipeline to assess the achievable reduction in positional uncertainties resulting from onboard processing of space-based observations, modeling sensors of varying quality. To this end, the simulation environment described in [2] is used to emulate the end-to-end operational concept in realistic conjunction scenarios based on actual events. The framework integrates a combination of commercial and open-source tools, such as MATLAB, Ansys's System Tool Kit (STK), and the Astrometry.net plate solver. Using this setup, space-based observation scenarios are simulated by incorporating various capabilities such as orbital dynamics, sensor optics and radiometric sensitivity, and space lighting conditions. Note that, as done in [2], object's trajectories are reconstructed starting from real-world data on historical at-risk objects. Particularly, Special Perturbations (SP) ephemerides are used to generate the "true" trajectories for each conjuncting pair. In parallel, for the secondary (uncooperative) object we retrieve Two-Line Elements (TLEs), which the simulated primary object uses both to predict observation windows and to initialize the OD process. This deliberate SP–TLE mismatch reflects operational reality, where the primary lacks high-fidelity knowledge of the secondary, and thus introduces realistic state and timing errors in the onboard analyses.

Materials Research Proceedings 69 (2026) 1042-1047 https://doi.org/10.21741/9781644904251-180

A range of optical sensors is simulated using the same underlying model (STK's high-fidelity EOIR tool) but varying sensor parameters, including optical aperture, FoV, quantum efficiency, fill factor, readout noise and dark current. The set of simulated sensors, along with their specific parameters, matches that used in the detection-rate studies [2] and spans from low-quality star trackers to small imaging cameras for SmallSats.

Using STK's EOIR tool, synthetic imagery of the observed scenes is then generated. Such images are then post-processed to extract relevant target information for OD, as illustrated in Fig. 1. Specifically, after obtaining an astrometric solution with Astrometry.net [3], a free commercial plate solver, centroid detection algorithms implemented in MATLAB extract time-tagged angular measurements of detected targets, including right ascension (RA) and declination (DEC). Only extracting RA/DEC values from images is insufficient for meaningful OD in conjunction assessments; each RA/DEC pair must be accompanied by an uncertainty estimate. A tailored method is therefore applied to quantify the astrometric accuracy of angular measurements derived from optical observations. To follow, this method is described in more detail, since uncertainty characterization is a focus of the present work.

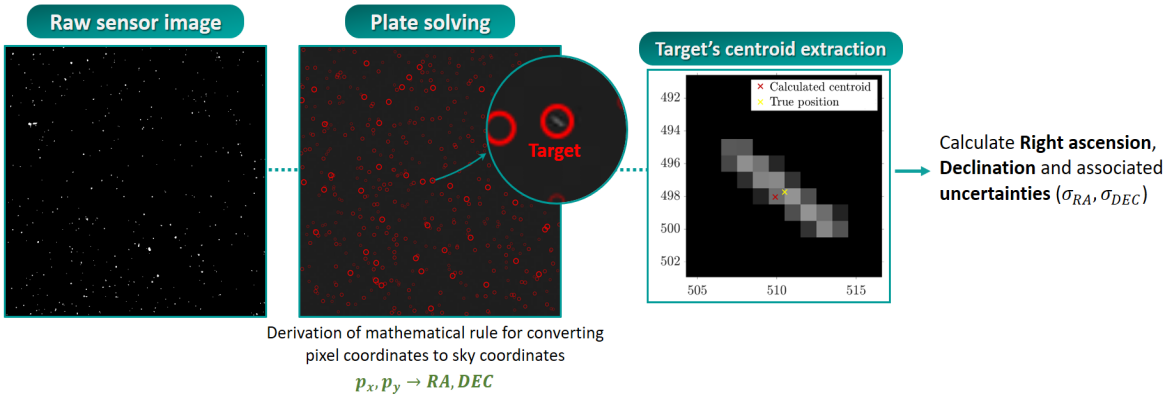

Fig. 1. *Main steps of the employed image processing pipeline.*

Estimation of Measurement Uncertainties

For space-based measurements, uncertainty arises from several independent sources, including coordinate fitting, centroiding, parallax, and timing errors. The total variance of a single observation is expressed as:

$$\sigma_{\text{tot}}^2 = \sigma_{\text{starfit}}^2 + \sigma_{\text{centr}}^2 + \sigma_{\text{par}}^2 + \sigma_{\text{timing}}^2 + \sigma_{\text{unknown}}^2 \quad (1)$$

where the terms are combined in quadrature, assuming uncorrelated errors. σ_{unknown}accounts for residual effects and is neglected here. All terms may be expressed in either pixels or arcseconds by applying the sensor's pixel scale. The general expression in Eq. 1 was originally introduced by [3] for quantifying the data quality of the Space-Based Visible sensor and it was later used for MOST satellite's observations [5] as well. The following discussion provides details on how each term in Eq. 1 is calculated here.

The Coordinate Fit Error (σ_{starfit}) represents the quality of the astrometric plate solution and depends primarily on the solver accuracy, the sensor's pixel scale, and star density in the field. To estimate σ_{starfit}, the residuals between measured and catalogued star positions from Astrometry.net are analyzed. The RMS residual in pixels is converted to arcseconds by multiplying by the pixel scale. Across multiple simulated images generated using EOIR, RMS errors ranged from 0.4–1.1 pixels. Comparing these values with those reported in the literature, they appear slightly higher than what can be reliably achieved with current solvers (0.01–0.2 px). This discrepancy is attributed to Astrometry.net's general-purpose nature, as it is not fine-tuned to specific optical

Materials Research Proceedings 69 (2026) 1042-1047 https://doi.org/10.21741/9781644904251-180

systems. For more realism, σ_{starfit} is modeled as a random value between 0.2–0.5 pixels, equally contributing to RA and DEC ($\sigma^2_{\text{starfit}} = \sigma^2_{\text{starfit, RA}} + \sigma^2_{\text{starfit, DEC}}$).

The Centroiding Error (σ_{centr}) quantifies the precision in locating the streak center and is here estimated as $\sigma_{\text{centr}} = 0.5 \cdot \text{FWHM}/\text{SNR}$ [6], where FWHM is the full width at half maximum of the source and SNR its signal-to-noise ratio. For elongated streaks, FWHM differs along and across the motion direction. As shown in Fig. 2, the procedure involves: 1) identifying the streak orientation via Principal Component Analysis (PCA) on the pixel coordinates; 2) rotating the Region of Interest (ROI) to align the streak horizontally; 3) extracting intensity profiles along and perpendicular to the streak; 4) computing FWHM values at half-maximum crossings. Although the uncertainties should ideally be projected into the inertial reference frame, for simplicity they are treated as isotropic. Thus, $\sigma_{\text{centr, RA}} = \sigma_{\text{centr, DEC}} = \text{FWHM}_{\parallel}/(2\sqrt{2} \cdot \text{SNR})$.

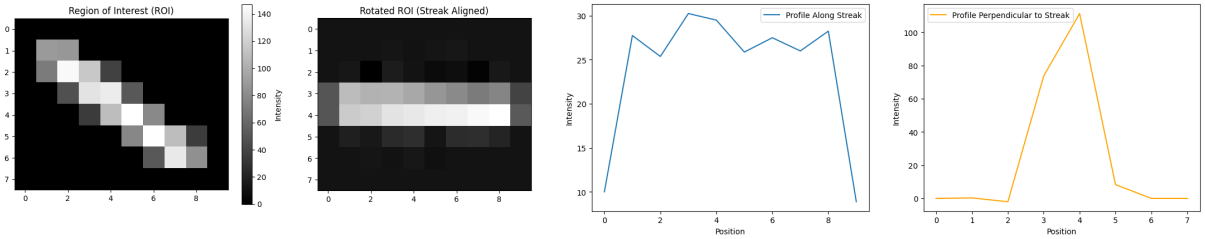

Fig. 2 *Steps for calculating the FWHM along and across the principal direction of an oblique streak*

Uncertainty in the observer's position introduces angular error due to parallax σ_{par}. For a platform position uncertainty σ_{eph} and target range R: $\sigma_{\text{par}} \approx \sigma_{\text{eph}}/R$, expressed in radians and converted to arcseconds by multiplying by 206,265. For GNSS-equipped satellites ($\sigma_{\text{eph}} < 15$ m) observing targets 300–800 km away, the parallax error ranges from 10.3 arcsec (300 km) to < 4 arcsec (800 km). Assuming no directional bias, $\sigma_{\text{par, RA}} = \sigma_{\text{par, DEC}} = \sigma_{\text{par}}/\sqrt{2}$.

Timing errors (σ_{timing}) arise from uncertainties in time-tagging observations. The resulting angular error is $\sigma_{\text{timing}} \approx \omega \cdot \sigma_t$, or equivalently, $\sigma_{\text{timing}} \approx \frac{v_{\text{FPA}}}{R} \cdot \sigma_t$, where v_{FPA} is the relative velocity projected onto the focal plane. Modern satellites synchronized via GNSS achieve $\sigma_t <$ 30ns, yielding sub-milliarcsecond errors (≈ 0.002 arcsec in worst cases), so σ_{timing} is neglected. Combining the three dominant terms and assuming error isotropy (i.e., $\sigma^2_{\text{i, tot}} = \sigma^2_{\text{i, RA}} + \sigma^2_{\text{i, DEC}}$), the total uncertainty per coordinate becomes:

$$\sigma_{\text{RA}} = \sigma_{\text{DEC}} = \frac{\sqrt{2}}{2}\sqrt{(rnd \cdot p_{\text{scale}})^2 + \left(\frac{\text{FWHM}_{\parallel} \cdot p_{\text{scale}}}{2 \cdot \text{SNR}}\right)^2 + \left(\frac{15}{R} \cdot 206{,}265\right)^2} \quad (2)$$

where rnd is a random value between 0.2–0.5 px and p_{scale} the pixel scale (arcsec/px).

Using Eq. 2, the total calculated angular error for the sensors simulated here ranges from ~8 to 51 arcsec. This estimate assumes that objects are detected at distances between 300 and 800 km with an SNR between 3 and 8, which is typical for the application at hand. Again, note that these angular error values do not solely reflect the intrinsic sensor resolution, which is included through p_{scale}. Deriving measurement uncertainty for optical observations requires accounting for the multiple factors in Eq. 2. Simply corresponding a sensor's resolution to its measurement accuracy in orbit is simplistic, as it neglects variable elements related to the observation strategy, specific application, and the accuracy of the platform's position and timing knowledge.

Materials Research Proceedings 69 (2026) 1042-1047 https://doi.org/10.21741/9781644904251-180

Orbit Determination

Once RA/DEC centroid coordinates and one-sigma uncertainties were collected for each simulated observation within a conjunction scenario, OD processing was performed using Ansys' ODTK, a comprehensive OD environment that seamlessly integrates with STK. Sequential estimation methods, and in particular the Extended Kalman Filter (EKF), were selected for their suitability to real-time applications such as the one considered here.

Each OD process begins by importing the RA/DEC measurements and one-sigma uncertainties into ODTK. The EKF is then initialized with an initial state derived from the secondary object's TLEs at the epoch of the last ground contact, denoted t_{LGC}. This instant represents the assumed final opportunity for the ground segment to upload an orbit solution to the primary before it must rely solely on its own onboard observations. In this analysis, t_{LGC} is varied between 1 and 10 hours before the TCA, while the simulated measurements typically occur within 40 to 120 minutes before TCA, when illumination and geometry are most favorable. EKF initialization also requires a covariance matrix for the secondary object, which should be representative of the orbit knowledge available at t_{LGC} from the ground. Since TLEs do not include uncertainty information, realistic covariance levels were derived from publicly available Vector Covariance Messages (VCMs). Accordingly, the simulated initial covariances were set between 0–200 m in position and 0–0.2 m/s in velocity, with components defined in the in-track, cross-track, and radial directions. Orbit propagation in ODTK was performed using the High Precision Orbit Propagator (HPOP), which numerically integrates the equations of motion considering gravitational harmonics, drag, and solar radiation pressure. The same propagator was used in STK to generate the reference trajectories, though with slightly different dynamic parameters to reflect the primary's imperfect knowledge of the secondary's physical properties and environment. Once initialized, the EKF processes the simulated onboard angular measurements to update the secondary's estimated state and covariance at each observation time.

Results

Figure 3 analyzes the sensitivity of OD performance to the initial position and velocity covariances. When the prior knowledge from the last ground update was poor—e.g., velocity uncertainties above 0.15 m/s or position uncertainties exceeding 150 m—onboard optical measurements from nearly all simulated sensors were able to reduce the final covariance magnitude in a meaningful way, often by 40–60%. However, enthusiasm for this result should be tempered by the fact that the smaller, lower-quality simulated sensors—although apparently effective from an OD standpoint—were rarely able to detect the target objects at all. In other words, between detection performance and measurement accuracy, the former emerges as the primary bottleneck preventing such sensors from being reliably used in operational contexts. As expected, for objects initialized with high-quality states, the gains became progressively smaller. While in recursive state-estimation filters every measurement, even one with high uncertainty, contributes information and cannot degrade the estimate [7], the achieved improvements were not significant enough to justify the operational adoption of most simulated sensors for already well-tracked objects. The only sensors providing both consistent detections and meaningful uncertainty reduction had apertures larger than 5 cm, narrow FoVs, and low electronic noise—comparable to high-performance star trackers or small imaging telescopes. Specifically, total angular errors exceeding 15 arcsec were found insufficient to improve the tracking of well-characterized active satellites.

Figure 4 illustrates the influence of the time elapsed between the last ground-based OD and the onboard measurement campaign. When ground-based OD can be performed within roughly one orbit (1–1.5 h) before TCA, the additional improvement provided by space-based observations becomes negligible. In all other cases, the total position uncertainty decreases by nearly an order of magnitude compared to uncorrected propagation. Currently, NASA takes final Go/No-Go

Materials Research Proceedings 69 (2026) 1042-1047 https://doi.org/10.21741/9781644904251-180

maneuver decisions about 12 hours before a potential collision, while ESA does so about 24 hours before TCA but preserves the option to cancel or refine the maneuver if additional ground-station accesses are available to upload updated commands. Other agencies adopt similar practices. This suggests that the operational concept proposed here, targeting observations in the last orbits before TCA, is generally effective.

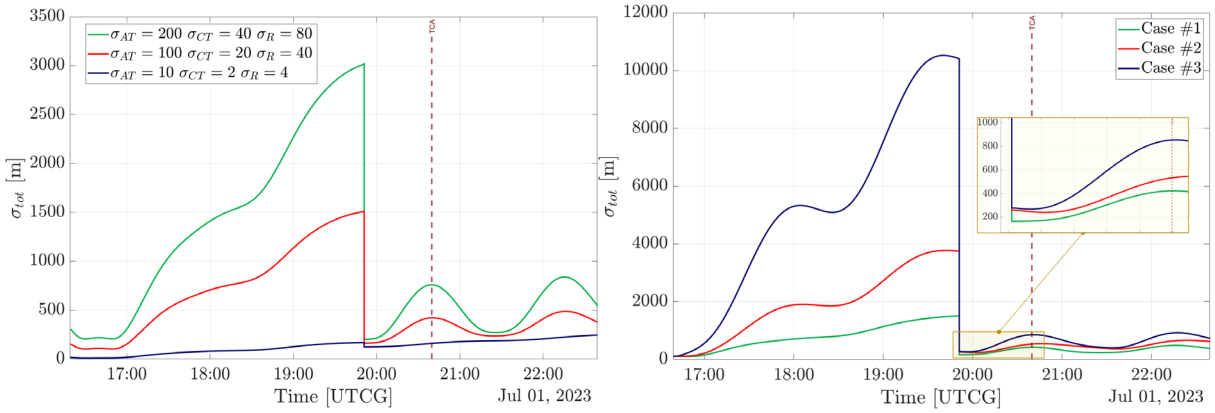

Fig. 3 *Impact of different initial positional uncertainties (left) and velocity uncertainties (right), with specific values reported in the legend*

Conclusion

This work analyzes the feasibility of using onboard optical sensors to refine conjunction risk estimates in LEO, by autonomously acquiring and processing astrometric measurements in the last orbits before TCA. The results show that for debris at current uncertainty levels, most simulated sensors yield meaningful uncertainty reduction if detections succeed, whereas for well-tracked active satellites only sensors achieving <15 arcsec total angular error provide tangible benefits. Operationally, these findings support hybrid schemes where modest onboard payloads complement ground networks, especially for poorly tracked objects and in late-warning regimes.

Keywords: Quasi-Satellite-Orbits, Trajectory Design, Sequential Convex Programming

Abstract. This paper presents advanced methods for designing scientific trajectories in the unique dynamical environment of the Martian moons, with a particular focus on stability analysis and station-keeping strategies. Such trajectories, aimed at deepening the understanding of Phobos and Deimos characteristics, have been proposed in different mission concepts over the past decade. The Japan Aerospace Exploration Agency's Martian Moons eXploration (MMX) mission, scheduled to visit Phobos in 2026, will mark the first practical implementation of these concepts. To build upon and complement the preparatory studies conducted for MMX, this work provides an in-depth analysis of orbital dynamics and long-term trajectory design specifically around Deimos. The results contribute to a broader framework for mission planning in irregular and weak-gravity environments, with implications for future exploration of small celestial bodies.

Introduction

Due to the strong gravity pull of Mars and the mass of Deimos being too small to capture a satellite, it is not possible to orbit the Martian moonlet in the usual two-body sense. Quasi-Satellite-Orbits (QSOs) [1] are a special kind of stable retrograde orbits in the restricted three-body problem that have gained attention as a viable candidate for future deep-space missions towards remote planetary satellites due to their mapping capabilities and high stability, coupled with low station-keeping costs.

These orbits can be found by iterative differential correction starting from a desired value of orbital radius. Additionally, out-of-plane motion can be also induced, in order to increase the surface coverage. However, the entity of the out-of-plane component must be limited, as it tends to destabilize the QSO, leading to an impact on Deimos or to an escape far from it. This work studies QSOs around Deimos, assessing their stability, their sensitivity to injection error and proposing a station-keeping strategy.

Dynamics

Due to the very low gravitational pull of Deimos, Hill's approximation of the Circular Restricted Three-Body Problem can be used to describe the dynamics [2], with the equations of motion that read:

$$\begin{aligned} \ddot{x} - 2\dot{y} &= g_x + 3x \\ \ddot{y} + 2\dot{x} &= g_y \\ \ddot{z} &= g_z - z \end{aligned} \qquad (1)$$

where g represents the gravitational acceleration of Deimos, computed accordingly to a high-fidelity polyhedron shape model. Indeed, at the distances of the chosen QSOs from the surface of the moonlet, the error between the simple spherical gravity approximation and the polyhedron

model is up to 10-20%, as visible in Figure 1. The polyhedron approximation is computed as derived in [3] using the reference shape model of [4].

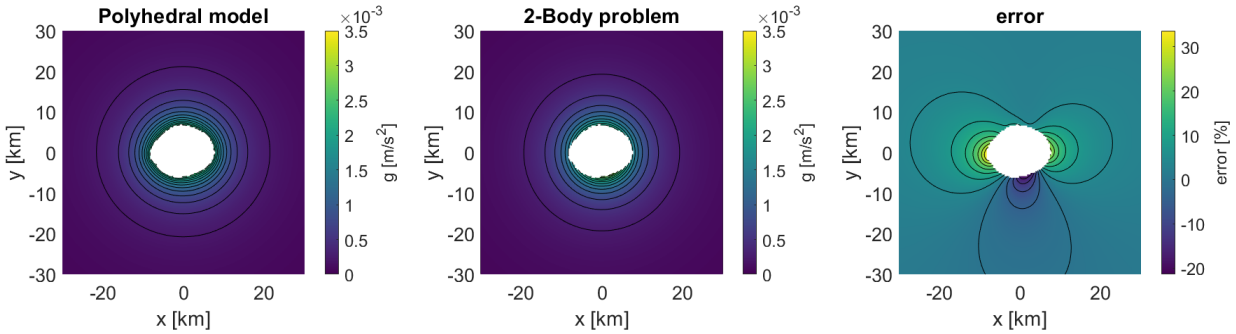

Figure 1: Difference between irregular and spherical gravity field models.

In addition, also a full ephemerides model should be considered to accurately describe the motion in the proximity of the small body. Consequently, two different dynamic models have been used in this work:

- A simplified model, in the Hill's reference frame, considering Martian gravity and a shape model to compute Deimos' gravitational attraction.
- A high fidelity model, propagated in an inertial reference frame centered at Mars. Here, Martian point mass and J_2 gravitational attraction are considered, together with Deimos shape model gravity. The motion of Deimos with respect to Mars is recovered using NASA spice ephemerides, with the mar097 and de432 kernels.

Stability analysis

The in-plane and out-of-plane periodicity of QSOs is assessed for a wide range of initial conditions. In particular, QSOs have been generated starting from an offset from Deimos on the x-axis of the Hill's reference frame ranging from 15 to 100 km. The prediction-correction is carried out in the simplified Hill model, with each orbit that is then re-propagated in full-ephemeris. More precisely, each QSO is computed considering only an in-plane initial velocity vector, then an out-of-plane component is included, progressively increasing the angle with respect to the x-y plane.

The objective of this analysis is to assess what is the limit on the out-of-plane component of the velocity vector, that tends to destabilize QSO motion as visible in Figure 2. Going further from Deimos the non-spherical gravitational attraction has a less important perturbing effect, with out-of-plane QSOs that are possible for higher inclinations of the initial velocity vector. This is outlined by Figure 3, in which the motion is bounded also for an out-of-plane angle of 20°.

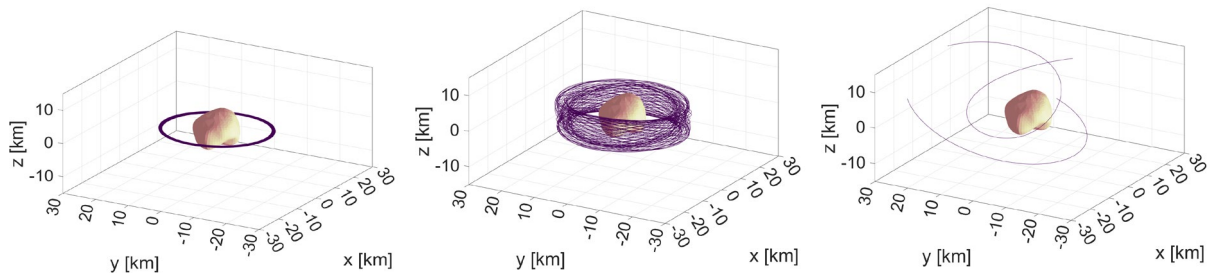

Figure 2: 60 km radius QSO. Motion computed with an in-plane initial velocity vector (left), and with a 10° (center) and 20° degree angle (right) with respect to the plane.

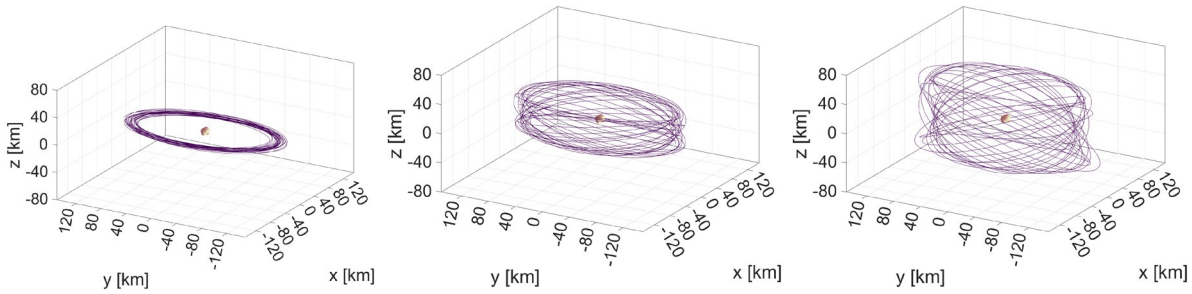
Materials Research Proceedings 69 (2026) 1048-1053 https://doi.org/10.21741/9781644904251-181



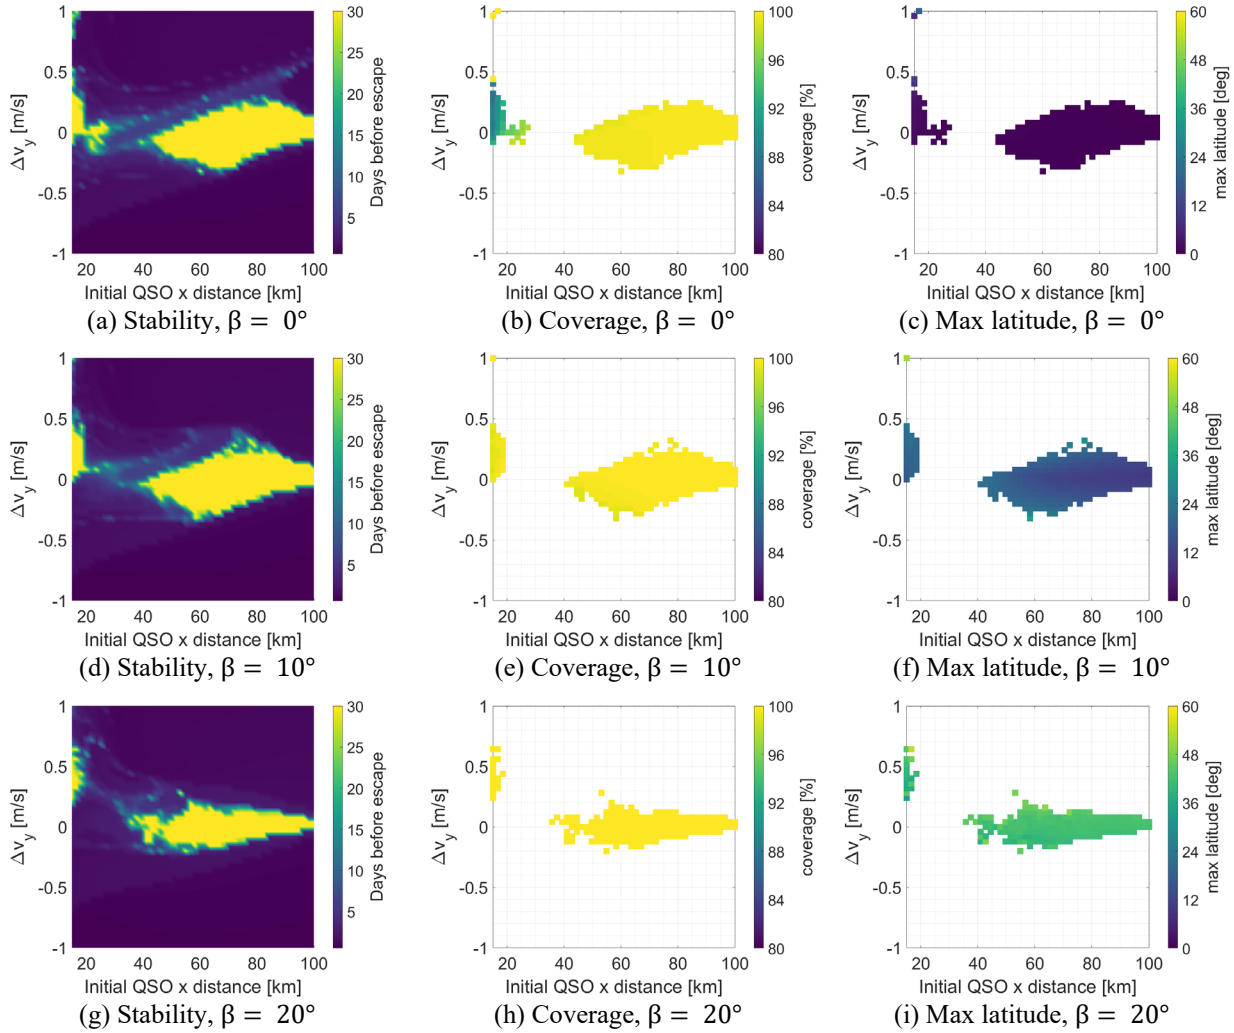


Figure 3: 60 km radius QSO. Motion computed with an in-plane initial velocity vector (left), and with a 10° (center) and 20° degree angle (right) with respect to the plane.

These results have then been generalized, by means of a sensitivity analysis of the stability of QSOs with respect to their initial distance and velocity with respect to Deimos. In this work, the stability analysis is carried out by propagating the orbit for a large number of revolutions in the high fidelity model, and by checking if the motion is bounded around Deimos or if the spacecraft escapes from the moonlet. Approaches based on the eigenvalues of the monodromy matrix are also possible [5], however, the necessity of using the full-ephemeris dynamics with non-spherical Martian moon gravity drove the choice towards a numeric approach for this work, with high-fidelity propagation.

(j) Stability, β = 30° (k) Coverage, β = 30° (l) Max latitude, β = 30°

Figure 4: QSO stability and coverage analysis at different values of out-of-plane velocity component.

The result for in plane motion is shown in Figure 4a, which reports the days of bounded QSO motion over a maximum propagation interval of 30 days, in the full-ephemeris model. The plot presents the distance from Deimos along the Mars-Deimos line on the x-axis and possible tangential perturbations on the initial velocity on the y-axis. It can be noted that planar bounded QSO motion exists for almost the whole range of distances considered, with the exception of the region from 25 to 40 km. This difference with respect to the simplified Hill motion, for which bounded motion exists for all ranges, is probably due to the effects of the actual shape of Deimos' orbit around Mars, coupled with the highly irregular gravity field. Furthermore, it can be seen from the figures how the stability region shrinks for increasing value of initial out-of-plane velocity component.

Naturally, an additional limiting factor is the Δv_y perturbation on the initial velocity, that shall always remain within around 0.5 m/s to have a bounded QSO. Scientific performance of bounded orbits is also reported in Figure 4b, showing a percentage of visible surface up to 100%. This shows that from a sufficient distance almost the entire surface of Deimos can be covered, even with planar QSOs. The last plot on the right (Figure 4c) is the maximum latitude of the ground track of the spacecraft on Deimos. For planar motion it is obviously always zero. An exception arises for some perturbed low altitude orbits, that end up having an out-of-plane motion due to the non-symmetrical gravitational attraction of Deimos.

For out-of-plane QSOs the situation is similar, as visible from Figure 4d to Figure 4l. With the increase of the out-of-plane component of the initial velocity, the region of bounded motion in the $x - v_y$ plane tends to shrink and less QSOs are found for lower values of x offset. Again, this is due to the non-symmetrical shape of Deimos, that has a more important impact on the dynamics if the spacecraft is close to the moonlet.

Scientific orbit maintenance

In this Section, a station-keeping strategy for QSOs is explored, based on convex optimization techniques, which have found application in a wide variety of trajectory computation problems in the space domain [6, 7].

In this case, Sequential Convex Programming (SCP) techniques have been put in place, incorporating the effects of the irregular gravity field of the body in the trajectory generation. More in detail, an iterative station keeping algorithm is designed to compute the optimal control actions to maintain the nominal QSO, computed according to Hill three-body problem dynamics. In particular, each time the distance between the chosen QSO in the simplified model and the full-ephemeris propagation goes over 3 km, the GuSTO algorithm is used to bring the error to zero while minimizing $\boldsymbol{\Delta V}$, leaving a free maneuvering time. The example demonstrates the applicability of this strategy for a 30 km QSO with an initial velocity off-plane angle of 5°, which

would be unstable in the full ephemeris model. In particular, Figure 5 shows that the strategy is successful, being able to periodically correct the orbit for periods larger than one week with an average daily $\boldsymbol{\Delta V}$ equal to 1.12 m/s.

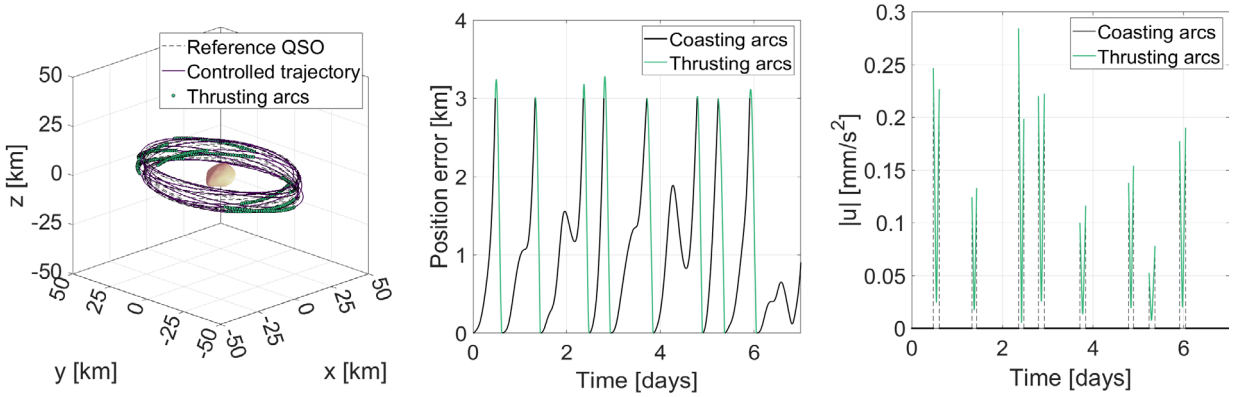

Figure 5: Results of station keeping analysis over a week of controlled motion in unstable 3D QSO region.

Conclusions

The analyses presented in this paper show that QSOs can be viable choices to meet high level requirements of typical scientific missions exploring Martian moon environment, while guaranteeing high orbital stability. Additionally, operational safety with respect to navigation and injection errors is also assessed for both planar and 3D orbit, in order to understand the applicability of the latter for high latitude observations. Finally, a SCP algorithm is proposed to iteratively compute dynamically feasible low-ΔV trajectory correction maneuvers to maintain periodic off-plane motion.

Abstract. The increasing frequency and severity of natural disasters pose significant challenges to the insurance industry, which requires innovative approaches to risk assessment and policy management. This paper explores the role of remote sensing in improving the ability of insurance companies to manage natural disaster policies, with a specific focus on the IRIDE constellation. Using services designed through satellite imagery and geospatial data, insurers can better understand risk exposure and improve their response strategies. Remote sensing technologies offer the advantage of monitoring large areas with high precision, detecting changes in land use, water levels, and atmospheric conditions that can influence insurance claims. This study aims to analyze how remote sensing helps insurers prepare for and respond to catastrophic events, focusing in particular on the use of IRIDE for the scope.

Introduction

The increasing frequency and intensity of natural disasters, coupled with the vulnerability of Italy's geographic and urban infrastructure, have created an urgent need for more effective disaster risk management strategies, particularly within the insurance sector. In 2023, global insured losses from natural disasters exceeded € 100 billion, a number expected to double within the decade due to climate change, according to the latest estimates from the Swiss Re Institute. Despite this, only about 25% of Italy's natural disaster losses are insured, the public finances absorbing most of the costs; approximately € 3.5 billion annually. This alarming trend confirms the need to apply innovative tools for risk assessment, monitoring, and post-event analysis. This project explores the application of remote sensing technologies, in this instance the Italian Earth observation constellation IRIDE, to improve the operational capabilities of insurance companies in handling policies for risks and catastrophes and risk modelling.

Use of Space Technologies by Insurance Companies

The use of satellite technology in the civil and commercial sectors is becoming more and more common and frequent. Therefore, many companies find themselves having to interface, along with its exponential development, with a scientific sector that is becoming less and less alien. The range of services that satellite technology can provide is becoming wider and more accessible, so the products that can be developed from it. Revenues from EO data in 2023 in the insurance and finance segment increase from approximately € 340 million to nearly € 900 million in 2033 [1].

In this context, a market analysis is conducted that highlights the strengths, weaknesses, opportunities, and threats of this business.

Several strengths of the adoption of space technologies in the insurance sector can be identified, including improved efficiency in pricing policies, the ability to offer more personalized policies at competitive prices, a reduction in insured and operational losses, and the development of new business opportunities, such as parametric insurance and community-based catastrophe insurance.

Materials Research Proceedings 69 (2026) 1054-1058 https://doi.org/10.21741/9781644904251-182

Regarding opportunities, Italian companies are now required to obtain a Natural Catastrophe Insurance policy (CATNAT), which introduces, for the first time in the Italian regulatory framework, a mandatory insurance requirement for catastrophic risks, limited to the productive sector. This development requires insurance companies to be well prepared to manage these risks in the most efficient way. Another opportunity lies in the possibility for insurance companies to establish partnerships to bridge the knowledge gap regarding Earth observation and related services. Using the data, images, and services provided by the IRIDE constellation, they can enhance their capabilities in risk assessment and management.

However, there are also several threats and weaknesses in this market, such as the innovation inertia of the insurance sector, the lack of social awareness about the need to subscribe to policies, the requirement for big data management and highly specialized skills to handle Earth observation tools, and the still limited commercial adoption of EO techniques.

Chain of Acquisition of Data, Creation and Selling of Services

The current value creation model within the EO sector follows a multi-step value chain, which can be visualized in Figure 1. The initial stage includes the data providers, comprising entities that own and operate the space and ground segments responsible for acquiring raw EO data. Subsequently, the providers of products and services act as intermediaries, leveraging advanced data processing and analytics to transform raw data into customized solutions that address specific user requirements.

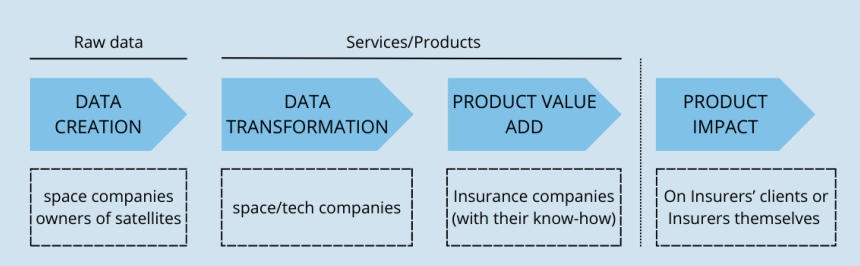

Figure 1: Value chain

Finally, in the context of this research, end users are represented by insurance companies, which use these refined data products to improve decision-making, optimize risk assessment, and streamline operational processes.

Satellite technologies can be considered a valuable investment in the insurance segment. Despite this, there are various ways to invest in this technology. In particular, companies can choose to invest in an internal team that processes raw data and transforms it into services, or they can form external partnerships with companies that have the resources and expertise to create semi-finished services to sell to insurance companies.

An Italian insurance company was interviewed, revealing the idea that it would be preferable to establish advanced partnerships, delegating the more complex aspects of satellite analysis to specialized partners. The current trend emerged leans toward integrating satellite technology into existing company processes without significantly disrupting the traditional insurance model.

Use of IRIDE Constellation

IRIDE is a satellite constellation for Earth observation initiated by the Italian Government, supported by resources from the National Recovery and Resilience Plan (PNRR). IRIDE will be completed by 2026 under the management of the European Space Agency (ESA), with the support of the Italian Space Agency (ASI). IRIDE satellites will offer 8 macro services for marine and coastal monitoring, air quality, ground motion monitoring, land cover analysis, hydro-meteorological and climate observation, water resource monitoring, emergency management, and

Materials Research Proceedings 69 (2026) 1054-1058 https://doi.org/10.21741/9781644904251-182

security. In total the constellation will be composed by 6 sub-constellations, placed in Low Earth Orbits to obtain more frequent and detailed images: HEO (Multi1) and EAGLET-2 (Multi2) have a multispectral sensor, NIMBUS-VHR (Opt) an optical one, NIMBUS-SAR (SAR1) and NOX (SAR2) have on-board a SAR sensor and PLATINOHYP (Iper) a hyperspectral sensor. Each constellation is defined by the orbital parameters of the satellites and the specifications of the sensors on board [2]. Some modifications and assumptions have been applied to obtain repeating ground tracks and improve coverage, following the system of equations 1 [3], which aims to obtain the new inclination (i) to respect the SSO requirement, and the new semi-major axis (a) to meet the periodicity constraint.

The propagation method used in the simulation is the SGP4 to compute satellites' positions and velocities; and to build a complete satellite simulation scenario, the Satellite Communications Toolbox in Matlab is adopted.

$$\begin{cases} i = cos^{-1}\left(\frac{-2\dot{\omega}_d a^{\frac{7}{2}}}{3\sqrt{\mu}J_2 R_e^2}\right) \\ P_\Omega = \frac{2\pi}{n+\frac{3nR_e^2 J_2\sqrt{1-e^2}}{4\left(a(1-e^2)\right)^2}(3sin^2 i-2)+\frac{2-3nR_e^2 J_2}{4\left(a(1-e^2)\right)^2}(4-5sin^2 i)} \\ k_{rep}P_\Omega\left(1-\frac{T_E}{T_y}\right) = k_{day}T_E \end{cases} \quad (1)$$

Coverage

To assess the performance of a constellation, it is crucial to analyze the number of days required to achieve meaningful coverage. The methodology used will take into account the exact area observed by each sensor type considering both the direction of the sensor and the acquisition mode [4].

Table 1 reports the percentages of coverage for each constellation reached in an interval of time of Italian territory. SAR1 results in being the most efficient constellation while the Optical is the least.

Table 1: Constellations' coverage

	Period [days]	**Coverage**
SAR1	6	98.93%
SAR2	15	76.87%
Opt	15	66.53%
Iper	15	83.59%
Multi1	10	82.23%
Multi2	6	94.97%

Revisit Time

Spatial coverage alone is insufficient without considering a temporal factor, which provides insights of how often and for how long the spacecraft is available within a given time frame. The goal of this analysis is to estimate and evaluate the revisit times of each constellation, ensuring that they meet the requirements of the end users.

All constellations are in Sun Synchronous Orbits (SSO) except from SAR1 which is in a Mid Inclination Orbit (MIO). For a given inclination of SSO, the revisit time decreases as the latitude increases, while SAR1 orbit is designed to have 6 satellites at 44 degrees inclination and the remaining 6 at 49 degrees, which results in having a lower revisit time around the latitude of 44

Materials Research Proceedings 69 (2026) 1054-1058 https://doi.org/10.21741/9781644904251-182

degrees, while only the 6 satellites with 49 deg inclination can access higher latitudes, resulting in less accesses to these areas.

Optical and SAR2 constellations have the highest revisit time due to their limited number of satellites. Additionally, the revisit time of each constellation depends much more on latitude than on longitude.

Ground Station Access

The primary purpose of Earth observation satellites is to collect data, such as imagery or environmental metrics. Ground stations receive this data via down-link for processing, analysis, and distribution. In the study of the link with ground stations, only those located within European territory are considered. It has been verified that satellites, after acquiring and processing images and data over Italy, can transmit and communicate with ground stations within Italian territory almost instantaneously (e.g. for the transmission of 1GB, see Equation 2, while remaining visible for the required duration. In fact, the duration of a typical communication session with a single satellite from one of the IRIDE constellations ranges between 6 and 8 minutes, which is sufficient for data transmission.

$$T = \frac{1GB(8Bit)}{400Mbps} = 20s \tag{2}$$

Requirements and IRIDE's adaptability for specific case studies of natural disasters

The events considered in this study are earthquakes, landslides, floods, fires, and critical infrastructure. For each event, the necessary requirements for their observation through remote sensing are investigated, as reported in Table 2 and retrieved from past literature. For each event, the most suitable IRIDE constellations are selected based on the requirements listed above. While resolution (Res) and sensor type are easily met, a more detailed analysis is conducted for revisit time (RT), identifying critical locations for each case study and evaluating them over a long time interval. When the use of the SAR1 constellation is required, it meets all requirements thanks to its high spatial and temporal efficiency. In contrast, the optical and hyperspectral constellations almost always require integration with external satellites due to their high revisit time, which does not meet the necessary requirements. Additionally, the combined use of MULT1 and MULT2 is sufficient for studying events requiring multispectral observation.

Table 2: Requirements for events' observation

	Sensor	**Res [m]**	**RT [days]**
Earthquakes	Optical SAR	5 20	1-7
Landslides	Optical Multi & InSAR	1 10	5
Floods	Optical SAR Multi	1-5 300 30	1-3 <1
Fires	Multi Hyper	10-500 ≥30	1-5 7
Critical In.	DinSAR (spotlight)	1-5	1-7

Conclusions

In conclusion, to scale EO for broader commercial use changes in data collection, sale and application are required. Despite EO can facilitate various industries, its commercial adoption has been slow, particularly in the insurance sector, due to technology inertia and financial barriers.

This research highlights the IRIDE program as a key solution, providing continuous and high resolution EO data for disaster monitoring and prevention. With the additional possibility of integrating IRIDE with other external constellations, insurance companies can improve risk assessment and develop advanced models such as parametric insurance. In addition, EO will complement, rather than replace, existing methods like in-situ sensors and drones, creating a comprehensive risk management approach.

As extreme weather events increase, creating partnerships between space agencies, insurers, and technologies providers will be crucial for maximizing EO's potential in disaster resilience.

Keywords: IOD, SST, SSA, Probabilistic Admissible Region, Tracklet Correlation, Space Surveillance, Space Debris, Astrodynamics, Gaussian Mixture Models

Abstract. This work considers the catalogue generation problem using ground-based passive optical data. In this context, surveillance observations often yield tracklets with very short arcs. These tracklets consist of a set of angular measurements closely spaced in time, covering only a small part of the object's orbit. This data is insufficient for conventional (Initial) Orbit Determination (IOD) and no full orbit can be derived. A different approach using the Admissible Region (AR), defined as the set of possible range and range-rate pairs consistent with the tracklet, is an effort to tackle this problem. Here we apply the Probabilistic Admissible Region, which is a probabilistic representation of the AR, to real-world optical data and use it to perform tracklet correlation and IOD to provide an experimental validation of the methodology.

Introduction

In the past decades the number of Resident Space Objects (RSO) has increased drastically. This trend is likely to continue and accelerate as more commercial and military activity in space is enabled by, among other things, the proliferation of launch capabilities accompanied by reduced cost, and increasingly favourable economics in satellite production. Moreover, these assets are widely integrated in civil and military systems and services, making the safety and operability of these assets a critical mission. A core activity in this mission is the generation and maintenance of a RSO catalogue. Catalogue generation is the process of finding new or previously lost RSO and determining their state, while catalogue maintenance is the process of maintaining the states of objects that are already in the catalogue.

This work considers the catalogue generation process using passive optical sensors. More specifically, it considers the data association problem for tracklets, sometimes called the tracklet-to-tracklet correlation or tracklet linking problem, using the Probabilistic Admissible Region.

A *tracklet* is a set of measurements of a single RSO closely spaced in time, and in the context of Initial Orbit Determination (IOD) often constitutes a *Too Short Arc* (TSA) [1, 2]. A TSA is too short in the sense that it has little geometric diversity, that is, it covers only a small part of the orbit. Such tracklets are insufficient for conventional IOD or OD processes and must be paired with other tracklets originating from the same object first. The challenge is that we do not know a priori which object a tracklet belongs to, and hence which tracklets should be paired. This is the essence of the tracklet correlation problem.

In the case of optical measurements, TSA tracklets capture only angular information, namely, the right ascension and declination and their rates, collectively referred to as the tracklet's *attributable*. In principle, any value for the remaining state components (range and range-rate) is consistent with the observations. However, we can constrain the space of possible values by making some reasonable or educated assumptions about the orbital state. The *Admissible Region* (AR) concept captures this approach. The AR was originally introduced for orbit determination of

Materials Research Proceedings 69 (2026) 1059-1064 https://doi.org/10.21741/9781644904251-183

asteroids [1], and subsequently applied to space debris [2]. For Earth-orbiting objects, the AR is the set of admissible range and range-rate pairs under the assumption that the observed object is in fact in a bounded orbit about Earth. This requires the total energy to be negative and hence constrains the possible range and range-rate values. Additional constraints can be introduced, such as a minimum and maximum energy [3] and eccentricity value [4]. The extended concept is referred to as the *Constrained Admissible Region* (CAR). We can obtain a probabilistic representation of the CAR by assigning probabilities to admissible range / range-rate pairs, the resulting distribution is referred to as the *Probabilistic Admissible Region* (PAR). By assuming each admissible pair is equally probable, we arrive at a uniform distribution within the CAR [4]. Alternatively, one can assume that each semi-major axis / eccentricity pair within the given constraints is equally likely, this results in a non-uniform distribution within the CAR [5]. The PAR can be utilized to perform IOD [4] and/or tracklet correlation.

The main contribution of this work is an experimental validation of the utilization of the PAR for IOD and tracklet correlation using real-world optical data in the MEO regime. We present the full processing pipeline, from image data to (initial) orbital states and covariances of RSO, and its validation. While historically passive optical systems have been mostly utilized for cataloguing GEO objects, a growing number of telescope operators and space-based optical sensors calls for improved processing techniques for passive optical data for LEO and MEO. The data utilized in this work is obtained by the Airbus Robotic Telescope (ART) located in Extremadura, Spain, which is operated by the Space Situational Awareness team at Airbus Defence and Space, Friedrichshafen, Germany.

Method

ART is an optical telescope with an aperture of 40 cm and a focal length of 960 mm and is equipped with 150 megapixel back-illuminated CMOS sensor with a rolling shutter, giving it a field-of-view of $3.18° \times 2.38°$. ART is scheduled to either track satellites (using TLEs or ephemerides) or perform sidereal observations (inertial pointing). The resulting data are images in which the satellites and stars appear as point sources and streaks, respectively, for tracking observations, and streaks and point sources, respectively, for sidereal observations.

From the image data, an astrometric solution is obtained [6], resulting in a set of timed measurements of the sky coordinates, i.e., the right ascension α and declination δ. Measurements in consecutive images are then associated to form tracklets. Every measurement receives a rolling shutter, diurnal aberration, light-time and atmospheric refraction correction. The last two corrections require additional state information, and we refer the reader to the discussion and conclusion section for a discussion on this point.

If a tracklet is a TSA, no (traditional) IOD can be performed and we instead compute the attributable of the tracklet, which is composed of α and δ and the corresponding rates at the middle point of the tracklet, providing incomplete state information. It is computed by fitting a linear or quadratic motion model in α and δ to the measurement data [7].

From the attributable we compute the constrained admissible region (CAR) by imposing a minimum and maximum range, range-rate, semi-major axis and eccentricity. Next, we sample the CAR either uniformly in $(\rho, \dot{\rho})$ or uniformly in (a, e) (yielding a non-uniform distribution in $(\rho, \dot{\rho})$). The result is a set of 6-dimensional state vectors that provides an empirical probabilistic representation of the CAR, namely the PAR. The uncertainty in the attributable can be incorporated by sampling the Gaussian distribution derived from the least-squares fit, and computing the corresponding constraints for each sample separately. To obtain a more efficient representation of the distribution, we fit a 6-dimensional Gaussian Mixture Model (GMM) to the set of sampled states.

The tracklet correlation procedure is as follows. Given a pair of tracklets, the PAR associated with one of the tracklets is propagated to the epoch of the other. It is propagated using a random

Materials Research Proceedings 69 (2026) 1059-1064 https://doi.org/10.21741/9781644904251-183

sample of n^2m states, with n the state dimension and m the number of Gaussian components (e.g., for m = 50 we sample 1800 points). The large number of states necessitates a simple propagator, here an analytical J2 propagator is used [8]. Once propagated, we compute the product of the two distributions (a product of two GMMs, yielding another GMM). A simple criterion for establishing the correlation status is to consider the tracklets correlated if the distributions overlap and not correlated if they do not. A more reasonable and effective criterion can be found by looking at how similar the distributions are, quantified by the normalization factor obtained in computing the product of the distributions. This shall be described in more detail in the next section.

Note that the product of two PARs of a given tracklet pair gives an estimate of the orbit of an object that would have generated these tracklets at their respective epochs. More precisely, a (non-Gaussian) distribution of possible orbits is obtained, i.e., a covariance. We may assign the mean or the densest part of the distribution as the estimated orbit of the object.

Results

We consider a set of 194 tracklets obtained by tracking a set of 47 unique GNSS satellites over a period of approximately 82 hours, with the tracklets containing 3 to 22 measurements (mean 16.47) covering a time interval of 8.6 to 78.9 seconds (mean 68.9). The orbital period of these satellites ranges from 12 to 14 hours, hence these tracklets clearly constitute TSAs. Compared to accurate ephemeris data, the measurements have a bias of $(b_\alpha, b_\delta) = (-0.12'', 0.01'')$ and a standard deviation of $(\sigma_\alpha, \sigma_\delta) = (0.35'', 0.36'')$. For every tracklet we implement the described correlation procedure against every other tracklet. This means that for n tracklets we have n(n - 1) combinations, which in this case equates to 37442, of which 876 are correlated. To compute the PAR we sample 5000 pairs from a uniform (a, e) prior and use the following constraints: $\rho \in [350, 50000]$ km, $\dot{\rho} \in [-15, 15]$ km/s, $a \in [10000, 40000]$ km and $e \in [0, 0.1]$.

Fig. 1 shows the true positives (TP), false negatives (FN), true negatives (TN) and false positives (FP) for different number of Gaussian components used to represent the PAR. The basic criterion for correlation is used, i.e., whether or not there is overlap between the distributions. A low TP rate is observed for each case accompanied by a relatively high FP rate, especially for low number of Gaussian components.

We can improve the result by considering the sum of the normalization factors used to compute the product of the overlapping distributions, which provides a measure of similarity between the distributions, and shall be denoted with z. Note, this measure is only available for TPs and FPs, as the distributions do not overlap for the FNs and TNs. Fig. 2 shows the distribution of log z for the TP and FP rate using 100 Gaussian components. We observe a non-perfect separation of the TP and FP rates, but clearly a better correlation criterion can be determined. An optimal decision boundary can be computed given some fixed cost and reward for rejecting TPs and FPs, respectively. In practice, these values should reflect certain operational considerations. Here, we simply set the cost for rejecting TPs and FPs at 5 and -1, respectively, and compute the decision boundary that minimizes the cost. The decision boundary in Fig. 2 is shown as a dashed vertical black line and has a value of 25.88. This decision boundary provides a significant improvement over to the basic correlation criterion: 1214 FPs are rejected at the cost of rejecting only 23 TPs, resulting in a TP and FP rate of $\frac{848}{876}$ and $\frac{871}{36566}$, respectively.

For the cases where the PAR is represented using only a few Gaussian components, there is more overlap between the TP and FP distributions, resulting in more TP and/or less FP rejections. This highlights the (somewhat obvious) merit to accurately model the PAR.

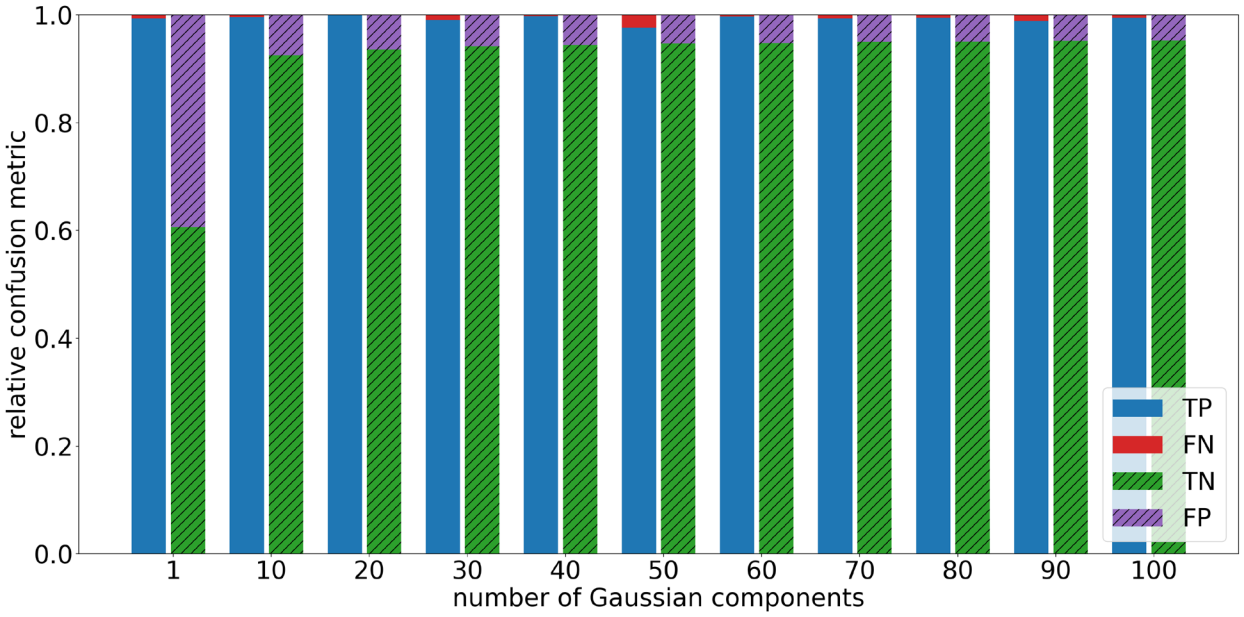

Figure 1: Tracklet correlation result for different number of Gaussian components, using the basic correlation criterion

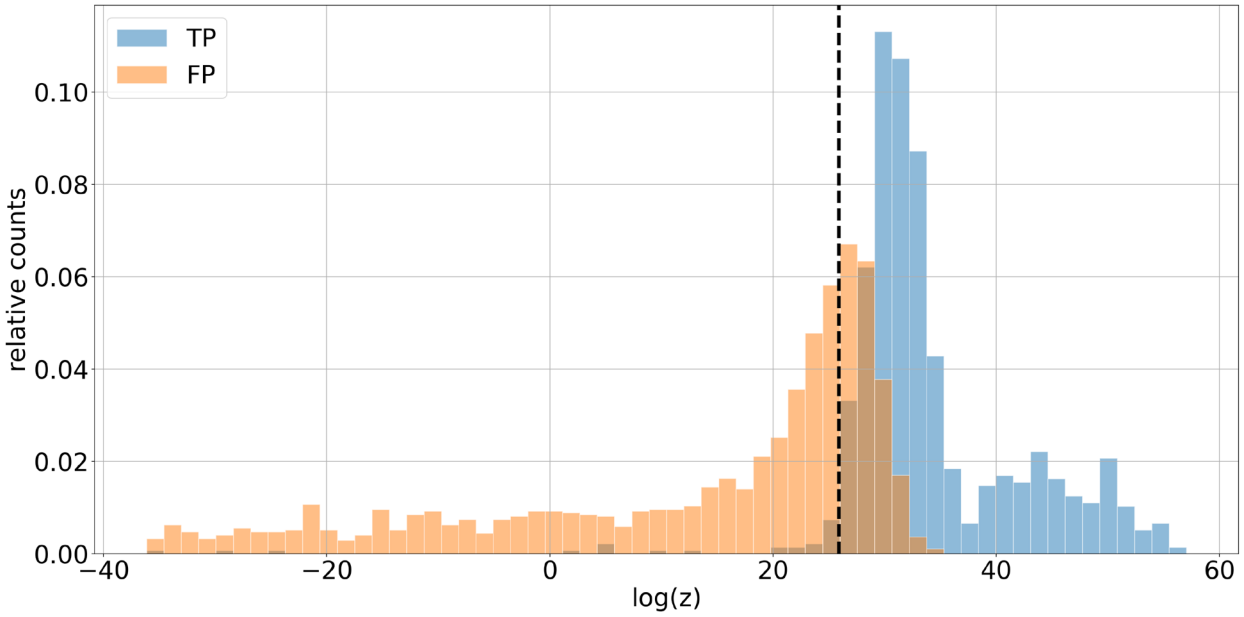

Figure 2: TP and FP rate distribution (100 Gaussian components) for the logarithm of the sum of the PAR products' normalization factors. The black horizontal line is the optimal decision boundary.

Next, for each TP pair, we compare its IOD solution (obtained by taking the mean of the PAR product of the two tracklets at the epoch of tracklet 2) to accurate external ephemeris data from the CDDIS database. Fig. 3 shows the IOD solution in terms of the RSW error (again using **100** Gaussian components) as a function of the angular separation between the tracklets. We see that the radial error (R) is generally larger than the along-track (S) and cross-track (W) error. Indeed, this is expected since it is the radial component that is not directly measured but inferred from the orbit instead. A reduction in the error is observed for increasing angular separation, which is most pronounced for the radial component. For sufficiently large angular separations (<70°), the radial error has a standard deviation in the range of 5 to 12 km, and the along-track and cross-track error

are around 2 km. Note that the accuracy of the IOD solution is in the end limited by the simplified models used in the correlation process. It is recommended to perform orbit determination on the combined tracklet data using more accurate models, with the PAR IOD solution as an initial guess.

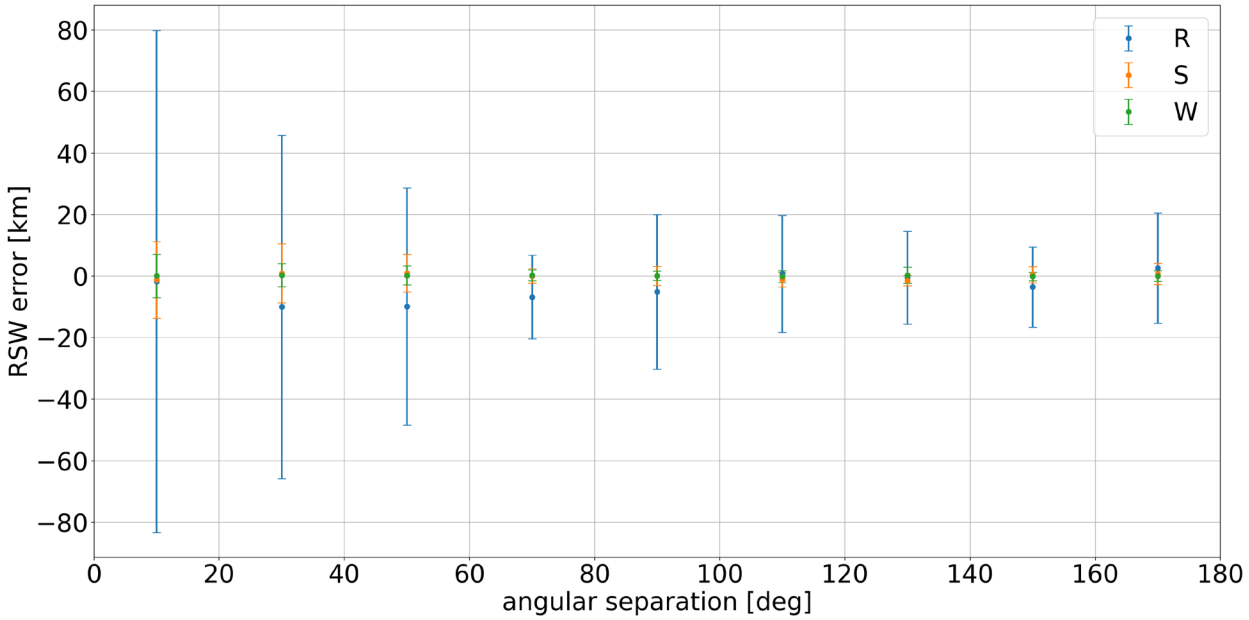

Figure 3: Mean RSW error for the PAR IOD solutions with 100 Gaussian components as a function of the angular separation between the correlated tracklets.

Discussion and conclusion

From the results we have seen that an accurately represented PAR can be used to effectively discriminate correlated from uncorrelated tracklets. A very small FN rate and FP rate is observed but in absolute terms a significant number of FP remain. The reason for this is the fact that many of the uncorrelated tracklets pairs are consistent with the observations under the given constraints. We can use the IOD solution to verify or reject the correlation result by associating it to an existing catalogue; or test it against a third tracklet; or schedule a follow-up observation in an attempt to reacquire the object. In the case of a high FP count, however, the last option may put an unnecessary high burden on the sensor network.

In the method section it was mentioned that a light-time and atmospheric refraction correction are applied, but in a true cataloguing generation scenario these cannot be directly computed. Instead, they need to be incorporated into the correlation process. We can compute these corrections once we have determined the set of admissible states and iterate as needed. This will influence the uncertainty in the attributable and its effect on the correlation process shall be considered in future work.

Another point of discussion is the selection of the constraints. In this work, the target population was in MEO and relatively loose constraints were chosen to capture this fact. How the choice of constraints affects the performance of the correlation process needs to be studied, and a structured method of choosing them is needed.

To conclude, the Probabilistic Admissible Region shows promise as tool in tracklet correlation and IOD for the catalogue generation of LEO and MEO objects. Future work aims to further improve and validate the methodology for LEO and space-based data.

Abstract. The Near-Zero Inclination Geosynchronous Synthetic Aperture Radar (NZI-GEOSAR) concept enables high-frequency observations with stable geometry for interferometric applications. However, orbit stability at GEO altitude is strongly affected by perturbative forces that challenge the control strategy efficiency. This work quantifies the relative contribution of lunisolar gravitational effects, solar radiation pressure, Earth's non-sphericity to the orbit maintenance of a NZI-GEOSAR mission implementing the Tangential-Normal (TN) control strategy proposed in [1]. Simulation results show that the lunar gravitational perturbation dominates the ΔV budget, accounting for about 85% of the total control effort, while solar and geopotential effects have minor influence. Moreover, a 14% ΔV increase between epochs is observed, driven by the 18.6-year lunar node regression cycle.

Introduction

Earth Observation missions increasingly rely on advanced spaceborne Synthetic Aperture Radar (SAR) systems to provide high-resolution, all-weather imaging for scientific and civil applications. Within this framework, the GEOSAR concept - proposed since 1978 in several configurations - offers the unique capability of wide-swath, near-persistent observation from geostationary orbit, enabling revisit intervals of 24 hours or less over continental scales due to its synchronicity with Earth's rotation. Recent developments confirm the growing interest in this architecture: China's Ludi-Tance 4-01 satellite, launched in August 2023 on a 16° inclined GEO orbit, represents the first operational GEOSAR mission [2], while ESA's Hydroterra+ concept, shortlisted under the Earth Explorer 12 call, envisions a C-band Near-Zero-Inclination (NZI) GEO system for twice-daily monitoring of Europe and the Mediterranean [3].

A key requirement for such systems - especially in NZI configurations - is the implementation of an orbit control strategy that preserves spatial and temporal coherence for interferometric SAR (InSAR) applications. Maintaining small cross-track baselines and stable Doppler bandwidth overlap is challenging at GEO altitude, where even small orbit deviations induce significant ground-projection errors. Perturbative accelerations due to Solar Radiation Pressure (SRP), Earth's oblateness, and lunisolar gravity can destabilize the orbit and degrade imaging performance even over short timescales. To meet these constraints, tailored control strategies have been proposed in [1], with the Tangential-Normal (TN) approach emerging as the most efficient trade-off between interferometric performance and propellant consumption. Such previous analyses, however,

Materials Research Proceedings 69 (2026) 1065-1070 https://doi.org/10.21741/9781644904251-184

considered all perturbations simultaneously, without isolating their individual contributions. This limits the understanding of the physical origin of the ΔV demand in GEOSAR configurations.

The present work aims to identify and quantify the dominant perturbative sources affecting orbit stability and InSAR coherence in NZI-GEOSAR systems, clarifying how solar, lunar, and geopotential effects drive ΔV consumption over different epochs. The analysis compares multiple simulation scenarios in terms of ΔV budget and fuel usage, providing physical insight into orbital distortion mechanisms, useful for the optimization of control strategies for GEOSAR missions.

This paper is organized as follows. Section I explains the methodology behind the conducted orbit perturbation, Section II provides the simulation setting and the results, discussing the impact of them on the TN control strategy.

Orbit Perturbations Analysis

The efficient applicability of the Tangential-Normal control strategy [1] can be appreciated from two different perspective in Fig. 1 by comparing the drifting behaviour of the perturbed orbit and the stable behaviour of the controlled one. In the analyses that have been already conducted, the orbit control simulations are performed in totally perturbative orbit environments in GMAT software [4]. This implies that Earth gravitational potential up to 21 degree and order, Moon and Sun gravitational attractions, and SRP are activated in the orbit propagator to take into account all the perturbing accelerations acting on the system in the reference epoch (i.e., 15th March 2036 00:00:00 UTCG). Spacecraft mass is 2000 kg, the exposed area to the Sun is nominally 50 m^2, thus leading to 0.025 kg/m^2 of area to mass ratio A/m; the reflectivity coefficient C_r is 1.8. This simulation setting enabled the estimate of a realistic total ΔV budget that has to be allocated for orbit maintenance tasks.

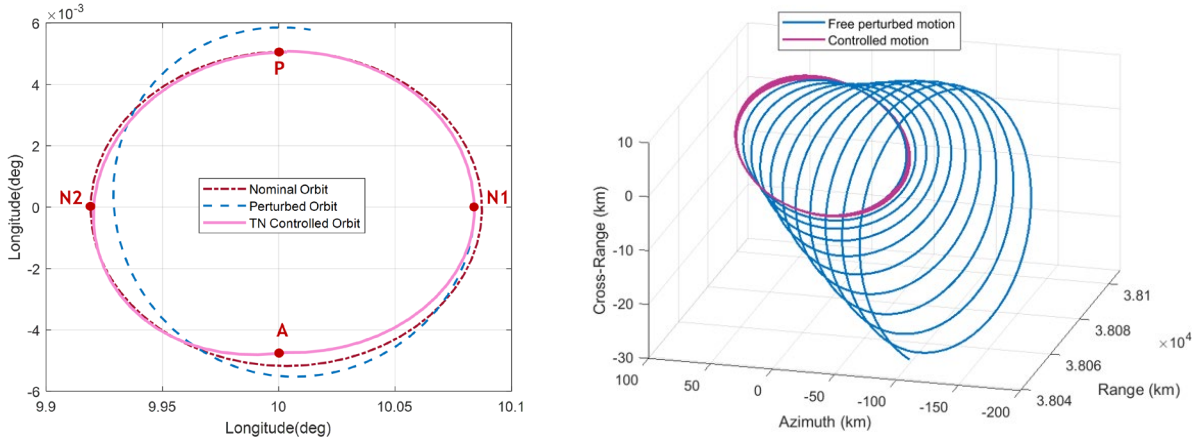

Figure 1 – Left: one-day comparison between the nominal orbit defined in [1], the perturbed orbit, and the TN controlled orbit from the ground-track point of view. P is perigee, A is apogee, N1 is the first orbit node, N2 is the second orbit node. Right: 10-days comparison between the free perturbed motion and the TN controlled motion in the topocentric Range-Azimuth-Cross-Range frame of a target placed at 16.75°E, 46°N, 0 km altitude

However, by switching to the analyses of the individual perturbations, it is possible to assess the impact of each force on the ΔV budget and the consequent fuel mass usage. Specifically, each perturbing force can be activated separately in the GMAT propagator so that its impact on the orbit stability and the maintenance cost can be properly appreciated and disentangled.

In general, the perturbative environment experienced by a GEOSAR satellite is governed by the complex gravitational interaction within the Earth-Moon-Sun system, which generates motions spanning a wide range of characteristic frequencies - from the daily Earth rotation to the lunar month, the solar year, and slow precessions of orbital planes and apsides extending up to tens of

Materials Research Proceedings 69 (2026) 1065-1070 https://doi.org/10.21741/9781644904251-184

thousands of years. Each of these perturbations acts, when isolated, with distinct frequency signatures and affects different orbital components, thus requiring specific orbit control actions to be counteracted. Among these phenomena, the most relevant long-term perturbation is linked to the regression of the lunar nodes, which completes a full cycle every 18.6 years, accompanied by an apsidal precession of approximately 8.85 years [5]. The lunar orbit, inclined by about 5.15° to the ecliptic, combined with the 23.44° tilt between the ecliptic and the Earth's equator, leads to a variable apparent inclination of up to ± 28.6° with respect to the equatorial plane. In general, the 18.6-year regression of the nodes periodically changes the direction and magnitude of the lunar gravitational acceleration acting on the GEO spacecraft, modulating the out-of-plane component of the perturbing force and, consequently, the ΔV required for North-South orbit maneuvers. When the Moon reaches higher declinations, the normal component of its gravitational force increases, leading to a higher ΔV demand for the spacecraft inclination control; conversely, when the Moon is near the equatorial plane, this requirement is minimized.

The Sun, although less variable in apparent motion, also contributes to the perturbative environment. Its declination range (± 23.44°) and distance to Earth vary only slightly throughout the year, making its influence on out-of-plane dynamics nearly constant over time. Additionally, this gravity contribution also determines in-plane oscillations, driving periodic variations in eccentricity and argument of perigee with annual frequency [6]. Another relevant aspect is that the interaction between solar and lunar perturbations can produce short-term beating patterns that slightly modulate the needed ΔV, particularly when their declinations align constructively or destructively. The different trend of the declination of these third bodies (i.e., Moon and Sun) can be appreciated in Fig.2, where a temporal window of 20 years is considered to confirm the peculiar periodicity of the relevant motions.

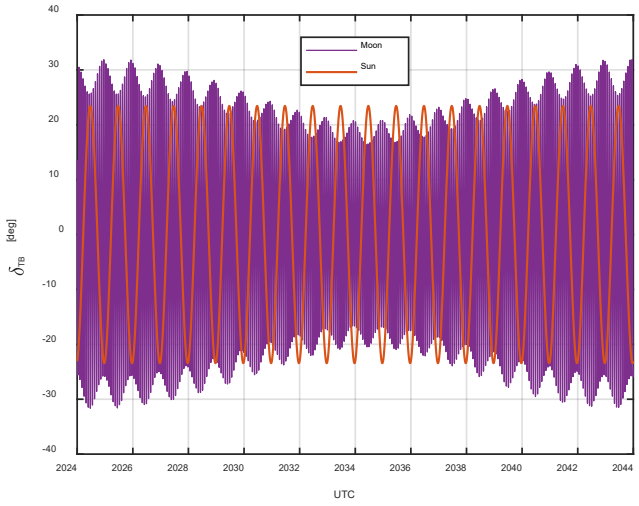

Figure 2 - Trend of the declination (δ_{TB}) of the involved third bodies (Moon, Sun) over a 20-year simulation period

The ephemerides of the Moon and the Sun are here generated through the JPL Horizons on-line solar system data calculator [7] considering the nominal fixed GEOSAR satellite point whose definition is provided in [1]. It is worth noting that, since the GEO observer is displaced from the Earth center, the apparent declination of the Moon reaches a maximum value that is slightly higher (± 31.7°) in absolute terms.

In addition to third-body effects, the Earth's non-sphericity - especially the equatorial asymmetry represented by the C_{22}, S_{22} geopotential spherical harmonics [8] - induces a longitudinal drift of the GEO point, causing an East-West motion that must be compensated by

Materials Research Proceedings 69 (2026) 1065-1070 https://doi.org/10.21741/9781644904251-184

tangential maneuvers. This perturbation is time-invariant and geometry-dependent, defining two stable (75°E, 255°E) and two unstable (165°E, 345°E) equilibrium longitudes. Finally, SRP acts primarily along the radial and tangential directions, depending on the spacecraft attitude and Sun-spacecraft geometry [8]. The main effects are small periodic eccentricity variations and minor diurnal oscillations in the ground track. Although the SRP long-term impact on orbit stability is limited, it can slightly perturb the along-track position, especially, for example, during spacecraft attitude transitions.

Simulations and Results

The impact of the perturbing forces can be appreciated looking at the orbit evolution in the topocentric reference frame centered in target B5, whose geodetic coordinates are 16.75°E, 46°N, 0 km altitude [1]. Fig. 3 depicts the controlled orbit evolution for a 30-days simulation under different propagator settings.

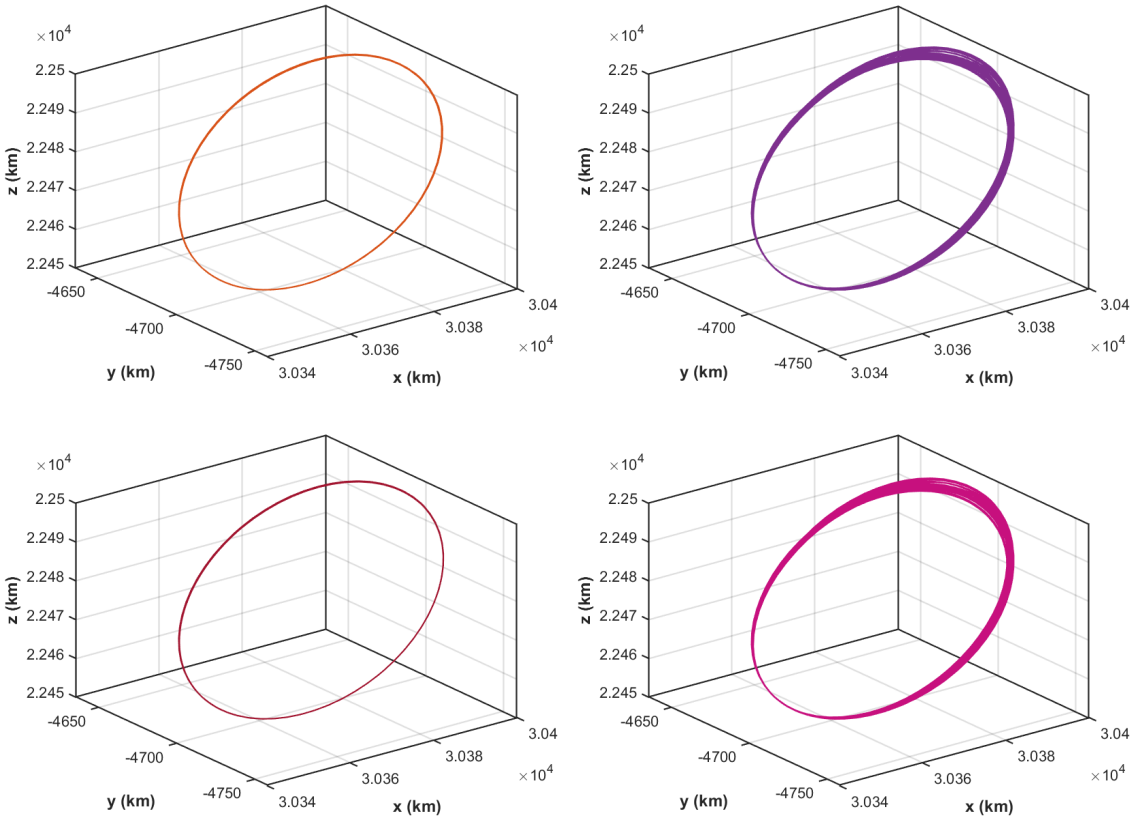

Figure 3 Controlled orbit evolution in the topocentric reference frame centered in beam B5, simulation of 30 days performed in GMAT activating different perturbing effects. Upper left: only Sun gravity is activated; Upper right: only Moon gravity is activated; Bottom left: only SRP and Earth non-sphericity are activated; Bottom right: all the perturbing forces are activated

The comparison among the different cases demonstrates that orbits propagated under lunar-only perturbations (Fig. 3 Upper right) closely reproduce the deviations observed when all perturbations are active (Fig. 3 Bottom right). This further confirms that lunar gravity is the primary driver of orbital plane distortion. Indeed, the Sun gravity contribution (Fig. 3 Upper left) is less impactful than the Moon one, causing smaller deviations of the orbit. When only SRP and Earth's non-sphericity are activated (Fig. 3 Bottom left), the orbit is very stable, remaining tightly bound around the nominal position, with very minor oscillations mostly confined to the along-track direction.

Materials Research Proceedings 69 (2026) 1065-1070 https://doi.org/10.21741/9781644904251-184

Beyond the geometric orbit representations, a quantitative comparison in terms of ΔV budget is performed to assess the effect of each perturbation source. Two distinct simulation epochs are selected to capture the temporal variability of the lunar gravitational influence, which - as previously discussed - is expected to dominate the long-term evolution of the orbital dynamics. Specifically, two epochs separated by approximately nine years are selected, corresponding to the phases of minimum and maximum lunar declination within the 18.6-year nodal regression cycle. According to the declination trends in Fig. 2, 15 March 2033 00:00:00 UTCG and 15 March 2042 00:00:00 UTCG are chosen as the initial epochs for one-year controlled simulations in GMAT.

Table 1 summarizes the resulting ΔV and propellant consumption (i.e., fuel mass usage, m_{fuel}), assuming a 2000 kg spacecraft equipped with a chemical propulsion system of specific impulse of 300 s. The results clearly indicate that the Moon's gravitational perturbation is the dominant source of instability for the NZI GEOSAR configuration, whatever the selected epoch is. When only the lunar attraction is active, the required ΔV accounts for approximately ~85 % of the total control effort, while the solar contribution remains below ~35 %. Additionally, the combined ΔV of the Sun and Moon acting separately slightly exceeds the total ΔV obtained when both perturbations are applied simultaneously. This behavior reveals a geometric partial compensation between the lunar and solar accelerations: depending on their relative phase and declination, the normal components of their perturbative forces can partially counteract each other, reducing the total control effort required. In contrast, when third-body effects are neglected, the ΔV requirement drastically drops to ~6 m/s, confirming that SRP and Earth's non-sphericity have a limited impact on long-term orbit stability.

Table 1 – ΔV budget and fuel usage comparison

Epoch	Active Perturbations	ΔV [m/s]	m_{fuel} [kg]
2033	ALL	87.55	61.11
	ONLY MOON	74.97	52.44
	ONLY SUN	32.45	22.86
	NO THIRD BODY	6.35	4.49
2042	ALL	102.15	71.13
	ONLY MOON	87.13	60.82
	ONLY SUN	32.41	22.84
	NO THIRD BODY	6.37	4.51

The comparison between the epochs reveals a ΔV increase of about 14%, in 2042 epoch, which can be directly attributed to the 18.6-year regression of the lunar nodes modulating the inclination of the Moon's orbital plane relative to the Earth's equator. In 2042, when the lunar declination reaches its maximum amplitude, the normal component of the perturbative acceleration is increased, leading to a larger ΔV associated with out-of-plane maneuvers. Conversely, in 2033, the smaller lunar declination corresponds to a dynamically favorable configuration requiring less control effort. As expected, the Sun's gravitational influence remains nearly constant across epochs due to the quasi-stationary geometry of the Earth-Sun system.

Conclusions

A detailed analysis of the perturbative accelerations on a NZI GEOSAR orbit has been conducted through high-fidelity GMAT simulations implementing the Tangential-Normal control strategy. Each perturbation source has been individually activated to quantify its contribution to orbit stability and control effort. Results confirm that the lunar gravitational attraction is the dominant disturbance, responsible for nearly 85% of the total ΔV required for orbit control. The comparison between 2033 and 2042 epochs shows a ΔV increase of about 14%, consistent with the 18.6-year

lunar node regression cycle that modulates the Moon's declination and strengthens its out-of-plane effect during maximum inclination phases. Overall, the study demonstrates that third-body geometry and epoch selection can relatively influence orbit-keeping efficiency. These results highlight the need for third bodies geometry-dependent control planning and propellant allocation strategies in future GEOSAR missions to ensure long-term interferometric performance with minimized fuel consumption.

Abstract. The increasing number of space exploration missions presents a novel challenge with regards to planning and operations. Current architectures are composed of distinct teams and models performing separate tasks like navigation, planning, and science, which can lead to inefficiencies and delays. This work proposes a Digital Twin (DT) architecture which supports end-to-end mission design, operations, and scientific analysis. The proposed DT combines models of the spacecraft, its scientific payloads, and the target body, linked through a data processing layer that enables continuous monitoring, simulation, and decision support. A case study of a spacecraft exploring an asteroid and interacting with its surface through a lander and sampling arm is presented. This example specifically shows the importance of reduced order models (ROMs) to efficiently predict and interpret surface interactions. This approach highlights the potential of integrated DT architectures to enhance coordination, adaptability, and scientific return in future deep space missions.

Introduction

The number of missions exploring the solar system is increasing rapidly over time, from spacecrafts going to the Jovian system investigating the habitability of its moons, to mission improving our planetary defense capabilities by visiting near earth objects like Didymos and Apophis. These missions are complex, with various instruments that are necessary to meet science objectives, many different subsystems with intricate connections, and large ground teams that must analyse, plan, and operate these missions [7]. While miniaturization has driven down spacecraft manufacturing costs, the operational burden on the ground segment has not scaled down equivalently, in fact, the demands on mission planning and coordination are growing due to increasing number of deep space missions.

Currently, the planning and operation of these missions is performed by separate groups, e.g. hardware design, trajectory planning, navigation analysis, and science investigation groups. During all phases of the mission, decisions made by each group have a large influence on the other and require frequent iterations. This siloed approach leads to inefficiencies and repeated iterations, especially as small design or operational decisions can propagate significantly through the mission's architecture and affect science return. To address this challenge, this work proposes the integration of novel Digital Twin (DT) and modelling methodologies to improve operational efficiency and enhance scientific outcomes across all mission phases, from design to post-mission data analysis. DTs are virtual models of physical processes where data is exchanged (often real-time) to update the state of the virtual model. DTs have already been explored for individual subsystems of spacecrafts, like for example the EPS of Artemis [8]. However, here we propose to have a more holistic view of the mission Specifically, we envision a DT that encapsulates the spacecraft, its instruments, and the target planetary body. The central objective is not just

Materials Research Proceedings 69 (2026) 1071-1076 https://doi.org/10.21741/9781644904251-185

engineering health monitoring, but mission science: continuously assessing whether science goals are being met, adapting operations in response to unexpected conditions, and extracting maximum insight from acquired data. In this work we present a general overview of this problem, and give an example related to a spacecraft trying to interact with the surface of a Small Solar-system Body (SSB) like an asteroid or small planetary moon.

Digital Twin

With an increase in computing power, larger numbers of spacecrafts, and more complex space systems the use of DTs in spaceflight has seen an increase in the last decades. Examples can be found for rover operations [10], spacecraft electrical power systems [8], and astronaut training [9]. For a more comprehensive overview, the reader is directed to [6]. There are many different definitions of what exactly a DT is, which also depend on the specific domain in which they are used. In general, there are two key characteristics that are common:

- It is a digital representation of a process/object/system in the physical world.
- There is a bidirectional exchange between the DT and the physical system.

In several cases there is also a (quasi) real-time aspect to the DT, as they are often used in critical processes like structural health monitoring where quick responses are required [5]. Due to the inherent delays present in deep space operations the real-time aspect is not considered for the DTs here.

Figure 1 shows the proposed architecture of the DT for science operations. It mainly consists of two blocks, representing the physical and digital environment. The physical environment consists of both the target objects (e.g. asteroid, moon, planet, etc.) and the spacecraft including all its scientific payloads, sensors, and actuators. The digital block consists of three sub-blocks: the spacecraft model, target model, and data processing blocks. The spacecraft model contains digital representations of the different subsystems and serves two purposes: interpreting incoming data from the physical spacecraft and simulating proposed commands sent from ground. The target block represents the current state of knowledge of the target. It can be used to understand the incoming observations, plan them based on the perceived lack of knowledge, and as a simulation tool for the simulated spacecraft. Finally, the data processing block contains all the decision making logic. It creates commands based on the current state of the spacecraft and target, it then performs predictive simulations using these commands, and finally decides on the actual command sent to the physical spacecraft (either human-in-the-loop or autonomously).

The individual spacecraft and target model blocks do not necessarily present novel ideas. Engineers have already implemented models and digital twins of the spacecraft itself during previous missions [8] and scientists have done the same for the target of interests of individual or combined missions [1]. The main novelty of the proposed architecture is to combine the different blocks into a single architecture and use the data processing block to monitor the system as a whole, perform scientific interpretation of the data, and plan the next steps. The advantages of this approach is the fact no long iterations between the different teams and their separate models/DTs are necessary, decreasing the turnaround time and making the mission more flexible to new observations. It also ensures that any unexpected events and faults in the spacecraft are propagated throughout the whole system, directly observing the consequences.

Materials Research Proceedings 69 (2026) 1071-1076 https://doi.org/10.21741/9781644904251-185

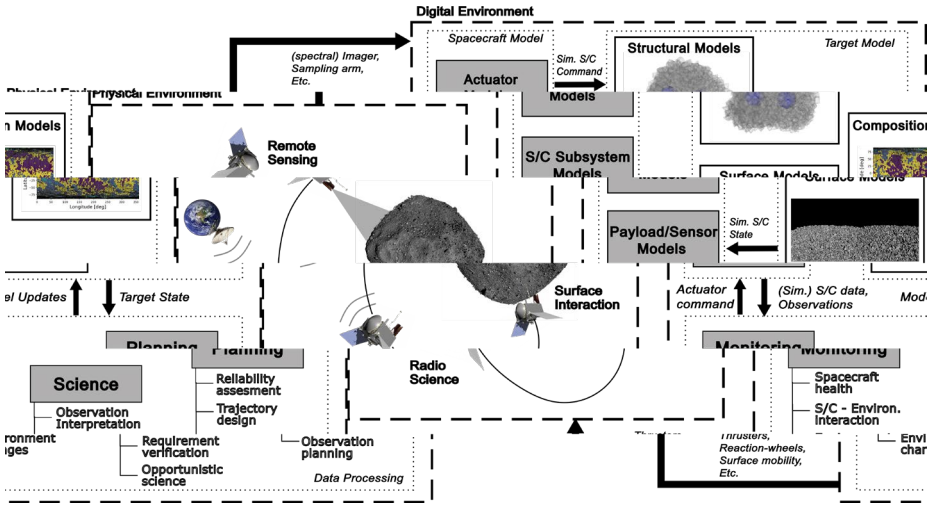

Figure 1 Schematical representation of the Digital Twin for space exploration and science

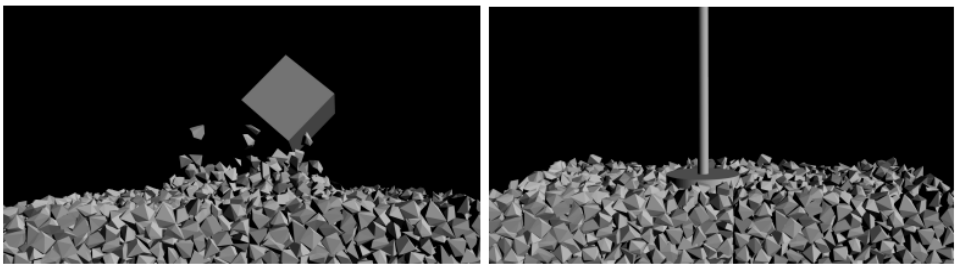
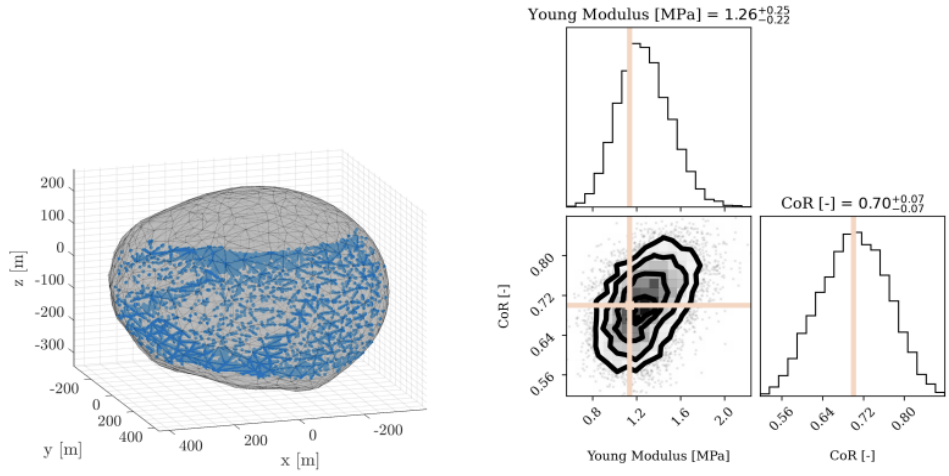
The main complexity of this architecture lies in the efficient modeling of the systems and efficiently using the sensors and instruments available on the spacecraft. For example, a large number of Small Solar System Bodies (SSBs) are thought to have a large amount of granular material, also known as regolith, and boulders on their surface. The interactions between the individual regolith particles, the boulders, and the spacecraft itself are governed by complex contact forces and are hard to model on Earth due to the low-gravity environment on these SSBs. Modeling SSBs thus requires complex discrete element models (DEMs), which have a high computational burden. Running many DEM simulations for interpreting continuously the novel observations and performing statistical predictions can take several days to weeks [4], thus reacting to these new observations becomes infeasible. Hence, reduced order models (ROMs) are needed that can be more efficiently used inside the DT. The focus for the following will be on how to generate these ROMs and how they can be used inside the DT framework. 3

Case Study: SSB landing and sampling



Many missions have attempted, or are planning to attempt, interactions with the surface of a SSB. For example, NASA's OSIRIS-Rex succesfully obtained a sample from the asteroid Bennu using its TAGSAM robotic arm, while JAXA's Martian Moons eXploration (MMX) will deploy a rover on the surface of the Martian moon Phobos. One of the main difficulties for these missions is the uncertainty related to the surface properties of SSBs. These properties are related to, for example, their size distribution, strength, contact parameters, and density. Determining these parameters not only serves to reduce the risk of an interaction, but also to improve our scientific knowledge as these parameters can tell us about the formation and evolution of these SSBs.

For this test case, a Hayabusa-2 like mission is used where first a lander is placed on the surface and afterwards a sampling manuever is performed. In this case, the DT architecture can help in interpreting the data from different instruments and the initial landing to inform the sampling strategy. First, the simulation setup is performed using a DEM code called GRAINS (more information regarding this code can be found in [2]). The surface conditions are first determined by observations from the optical and thermal imagers, which can obtain particle size and shape distributions (PSDs). Using these observations and the results from the radio science instrument to determine the local gravity level, the surface is created inside the DEM by generating a set of particles using the determined PSD and letting it settle under the local gravity level. This model can be continuously updated by new measurements of the imagers and/or the radio science



experiment. Once the surfaces are created, objects representing the lander and sampler can be incorporated, see Figures 2a and 2b.

As discussed before, a ROM of the surface interaction needs to be generated to perform statistically relevant reliability assessments and parameter estimation. This is achieved using a data-driven approach where a small number of DEM simulations are used to fit a ROM that can be more efficiently used. This ROM is created by a non-intrusive polynomial chaos method, which samples the initial conditions and system parameters in an optimal way, and takes the input-output relationship of these sample simulations to create a fit based on a family of orthogonal polynomials that represent the prior distribution of the input variables. A more detailed description of this method is given in [3].

It was found that the generated ROM for the landing has a maximum error of around 5 percent. Using this model, a reliability assessment was made for a hypothetical landing scenario on Didymos, show in Figure 2c. After the actual landing is performed, a Markov Chain Monte Carlo (MCMC) method was used to determine the contact parameters of the surface material. The MCMC method required 50000 samples to achieve an acceptable accuracy, using the original full order DEM model would take around 14.26 years to run. With the ROM this was reduced to around 6 minutes (excluding the one time cost of generating the ROM, requiring around 12 hours). This info can then be used for the sampling maneuver to derive a more robust maneuver. Similarly to before, after the sampling maneuver an MCMC method was performed to have a final estimate of the surface parameters, which are shown in Figure 2d.

(a) Lander. (b) Sampler.

(c) Distribution of landing locations. (d) Results of the model calibration.

Figure 2 Results for the test case of the landing and sampling of a SSB.

Having a combined DT of the spacecraft, the sampling arm, and the surface of the SSB will help in planning this operation, tracking the succesful execution of this maneuver, and interpret

the data for scientific purposes. The main difficulty here is the complexity of these types of simulations (requiring discrete element models (DEM) to simulate the motion of the surface particles, the spacecraft, and their interaction), and efficiently using the sensors and instruments available on the spacecraft. For both real-time tracking and post-processing the spacecraft data, reduced order models are needed that can be more efficiently run.

Conclusions

Here it was discussed how concepts from digital twins (DT) can be used in deep space missions, specifically looking at science operations. This DT serves multiple roles: (1) it supports pre-arrival parametric analysis, enabling assessment of operational feasibility and risk under different conditions; (2) it facilitates real-time mission support by quickly evaluating the implications of sensor data; and (3) it enables inverse modeling, where in-situ measurements are used to infer target properties, advancing scientific understanding of the Solar system. Concluding, this work highlights the potential of Digital Twin architectures to improve science operations for planetary missions. By integrating spacecraft dynamics, instrumentation, and environmental interaction into one model, decision-making can happen more efficiently, mission performance is optimised, and scientific return is maximised. Our SSB surface interaction case study gives an example of how this approach can be practically applied, from pre-mission design through to data interpretation, in one of the most complex and uncertain operational scenarios in planetary exploration.

The Legal Conundrum of Mega-Constellations: A Call for a Sustainable Space Governance Framework

Margherita PENNA[1,a *]

Keywords: Mega-Constellations, Harmful Contamination, Liability, Space Law, Environmental Law, Polluter Pays Principles, Remediation Fund

Abstract. The rapid deployment of mega-constellations in Low-Earth Orbit (LEO) exposes a critical failure in current International Space Law (ISL) to ensure sustainability and equitable access. Existing space *hard* and *soft law* is insufficient to curb the exponential growth of space debris, creating a significant negative environmental externality. This paper argues that International Environmental Law (IEL) principles, such as the polluter pays principle (PPP) should be integrated into the space legal sphere. Also, it proposes the establishment of some policy tools, which would be extremely in protecting space from a "tragedy of the commons".

Introduction

The New Space Economy (NSE), primarily driven by private actors, represents a vast shift from the initial era of the space race. Space has been transforming into a realm of commercially driven economic activities, extending well beyond traditional government-led missions. A robust and growing market for space ventures exists since space activities – from launching objects to operating them in orbit – generate economic value. At the core of NSE are mega-constellations, such as SpaceX's Starlink, which provide crucial services in the field of communication. However, these systems, composed of tens of thousands of satellites, pose significant risks, including near misses in orbit, interference with astronomical observations, and the looming threat of the Kessler Syndrome, which could render key orbital lanes unusable. Given the massive deployment of objects and private sector dominance, understanding the international rights and obligations regarding the sustainability and environmental impact of these complex infrastructures is a pressing matter. This work argues that International Space Law (ISL) lacks the specific binding norms necessary to govern the fallout of mega-constellations. The current legal framework fails to address the negative impacts of mass satellite launches, allowing operators to externalize environmental costs. To address this, principles of International Environmental Law (IEL) should be introduced into the legal discourse on space. A novel interpretative framework is needed for future space governance to ensure long-term sustainable use of outer space [1]. This paper proposes incorporating international environmental obligations, an updated licensing regime for mega-constellations, and establishing a dedicated fund for space debris remediation.

The Problem: Mega-Constellations.

Starting from the 2000s, a shift in the development of space systems has occurred, in particular in Low-Earth Orbit (LEO) – around 500 to 2000 km of altitude – and in relation to space communication systems. Indeed, most of the space objects now launched into space are communication satellites, deployed in LEO, in highly articulated connected systems. The reason behind the increased number of complex satellite systems lies in the fact that in LEO, a single satellite can cover a smaller fraction of Earth's surface. Therefore, to have a continuous service and full coverage a 'constellation' of communication satellites is required. Constellation projects need to be filed according to the international regime regulated by the International

Telecommunication Union. Current or expected LEO constellations include SpaceX's Starlink (5,399 operational, 42,000 expected), EUTELSAT's OneWeb (636 operational), Amazon's Kuiper (2 deployed, 3,236 expected), China's Guowang (12,992 expected), and Rwanda's Cinnamon (337,320 expected) [2]. The upsurge in the number of constellations raises serious concerns about the sustainability of space activities. From a technical point of view, the LEO constellations aim to use a radio spectrum which is often already in use by satellites located in the Geostationary Orbit (GEO). Radio interferences may indeed occur when a mega-constellation flies over the beam of a GEO satellite, but also when two constellations interfere with each other in LEO. Also, mega-constellations raise issues at optical wavelengths, interfering with astronomical observation of the known Dark and Quiet Skies. It has been witnessed that Starlink is already creating "artifacts in astronomical observations", [3] impeding scientific investigation of the skies. Lastly, mega-constellations are exponentially augmenting the risk of collisions and near-misses among satellites (due to the high congestion of LEO) and consequently, the cascading risk of never-ending space debris creation, till the point feared by the Kessler Syndrome.

Technical risks are paired with political and environmental ones; first and foremost, inequality in the use of space between the owners of those constellations and new emerging and developing space actors. Such inequality is combined with a *de facto* discrimination in the allocation of radio frequency, following the first-come, first-served approach established by the International Telecommunication Union's Regulation. Indeed, even if art. 44 of the ITU Constitution recognizes radio spectrum as a "natural limited resource", it still partially regulates allocation of slots without considering an equitable and sustainable access to space [4]. Additionally, the development of mega-constellations raises concerns about their environmental impact, both in the short term and long term. The normative concerns pertain to issues of inequality in the access to space and use of radio frequency, in contrast with ISL principles, discrimination among the space actors, risks of harmful contamination of the environment and of harmful interference in the activities of others [5]. International space law has traditionally laid down the framework of analysis, even though it is argued, in the next paragraph, that is struggling to provide adequate answers.

What Is Missing in International Space Law

Historically, international space law has not specifically addressed sustainability, leaving environmental considerations on and in space on the side. There is no direct and enforceable obligation in the framework of the five space treaties [6,7,8,9,10] regarding the sustainability of space activities. Nevertheless, it is worth taking into consideration those norms from which environmental obligations may be inferred, starting from the Outer Space Treaty (OST) of 1967 [11]. Art. I OST codifies the freedom of access, use, exploration and scientific investigation of outer space and celestial bodies to all States, "for the benefit and in the interest of all countries" and on a basis of equality. These freedoms are inherent to sustainability and vice versa [12], particularly in relation to their equitable nature. Then, Art. IX OST does create an obligation to avoid "harmful contamination" (both forward and backward) and "adverse changes in the environment of the Earth", even though said interferences are considered in relation to the activities of other States Parties. Indeed, the provision obliges States to adopt appropriate measures for this purpose, but it fails to frame the obligation as a necessary protection to the space environment *per se*. Nonetheless, the reference to the prohibition of harmful contamination and the duty to consult may provide a basis for assessing the sustainability of space activities. A duty to consult is, in fact, also present among the principles of international environmental law, which will be addressed below. Some more hints can be drawn from the rules on responsibility and liability in ISL.

The OST establishes a framework of responsibility and liability for damages caused by both governmental and private space activities to which States shall respond. So, if the impact of mega-constellations on the space environment were to be framed as a harmful contamination interfering

with the free use of space by others, the concerned State Party could be found internationally responsible. Art. VI OST indeed establishes the international responsibility of States for all national activities. It adds, however, that all private activities shall undergo a process of authorisation and continuing supervision by "the appropriate State Party to the treaty". The prevailing interpretation of the norm recognizes States responsible for all national activities, not solely for authorising and supervising private ones [13]. Then, Art. VII OST considers the State that "launches or procures the launching of an object into outer space" or "from whose territory or facility a space object is launched" internationally liable for damage to another State Party or to its natural or judicial persons, caused by its space object [13]. The liability regime has been further elaborated in the Liability Convention [7]. However, the two regimes – responsibility and liability – do not seem to be connected. The Registration Convention [9] comes in handy in bringing the two regimes together.

The main controversy is that the liability of a State for damages subsists even in the absence of a wrongful act committed by the State itself or by a national private entity, but only in the presence of damages. While this differential nature with the general international responsibility regime underlines the importance of full compensation from space activities, several matters are left outside its scope of application. Indeed, mega-constellations are not *per se* wrongful, and, unless it is established that it produces damages to other space objects, natural or judicial persons, it does not raise questions of liability. Nevertheless, if the 'damages' were to include damages to the space environment *as such*, the liability regime of ISL could be leveraged in establishing a framework of environmental protection for space.

Amongst the five space treaties, the Moon Agreement [10] is the only one to incorporate a provision resembling an environmental obligation. Art. 7 establishes the obligation on State Parties to take all measures to avoid "disruption of the existing balance of [the Moon] environment, both by introducing adverse changes in that environment or by its harmful contamination". Despite the effort, the Moon Agreement has received a scarce number of ratifications, and it cannot be considered either binding over the international community or representative of a widespread State practice.

While the binding instruments regulating space activities lack provisions imposing environmental obligations over States, some non-binding instruments have addressed these *lacunae*. For instance, the UN General Assembly first endorsed the Inter-Agency Space Debris Coordination Committee (IADC) Space Debris Mitigation Guidelines (SDMG) in 2007 [14]. The SDMG – as more recently, the ESA Zero Debris Charter – aimed to curtail the production of short-term mission-related debris and limit long-term debris generation through end-of-life procedures. However, these guidelines lack references to constellations as an exacerbating factor, and most importantly, they are voluntary measures with no binding nature over States' activities, let alone private entities. Then the Committee on the Peaceful Uses of Outer Space (UNCOPUOS) adopted the Long-Term Sustainability Guidelines (LTSG) in 2019 [15]. Among these voluntary provisions, Guideline A.3 restates the centrality of continuous supervision of national space activities to assure their compliance with the aim of a long-term sustainability of outer space. Guideline A.4 stresses the importance of ensuring equitable, rational, and efficient use of spectrum and orbital regions. It also adds that end-of-life spacecraft should be removed from orbit or disposed of to avoid their long-term presence in LEO. For instance, the presence of mega-constellations' satellites in LEO – both functional and non-functional – has led to the impracticality of ensuring an equitable and rational use of space for all actors, resulting in the establishment of a *de facto* monopoly over the orbit. Notwithstanding the presence of some reference to sustainability, both *hard* and *soft* international space law seems to be insufficiently prepared to tackle the environmental legal sphere of space activities. Indeed, an intersection between environmental and space law is struggling to

Materials Research Proceedings 69 (2026) 1077-1082 https://doi.org/10.21741/9781644904251-186

be established, leading to a great deal of uncertainty on which environmental obligations States shall carry.

The Tools Offered by International Environmental Law

Art. III OST establishes that space law is not a self-contained regime and space activities shall be in conformity with international law and the UN Charter. Therefore, it has been recognised that international environmental law applies to space activities. Indeed, if mega-constellations are not *per se* unlawful economic activities according to international law, their effect on the space environment – and on Earth as well – might be in tension with several IEL principles, which apply alongside the above-mentioned ISL obligations. The implementation of environmental principles can reduce the risks of space debris creation, collisions and inequitable access to space. These principles appear in most of the environmental international treaties, as well as constituting parts of the States' environmental legal systems and are considered customary in nature [16]. Among these, the following are taken into consideration here: the principle of sustainable use; the principle of prevention; the precautionary principle; lastly, the polluter pays principle.

To start, the principle of prevention, firstly recognised in Principle 21 of the Stockholm Declaration (1972) [17], establishes that States are responsible to ensure that "activities within their jurisdiction or control do not cause damage to the environment of other States or of areas beyond the limits of national jurisdiction", i.e. outer space. In its current understanding, prevention entails a duty to both refrain from causing significant damages to the environment and pro-actively take measures in this direction; a duty to cooperate and consult; and lastly, a duty to conduct environmental impact assessments of potentially harmful activities [16]. The novelty embodied in this principle is that the focus has shifted from the liability for damages to other States onto the protection of the environment as such. To apply this principle in outer space would mean to impose over States to pro-actively assess national private activities environmental impact, for instance by evaluating the damages to the environment that mega-constellations may produce [18].

Secondly, it would be highly relevant to implement the precautionary principle into the regulatory space discourse. The space environment is characterised by a high-level of scientific uncertainties, due to the complex and mostly unknown nature of it. The precautionary principle states that "the lack of full scientific certainty shall not be used as a reason for postponing cost-effective measures to prevent environmental degradation", when there are threats of serious and irreversible damages (Principle 15 Rio Declaration) [19]. Even though the debate on the legal nature and limits of this principle is still on, it has been incorporated in treaty-law as well as been recognised in case-law of different supranational courts [16]. It can be at least concluded that if potential adverse effects of mega-constellations on LEO are not fully understood, the activities shall not proceed or at least States shall further investigate cost-effective measures on the matter.

Thirdly, considering the principle of sustainable development, it should be recognized once and for all that the sustainability of space activities is a critical issue to maintain long-term access to space, in light of the growing human dependency on it. The "Brundtland Report" firstly introduced the concept of sustainability [20], which in the space environment would be interpreted as the ability to conduct space activities indefinitely into the future in a manner that realises the objective of equitable access to the benefits of the exploration and use of outer space for peaceful purposes, in order to meet the needs of the present generations while preserving the outer space environment for future generations. Mega-constellations will likely occupy the whole LEO, rendering it inaccessible and unusable for upcoming space actors. In addition, future generations may not have the possibility to enjoy the benefit of exploring space, as it would inevitably be already occupied and exploited by present space actors.

Lastly, among environmental operational-oriented principles there is the polluter pays principle (PPP). The overarching idea is to balance environmental protection with other considerations. The polluter pays principle seeks to internalize the financial burden of pollution to the economic actors

Materials Research Proceedings 69 (2026) 1077-1082 https://doi.org/10.21741/9781644904251-186

who cause it, distributing the efforts among the various stakeholders involved. If indeed the damage caused to the environment remains within the limits of tolerability by the whole society it shall be internalized; otherwise, it is a matter of prevention of an intolerable damage to the environment. Considering the issue of mega-constellations, for the time being those who own such space infrastructures are externalizing over the whole community the costs – i.e., in terms of damages and pollution to the space environment – reinforcing the idea that space suffers from the "tragedy of the commons": the cost of the introduction of mega-constellations in the space environment is borne by the international community, while the benefits (at least in terms of economic profit) are advantageous only to the owners of such constellations. In light of this, it is argued that despite negotiating an *ad hoc* environmental space law treaty, it should be sufficient to enforce IEL principles in the current space legal framework.

Policy Recommendations to Address Negative Externalities

To bring environmental obligations into the space realm is a necessary step, but it is contended that it is insufficient if not paired with other actions of economic nature. Indeed, traditionally, a mere "command and control" approach is not sufficiently incentive for economic actors to shift their behaviour toward a more sustainable one. Firstly, an update to the current international license regime is considered necessary. The current regime, regulated by the ITU, is not equipped to face the expansion of mega-constellations [4]. The revised international license regime should pivot around an *a priori* planning (which already exists) while putting aside the first-come, first-served approach. In addition, there should be a fixed cap on the number of licenses that a State could grant to a single private actor, aiming at avoiding monopolistic behaviours. In addition, the licensing regime should introduce an internationally shared criterion of environmental impact assessments of proposed economic activities, as it has been advocated for on Earth.

Secondly, the basic interest of companies is profit maximization rather than loyalty toward an institutional actor; moreover, private space actors are not inclined to change their economic behaviour toward a sustainable one for the benefit of the space environment *per se* (which is a common good, both legally and economically speaking) if there is no incentive in doing so. Therefore, States should introduce incentives in the form of Pigou subsidies, for private actors who choose and implement sustainable technologies, offering an economically viable alternative. Some examples of financing sustainable behaviour in space have already been put into practice [21], but a definite and widespread environmental turn is needed, especially in light of the presence of massive satellite launches.

Thirdly, taking inspiration from proposals such as the Environmental Remediation Fund by the Nigerian Midstream Downstream Petroleum Regulatory Authority, a dedicated Space Debris Remediation Fund should be established. Participation in such a Fund would be a mandatory condition for launch authorization. This would internalize the cost of cleanup, ensuring that actors contribute to mitigating the debris they create. The Fund's primary duty would be to mitigate the negative impact of space activities when the licensees fail to do so.

To conclude, the increasing privatisation of space, often wrongly depicted as a "democratisation" process, is creating "in-groups" and "out-groups" in the space sector [22]. While this process has brought immense space innovation to the human population, it has failed to take into consideration the need to protect the space environment. Private space activities seem to have been undertaken not for the benefit of "humankind" but for "capitalistkind". Therefore, even if there is some industry acknowledgment of a sustainable use of space (i.e. the Space Safety Coalition group), it is the State's role to implement and enforce sustainable-oriented obligations over space activities. States shall take the lead in the protection of the space environment not only as a common good but as "the province of mankind" as established by the Outer Space Treaty.

Abstract. This paper presents a novel Sliding Mode Control (SMC) control formulated on the special orthogonal group SO(3) for spacecraft attitude control in Very Low Earth Orbit (VLEO). The approach addresses nonlinear rotation geometry and environmental disturbances without the singularities or redundancy of traditional attitude representations. A key innovation is the direct adaptive law that dynamically adjusts sliding manifold parameters, reducing reaching time and guiding the system toward desired dynamics once sliding is established. The controller is validated using the high-fidelity high-precision orbit propagator which accounts for the main environmental disturbances. Preliminary results demonstrate accurate attitude tracking performance in realistic maneuvering scenarios, confirming the controller's effectiveness for the challenging VLEO environment.

Introduction

The increasing interest in space missions operating in Very Low Earth Orbit (VLEO) has driven the development of advanced spacecraft attitude control strategies to ensure reliable performance in this challenging environment. In VLEO, perturbations arising from atmospheric drag become significant, requiring robust controllers to ensure precise pointing despite substantial uncertainties. In this context, a sliding mode–based attitude control law for VLEO spacecraft is proposed, designed to guarantee high pointing accuracy under severe disturbance and uncertainty conditions.

In this work, the attitude of the spacecraft is represented using rotation matrices defined on the Special Orthogonal Group SO(3). This choice provides a unique, global, and nonsingular representation of orientation, avoiding the well-known issues of singularities, redundancy, and normalization constraints associated with Euler angles and quaternions.

Sliding Mode Control (SMC) is a widely used nonlinear control technique, recognized for its robustness to parametric uncertainties and external disturbances. SMC operates through a two-phase mechanism: first, system trajectories are driven in finite time toward a subset of the system states named sliding surface. Then, the trajectories evolve on this surface, yielding reduced-order dynamics with strong disturbance rejection properties.

Recent developments showed that a sliding surface can be defined directly on the Lie algebra associated with $\mathrm{SO}(3)$, thus preserving the intrinsic geometric structure of the attitude representation. This approach ensures global consistency and facilitates a systematic stability analysis [1,2].

Building upon these geometric formulations, this work introduces a time-varying SMC strategy that operates directly on $\mathrm{SO}(3)$. The proposed controller incorporates an adaptive mechanism that continuously adjusts the sliding manifold parameters in real time. During the reaching phase, this adaptation accelerates convergence by reshaping the manifold to align with the evolving system trajectories, while once sliding motion is achieved, the adaptive law steers the manifold toward the desired configuration, ensuring the intended closed-loop behavior [3].

Control framework on SO(3)

Attitude and velocity errors. Let $R(t) \in \mathrm{SO}(3)$ denote the current attitude of a rigid body and let $R_d(t) \in \mathrm{SO}(3)$ be a smooth, time-varying reference attitude. The corresponding body-fixed angular velocities are

$$\Omega = \left(R^\top \dot{R}\right)^\vee,\ \Omega_d = \left(R_d^\top \dot{R}_d\right)^\vee \in R^3, \tag{1}$$

where $(\cdot)^\vee : \mathfrak{so}(3) \to R^3$ is the vee operator and $\mathfrak{so}(3)$ is the Lie algebra of $\mathrm{SO}(3)$. The rotation error and angular velocity error are defined as

$$R_e = R_d^\top R \in \mathrm{SO}(3),\ \ \Omega_e = \Omega - R_e^\top \Omega_d \in R^3. \tag{2}$$

These errors quantify the geometric deviation of the current configuration from the desired trajectory directly on the manifold.

Kinematic Sliding Group and Control Law. Following the geometric sliding-mode design of [2,4], the sliding variable can be defined as follows:

$$s(R_e, \Omega_e) = \Omega_e + \lambda\, \Omega_u(R_e), \qquad \lambda > 0, \tag{3}$$

where log:$\mathrm{SO}(3) \to \mathfrak{so}(3)$ the matrix logarithm mapping the rotation error to the Lie algebra. Here, λ is a time-varying parameter according to the following adaptive law:

$$\dot{\lambda} = \mathrm{Proj}_{\lambda \in \Lambda}\left(-\gamma\, \mathrm{sign}(\langle J\Omega_u, s\rangle) - c\left(\lambda - \bar{\lambda}\right)\right), \tag{4}$$

where $\gamma > 0$ is an adaptation gain, and the Proj operator ensures λ remains in a feasible positive set $\Lambda \in R^+$. The adaptive law exhibits a two-term structure. The first term dominates when the system state is far from the sliding surface, accelerating convergence by dynamically steering the surface toward the system trajectories. As the sliding motion is established, this term vanishes, and the second term ensures that λ smoothly converges toward its desired nominal value $\bar{\lambda}$.

Finally, the control torque is designed as:

$$\tau_u = (J\Omega)^\wedge(\lambda\Omega_u(R_e) - \eta) - J\lambda\dot{\Omega}_u + J\dot{\eta} - Jk_s\langle Js, s\rangle^\sigma s + Jc\left(\lambda - \bar{\lambda}\right)\Omega_u(R_e), \tag{5}$$

where $k_s, > 0$ are control gains, $\bar{\lambda} > 0$ is final value reached by the λ parameter, η is the reference twist to be tracked expressed in the body frame, and $\langle\cdot,\cdot\rangle$ denotes the Euclidean inner product in R^3 and σ is a strictly positive value that varies between 0 and 0.5, in particular the latter

Materials Research Proceedings 69 (2026) 1083-1088 https://doi.org/10.21741/9781644904251-187

yields the discontinuous version of the controller. The resulting closed-loop system achieves almost-global stability on $SO(3)$, with finite-time reachability of the sliding manifold and exponential convergence in a neighborhood of the identity rotation matrix.

Simulation Environment

The spacecraft dynamics and control performance were evaluated using a high-fidelity six-degree-of-freedom numerical simulator developed in MATLAB/Simulink for VLEO operations. The simulator integrates coupled translational and rotational equations of motion in the Earth-Centered Inertial (ECI) reference frame, incorporating Earth's gravitational (EGM2008) and magnetic (IGRF-13) fields, atmospheric disturbances (NRLMSISE00), and solar radiation pressure (SRP). Attitude dynamics employ quaternion representation to avoid singularities, accounting for spacecraft inertia, environmental torques, control actuator torques, and momentum exchange with the reaction wheel (RW) assembly.

The simulation settings are reported in Table 1.

Table 1 Simulation settings including spacecraft properties, control hardware, sensor accuracy, initial conditions and space weather conditions.

	Parameter	Value
Spacecraft Mass Properties	Spacecraft Mass [kg]	29
	Inertia moments (I_{xx}, I_{yy}, I_{zz}) [kg/ m²]	1.117, 1.378, 0.508
	Residual Dipole (per axis) [Am²]	0.05
Control Hardware	RW Configuration	4-wheel pyramidal
	RW Tilt Angle [°]	26.57
	RW Saturation Momentum [Nms]	0.1
	RW Maximum Torque [mNm]	6
	Max. Magnetic Dipole [Am²]	2.6
Sensor Accuracy (1σ)	Position (X, Y) [mm]	1.5
	Position (Z) [mm]	1.25
	Velocity (X, Y) [mm/s]	0.015
	Velocity (Z) [mm/s]	0.03
	Angular Velocity [rad/s]	0.001
Initial Conditions	Epoch [UTC]	March 1, 2025, 10:00:00
	Position (ECI) [km]	[-2342.68, -6253.75, 0]
	Velocity (ECI) [km/s]	[-0.84, 0.32, 7.67]

	Angular Velocity [°]	[0, 0, 0]
Space Weather Conditions (2001 Halloween storm)	$F_{10.7}$ (81-day-averaged, daily)	237
	Ap indeces	142

External disturbances encompass gravity gradient, magnetic, aerodynamic, and SRP torques. To minimize computational overhead, aerodynamic and SRP perturbations are pre-computed and stored in lookup tables rather than evaluated in real-time. The aerodynamic database, generated using the Cercignani–Lampis–Lord (CLL) gas–surface interaction model, combines data from a panel method in the free molecular flow regime [5] and high-fidelity Direct Simulation Monte Carlo (DSMC) runs in SPARTA [6] through a co-Kriging interpolation, increasing the accuracy of the aerodynamic force and torque coefficients parametrized by the angle of attack and sideslip angle relative to the body reference frame (BRF). The SRP database, computed via ray-tracing technique [7], contains force and torque distributions parametrized by solar azimuth and elevation angles with respect to the BRF. During propagation, disturbance forces and torques corresponding to instantaneous attitude configurations are retrieved through cubic spline interpolation of the lookup tables using the current relative orientation angles.

Materials Research Proceedings 69 (2026) 1083-1088 https://doi.org/10.21741/9781644904251-187

Results and Conclusions

The proposed control strategy enabled the spacecraft to successfully execute the complete multi-phase manoeuvre sequence, comprising slew, coast, and fine motion control phases, with smooth and stable dynamic behaviour.

Table 2 summarizes the time intervals associated with each manoeuvre phase, together with the selected convergence thresholds and the corresponding convergence times. The thresholds were chosen to both challenge the controller's performance and satisfy the mission requirements for fine pointing accuracy. The most stringent threshold corresponds to the onset of the fine motion phase, where the highest attitude precision is required.

The control frequency was set equal to the simulation integration step, i.e., 10 Hz, in accordance with the limitations of GNSS-based attitude measurements (here assumed to be available and aiding estimation) and the actuation bandwidth of the reaction wheels. Although higher control update rates are typically feasible, this frequency was assumed appropriate for the considered system constraints.

Despite the agility of the commanded profile, featuring pitch excursions of ±20° and angular rates on the order of 10^{-2} rad/s, the actuator torques remained unsaturated, Fig.2, exhibiting only brief peaks of less couple seconds during rapid slews. Across all phases, attitude convergence was achieved within a few seconds, as can be seen from Fig. 3, with steady-state errors consistently maintained below 0.01°.These results confirm the controller's effectiveness in achieving precise attitude tracking under the simulated dynamic and demanding VLEO conditions.

Abstract We present a ROS 2-based multi-robot control framework for cooperative lunar exploration, designed to support heterogeneous rover teams operating in unstructured planetary environments. The framework integrates a novel gradient-based traversability plugin compatible with the Nav2 navigation stack, enabling terrain-aware path planning tailored to individual rover capabilities. Each agent is equipped with an executive system supporting local autonomy and reactive decision-making, allowing independent operation while enabling coordinated missions through minimal inter-agent communication. The system has been validated in a Gazebo Fortress simulation environment using realistic lunar terrain reconstructions and plausible physical parameters.

Introduction

Planetary rover missions demand robust exploration solutions to address the limitations of single-agent scenarios in mapping, sensing, and resource utilization. The pursuit of heterogeneous teams with differences in locomotion, perception, and scientific payload offers greater mission flexibility and resilience in unpredictable extra-terrestrial scenarios. A scalable, modular robotic framework must address three main challenges: (i) robust perception and localization, (ii) reliable terrain traversability analysis, and (iii) intelligent coordination among agents. Planetary rover exploration missions increasingly require fine-grained, large area mapping to detect resources, study geological features, or deploy distributed sensor networks. Single-robot solutions often fall short in efficiently covering wide areas or collecting multi-perspective data required for accurate modeling [1]. Multi-robot systems [2, 3] represent a significant advancement by enabling cooperative exploration strategies and distributed sensing. However, their success depends on robust navigation and coordination strategies, efficient communication, and intelligent task allocation. Furthermore, mobility in extraterrestrial environments, particularly on the Moon and similar planets, is severely constrained by rough terrain, steep slopes, and obstacles such as craters and boulders. Designing effective navigation systems for rovers thus requires not only precise perception and localization, but also reliable terrain analysis and traversability assessment. This work, conducted within the framework of the Italian project Space It Up (SIU) which promotes innovation in human and robotic space exploration envisions a team of heterogeneous, autonomous rovers cooperating to perform complex planetary missions such as searching for water or rare earth elements. Unlike other systems [4, 5], our approach addresses multiple levels of heterogeneity among agents. This includes not only differences in locomotion capabilities but also variations in scientific instrumentation, with agents equipped with complementary or redundant payloads tailored to specific mission goals. In this paper, we present a multi-robot control framework that enables a team of heterogeneous robots to safely navigate lunar-like environments and

Materials Research Proceedings 69 (2026) 1089-1094 https://doi.org/10.21741/9781644904251-188

collaboratively perform exploration and inspection tasks by leveraging distributed sensing capabilities and diverse locomotion modalities. The framework is built upon the Robot Operating System 2 (ROS2) middleware and integrates a high-fidelity lunar simulation environment based on Gazebo Fortress. Our primary contributions include: (i) the architectural design of a scalable multi-robot system, in which each agent is equipped with an executive system [6] grounded in cognitive control and supervisory attention to support local autonomy and reactive decision-making; (ii) a rover-specific navigation module tailored to challenging lunar terrains; and (iii) a modular simulation environment for testing and validating multi-robot operations in realistic lunar scenarios, supporting a wide range of heterogeneous platforms. This architecture allows agents to perform independent and autonomous exploration tasks, while also enabling coordinated multi-robot missions through minimal and sparse inter-agent communication between the executive systems.

Related Works

Multi-robot exploration and coordination for planetary missions have been extensively investigated in recent years. The CADRE mission [5] introduces a cooperative autonomous distributed robotic exploration framework for lunar surface operations, employing a team of three rovers with dynamic leader election and centralized strategic planning. Although CADRE shares our focus on lunar multi-robot systems, our approach differs in its management of heterogeneity and in the integration of terrain-aware navigation directly within the costmap layer. Building upon the CADRE system, Nayak et al. [8] proposes a map partition-based exploration algorithm that divides unexplored space into non-overlapping regions assigned to individual robots. Similarly, our framework supports coordinated exploration through distributed executive systems, but it emphasizes autonomous single-agent capabilities with minimal inter-agent communication, avoiding the need for periodic centralized replanning. While their method prioritizes exploration efficiency, our approach integrates traversability assessment directly into the navigation planning process. Exploration efficiency is also the central focus of [9], where the authors introduce a distributed grid-based local planner (MGG) combined with a global sparse graph for frontier tracking. In their formulation, navigation constraints are natively incorporated into the overall planning process. In contrast, we adopt a more modular architecture in which 3D navigation is handled by a dedicated layer within the Nav2 costmap framework, allowing seamless integration with existing grid-based planners such as DWB, TEB, or A*.

System Architecture

The proposed architecture supports heterogeneous robotic platforms with diverse locomotion and perception capabilities (see Fig. 1, left). Each agent integrates an executive system that enables local autonomy, cognitive control, and supervisory attention; a perception subsystem supporting localization and mapping; and a planning and navigation module tailored to the locomotion characteristics of planetary rovers. The framework is built upon the ROS 2 middleware, where terrain-aware navigation is achieved through an extension of the standard Nav2 stack to incorporate traversability information into the planning process.

Materials Research Proceedings 69 (2026) 1089-1094 https://doi.org/10.21741/9781644904251-188

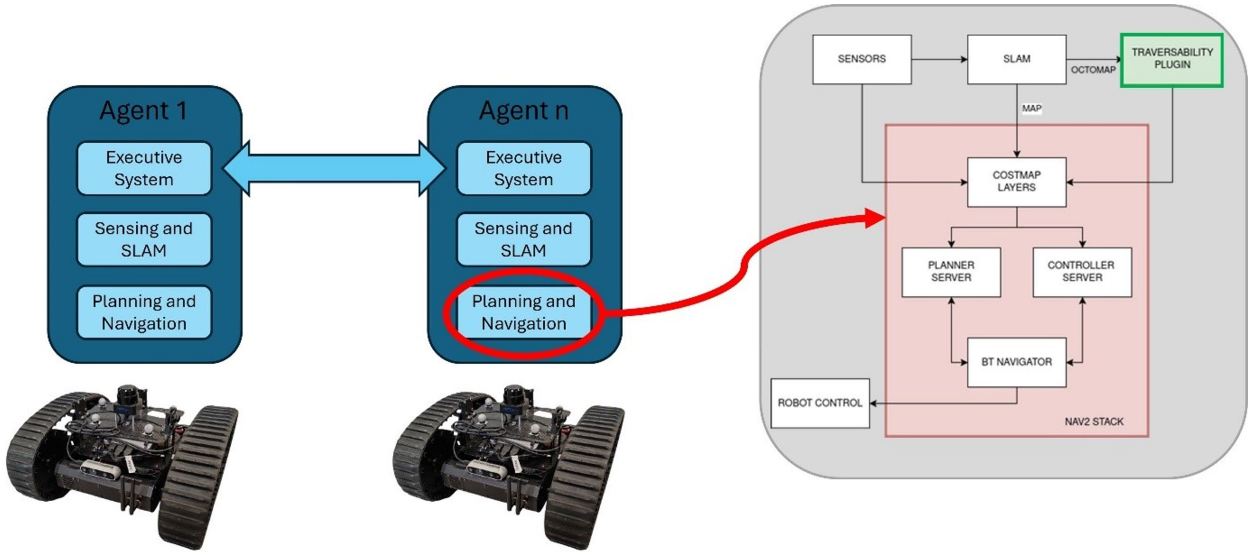

Figure 1: Multi-robot system architecture: executive layer, navigation module, perception subsystem.

Executive and Autonomy Layer. Each robot employs an executive system responsible for local task management and high-level decision making [6]. This system maintains a longterm repository of agent-specific, hierarchically organized skills, each defined by planning constraints such as preconditions and postconditions. Skills can be invoked at runtime and instantiated as hierarchical behaviors within a Working Memory (WM), where they are monitored and executed. When multiple skills or behaviors are simultaneously enabled, attentional regulation mechanisms resolve conflicts over shared resources [12, 13]. This cognitive control process enhances reactivity in dynamic lunar environments and ensures resilience to communication dropouts. Within this executive loop, collaborative multi-agent tasks are dynamically allocated, explicitly incorporating communication behaviors to support interagent synchronization.

Navigation and Traversability

We assume that each agent is equipped with 3D SLAM capabilities based on graph optimization, generating its own map referenced to the ground-station frame. To address terrainaware autonomous navigation in unstructured environments, we developed a gradient-based traversability plugin operating at the Nav2 costmap level. This approach seamlessly integrates with existing navigation stacks without modifying core planning algorithms, enabling terrain-aware path planning tailored to each rover's locomotion capabilities. The plugin processes 3D occupancy data to compute terrain traversability. An elevation map is first constructed by projecting OctoMap voxels onto a 2D grid, where each cell (i, j) stores the maximum elevation $h(i,j) = max_{v \in V_{ij}} z_v$, with V_{ij} being the set of occupied voxels within that cell and z_v the vertical coordinate of voxel v. Local terrain gradients are then computed using centered finite differences:

$$\left.\frac{\partial h}{\partial x}\right|_{i,j} \approx \frac{h(i+1,j) - h(i-1,j)}{2\Delta r}, \qquad \left.\frac{\partial h}{\partial y}\right|_{i,j} \approx \frac{h(i,j+1) - h(i,j-1)}{2\Delta r} \tag{1}$$

where $\partial h/\partial x$ and $\partial h/\partial y$ represent slopes in the horizontal (x) and lateral (y) directions, and Δr is the costmap resolution. The slope angle is computed by combining gradients, and traversability costs are assigned as:

Materials Research Proceedings 69 (2026) 1089-1094 https://doi.org/10.21741/9781644904251-188

$$\theta(i,j) = \arctan\left(\sqrt{\left(\frac{\partial h}{\partial x}\right)^2 + \left(\frac{\partial h}{\partial y}\right)^2}\right), \qquad C(i,j) = \begin{cases} C_{lethal}, & if\ \theta(i,j) \geq \theta_{max} \\ \alpha \cdot \theta(i,j), & otherwise \end{cases} \quad (2)$$

Where $\boldsymbol{\theta_{max}}$ is the rover's maximum traversable slope threshold and α normalizes costs to the Nav2 range $\mathbf{[0, 254]}$ accounting for rover locomotion characteristics. Spatial filtering further reduces computational overhead by processing only OctoMap voxels within a configurable radius of the robot, maintaining efficiency while preserving local terrain representation. The plugin integrates into the costmap pipeline between static/SLAM mapping and obstacle inflation layers, enriching global and local costmaps with terrain-aware traversability values while preserving compatibility with all Nav2-based planners.

Simulation and Validation

To validate the proposed system, a realistic simulation of the lunar surface was developed, based on reconstructions of the Apollo 14 landing site and plausible physical parameters. The Gazebo Fortress-based environment supports synchronized multi-robot scenarios and includes a variety of terrain features such as craters, slopes, and boulders (see Fig. 2). The framework provides full configurability for defining the number and initial placement of agents, the types of sensors they are equipped with, and the environment physical parameters (e.g., Earth or lunar gravity).

Figure 2: Snapshots of the simulated lunar environment, with representation of the perceived terrain and traversability costmap (upper-right window).

Experimental Workflow. To evaluate our system, we designed an experimental scenario inspired by the SIU case study, in which a team of two heterogeneous robots is tasked with exploring a designated area in search of traces of rare earth elements (REEs). Specifically, the first rover is equipped with a spectrometer (e.g., multispectral or gamma-ray) to remotely detect candidate regions where REEs may be present, while the second rover carries a hyperspectral camera to perform close-range analysis of these candidate areas. The experiments proceed as follows. At the beginning of each trial, the two robots are deployed in the virtual lunar environment at random initial poses, while n target spots are randomly distributed across the terrain. The robots are initially unaware of the positions of these target spots, which become detectable only when they fall within the sensing range of the spectrometer. The first rover is responsible for sweeping the area to identify potential target spots, whereas the second rover must approach and closely scan each detected location. The overall objective is to safely explore the area, identifying and analysing all target spots. An initial set of proof-of-concept trials was performed. Preliminary results,

obtained in scenarios covering approximately 50 m^2 and involving a small number of target sites ($n \in [3, 9]$), show that the robot team can successfully navigate the environment, avoid obstacle such as craters and rocks, and cooperatively detect and analyse the designated targets.

Conclusion

In this paper, we proposed a scalable multi-robot strategy that emphasizes heterogeneity and modularity to enable more robust and efficient lunar exploration. The system integrates a terrain-aware navigation module and an executive layer supporting local autonomy and cooperative behaviors through minimal inter-agent communication. The framework has been validated in a realistic lunar simulation environment, using plausible physical parameters and high-fidelity 3D reconstructions of the lunar surface, demonstrating effective performance across different rover configurations and terrains. Current efforts focus on validating the system on physical rovers and enhancing autonomous capabilities for multi-robot planetary exploration.

Keywords: Active Vibration Control, Offset Piezo Stack Actuators, H∞ Control, Finite Element Analysis, Eddy Current Sensor, Tip Deflection Measurement

Abstract. This paper presents an integrated active vibration control (AVC) and structural health monitoring (SHM) framework for flexible spacecraft panels using offset piezoelectric stack actuators (OPSA). A three-dimensional ANSYS finite-element model of a hub–panel assembly with eccentric OPSA mounting is reduced to a low-order state-space model retaining the first two bending modes. Based on this model, a mixed-sensitivity H_∞ controller is designed for robust vibration suppression and compared with an LQR baseline. For SHM, root delamination is represented as an equivalent stiffness loss at the clamp over a 0–40% damage range, and damage-sensitive features are extracted from the closed-loop impulse response, including modal frequency drops, RMS control voltage, residual tip vibration, and settling time. A physics-informed Gaussian process regressor trained on 200 virtual experiments accurately estimates the damage parameter, achieving $R^2 \approx 1.000$and an RMSE of about 0.25% damage. Over the investigated range, RMS control voltage increases from 48.2 V to 144.6 V, while residual tip amplitude rises from 0.315 mm to 0.633 mm, confirming strong monotonic sensitivity to structural degradation. The results demonstrate that the OPSA–H_∞ loop can provide both robust vibration suppression and a dual-use sensing channel for quantitative damage estimation without additional dedicated SHM hardware.

Introduction

Prior work has demonstrated the effectiveness of offset piezoelectric stack actuators (OPSA) for active damping of large flexible structures, and several authors have employed LQR, PPF, μ-synthesis, and smart-device concepts to suppress vibrations of solar arrays and similar appendages [1, 2, 3]. Recent studies further address optimal actuator/sensor placement and controller design using genetic algorithms and H∞ -based criteria [4, 5, 6]. Although well-established techniques including LQR, positive position feedback (PPF), and μ-synthesis have been widely applied, these approaches primarily focus on control performance, with comparatively little attention devoted to simultaneous structural health monitoring (SHM).

This paper proposes a compact dual-use framework in which an H_∞controller developed for active vibration suppression is also utilized for structural health monitoring of a flexible spacecraft panel with OPSA actuation. The main contribution is the integration of robust control and damage estimation within the same hardware and closed-loop architecture, allowing both frequency-based and control-derived features to be exploited for monitoring without additional dedicated SHM sensors. The study is limited to finite-element-based numerical validation, but it establishes a concise proof of concept for future experimental implementation and controller adaptation based on the estimated damage state.

Mathematical Modeling

The hub–flexible panel idealized as cantilever shown in Fig. 1. Offset piezoelectric stack actuator (OPSA) is integrated on beam. The cantilever panel is modeled in ANSYS using SOLID186 elements for the aluminum structure and SOLID226 elements for the OPSA stacks. A reduced-order state-space model retaining the first two bending modes is derived from the FEA. The cantilever has dimensions of 1.1×0.25×0.002 m, and is discretized using a uniform mesh size of 5 mm.

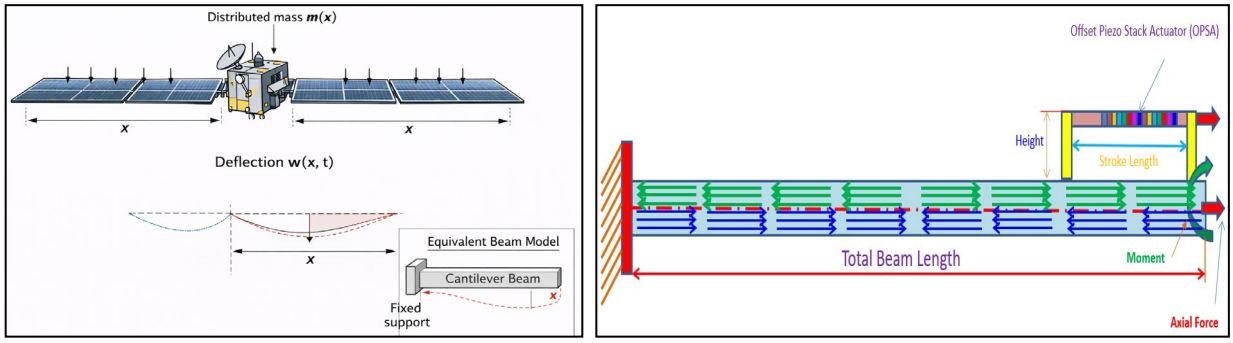

Figure. 1. Schematic of the flexible cantilever spacecraft panel with OPSA actuation and tip-response measurement used for integrated vibration control and damage monitoring

We model the coupled piezo-actuated structure using the FE formulation [3]:

$$M\ddot{u} + C\dot{u} + K_{\phi\phi}u + K_{u\phi}\phi = F + B_u v \tag{1}$$

where $\mathbf{M}, \mathbf{C}, \boldsymbol{K}$ are mass, damping and elastic stiffness matrices; $\mathbf{K}_{u\phi}$ piezoelectric coupling; $\mathbf{K}_{\phi\phi}$ dielectric stiffness; $\mathbf{u}$ structural DOFs; $\mathbf{F}_m$mechanical loads; v actuator voltages; ϕ denotes the lectric potential degree of freedom (DOFs) of the piezoelectric stacks; and $\mathbf{B}_u$ locate loads and actuators.

Root Delamination Modeling & Active Vibration Control (AVC)-Assisted Structural Health Monitoring (SHM)

Root delamination is modeled as an equivalent reduction in bending stiffness at the clamped end of the cantilever panel. A scalar damage parameter $d \in [0,0.4]$ is introduced, where $d = 0$ represents the pristine (healthy) structure and $d = 0.4$ corresponds to a 40% stiffness reduction. Root damage is therefore represented through a compact stiffness-loss parameter that preserves the dominant effect of localized delamination on the low-order bending dynamics. Since the present control problem is focused on the dominant flexible response, the full finite-element model is projected onto a reduced modal basis retaining the first two bending modes. This parameter is calibrated to reflect mode-dependent stiffness degradation, consistent with the characteristic behavior of flexible structures under localized root damage.

The integration of the H_∞ active vibration control (AVC) system with structural health monitoring (SHM) establishes a novel dual-use framework for non-invasive damage detection. By exploiting control-derived features—such as modal frequency shifts and actuator voltage demands—the damage parameter d can be accurately estimated using the existing control hardware alone. This approach provides a compact and computationally efficient damage indicator, eliminating the requirement for additional dedicated sensors and thereby reducing overall system cost and complexity.

Materials Research Proceedings 69 (2026) 1095-1100 https://doi.org/10.21741/9781644904251-189

Physics-Informed Damage Estimation Using Gaussian Process Regression

To estimate the damage level, we trained a Gaussian Process Regressor (GPR) on a dataset comprising control-derived features from the H_∞ loop. We define damage-sensitive SHM features as the first two frequency drops ($\triangle f_1$, $\triangle f_2$) , RMS control voltage V_{RMS} , residual tip displacement x_{res}, and settling time T_s, all extracted from the time-domain closed-loop response to a standardized impulse.

Mixed-sensitivity $\mathbf{H}_\infty$ Control Design

The OPSA-actuated panel, reduced to the first two bending modes, is written in the standard generalized plant form

$$\begin{bmatrix}\dot{x}\\ z\\ y\end{bmatrix} = \begin{bmatrix}A & B_1 & B_2\\ C_1 & D_{11} & D_{12}\\ C_2 & D_{21} & 0\end{bmatrix}\begin{bmatrix}x\\ w\\ u\end{bmatrix} \tag{2}$$

where x is the modal state, u is the OPSA control voltage, w collects exogenous inputs (reference and base disturbance), z stacks the performance outputs, and y is the measured tip signal. The matrices C_1, D_{11}, D_{12} embed the mixed-sensitivity weights W_1, W_2, W_3 so that

$$z \triangleq \begin{bmatrix}W_1(s)e\\ W_2(s)u\\ W_3(s)y\end{bmatrix},\ e = r - y \tag{3}$$

with r the tip reference, $S(s)$ and $T(s)$ the sensitivity and complementary sensitivity of the closed loop, and W_1, W_2, W_3 shaping vibration suppression, control effort, and high-frequency robustness, respectively.

A dynamic output-feedback controller is as in Eq. 4;

$$K(s):\ \begin{cases}\dot{x}_K = A_K x_K + B_K y,\\ u = C_K x_K + D_K y,\end{cases} \tag{4}$$

is sought such that the lower linear–fractional transformation $T_{zw}(s) = F_l(G, K)$ from w to z has bounded induced L2 gain,

$$\|T_{zw}(s)\|_\infty = \sup_{w\epsilon\mathbb{R}} \bar{\sigma}\left(\left(T_{zw}(jw)\right)\right) < \gamma \tag{5}$$

where $\bar{\sigma}(.)$ denotes the maximum singular value. In terms of the closed-loop maps

$$S(s) = (I + K(s)P(s))^{-1}, \qquad T(s) = I - S(s) \tag{6}$$

with $P(s)$ the nominal plant from u to y, this corresponds to the mixed-sensitivity optimization.

$$\left\|\begin{bmatrix}W_1(s)e\\ W_2(s)u\\ W_3(s)y\end{bmatrix}\right\|_\infty < \gamma \tag{7}$$

which enforces low sensitivity in the modal band, bounded OPSA voltages, and rapid loop roll-off at high frequency, jointly limiting spillover into truncated modes. The resulting H_∞controller

Materials Research Proceedings 69 (2026) 1095-1100 https://doi.org/10.21741/9781644904251-189

is computed using standard Riccati-based synthesis and provides robust performance across the family of plants generated by the root-stiffness (damage) parameter *d*.

In the present design, the mixed-sensitivity H_∞ framework is used to balance three objectives simultaneously: suppression of low-frequency flexible-mode vibration, limitation of actuator voltage demand, and attenuation of high-frequency amplification associated with truncated dynamics. The selected weighting functions therefore shape the closed-loop response to achieve robust disturbance rejection near the dominant bending modes while avoiding excessive control effort and spillover. This makes the controller suitable for flexible spacecraft structures, where reduced-order modeling and uncertainty in higher modes are unavoidable.

Integrated Results and Discussion

As shown in Fig. 2, the Bode diagram for Mode 1 indicates that both controllers substantially reduce the open-loop resonant peak, but the mixed-sensitivity H∞ design achieves the largest attenuation and a more favorable phase roll-off than LQR, implying stronger modal damping and improved phase margin. The corresponding Nyquist plot confirms closed-loop stability for both controllers, while the H∞ locus is more contracted and remains further from the-1 +0j point than the LQR curve, demonstrating superior robustness to gain and modeling uncer-tainties.

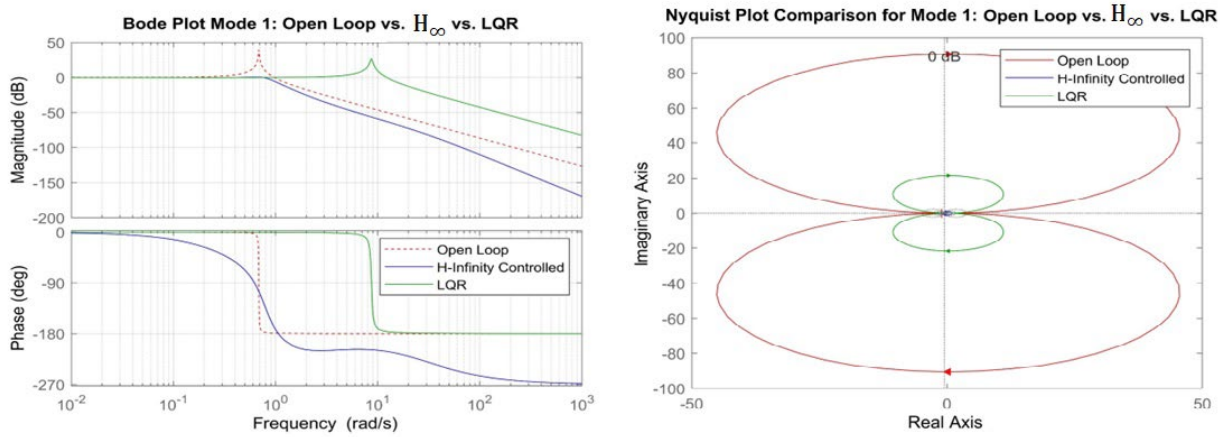

Figure. 2. Bode and Nyquist comparisons of the closed-loop response for the H∞ and LQR controllers, illustrating improved robustness and attenuation near the dominant flexible mode.

Table 1: Actual and predicted damage levels obtained from Gaussian process regression using selected vibration and control features.

Damage [%]	$\triangle f_1$ [Hz]	$\triangle f_2$ [Hz]	RMS Voltage [V]	Residual Amplitude [mm]	Settling Time (s)	Predicted Damage (%)
0	0	0	48.2	0.315	4.20	0.02
10	5.13	6.73	60.5	0.363	4.85	9.98
20	10.56	13.98	77.9	0.426	5.69	20.20
30	16.33	21.90	103.8	0.511	6.81	30.90
40	22.54	30.72	144.6	0.633	8.4	39.90

Table 1 and Fig. 3 jointly characterize that as the damage level increases from 0% to 40% stiffness loss, the first and second natural frequencies exhibit progressively larger drops, with the second mode consistently more affected, reflecting its higher sensitivity to root stiffness changes. In parallel, the RMS control voltage, residual tip amplitude, and settling time all increase monotonically, showing that the H_∞ controller must supply higher effort to stabilise a

Materials Research Proceedings 69 (2026) 1095-1100 https://doi.org/10.21741/9781644904251-189

progressively softer structure. The dual-feature SHM index constructed from RMS voltage and residual vibration follows the same smooth trend, further confirming the damage sensitivity of control-derived indicators.

The Gaussian-process regressor trained on these features reconstructs the scalar damage parameter with excellent accuracy, achieving a test-set coefficient of determination $R^2 \approx 1.000$ and a root-mean-square error of about 0.25% damage over the full 0–40% range. An ablation study shows that a control-only feature set (RMS voltage, residual vibration, settling time) attains nearly the same performance as the frequency-only set ($\triangle f_1$,$\triangle f_2$) confirming the strong monitoring value of control-derived features. A complementary boosted-tree feature-importance analysis identifies the fundamental frequency drop $\triangle f_1$ as the dominant predictor, in line with classical SHM, while the control-based features supply redundant but complementary information that is expected to become more valuable in experimental conditions with sensor noise and modelling errors. Overall, these results confirm the feasibility of the proposed unified AVC–SHM framework.

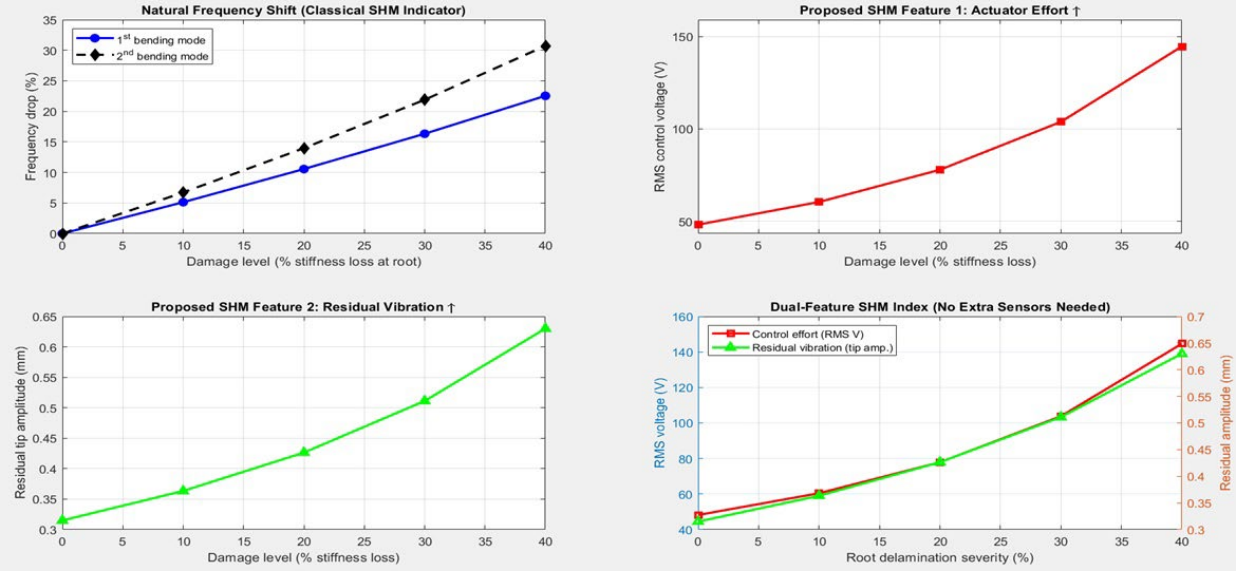

Figure. 3. Variation of frequency-based and control-derived features with increasing damage level, showing their monotonic sensitivity to root stiffness degradation.

The observed closed-loop trends are also consistent with the underlying structural mechanics. As root stiffness degrades, the effective rotational constraint at the clamped end weakens, reducing modal stiffness and increasing the dynamic compliance of the panel. This explains the progressive reduction in modal frequencies, together with the simultaneous increase in residual tip vibration and settling time. From the control viewpoint, the H∞ compensator must inject greater actuator voltage to maintain comparable vibration suppression as the structure becomes softer, which is why the RMS control effort rises monotonically with damage severity. The stronger sensitivity of the second bending mode further suggests that higher-order flexible dynamics are more influenced by localized root degradation, making Δf_2 a particularly informative damage feature.

These results also highlight the practical value of the proposed dual-use framework. While frequency-based indicators remain effective, the control-derived quantities $(V_{\mathrm{RMS}}, x_{\mathrm{res}}, T_s)$are directly available from the closed-loop response and therefore offer a convenient monitoring channel without dedicated additional SHM hardware. This is particularly attractive for spacecraft applications, where extra sensing hardware increases mass and integration complexity. The present results are based on finite-element-derived virtual experiments and should therefore be interpreted

as proof-of-concept performance prior to future experimental validation under broader uncertainty conditions.

Conclusion

This paper presented an integrated framework for active vibration control and structural health monitoring of flexible spacecraft panels using offset piezoelectric stack actuators. A reduced-order finite-element model was used to design a mixed-sensitivity H_∞controller, whose closed-loop performance showed improved robustness and stronger attenuation than an LQR benchmark around the dominant flexible modes. In addition, frequency-based and control-derived features extracted from the same closed-loop response exhibited monotonic sensitivity to increasing stiffness degradation, enabling accurate damage estimation through Gaussian process regression. These results support the feasibility of combining vibration suppression and damage monitoring within a single smart structural framework. The present study is limited to numerical validation, and future work will focus on experimental implementation and more realistic uncertainty conditions.

Keywords: Nonlinear Orbit Control, Hardware-In-The-Loop, FPGA

Abstract. This study presents the implementation and Hardware-In-The-Loop testing of a Lyapunov-based nonlinear orbit control algorithm. The controller, formulated in modified equinoctial elements, compensates for perturbations associated with aerodynamic drag and Earth oblateness, assuming steerable and throttlable low-thrust propulsion. The algorithm employs a scaling method to preserve numerical precision within limited memory resources. After implementation on an Artix-7 FPGA, a Monte Carlo Hardware-In-The-Loop campaign is performed simulating a LEO-GEO transfer with uncertain orbital parameters at departure. The results show good agreement with those from numerical simulations, which encourages further investigation of FPGA-based nonlinear control for satellite missions.

Introduction

Nonlinear orbit control techniques are attracting growing interest, but their use, particularly in low-cost missions based on the extensive use of commercial off-the-shelf (COTS) components, still raises some concerns. These are usually driven by (i) the greater complexity of implementing the nonlinear law, compared with the linear one, on flight hardware and (ii) the possibility of unstable control when processing low-resolution fixed-point measurements and parameters [1].

In this work, a Lyapunov-based nonlinear orbit control, extensively tested through double-precision numerical simulations in the past, is implemented on a commercial-grade Field Programmable Gate Array (FPGA) and tested through a Hardware-In-The-Loop (HiL) analysis. In particular, the feedback law is designed to compensate for aerodynamic drag and gravitational perturbations due to Earth oblateness, and provides real-time orbit control for a satellite equipped with a steerable and throttleable propulsion system [2].

After implementation on FPGA, the feedback law gains are selected for the case study of a non-coplanar LEO-GEO transfer. A HiL Monte Carlo campaign is performed, and the results are compared with those obtained from numerical simulations.

Nonlinear orbit control

Orbit dynamics is modeled using the modified equinoctial elements (MEE), which avoid singularities occurring when the orbit eccentricity or inclination approach zero, defined as [3]

Materials Research Proceedings 69 (2026) 1101-1106 https://doi.org/10.21741/9781644904251-190

$$\begin{cases} p = a(1-e^2) \\ l = e\cos(\omega+\Omega) \\ m = e\sin(\omega+\Omega) \\ n = \tan(i/2)\cos\Omega \\ s = \tan(i/2)\sin\Omega \\ q = \Omega+\omega+\nu \end{cases} \tag{1}$$

where a, e, ω, Ω, i and ν are the classical orbital elements semi-major axis, eccentricity, argument of pericenter, right ascension of the ascending node (RAAN), inclination, and true anomaly.

Setting $\boldsymbol{z} = [x_1\ x_2\ x_3\ x_4\ x_5]^T = [p\ l\ m\ n\ s]^T$, the dynamics equations of motion can be represented in the following compact form [2]

$$\dot{\boldsymbol{z}} = G\boldsymbol{a} = \sqrt{\frac{x_1}{\mu_E}} \begin{bmatrix} 0 & 2\frac{x_1}{\eta} & 0 \\ sinx_6 & \frac{(\eta+1)cosx_6+x_2}{\eta} & -x_3\frac{x_4sinx_6-x_5cosx_6}{\eta} \\ -cosx_6 & \frac{(\eta+1)sinx_6+x_2}{\eta} & -x_2\frac{x_4sinx_6-x_5cosx_6}{\eta} \\ 0 & 0 & \frac{1+x_4^2+x_5^2}{2\eta}cosx_6 \\ 0 & 0 & \frac{1+x_4^2+x_5^2}{2\eta}sinx_6 \end{bmatrix} \boldsymbol{a}$$

$$\dot{x}_6 = \sqrt{\frac{\mu_E}{x_1^3}}(1+x_2cosx_6+x_3sinx_6)^2 + \sqrt{\frac{x_1}{\mu_E}}\frac{x_4sinx_6-x_5cosx_6}{1+x_2cosx_6+x_3sinx_6}a_h \tag{2}$$

$$\dot{x}_7 = -\frac{a_T}{c}x_7$$

where $\mu_E = 3.986 \cdot 10^5$ km^3/s^2 is the Earth gravitational parameter, $\eta = 1 + l\cos q + m\sin q$, $x_7 = m(t)/m(t_0)$ is the mass parameter, c is the characteristic velocity of the propulsion system, and $\boldsymbol{a} = \boldsymbol{a_T} + \boldsymbol{a_P} = [a_r\ a_\theta\ a_h]^T$ is the vector collecting the thrust ($\boldsymbol{a_T}$) and perturbation ($\boldsymbol{a_P}$) accelerations acting on the spacecraft, expressed in the local-vertical local-horizontal (LVLH) reference frame.

In the following analysis, the perturbation acceleration term includes the effect associated with (i) the main zonal harmonics term (J_2) of the Earth gravitational field and (ii) the aerodynamic drag, leading to

$$\begin{cases} a_r = \frac{3}{2}\frac{\mu_E}{(p/\eta)^4}J_2(-1+3\sin^2\nu\sin^2 i) - \frac{1}{2}\frac{\rho S c_D}{m(t_0)x_7}v_R\sqrt{\frac{\mu_E}{p}}e\sin\nu \\ a_\theta = -3\frac{\mu_E}{(p/\eta)^4}J_2(\sin\nu\sin^2 i\cos\nu) - \frac{1}{2}\frac{\rho S c_D}{m(t_0)x_7}v_R\left[\sqrt{\frac{\mu_E}{p}}(1+e\cos\nu) - \omega_E\frac{p}{\eta}\cos L\cos\zeta\right] \\ a_h = -3\frac{\mu_E}{(p/\eta)^4}J_2(\sin\nu\sin i\cos i) - \frac{1}{2}\frac{\rho S c_D}{m(t_0)x_7}v_R\omega_E\frac{p}{\eta}\cos L\sin\zeta \end{cases} \tag{3}$$

where $\boldsymbol{v_R} = \left[\sqrt{\frac{\mu_E}{p}}esin\nu\hat{r}\ \sqrt{\frac{\mu_E}{p}}(1+ecos\nu) - \omega_E\frac{p}{\eta}cosLcos\zeta\hat{\theta}\ \omega_E\frac{p}{\eta}cosLsin\zeta\hat{h}\right]^T$ is the relative velocity of the spacecraft with respect to the atmosphere rotating with the Earth at the rate $\omega_E = \frac{2\pi}{86164}$ s^{-1}, $\sin\zeta = \frac{\cos i}{\cos L}$, and L is the latitude.

The thrust acceleration is represented by the following feedback law derived in Ref. [2], obtained for the state vector $\boldsymbol{x} = [\boldsymbol{z}^T\ x_6\ x_7]^T$ and the control vector $\boldsymbol{u}_T = T/m(t_0)$, where T is the

Materials Research Proceedings 69 (2026) 1101-1106 https://doi.org/10.21741/9781644904251-190

thrust. The goal of the control is to set to zero the following vector function $\psi(\boldsymbol{z}) = [x_1 - p_d = 0\ x_2^2 + x_3^2 - e_d^2 = 0\ x_4^2 + x_5^2 - tan^2(i_d/2) = 0]^T$, hence establishing the desired orbital elements p_d, e_d and i_d

$$\boldsymbol{u}_T = -u_T^{max} \frac{x_7(\boldsymbol{b}+\boldsymbol{a_P})}{max(u_T^{max}, x_7\|\boldsymbol{b}+\boldsymbol{a_P}\|)} \tag{4}$$

With

$$\begin{cases} b_1 = \frac{2}{\eta}\sqrt{\frac{x_1}{\mu_E}}[k_1 x_1(x_1 - p_d) + k_2(x_2^2 + x_3^2 - e_d^2)(\eta^2 + x_2^2 + x_3^2 - 1)] \\ b_2 = -2k_2\sqrt{\frac{x_1}{\mu_E}}(x_3 cosx_6 - x_2 sinx_6)(x_2^2 + x_3^2 - e_d^2) \\ b_3 = \frac{k_3}{\eta}\sqrt{\frac{x_1}{\mu_E}}(x_4 cosx_6 + x_5 sinx_6)\left(x_4^2 + x_5^2 - tan^2(i_d/2)\right)(x_4^2 + x_5^2 + 1) \end{cases} \tag{5}$$

where the gains k_1, k_2 and k_3 are selected by the user.

Design of the Hardware-In-The-Loop test environment

A HiL setup, developed in Simulink, was used to test the nonlinear feedback law after implementation on flight hardware. For the analyses, the AMD Artix-7 XC7A35T-1CPG236C FPGA, integrated into the BASYS3 development board, was selected. The testbed, shown schematically in Figure 1, includes a host PC running a Simulink model connected to the FPGA: orbit propagation, using Eq. 2 and conversion of MEE to classical orbital elements, is performed in Simulink, while $\mathbf{u}_T$ is calculated by the FPGA and injected into the Simulink model via a JTAG interface.

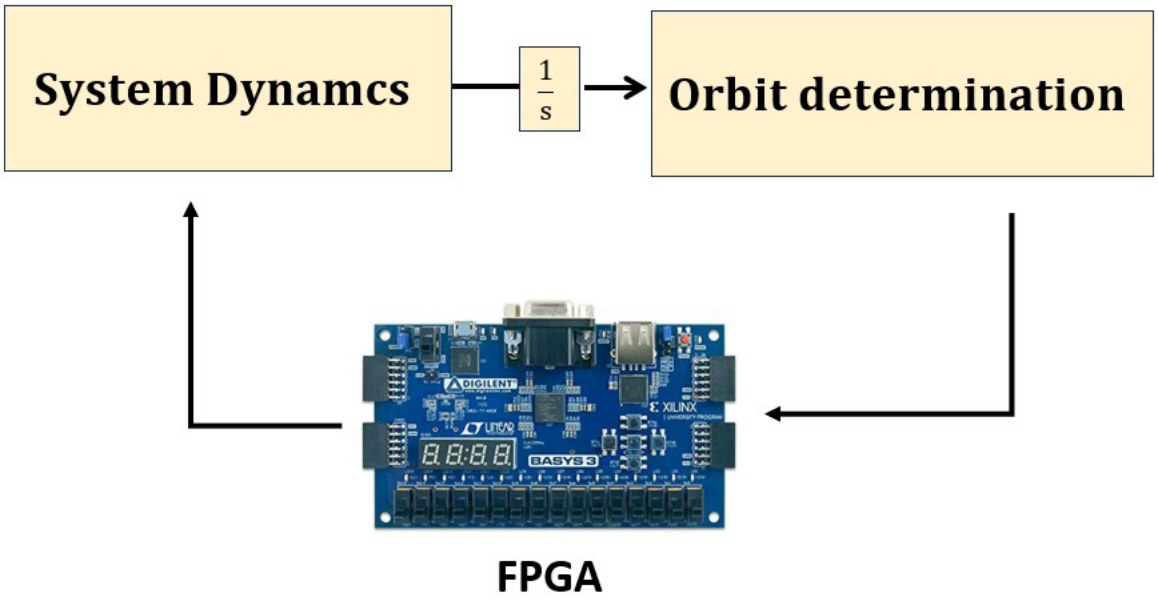

Figure 1: Scheme of the Hardware-In-The-Loop testbed including the AMD Artix-7 FPGA within the BASYS3 development board

Eq. 3-5 were converted to VHDL language using Simulink blocks of the *HDL Compiler* toolbox. The variables and parameters in the above-mentioned equations were converted from

Materials Research Proceedings 69 (2026) 1101-1106 https://doi.org/10.21741/9781644904251-190

floating-point double precision to fixed-point after selecting a word length and a resolution, defining the total number of bits used to represent a number and the fraction of the word length representing decimal values. Since the word length is limited by the memory resources available on the FPGA, the resolution cannot be arbitrarily selected, but must be determined from a tradeoff analysis.

The implementation of the nonlinear feedback law on the FPGA imposed a maximum word length of 18 bits. To increase the resolution for a fixed word length, the maximum representable value must be reduced and this was effectively obtained by scaling the variables and parameters in Eqs. 3-5. Distances and time were scaled by the factors DU$= R_E^{-1}$, where $R_E = 6378.136$ km is the mean Earth equatorial radius, and TU$= 806.8^{-1}$ 1/s, selected so that $\mu_E = 1$ DU^3/TU^2. Furthermore, noting that the variables $|x_i| < 1$ for $i = 2,3,4,5$, it is possible to set $k_s = \sqrt{2^{(\text{wordlength}-\text{resolution}-1)}} \geq 1$ and introduce the scaled factors

$$\begin{cases} \tilde{k}_i = \frac{k_i}{k_s} & i = 2,3 \\ \tilde{x}_i = x_i\sqrt{k_s} & i = 2,3,4,5 \end{cases} \tag{6}$$

To rearrange Eq. 5 as follows

$$\begin{cases} b_1 = \frac{2}{\eta}\sqrt{\frac{x_1}{\mu_E}}\left[k_1 x_1(x_1 - p_d) + \tilde{k}_2\left(\tilde{x}_2^2 + \tilde{x}_3^2 - \left(\sqrt{k_s}e_d\right)^2\right)(\eta^2 + x_2^2 + x_3^2 - 1)\right] \\ b_2 = -2\tilde{k}_2\sqrt{\frac{x_1}{\mu_E}}(x_3\cos x_6 - x_2\sin x_6)\left(\tilde{x}_2^2 + \tilde{x}_3^2 - \left(\sqrt{k_s}e_d\right)^2\right) \\ b_3 = \frac{\tilde{k}_3}{\eta}\sqrt{\frac{x_1}{\mu_E}}(x_4\cos x_6 + x_5\sin x_6)\left(\tilde{x}_4^2 + \tilde{x}_5^2 - \left(\sqrt{k_s}\tan(i_d/2)\right)^2\right)(x_4^2 + x_5^2 + 1) \end{cases} \tag{7}$$

Such that values of k_2 and k_3 larger than $2^{(\text{wordlength}-\text{resolution}-1)}$ and values of $|x_i| \leq 2^{-\text{resolution}}$, for $i = 2,3,4,5$, can be represented without affecting $\boldsymbol{b}$.

Together with the constraints on word length and resolution, the inputs to the FPGA from the Simulink model (i.e. MEE, x_i, $\tilde{x}_i$, etc.) have to be delivered at a constant frequency, actually limited by the sampling and processing frequencies of measurement sensors and orbit-determination devices that typically work in the range 1–100 Hz.

Monte Carlo Hardware-In-The-Loop test campaign

The FPGA implementation of the nonlinear feedback law was tested through a Monte Carlo (MC) HiL campaign, simulating an orbital transfer from a low-Earth orbit (LEO) to a geostationary orbit (GEO). The orbital elements for the two orbits are reported in Table 1, where the uncertainties for the LEO elements are selected as twice the orbit injection error of the Vega-C launch vehicle [4]. The selected satellite parameters are those of an ordinary 6U CubeSat, with wet mass at launch $m_0 = 15$ kg, $c_D = 2.2$, $A = 0.06$ m^2, equipped with a propulsion system providing a thrust $T = 5$ mN with $c = 32.361$ km/s [5].

Table 1: Initial and target orbit parameters

Orbit	p [km]	e	i [deg]
LEO	6778 ± 30	(5 ± 2.4)·10^-3	30 ± 0.3
GEO	42164	5·10^-3	0.5

Materials Research Proceedings 69 (2026) 1101-1106 https://doi.org/10.21741/9781644904251-190

According to Ref. [2], the gains k_2 and k_3, appropriately scaled for the thrust level considered in this study, should be approximately equal to 300, hence requiring 9 bits to be represented. It can be noted that the next larger value to be represented is $p_d = 42164$ km ≈ 6.6 DU, requiring just 3 bits for the integer part. Since a resolution of 10 bits is required to represent e and i, then the solution is not compatible with the maximum word length of 18 bits. To solve this issue, the scaling gain was selected by determining the minimum number of bits necessary to represent $\log_2(\sqrt{300}) < 5$, producing $k_s = 2^5 = 32$ and resulting in a resolution of $2^{-12} \approx 2.44 \cdot 10^{-4}$, compatible with the representation of e and i for the problem at hand.

A MC HiL campaign of 100 simulations was run by randomly selecting the initial orbital elements from Table 1 and setting a sampling frequency of 10 Hz. Simulink rates are treated as actual hardware rates with a target clock frequency of 100 MHz. The final time for the simulations is fixed to 15000 TU $\approx$ 140 days. The evolution in time for p, e, and i are shown in Figures 2–4. The mean error and standard deviation, computed using the values of p, i, and e over the last 1 TU are reported in Table 2, together with those obtained from the numerical simulations (64-bit double precision) run entirely in Simulink on the host PC.

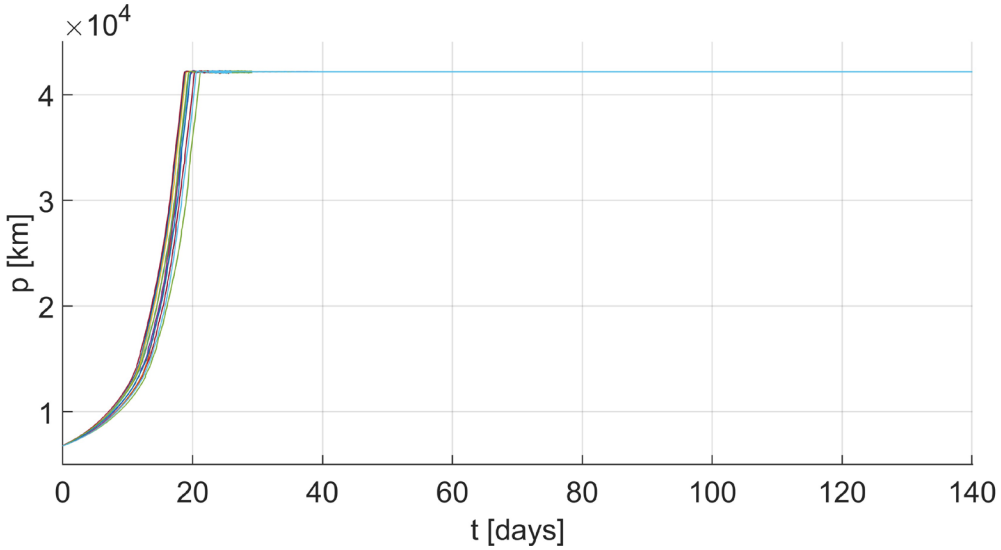

Figure 2: Results of the MC HiL campaign: p

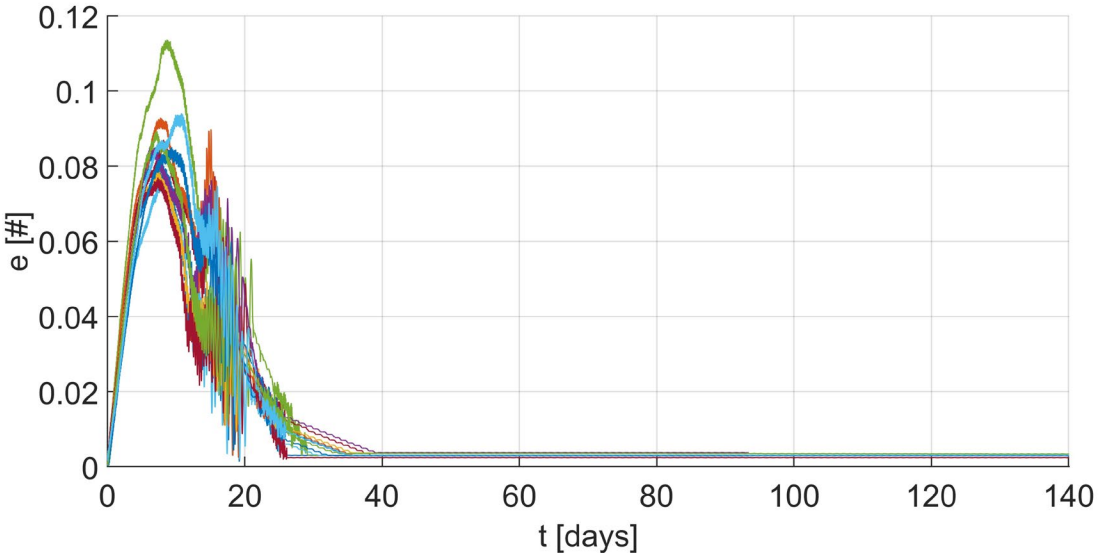

Figure 3: Results of the MC HiL campaign: e

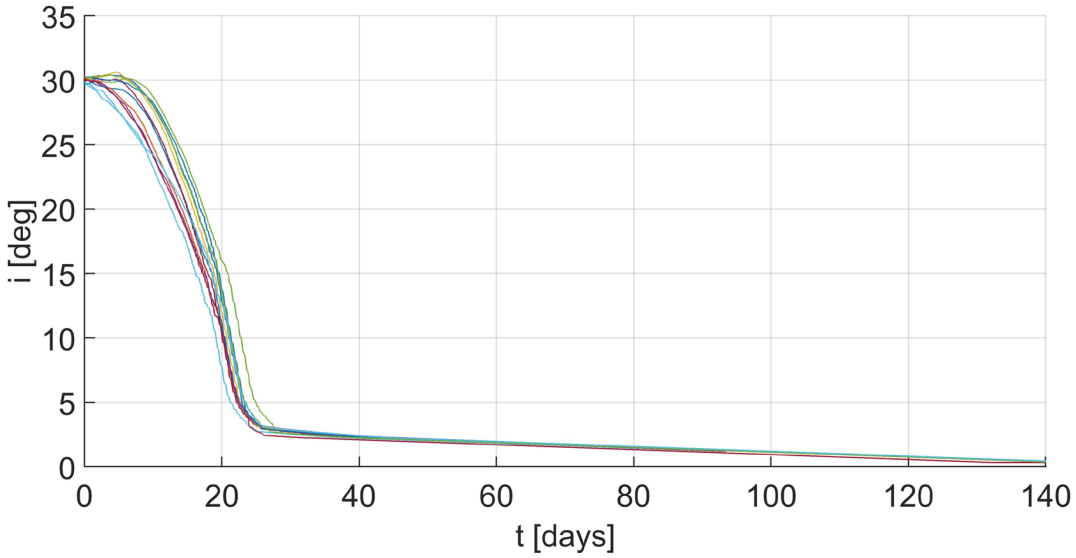

Figure 4: Results of the MC HiL campaign: i

Table 2: Mean error and standard deviation for the numerical and HiL simulations

Parameter	$p_f - p_d$ [km]	$e_f - e_d$	$i_f - i_d$ [deg]
Mean value MC numerical simulations	0.49	$1.17 \cdot 10^{-3}$	0.21
Mean value MC HiL simulations	0.68	$2.06 \cdot 10^{-3}$	0.33
St. deviation MC numerical simulations	0.54	$2.30 \cdot 10^{-4}$	0.003
St. deviation MC HiL simulations	0.71	$5.52 \cdot 10^{-4}$	0.031

Final remarks

The results of the MC HiL campaign show good agreement with those obtained from numerical simulations. In particular, the study demonstrates that the adequate selection of scaling factors allows preservation of the stability of the nonlinear feedback control law and suggests that it is suitable for use in future missions.

Abstract. In this work a tensor-algebra formulation of differential zero-sum games is applied to determine optimal control policies for multiple satellites performing simultaneous in-orbit servicing with collision avoidance constraints.

Introduction

Since the late 1980s, the term in-orbit servicing (IOS) has referred to a set of proximity or contact operations performed between satellites or their appendages to achieve specific mission objectives, such as assembly, refurbishing, debris removal and recognition [1]. As these operations become more complex and involve a growing number of spacecraft, the need to implement guidance and control laws capable of ensuring an adequate degree of autonomy and safety emerges.

In this work we propose the use of dynamic game theory to determine the optimal control policy for a set of N satellites simultaneously performing in-orbit servicing operations. Because the satellites operate simultaneously and in close proximity, an additional goal is to avoid collisions. This scenario can be represented as a collection of multi-agent differential games [2], resulting in a peculiar cooperative zero-sum game whose solution is a specific Nash equilibrium obtained when all the players implement an optimal control policy [3, 4].

Applications of zero-sum games in flight mechanics have been proposed since the 70s, when the limits in computational resources translated into simplified scenarios, often assuming planar motion or constant speed [5, 6]. As computer technology progressed, zero-sum game models are increasingly used also in complex scenarios, such as 3-dimensional dynamics, but are still limited in the number of players involved [7-9].

The method proposed here to solve the N-satellite zero-sum game, with N arbitrarily large, is based on tensor algebra and the differential game is modelled as a Multi-Linear Dynamical System. Each pair of satellites represents a couple of pursuer and evader and the solution of the game for all the pairs of satellites leads to the achievemnt of a shared goal for the formation. A visual example of the application proposed is shown in Figure 1. Each one of the 3 pairs of satellites play a pursuer evader game, with the pursuer satellite trying to get closer to the evader one and vice-versa. By solving the 3 competitive problems together and selecting an adequate cost functional, in case of loss of the initial triangular configuration the game as a whole leads to its restoration. In fact, it represents an extension to cooperative zero-sum games, applied to in-orbit servicing, of previous works developed by the authors, including the tensor Kalman filter and tensor linear quadratic Gaussian controller [10, 11]. Numerical simulations in Matlab are used to test the method at hand.

Materials Research Proceedings 69 (2026) 1107-1113 https://doi.org/10.21741/9781644904251-191

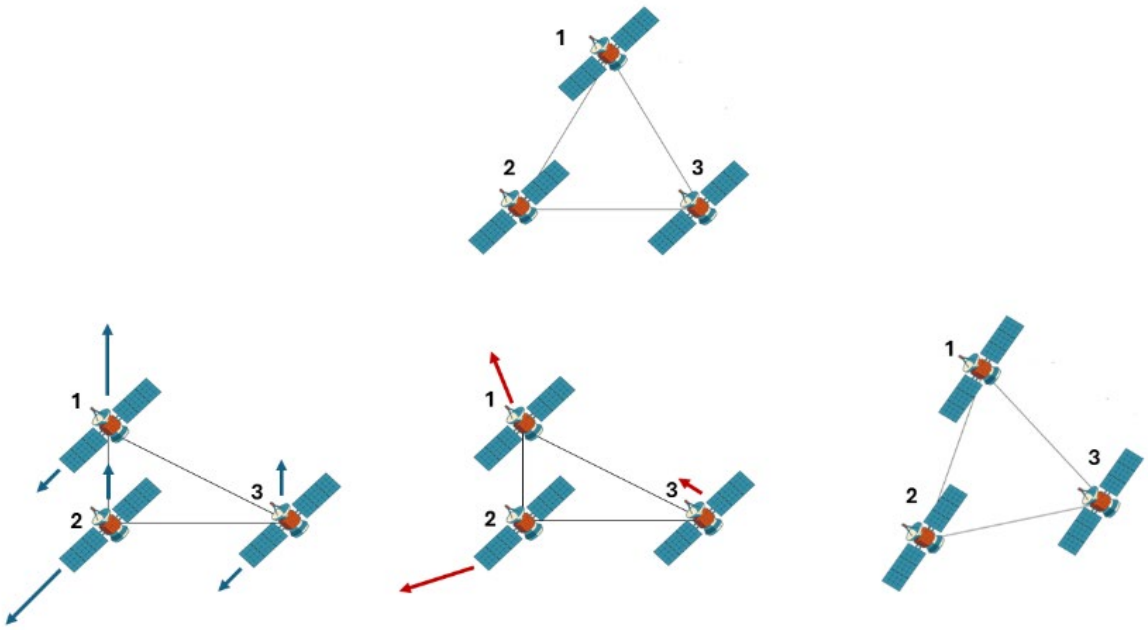

Figure 1: Scheme of a 3-satellite formation where each pair plays a competitive pursuer-evader game; the three competitive games correspond to a cooperative game among all the satellites: the formation recovers the initial triangle configuration while avoiding collision

Differential zero-sum games

Dynamic game theory offers the theoretical foundation for identifying the optimal control strategies of multiple agents that interact with one another—referred to as players in the game. In a dynamic game, each player's cost functional J depends not only on its own state and control variables but also on those of the other players. When the states and control policies of all players evolve over time according to differential equations, the game is referred to as a differential game.

Differential games can be categorized as competitive, where players have opposing interests (i.e., a reduction in the cost functional of one player results in an increase in that of another), or cooperative, where players adopt control strategies that jointly minimize each individual's cost functional. In a dynamic game, a Nash equilibrium is reached when no player can reduce their cost functional by unilaterally modifying their own control policy [12]. In other words, a player's cost can only be further minimized if the other players also adjust their control strategies.

An optimal equilibrium—and the corresponding optimal control policies for all players—can be determined under the assumption that the sum of the players' cost functionals equals zero, resulting in what is known as a zero-sum game.

The system dynamics and cost functional of a 2-party zero-sum game are provided below

$$\dot{\mathbf{x}} = f(\mathbf{x}, \mathbf{u}^P, \mathbf{u}^E, t) \tag{1}$$

$$J(\mathbf{x}, \mathbf{u}^P, \mathbf{u}^E, t) = \Phi(\mathbf{x}, t)\big|_{t_0}^{t_f} + \int_{t_0}^{t_f} L\,(\mathbf{x}, \mathbf{u}^P, \mathbf{u}^E, t)dt \tag{2}$$

where $\mathbf{x}$ is the relative state vector, collecting the relative position and velocity components between the two players, $\mathbf{u}^P$ and $\mathbf{u}^E$ are the control inputs of the pursuer and the evader, respectively the player that aims to minimize and maximize J, and t indicates time, with subscripts

0 and f referring to the initial and final values, Φ is a functional representing target initial and final conditions and L represents a cost to be minimized from t_0 to t_f.

The value of the cost functional correspoding to the optimal pursuer-evader game is given by

$$J(\mathbf{x}, \mathbf{u}^{P*}, \mathbf{u}^{E}) \leq J^*(\mathbf{x}, \mathbf{u}^{P*}, \mathbf{u}^{E*}) \leq J(\mathbf{x}, \mathbf{u}^{P}, \mathbf{u}^{E*})$$

$$\forall \mathbf{u^P} \in \mathcal{U}^P, \forall \mathbf{u^E} \in \mathcal{U}^E \tag{3}$$

where the symbol $*$ indicates the optimal value, and $\mathcal{U}^P$ and $\mathcal{U}^E$ are the sets of control inputs. For J^* continuously differentiable in t and $\mathbf{x}$, the optimal control $\mathbf{u}^P$ and $\mathbf{u}^E$ can be determined solving the following partial differential Isaacs' equations , and they represent a saddle point for J^*

$$\frac{\partial J^*}{\partial t} + \min_{\mathbf{u}^P} \max_{\mathbf{u}^E} \left\{ \frac{\partial J^*}{\partial \mathbf{x}} \dot{\mathbf{x}} + L \right\} = 0 \tag{4}$$

The solution of Eq. 4 can be simplified by the hypothesis of separable games

$$\begin{cases} \mathbf{u}^{P*} = f_P(\mathbf{x}^P, \mathbf{x}^E, t) \\ \mathbf{u}^{E*} = f_E(\mathbf{x}^P, \mathbf{x}^E, t) \end{cases} \tag{5}$$

where f_P and f_E are functions describing the evolution of $\mathbf{u}^{P*}$ and $\mathbf{u}^{E*}$ determined as solutions of the problem.

Tensor modeling of zero-sum games

A number m of pursuer-evader games of N players can be represented as a Multi-Linear Dynamical System (MLDS) based on tensor algebra [13]

$$\dot{\mathbf{x}} = A\mathbf{x} + B \bigotimes_{(2-5)}^{(1-4)} \mathbf{u} \tag{6}$$

where $\mathbf{x} \in \mathbb{R}^{n \times m}$ is the relative state tensor of n state variables, $\mathbf{u} \in \mathbb{R}^{s \times m \times p \times m \times m}$ is the control input tensor, collecting the s control actions for each player p ($p = 1$: pursuer, $p = 2$: evader) of the m games, $A \in \mathbb{R}^{n \times n}$ is the dynanic tensor, $B \in \mathbb{R}^{n \times m \times s \times m \times p}$ is the control tensor and the symbol $\bigotimes$ indicates the tensor product with respect to the dimensions indicated as super-and sub-scripts for, respectively, the first and the second factor. In this formulation of the MLDS $B_{(:,:,:,:,p=2)} = -B_{(:,:,:,:,p=1)}$.

The goal of the game is to minimize the cost functional given by

$$\frac{1}{2}\mathbf{x}_f \cdot (S\mathbf{x}_f) + \frac{1}{2}\int_{t_0}^{t_f} \left[\mathbf{x} \cdot (Q\mathbf{x}) + \mathbf{u} \cdot \left(R \bigotimes_{(4-6)}^{(1-3)} \mathbf{u} \right) \right] d\tau \tag{7}$$

where the symbol $\cdot$ indicates the scalar product, $S, Q \in \mathbb{R}^{n \times n}$, $R \in \mathbb{R}^{s \times m \times p \times s \times m \times p}$ and $R_{(:,:,:,:,:,p=2)} = -R_{(:,:,:,:,:,p=1)}$. Introducing the Lagrange multipliers tensor $\boldsymbol{\lambda} \in \mathbb{R}^{n \times m}$ and collecting Eqs. 6-7 it is possible to express the Hamiltonian for the problem by

$$H = \boldsymbol{\lambda} \cdot \dot{\mathbf{x}} + L = \boldsymbol{\lambda} \cdot \left(A\mathbf{x} + B \bigotimes_{(2-5)}^{(1-4)} \mathbf{u} \right) + \mathbf{x} \cdot (Q\mathbf{x}) + \\ + \mathbf{u} \cdot \left(R \bigotimes_{(4-6)}^{(1-3)} \mathbf{u} \right) \tag{8}$$

Eq. 8 allows deriving the optimal input tensor applying the Pontryagin minimum principle

$$\frac{\partial H}{\partial \mathbf{u}} = \boldsymbol{\lambda} \bigotimes_{(1-2)}^{(1-2)} B + R \bigotimes_{(4-6)}^{(1-3)} \mathbf{u}^* = 0 \rightarrow$$

$$R \bigotimes_{(4-6)}^{(1-3)} \mathbf{u}^* = -\boldsymbol{\lambda} \bigotimes_{(1-2)}^{(1-2)} B \tag{9}$$

After permuting the indices of R by $\begin{pmatrix} 1 & 2 & 3 & 4 & 5 & 6 \\ 1 & 4 & 2 & 5 & 3 & 6 \end{pmatrix}$ then $R^T \in \mathbb{R}^{s \times s \times m \times m \times p \times p}$ can be inverted and $\mathbf{u}$ can be explicited

$$R^T \bigotimes_{(2,4,6)}^{(1-3)} \mathbf{u}^* = -\boldsymbol{\lambda} \bigotimes_{(1-2)}^{(1-2)} B \rightarrow$$

$$\mathbf{u}^* = -\left(R^T\right)^{-1} \bigotimes_{(2,4,6)}^{(1-3)} \left(B \bigotimes_{(1-2)}^{(1-2)} \boldsymbol{\lambda}\right) \tag{10}$$

To determine the optimal input tensor, the Lagrange multipliers shall be determined from the Euler-Lagrange and boundary conditions

$$\begin{cases} \dot{\boldsymbol{\lambda}} = -\frac{\partial H}{\partial \mathbf{x}} = -A\boldsymbol{\lambda} - Q\mathbf{x} \\ \boldsymbol{\lambda}_f = \frac{\partial J}{\partial \mathbf{x}_f} = S\mathbf{x}_f \end{cases} \tag{11}$$

Assuming now $\boldsymbol{\lambda} = M\mathbf{x} + \boldsymbol{\nu}$ and applying the second of Eq. 11 the final values for the unknowns M and $\boldsymbol{\nu}$ are determined

$$\begin{cases} M_f = S \\ \boldsymbol{\nu} = 0 \end{cases} \tag{12}$$

And the following differential equation for the Lagrange multiplier tensor is determined

$$\dot{\boldsymbol{\lambda}} = \dot{M}\mathbf{x} + M\dot{\mathbf{x}} + \dot{\boldsymbol{\nu}} = -A\boldsymbol{\lambda} - Q\mathbf{x}$$

Introducing Eq. 6 into Eq. 10 leads to the following Tensor Differential Riccati Equations (TDRE) to be solved from the final conditions provided in Eq. 12

$$\begin{cases} \dot{M} = -MA + MB \bigotimes_{(2-5)}^{(1-4)} \left(R^T\right)^{-1} \bigotimes_{(2,4,6)}^{(2-4)} B \bigotimes_{(1)}^{(1)} M + \\ -A^T M - Q \\ \dot{\boldsymbol{\nu}} = MB \bigotimes_{(2-5)}^{(1-4)} \left(R^T\right)^{-1} \bigotimes_{(2,4,6)}^{(2-4)} B \bigotimes_{(1)}^{(1)} \boldsymbol{\nu} - A^T \boldsymbol{\nu} \end{cases} \tag{13}$$

Eq. 13 can be solved using the Tensor Runge-Kutta Integrator (T-RKI) and allows determining the optimal input tensor [10]

$$\mathbf{u}^* = K_x \bigotimes_{(5)}^{(1)} \mathbf{x} + k_v \tag{14}$$

where

$$\begin{cases} K_x = -\left(R^T\right)^{-1} \otimes_{(2,4,6)}^{(2-4)} B \otimes_{(1)}^{(1)} M \\ k_v = -\left(R^T\right)^{-1} \otimes_{(2,4,6)}^{(2-4)} B \otimes_{(1)}^{(1)} \mathbf{v} \end{cases} \tag{15}$$

Eqs. 14-15 allow determining the optimal control action for each player p of the m games. Applying $\mathbf{u}$, all the players attempt reaching the target state tensor $\mathbf{x}_f$ within the time interval $[t_0, t_f]$. Collision between players can be avoided selecting different values for the tensor R associated to different games.

Numerical study case

The formulation is studied considering $N = 5$ satellites operating in close proximity. For the sake of clarity, the simple problem of docking at a given set of coordinates is considered for the example. The MLDS for the problem is formulated extending to the tensor algebra the Hill–Clohessy–Wiltshire equations [14], as done in Ref [10].

The parameters for the problem at hand are the reference orbit angular speed $\omega = 0.00113\ rad/s$, the final time $tf = 2\pi/\omega$

$$Q = S \cdot 10^{-5} = \begin{bmatrix} I_{3\times3} & 0_{3\times3} \\ 0_{3\times3} & 0_{3\times3} \end{bmatrix}$$

and the components of R are selected such that the maximum thrust acceleration does not exceed $10^{-5}g$. The initial state tensor is selected randomly with position coordinates in the range $\pm 700m$ and velocity components in the range $\pm 7m/s$.

Figures 2-3 show, respectively, the variation in time of the Hill coordinates of satellites 2-5 with respect to the central satellite 1, and the change over time of the relative distances. Examining the figure it can be seen that all the satellites reach the target coordinates without collisions. In particular, the control operates such that the relative distance is kept high untile the relative configuration between the vehicles ensures that the target point can be reached without collisions.

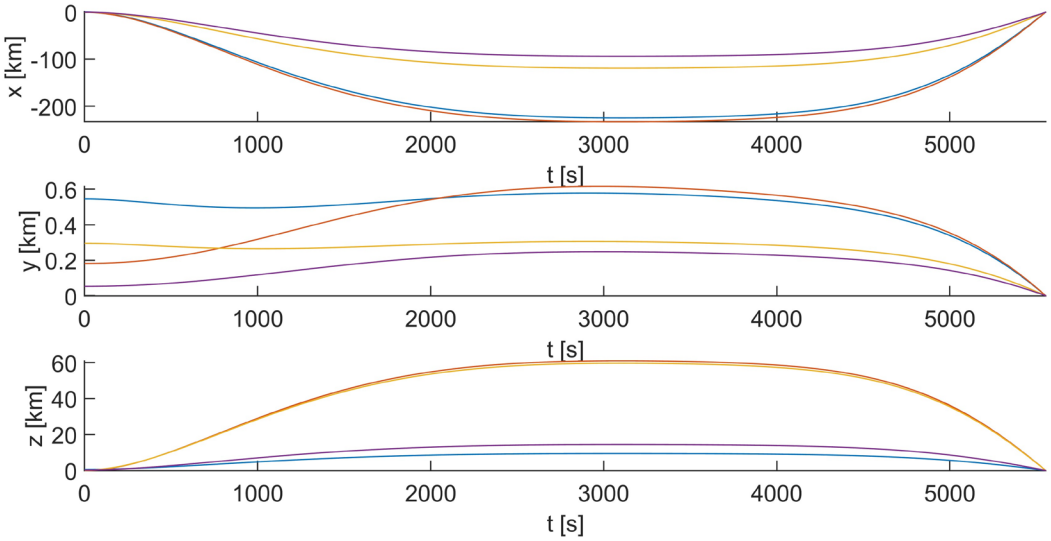

Figure 2: Relative coordinates of satellites 2-5 with respect to the central satellite 1

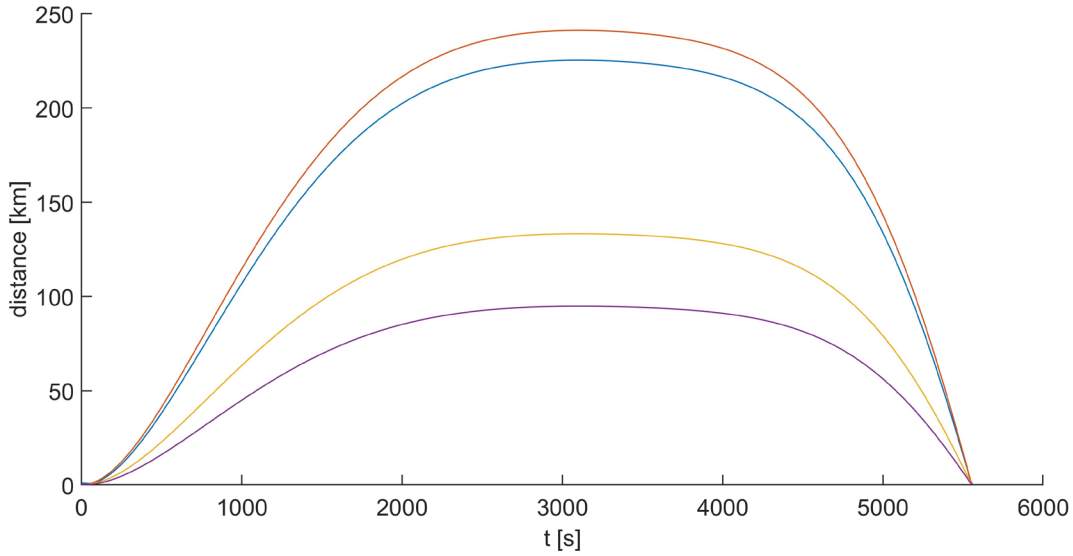

Figure 3: Relative coordinates of satellites 2-5 with respect to the central satellite 1

Final remarks

The tensor-based formulation of zero-sum games developed in this work provided encouraging results for applications in IOS missioons. Further advantages of model include: (i) exponential reduction (with N) of the computational time, (ii) inherent compatibility with parallel computing devices and (iii) the generation of synchronous control inputs.

Keywords: Satellite Constellations; Inter-Satellite Links; Communication Clusters; Static Digraph; Minimum Latency Routing

Abstract. Inter-satellite routing is key to enabling low-latency global connectivity in satellite constellations. Traditional models based on fixed topologies or discrete-time snapshots often overlook the geometric and temporal complexity of orbital motion, especially in sparse or heterogeneous systems. We introduce an event-based graph framework that captures all possible data exchanges within a constellation over a given time horizon. Each node represents a communication event—a finite interval during which one or more satellites can exchange data—while directed edges connect events that can be sequentially linked through shared satellites and overlapping time. The resulting structure is a static directed graph encoding all feasible routing paths based solely on mutual visibility. This compact formulation avoids redundancy typical of time-expanded graphs and naturally accommodates both permanent and temporary clusters, representing continuous or intermittent multi-satellite connectivity. Routing is performed on the event digraph using standard algorithms with latency- and hop-based metrics. Tests on LEO constellations demonstrate that the method efficiently identifies optimal paths and reveals key trade-offs between delay, hop count, and connectivity density, offering a scalable tool for constellation-level routing analysis.

Introduction

Satellite constellations are increasingly central to applications such as telecommunications, Earth observation, and navigation. Deploying multiple satellites enables data relaying strategies that reduce end-to-end latency: for instance, imagery acquired by one spacecraft can be forwarded through the constellation to another with earlier ground-station access. This capability relies on inter-satellite links (ISLs), traditionally implemented via radio-frequency (RF) communication and now evolving toward optical (laser) technologies offering higher data rates [1].

Effective routing in such constellations must account for the continuously changing network topology driven by orbital motion. Conventional routing methods based on static network snapshots [2, 3] perform well in dense or highly symmetric constellations but struggle to represent transient link opportunities in sparser systems. For example, Virtual Topology (VT) models divide operations into discrete snapshots [4, 5]. By discretizing time into fixed intervals, these approaches only partially capture the evolving connectivity, potentially overlooking routing opportunities with lower latency or hop count.

Materials Research Proceedings 69 (2026) 1114-1119 https://doi.org/10.21741/9781644904251-192

This work extends our previously proposed static-graph routing approach based on instantaneous ISL contacts [6], introducing a cluster-based framework that shifts the modeling perspective from individual satellites to communication events. Each node in the proposed graph corresponds to a cluster event—a group of satellites remaining mutually connected over a finite or continuous time span—rather than to a single satellite. The resulting static directed graph compactly encodes all feasible communication paths within the considered time horizon, allowing standard algorithms such as Dijkstra's to identify optimal routes in terms of latency or hop count.

Cluster Identification

Constellation Configuration. The proposed routing framework is demonstrated on a low Earth orbit (LEO) constellation of 128 satellites in circular, repeating-ground-track orbits following a Walker-delta pattern. The repeating-ground-track condition accounts for the effect of Earth's oblateness (J_2), ensuring closure of each satellite's ground track after one nodal day and 14 orbits. For an inclination of 53°, the corresponding semimajor axis is 7210 km (altitude ∼832 km), yielding a nodal orbital period of 102 min [7]. The remaining Walker parameters—the number of orbital planes p and the phasing factor f—are specified later for each configuration considered [8].

Temporary Clusters. A *communication cluster* is a subset of satellites that remain mutually reachable—directly or via multi-hop relays—over a finite interval $[t_{start}, t_{end}]$. The constellation is first modeled as a time-varying graph $G(t)$, whose nodes are satellites and edges represent active ISLs, established whenever the inter-satellite distance stays below a maximum distance, d_{max}, for a continuous duration (see [9] for the method used to determine ISL contact windows). Each link appearance or disappearance defines a discrete epoch tk, at which the adjacency matrix $\mathbf{A}(t_k)$ is updated and its connected components are extracted.

Clusters are determined by chronologically scanning the sequence $\{\mathbf{A}(t_k)\}$. At each epoch, every connected component of two or more satellites is compared with existing clusters: if the composition matches, the cluster's lifetime is extended; if satellites join or leave, the current cluster is closed and a new one begins. This yields a complete, non-overlapping description of all clusters over time: $C_\ell = (S_{i1}, S_{i2}, \dots, S_{im}, [t^\ell_{start}, t^\ell_{end}])$, where S_{i1} denotes one of the satellites in the cluster. Two types are distinguished: (a) *permanent clusters*, persisting throughout the simulation horizon; (b) *temporary clusters*, active only over finite intervals.

This abstraction compactly encodes the evolving network topology and underpins the static digraph formulation for routing analysis. Although illustrated on a symmetric configuration, the method is general and applies to heterogeneous constellations.

Global Continuous Connectivity. A constellation exhibits *global continuous connectivity* when it remains fully connected at all times, meaning that any satellite can reach any other via multi-hop relays at every instant. Each snapshot $G(t_k)$ contains a single connected component, ensuring end-to-end reachability despite individual ISL variations.

Materials Research Proceedings 69 (2026) 1114-1119 https://doi.org/10.21741/9781644904251-192

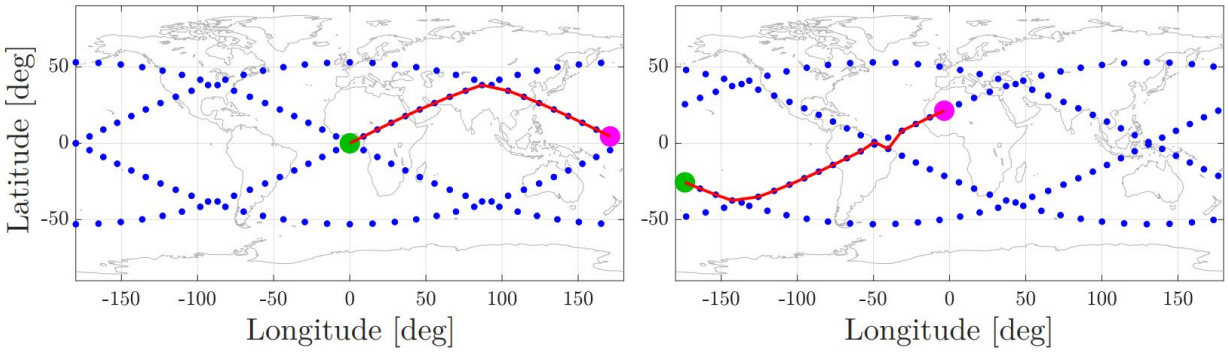

Figure 1. Global continuous connectivity for a 128-satellite constellation. Each panel shows a snapshot at (left) t = 0 s and (right) t = 3600 s, with satellites along their ground tracks (blue), source and destination (S_1, S_{128}) in green and magenta, and the routing path in red.

As an example, we consider a 128-satellite constellation with inclination 53°, arranged in p = 64 orbital planes with phasing factor f = 2, and maximum communication distance d_{max} = 2000 km. This configuration provides high inter-plane connectivity, with each satellite maintaining multiple cross-plane links throughout its orbit. Over one nodal orbital period (102 minutes), the cluster identification procedure yields a single permanent cluster containing all 128 satellites. While individual links appear and disappear as orbital geometry changes, global connectivity is maintained at every instant. This represents an ideal scenario where routing reduces to finding the shortest path without temporal coordination between communication events. Figure 1 shows two snapshots (t = 0 s and t = 3600 s) of routes between S_1 and S_{128}. Both routes consist of 17 hops, yet their satellite sequences differ due to orbital motion: some intermediate relays are replaced as the constellation geometry evolves, highlighting that even under continuous connectivity, optimal paths are time-dependent. To characterize constellation-wide connectivity, we compute the minimum hop-count paths between all satellite pairs. While global connectivity ensures that every pair is reachable, optimal routing paths change with orbital geometry. Because routing performance depends on satellites' instantaneous positions and ISL availability, we adopt a moving-window approach: the shortest-path analysis is repeated 100 times over one nodal orbital period, shifting the start time by 1/100 of the period at each iteration. Hop-count statistics show: mean 11.64, median 12, range [1–27], std 5.30, with the most frequent path length being 13 hops. The maximum of 27 hops occurs for nearly antipodal satellite pairs (e.g., separated by ∼180° in longitude and opposite hemispheres), where the shortest path must traverse approximately half the constellation circumference through sequential intra-plane and cross-plane links, each spanning at most d_{max} = 2000 km.

Static Digraph with Temporary Clusters

Definition and Design. Let $\mathcal{C} = \{C_1, \ldots, C_M\}$ be the set of identified clusters, and $\mathcal{S} = \{S_1, \ldots, S_N\}$ the satellites. We define a *static directed graph* $\mathcal{G} = (\mathcal{V}, \mathcal{E})$, where $\mathcal{V}$ includes both cluster nodes and satellite nodes, and $\mathcal{E}$ contains directed edges representing feasible information transfers. Each cluster C_k becomes a node active over its interval $[t^k_{start}, t^k_{end}]$. A directed edge $(C_k \rightarrow C_\ell)$ exists whenever (i) the two clusters *share at least one satellite* ($\exists\ S_i \in C_k \cap C_\ell$) and (ii) the transition respects *causality* ($t^\ell_{start} \geq t^k_{end}$), ensuring that data stored within C_k can be carried by the shared satellite(s) until C_ℓ becomes active. The edge weight reflects the full latency between the beginning of C_k and the beginning of C_l, $w(C_k \rightarrow C_\ell) = t^\ell_{start} - t^k_{start}$, thereby accounting for both the active duration of C_k and the waiting time until C_l starts. For hop-count optimization, all edges are assigned unit weights (w = 1). Each satellite S_i is also represented as a node connected to all clusters it belongs to via directed edges $S_i \rightarrow C_k$ and $C_k \rightarrow S_i$. This yields a single static digraph compactly

Materials Research Proceedings 69 (2026) 1114-1119 https://doi.org/10.21741/9781644904251-192

embedding both temporal and topological information, since each cluster aggregates extended intra-cluster communication periods.

Min-Latency Routing. Shortest-path algorithms such as Dijkstra's are applied to $\mathcal{G}$ using the weights $w(C_k \rightarrow C_\ell)$. The total latency along a path is the sum of these weights; when multiple paths yield identical latency, a modest penalty ϵ per edge favors shorter routes.

To illustrate this scenario, we consider a sparser 128-satellite constellation with the same inclination ($i = 53°$) and maximum distance ($d_{\max} = 2000$ km), but arranged in $p = 32$ orbital planes with phasing factor $f = 3$. Unlike the previous case, global connectivity is not maintained: multiple temporary clusters form and dissolve as satellites move along their orbits. Over one orbital period (102 min), the procedure identifies 2316 clusters. Cluster sizes range from 4 to 42 satellites (mean 20.5, median 6), with durations between 0.28 and 40 s (mean 22.5 s, median 14 s).

Dijkstra's algorithm on $\mathcal{G}$ yields the minimum-latency routes for each satellite pair, with hop count used as a tiebreaker. Three representative cases are reported for S_1 as source:

1. $S_1 \rightarrow S_2$: These satellites lie on adjacent planes and achieve direct visibility only after 15 minutes. However, both belong to an early cluster $C_{43} = (S_1, S_2, S_3, S_{19}, S_{20}, S_{21}, [76\text{ s}, 115\text{ s}])$, enabling relay through S_{19}. The minimum latency is therefore 76 seconds.
2. $S_1 \rightarrow S_3$: The same cluster enables multi-hop relay $S_1 \rightarrow S_{19} \rightarrow S_2 \rightarrow S_{20} \rightarrow S_3$, also with 76 s latency.
3. $S_1 \rightarrow S_4$: These satellites never communicate directly. The optimal path uses cluster C_{43} to route data from S_1 to S_3 (via S_{19}, S_2, S_{20}); then S_3 carries the data until cluster $C_{102} = (S_3, S_4, S_{121}), [258\text{ s}, 265\text{ s}])$ forms, completing the transfer through S_{121}. The total latency is 258 seconds (4.3 minutes), with 6 inter-satellite hops across 2 cluster transitions. The path is shown in Figure 2.

These examples illustrate how the cluster-based approach efficiently exploits both direct and multi-hop relay opportunities to minimize communication delay, even when satellites never share direct visibility.

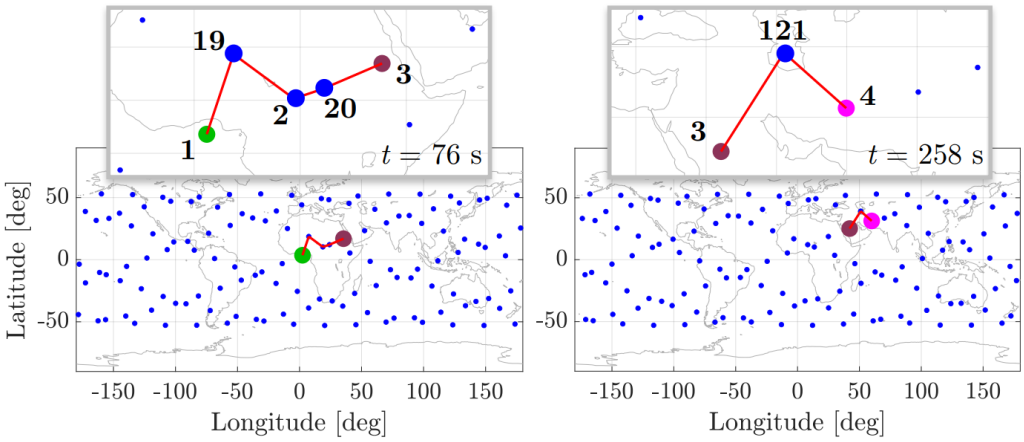

Figure 2. *Temporal routing for $S_1 \rightarrow S_4$. Left: data transfer within C_{43} at $t = 76$ s. Right: within C_{102} at $t = 258$ s, with S_3 linking the two clusters.*

Latency Matrix Computation. To characterize constellation-wide connectivity, we compute the minimum communication latency between all satellite pairs using the cluster-based routing framework. For each optimal cluster sequence identified by Dijkstra's algorithm, the corresponding hop count is computed as follows: within each cluster, a secondary shortest-path

search determines the minimum number of inter-satellite hops required to reach the shared satellite(s) connecting to the next cluster. The total hop count is the sum across all clusters in the sequence. Using the moving-window approach (100 runs, start time shifted by 1/100 of the nodal period), latency and hop-count values are computed for each realization and then averaged to obtain constellation-level statistics. The average latency is 5.01 minutes (median 5.67 min, std 3.49 min), ranging from immediate connectivity to 12.83 minutes. The average hop count is 11.87 (median 10, std 7.06), with a maximum of 38 hops observed. Figure 3 presents the mean latency and hop-count matrices side by side. Satellites are indexed sequentially by orbital plane (four per plane, for a total of 128).

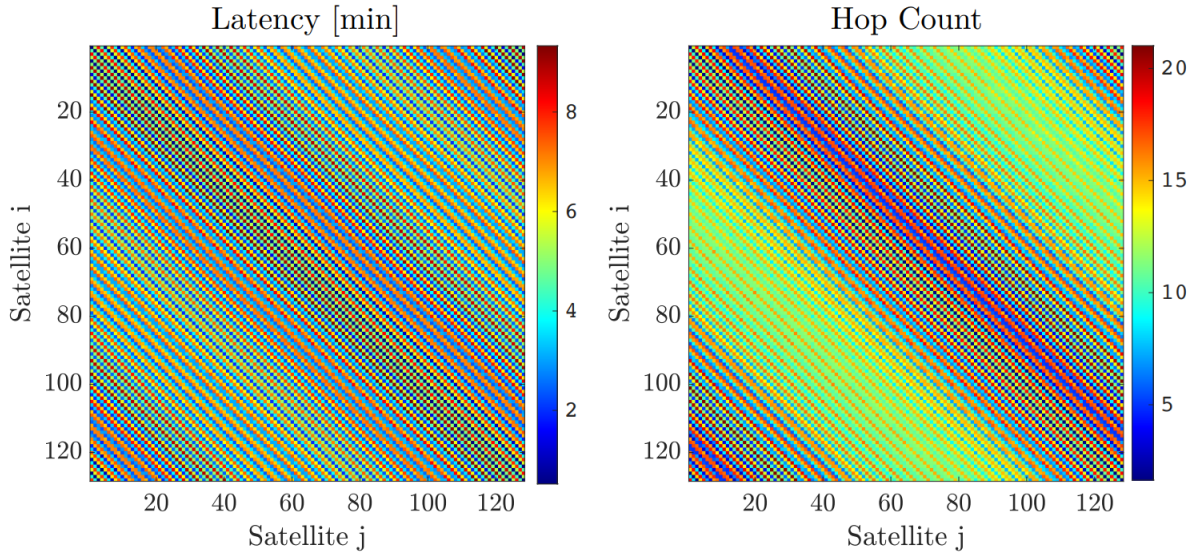

Figure 3. *Latency (left, in minutes) and hop count (right) between all satellite pairs, averaged over 100 realizations.*

Concluding Remarks

This work presents a cluster-based routing framework for satellite constellations that addresses the limitations of conventional snapshot-based methods. By shifting the modeling perspective from individual satellites to cluster communication events (groups of satellites that remain mutually connected over time intervals), the approach enables a compact static digraph representation that captures all feasible routing opportunities including short-lived connectivity windows that fixed-interval snapshots would miss. The framework was demonstrated on two configurations of a 128-satellite LEO constellation: one with global continuous connectivity and another with multiple temporary clusters. In the latter case, the cluster-based digraph enabled efficient minimum-latency routing through temporal coordination of communication events, achieving average latencies of approximately 5 minutes with typical hop counts around 12 satellites. The method is general and directly applicable to heterogeneous constellations with arbitrary orbital configurations, making it particularly suitable for sparse or asymmetric systems where traditional mesh-topology assumptions fail.

Keywords: LARES 2, LAGEOS, Precise Orbit Determination, General Relativity

Abstract. LARES 2 satellite has been launched on 13 July 2022 for testing general relativity and, in particular, the phenomenon known as Lense-Thirring effect or frame-dragging**.** In fact, Earth rotation drags spacetime and LARES 2 orbit with it. Precise Orbit Determination using laser-ranging data enables the accurate measurement of the orbital node shift. A key challenge is to isolate from this shift the contribution due solely to General Relativity, which is several orders of magnitude smaller than the one from the gravitational one. To solve this issue, orbital data from LARES 2 will be combined with the ones of LAGEOS satellite, along with state-of-the-art models of Earth's gravitational field. This paper describes the methodology which will be applied for the orbital analysis of the aforementioned satellite missions, which is essential to achieving the level of accuracy required by the scientific objectives of the LARES 2 space mission.

Lense-thirring effect and geodetic satellites

The relativistic effect consists in the dragging of space-time caused by the Earth rotation around its axis. A consequence of this phenomenon, defined as frame-dragging or the Lense-Thirring (LT) effect, is represented by the variation in the longitude of Earth satellites in the Earth Centred Inertial (ECI) reference frame, i.e. variation in Right Ascension of the Ascending Node (RAAN) **[1, 2]**.

Since for Earth satellites this variation in RAAN is millions of times smaller with respect to the one related to the perturbative effects of the gravitational field (the LT effect is large around a very massive body, in particular a black hole), in order to highlight it, it will be necessary to carry out an accurate process of orbit determination, called Precise Orbit Determination (POD) to be applied to geodetic satellites. In fact, this process must allow an extremely accurate estimate of all the other perturbing effects acting on the RAAN.

However, since the non-gravitational perturbations (atmospheric drag, solar radiation pressure, albedo) are intrinsically characterised by a greater uncertainty, due to the limited knowledge on the variability of the parameters involved in their modelling, they can be greatly reduced by considering satellites as spherical rigid bodies, with a very low surface-to-mass (A/m ratio). For example, LARES 2 satellite (launched in 2022) consists of a spherical monolithic piece made of nickel alloy with a diameter of 0.424 m and a weight of 294.8 kg. This design has already been tested on the LARES satellite (launched in 2012) that gave a measure of the LT effect in 2016 **[3]** The consideration of monolithic pieces reduces the thermal gradient on the surface, thereby further reducing the contribution to the solar radiation pressure related to absorption-emission phenomena on a spherical satellite. The spherical shape also guarantees an A/m ratio that is independent on the satellite attitude and cancels out the component of radiation reflected by the satellite in a specular manner **[4].**

Precise orbit determination of geodetic satellites

The POD is a mathematical process that aims to gain accurate knowledge of the spacecraft's state vector, i.e. the position **r** and velocity **v** vectors, as a function of time **[5]**. This process is approached by implementing an iterative technique involving both the analysis of a large number of measurements performed by laser ranging ground stations (about 40 in the world) and the use of an accurate orbital propagator. To estimate the LT effect, the analysis is temporally subdivided into time intervals, whose duration can be either 7 or 14 days.

In fact, in each of these time intervals, the stations make a certain amount of measurements. These measurements, that are very accurate, are statistically processed by the station itself, so that they are reduced to a smaller amount (some hundreds) that is representative of that time interval. The statistical treatment eliminates erroneous measures and gives greater weight to the most accurate measurements. This is accomplished on the basis of the errors that are associated (a priori) with the measures themselves, identified by their standard deviations. These representative measurements will form a vector $\mathbf{M} = [m_1, m_2,...m_m]$, called vector of measurements, whose elements, called normal points, are the satellite's Cartesian coordinates (positions) at instants t_1, t_2,...t_m belonging to the time interval under consideration. Then, starting from an initial estimate of the state vector (at the beginning of the interval), a very accurate numerical propagation is carried out along the entire interval, realised by a program (e.g. Geodyn II orbit determination software) that integrates numerically the equations of motion of the satellite subjected to the Newtonian force due to the Earth and the orbital perturbations: asymmetries of Earth's gravitational field, gravitational attractions of other celestial bodies, solar radiation pressure,... The temporal evolution of the state vector (and consequently of the satellite orbit elements) over the entire interval is thus determined. Following this, the normal points for the interval under consideration are fitted using the least squares method **[5]**. The minimisation of the sum of the squares of the distances between the satellite coordinates, obtained by orbit propagation, and the points corresponding to the measurements, is achieved by making an appropriate modification to the initial conditions of the interval. This modification, called differential correction, involves not only the state vector but also some chosen characteristic parameters related to the orbital perturbation model (value of the reflectance coefficient C_R of the satellite, empirical accelerations, ...), which constitute a vector **F** defined as force model. In fact, at each iteration, in addition to the position and the velocity vectors, also these parameters can be changed in the neighbourhood of their initial conditions, in order to find their accurate values. As said, the procedure is iterative: with the initial conditions updated, a new orbital propagation is performed, leading to a new temporal evolution of the coordinates to be fitted again with the measurements in the interval, and so on. The process ends at a pre-established threshold, for which the determined initial state vector is sufficiently accurate; this occurs when the so-called Root Mean Square (RMS), given by the square root of the sum of the squares of the distances, becomes less than a given value (a few centimetres). Once the iterative cycle is completed, the next time interval is analysed, using as initial conditions the state vector related to the end of the previous interval (corresponding to the last numerical propagation performed in the previous interval).

As described, the POD allows the determination of the precise values of the state vector at the beginning of each interval. Thus, the set of all the initial states of the various intervals will provide the complete temporal evolution of the satellite orbit.

The purpose of this article is to illustrate the procedure that allows the LT effect to be estimated by appropriately applying the POD to geodetic satellites.

Computing the residual of right ascension of the ascending node

To estimate the LT effect, pairs of contiguous time intervals are used, following the procedure described below.

Materials Research Proceedings 69 (2026) 1120-1124 https://doi.org/10.21741/9781644904251-193

Let us consider a generic couple of contiguous intervals, and indicate the first one with Δ_{t-1} and the second with Δ_t. In the Δ_{t-1} interval, the POD is applied, leading to accurately estimate the initial conditions of this interval. At this point, the next interval is considered, taking as an initial estimate for such an interval Δ_t the final conditions of the previous interval (last propagation in Δ_{t-1}), indicated as $[\mathbf{r}, \mathbf{v}, \mathbf{F}]_{t-1}^{fin}$ (in fact, the final instant of the interval Δ_{t-1} coincides with the initial instant of arc Δ_t). Since the conditions $[\mathbf{r}, \mathbf{v}, \mathbf{F}]_{t-1}^{fin}$ derive from a numerical propagation, they will be affected by a small error linked to uncertainties in modelling the perturbative effects (coefficients J_{lm}, $C_{R,\ldots}$) and effects not included in the perturbing model (for us, the LT effect). At this point, starting from the initial conditions$[\mathbf{r}, \mathbf{v}, \mathbf{F}]_{t-1}^{fin}$, the POD is applied to the interval Δ_t, leading to accurately determine the initial conditions of this interval. These conditions, indicated here as $[\mathbf{r}, \mathbf{v}, \mathbf{F}]_t$, will differ from those related to the initial estimate $[\mathbf{r}, \mathbf{v}, \mathbf{F}]_{t-1}^{fin}$, since, as said, the state $[\mathbf{r}, \mathbf{v}, \mathbf{F}]_{t-1}^{fin}$ is affected by a small error. The difference between the states $[\mathbf{r}, \mathbf{v}, \mathbf{F}]_t$ and $[\mathbf{r}, \mathbf{v}, \mathbf{F}]_{t-1}^{fin}$ is then evaluated, and to this difference will correspond a specific variation for each orbit element, called residual. In particular, as mentioned, to estimate the LT effect, it is necessary to consider the residual of RAAN, which can be expressed as:

$$\delta\dot{\Omega} = \frac{\Omega_t - \Omega_{t-1}}{\Delta_{t-1}} = \frac{\Delta\Omega}{\Delta_{t-1}} \qquad (1)$$

As evidence shows, the difference between the states has to be divided by the duration of the time interval Δ_{t-1} because the propagation error has been "accumulated" during the last propagation over this interval; $\delta\dot{\Omega}$ represents indeed the error on the RAAN, averaged over the propagation time (thus the residual of the RAAN has the dimension of an angular velocity).

The process will then be repeated between the interval Δ_t and the next one (Δ_{t+1}), taking as initial conditions for the interval Δ_{t+1} the final conditions resulting from the last orbit propagation on Δ_t, and so on. Once obtained all the points over the entire interval of study, these points have to be fitted by the least square method to get the experimental time evolution of the RAAN. Finally, this evolution has to be compared with the theoretical one (equation (2) below), to test if the two temporal variations coincide.

The LT effect will be intentionally not included in the dynamic model and therefore in the propagations, so that it can be associated with the residual that remains after removing the other contributions. The most important contribution is represented by the systematic error due to the uncertainties in the knowledge of the Earth's gravitational coefficients related to the even zonal harmonics. The errors associated with the other gravitational harmonics, the gravitational attraction of the other celestial bodies, atmospheric effect, the solar radiation pressure and the albedo are instead small compared to the relativistic effect.

The contribution associated with the even zonal harmonics will then be "eliminated" using the supplementary orbit technique, based on processing orbital data from the geodetic satellites LAGEOS and LARES 2 satellites.

Orbits with supplementary inclinations

To improve the estimation of the LT effect, the RAAN residuals of LARES 2 satellite will be advantageously combined with those of LAGEOS satellite. LARES 2 has been, indeed, specifically placed in a circular orbit with the same orbit elements as LAGEOS, except for the inclination (about 70 deg), which is supplementary to that of LAGEOS (about 110 deg). This choice has been dictated by the fact that the secular variation of the RAAN due to the even zonal harmonics depends, as is well known, on the cosine of the orbit inclination (all variations of RAAN due to J_l, with $l = 2, 4, \ldots$ have this term). It follows that, while the nodal line of LAGEOS rotates counterclockwise, that of LARES 2 rotates clockwise at the same angular velocity. As a result, the

sum of the residuals of RAAN of the two satellites can be neglected, as it is much smaller than the sum of the errors due to the non-consideration of the relativistic effect in the orbital propagations of LARES 2 and LAGEOS. The modelling of the orbital perturbations due to the lunisolar Earth's tides perturbations **[6]** has to be carefully analyzed. The same occurs for the errors related to the modelling of all the other perturbing actions considered in the numerical propagations (other gravitational harmonics, gravitational attraction of other celestial bodies, atmospheric effect, solar radiation pressure, etc…) and to the errors deriving from the fact that the orbits are not perfectly supplementary and their semi-major axes and eccentricities are not exactly the same (all these effects will of course be included in the systematic error budget associated with the experimental estimate of the relativistic effect, here described). This will make it possible to verify experimentally the very small variation of RAAN due to the LT effect predicted by the theory of General Relativity (GR), which occurs in anti-clockwise direction regardless of whether the inclination is direct or retrograde:

$$\dot{\Omega}_{\text{LT}-\text{ THEORETICAL}} = \frac{2GJ}{c^2 a^3 (1-e^2)^{3/2}} \qquad (2)$$

In Eq. (2), G is the gravitational constant and *c* is the speed of light and J the angular momentum of the Earth.

Conclusions

LARES 2 has been launched in 2022 with the goal of increasing the accuracy of the results obtained by the LARES mission. The satellite is producing high quality ranging data that are being processed by the scientific team of the mission. This analysis will also involve the geodetic satellite LAGEOS. In fact, LARES 2 has been specifically positioned into an orbit having a supplementary inclination compared to that of LAGEOS, to allow a more accurate estimate of the relativistic effect. Accordingly, the procedure described in this article will lead to a very precise verification of the theoretical prediction coming from General Relativity theory by means of the exploitation of experimental Satellite Laser Ranging data.

Acknoledgements

The authors wish to thank the Italian Space Agency for having funded the design of the LARES 2 satellite under agreement n. 2017-23-H.0 and the orbital analysis of LARES 2 under the agreement "Attività di analisi dei dati scientifici della missione LARES 2", the European Space Agency and AVIO for the VEGA C inaugural flight.

Keywords: Constellation Design, Multi-objective Optimisation, Collision Risk, Space Sustainability

Abstract. The rapidly increasing density of Low-Earth Orbit (LEO) space and the growing demand for time-critical Earth Observation (EO) tasks introduce new challenges for constellation design. Traditionally, optimisation efforts have prioritised coverage performance and system cost, while collision risk has been evaluated only at later operational stages. However, in an increasingly congested orbital environment, this separation is no longer sustainable. This paper addresses constellation design as a three-objective optimisation problem, where responsiveness, system cost, and orbit collision risk are treated as equally important objectives. A modelling framework is formulated, in which responsiveness is measured by the average revisit interval over a set of spatially distributed events, cost is approximated through a satellite-count-based linear model, and collision risk is estimated through a composite debris background and conjunction-based proxy. Two optimisation scenarios are examined: (i) responsiveness–cost optimisation while computing but not minimising risk, and (ii) full three-objective optimisation including risk as one of the objectives. Results demonstrate that explicitly optimising risk reshapes the Pareto frontier, favouring design configurations that provide comparable responsiveness and cost with substantially reduced collision risk. These findings support incorporating sustainability considerations at the conceptual design stage of future responsive EO constellations.

Introduction

Responsive Earth Observation (EO) has become fundamental to disaster assessment, emergency response, environmental monitoring, and security applications. Low-Earth Orbit (LEO) satellite constellations are particularly suitable for such missions due to their short orbital periods and high temporal revisit capability. However, the LEO environment is becoming increasingly congested. Collision risk, arising from both inter-constellation interactions and encounters with orbital debris, poses a growing challenge to long-term operational sustainability [1].

Conventional constellation design studies primarily optimise performance-driven metrics such as coverage, revisit time, and system cost [2-4]. In most cases, collision risk is considered only at later operational stages, for example during conjunction assessment and station-keeping planning [5,6]. This separation between early-stage architecture design and sustainability evaluation is increasingly problematic in an era of proliferating large constellations and escalating debris populations [7].

Recent discussions on the future of near-Earth space activities have emphasised the importance of evaluating collision probability in the context of orbital congestion. For instance, Rossi et al. highlight the challenges posed by debris accumulation and stress the need for systematic collision risk assessment [8]. The International Risk Governance Council similarly identifies the risks associated with new large satellite constellations as a central sustainability concern [9]. Meanwhile, Lucken et al. demonstrate the feasibility of modelling collision risk during constellation design, although their work does not directly address responsive observation missions [10].

Taken together, these studies indicate that collision risk should be incorporated directly into constellation architecture design rather than treated as a downstream operational concern. Accordingly, we treat responsiveness, cost, and collision risk as co-equal design objectives and pose the central question: how does the Pareto-optimal trade space change when collision risk is promoted from a diagnostic output to an optimisation objective? To answer this, we compare two scenarios for responsive LEO constellations: Case A, where responsiveness and cost are optimised and risk is only reported, and Case B, where all three objectives are jointly optimised with no imposed priority. By analysing the resulting Pareto frontiers and representative constellation architectures, we characterise how risk-aware optimisation reshapes configuration choices and identify conditions under which sustainability can be improved without significant loss in performance or cost efficiency.

Problem Formulation and Method

The objective of this study is to investigate how incorporating collision risk as a co-equal optimisation objective reshapes the design space of responsive LEO satellite constellations. To this end, we formulate the constellation responsiveness measure, cost model, and collision risk representation in a unified multi-objective optimisation framework.

The Walker constellation is used and parameterised by:

$$x = [N, P, h, i], \tag{1}$$

where total satellite count N, orbital plane number P, altitude h, and inclination i define coverage geometry and debris exposure. The search is constrained to realistic LEO ranges. Each satellite is equipped one sensor to observe the events.

A set of spatially distributed observation-demand events is used to represent task locations. The system responsiveness is expressed as:

$$T_{\text{rev,avg}} = \frac{\sum_e \omega_e W_e}{\sum_e \omega_e n_e}, \tag{2}$$

where ω_e is the event relative importance weight, W_e is the observation time window length, and n_e is the number of times observed within that window, which output by sensor-tasking module [11]. $T_{\text{rev,avg}}$ reflects the effective revisit cadence across all events. This choice is representative rather than prescriptive: alternative responsiveness definitions (e.g., time-to-first-access, percentile revisit, or coverage-weighted measures) can be substituted without changing the optimisation structure.

Cost is approximated as:

$$\text{Cost} = c_{\text{unit}} \cdot N, \tag{3}$$

where c_{unit} is satellite unit cost (which may include manufacturing, launch, and operation costs). This keeps the optimisation interpretable and extendable. More detailed models (bus/payload mass-based costing, rideshare discretisation, ground segment) can be introduced in place of this proxy.

Collision risk over mission lifetime is represented as the union of background-flux for space debris and constellation self-induced collision for constellation [12]:

$$R_{\text{coll}} = 1 - \exp\left(-k_{\text{bg}}\rho(h)N\right)\exp\left(-k_{\text{cs}}\frac{2N(P\text{-}1)}{T}\right), \tag{4}$$

Materials Research Proceedings 69 (2026) 1125-1130 https://doi.org/10.21741/9781644904251-194

here, $\rho(h)$is altitude-dependent debris flux, $T$is orbital period, and k_{bg} and k_{cs} are scaling factors to adjust two risk unit. These are calibrated placeholders intended for concept studies and to be replaced with engineering-grade models.

Two scenarios are explored with the set as Table 1:

Table 1: Scenarios setting

Case	Objective Vector	Interpretation
A	$[T_{\mathrm{rev,avg}}, \mathrm{Cost}]$	R_{coll} reported but not optimised
B	$[T_{\mathrm{rev,avg}}, \mathrm{Cost}, R_{\mathrm{coll}}]$	R_{coll} is explicitly minimised

NSGA-II is employed to obtain Pareto fronts and population distributions [13]. To emphasise method rather than tooling, any competent multi-objective optimiser could be used. The problem setting intentionally adopts lightweight but physically interpretable proxies, allowing the analysis to focus on trade-space structure and decision implications, rather than on high-fidelity physical modelling. These proxies are designed to be directly replaceable with engineering-grade components without altering the optimisation structure.

Results and Discussion

This section compares the optimisation outcomes obtained under Case A (responsiveness–cost optimisation with risk computed but not minimised) and Case B (full three-objective optimisation), focusing on the structure of the resulting design trade-space.

Figure 1 presents the scatter matrix for average revisit interval, cost, and self-induced collision opportunity for Case A and Case B. Diagonal panels show marginal distributions, while off-diagonal panels depict pairwise correlations (x-axis: column variable; y-axis: row variable). Clear geometric couplings appear: shorter revisit times require more satellites, increasing both cost and collision opportunity. Case A exhibits wide spreads and a pronounced high-risk tail, reflecting unconstrained growth of large constellations. Case B yields markedly narrower clusters, suppressing high-cost/high-risk solutions and producing a more compact and sustainable design space.

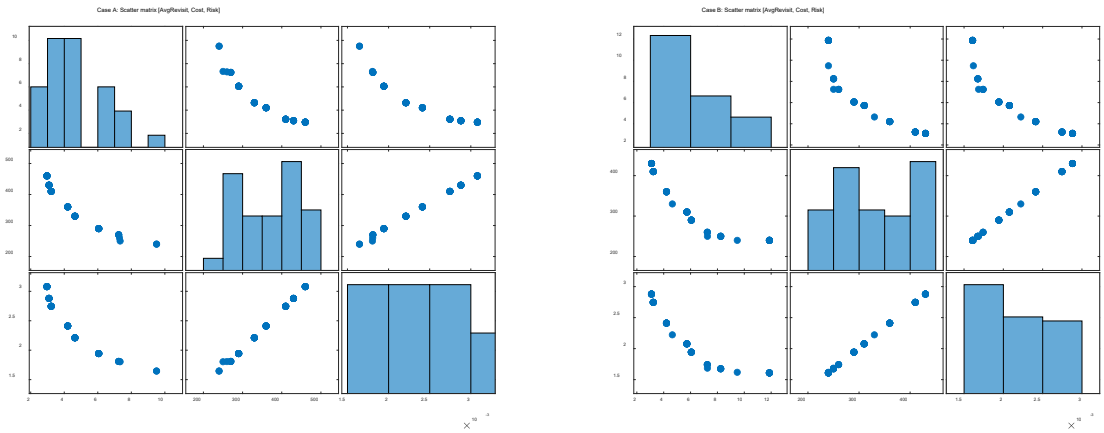

Figure 1: Scatter matrix of Case A and Case B.

In both cases, collision risk increases monotonically with (i) increasing satellite count (higher cross-sectional population density) and (ii) higher orbital altitude (higher debris flux in typical crowded LEO bands). This confirms the intended structural behaviour of the risk proxy: the model correctly captures macro-level variation in collision hazard.

Materials Research Proceedings 69 (2026) 1125-1130 https://doi.org/10.21741/9781644904251-194

For more details about differences between Case A and Case B distribution patterns. Case A retains many designs in high-cost / high-altitude regions where responsiveness is strong but risk is also significantly elevated. Case B suppresses these configurations, producing a population concentrated in lower-risk altitude bands (typically 420–500 km range) and with more moderate satellite counts. The optimisation pressure introduced by including risk does not eliminate high-performance solutions; instead, it filters out *imbalanced* designs that achieve responsiveness *only* through risk-intensive architecture choices.

Figure 2 compares the distributions of average revisit interval versus collision risk for Case A and Case B. For designs achieving comparable responsiveness, the solutions from Case B consistently exhibit lower collision risk than those from Case A. This indicates that, when risk is not explicitly controlled during optimisation, architectures with similar satellite counts may still display substantial variability and occasional escalation in risk. By contrast, incorporating collision risk as an optimisation objective drives the design space toward a more compact and systematically lower-risk region, even under similar cost constraints.

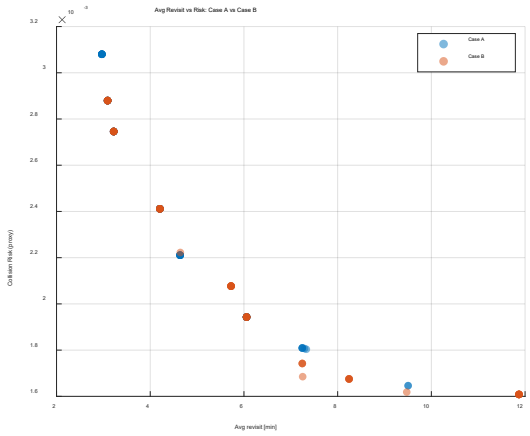

Figure 2: Avg Revisit and Risk of Case A and Case B.

The constellation design parameters obtained in the two cases are shown in Table 2. The optimisation outcomes highlight a clear structural shift when collision risk is treated as a co-equal design objective. Case A, which optimises responsiveness and cost alone, favours a 32-satellite constellation at 49° inclination. In contrast, Case B identifies a 24-satellite configuration with a significantly higher inclination (73.6°), achieving comparable revisit performance while reducing both cost and estimated collision probability. The higher inclination increases ground-track latitudinal coverage, enabling responsiveness to be maintained despite the reduced satellite count. Since the collision-risk proxy grows monotonically with constellation size, the reduction in N_{sat}directly yields a marked decrease in overall collision exposure. This illustrates that risk-aware constellation planning promotes architectural solutions that are simultaneously more sustainable and cost-efficient, without substantially degrading mission responsiveness.

Table 2: The constellation design parameters.

Case	N_{sat}	N_{planes}	h [km]	i [°]
A	32	8	400	49.3
B	24	8	405	73.6

The parallel coordinate plots for Case A and Case B (Figure 3) illustrate how the solutions distribute across the three objectives when normalised. A notable trend emerges in both scenarios:

Materials Research Proceedings 69 (2026) 1125-1130 https://doi.org/10.21741/9781644904251-194

cost and collision risk tend to vary in the same direction, reflecting their shared dependence on the constellation size.

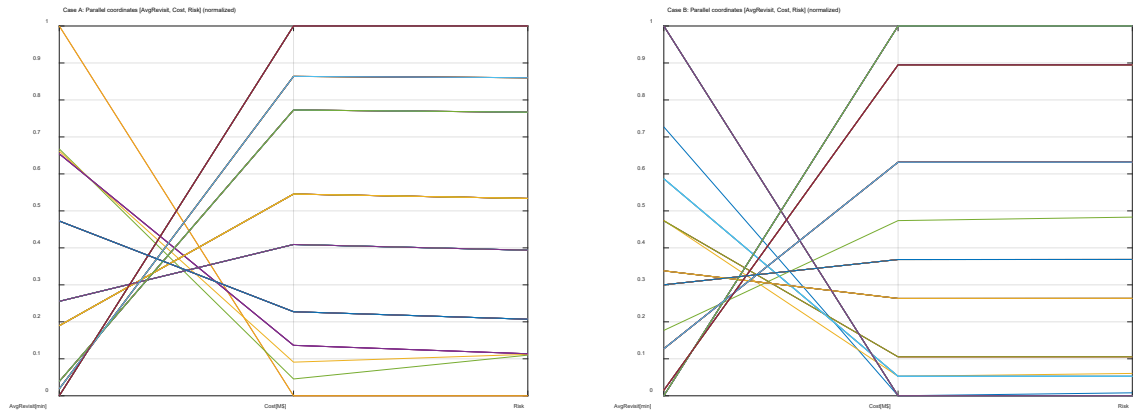

Figure 3: Parallel coordinates of Case A and Case B.

Since the cost proxy is proportional to the total number of satellites, $\mathrm{Cost} = c_{\mathrm{unit}}N$, and the collision risk proxy Risk includes both background flux exposure and an encounter-rate term that scale with N, increasing the constellation size simultaneously increases cost and elevates orbital exposure, thereby increasing the probability of conjunction or collision. As a result, the two quantities are positively correlated by construction, even before optimisation.

This structural correlation appears clearly in the Case A parallel coordinate plot, where several solutions achieving lower revisit intervals do so by increasing the satellite count, which in turn drives both cost and risk upwards. In this scenario, where risk is *not* included as an optimisation objective, the optimiser has no incentive to avoid these high-risk configurations; the design space therefore contains "high-performance but high-risk" constellations.

In contrast, in Case B, where risk is optimised jointly with cost and responsiveness, the parallel coordinate plot shows a visibly compressed range of collision risk across the final population. Solutions with high cost but also high risk are systematically excluded because they are dominated in the Pareto sense. This produces a frontier in which increasing satellite count no longer yields acceptable responsiveness gains, and the optimiser instead tends to explore constellations with fewer satellites but more favourable geometric factors, such as higher inclination and more efficient plane distribution, to preserve responsiveness without incurring excessive risk.

In other words, Case A can improve responsiveness primarily by adding satellites, but this pushes both cost and risk higher, which leads to wide spread in the "Risk" dimension. Case B avoids the part of the search space where both cost and risk increase together, encouraging structurally sustainable architectures, leading to narrower, lower band of risk values. This distinction directly explains why the best Case A and Case B solution settles at Table 2. This demonstrates that risk awareness reshapes the design strategy itself, rather than simply selecting among otherwise similar architectures.

Conclusion

This study demonstrates that treating collision risk as a co-equal design objective fundamentally reshapes the satellite constellation design trade space. When risk is only computed post-hoc, as in Case A, high-risk configurations may be incorrectly regarded as desirable due to their responsiveness–cost performance. However, when risk is explicitly included in optimisation (Case B), the resulting Pareto sets favour architectures that provide comparable responsiveness and cost while exhibiting significantly lower long-term collision risk. These findings highlight the

importance of incorporating sustainability and orbital safety considerations at the conceptual design stage, rather than deferring them to operations. The framework and insights presented here provide a basis for guiding responsible and resilient responsive EO system development.

Keywords: Aerodynamic Drag, Ephemeris Data Assisted Calibration, LEO Debris, Orbital Decay

Abstract. The reliable estimation of atmospheric drag-induced orbital decay is quite challenging due to the limited representation of solar and non-solar forcing mechanisms in atmospheric density models and the complex operational dynamics of some spacecraft. Such uncertainties widen the gap between modelled estimates and actual orbital parameters and also hamper the ability of mission designers and/or operators to accurately estimate the remaining lifetime of spacecraft in orbit. Medium- to long-term estimation or prediction of a defunct spacecraft orbit is even more challenging when the object is no longer subject to ground commands. In this work, we present a robust atmospheric drag model adapted to the ephemeris data-assisted calibration (EDAC) simulation method, to improve the simulation and prediction of short-, medium- and long-term evolutions of the orbital decay of LEO objects, as functions of specific solar-geophysical indices. We show that the simulated long-term evolution of atmospheric drag-induced orbital decay compares well with the historical data of objects and confirms its validity using independent data. We present the EDAC-adapted model as a novel and effective approach to atmospheric drag prediction.

Introduction

The long-term estimation (or simulation) of atmospheric drag effects on spacecrafts in low Earth orbit (LEO) is particularly useful for satellite orbital prediction and maintenance, collision avoidance and debris tracking, re-entry estimations, mission plannings and constellation design, and space weather impact assessments [1-4]. The continuous long-term comparison between observed orbital decay and simulated drag can help to improve atmospheric density models and empirical drag coefficients (and vice versa), leading to improved predictive accuracy of space assets (e.g., [5, 6]). However, accurate modelling of drag over a long period is quite challenging due to a number of complex and interrelated factors such as unpredictable solar-geophysical events and the associated complex variability in atmospheric density models, complex spacecraft geometries and other perturbative forces [4,7-11]. The uncertainties introduced by these factors can widen the gap between observational data and simulated results – a scenario that can hamper the ability of mission designers and operators to estimate the lifetime of on-orbit spacecraft. Since the changing physical or orbital parameters of spacecraft (which is associated with their design evolution) requires a repetitive lifetime estimations for appropriate mission planning [1], a robust and scalable model is crucial for improved knowledg of atmospheric drag effects on their orbits.

Continuous developments in empirical, physical, and hybrid modeling methods have undoubtedly improved atmospheric drag estimations, including the integration of real-time space weather indices [12], data assimilation and machine learning techniques (e.g., [13, 14]), dynamic drag coefficient (Cd) modelling (e.g., [3,15,16]), probabilistic lifetime estimations [8] and hybrid

Materials Research Proceedings 69 (2026) 1131-1139 https://doi.org/10.21741/9781644904251-195

physical-empirical comparative analyses [17]. However, many of these investigations have been focussed on active and/or controlled spacecraft with achievable stable flight configurations [1]; making the simulations less complex. The long-term estimation of a defunct and uncontrolled spacecraft orbit is more challenging, especially when the object is no longer responding to ground commands, which is the case for most space debris. In this work, we use a robust drag model that is adapted to the ephemeris data-assisted calibration (EDAC) simulation method, to improve the simulation and prediction of the evolution of orbital decay of LEO debris, as a function of solar-geophysical indices.

Data and method

In this work, we use a numerical integration method for orbital propagation using spherical coordinate system. The decay rate of the spacecraft orbital radius (r) or semimajor axis (a) is determined as a consequence of the rate of change of the satellite's radial velocity ($\dot{v}_r$). $\dot{v}_r$ is adapted to spacecraft ephemeris data-assisted calibration (EDAC) method by introducing a unitless normalisation coefficient (γ_{mod}) that minimizes the gap between the actual orbit decay (based on spacecraft ephemerides) and the modeled or simulated decay. Thus achieving a long-duration orbital decay rate (due to atmospheric drag) using the following set of coupled equations [4, 18]:

(1) $\dot{r} = v_r$

(2) $\dot{v}_r = -\dot{\emptyset} r^2 \rho \left(\frac{A_s C_d}{m_s}\right)$

(3) $\dot{\emptyset} = \frac{v_\emptyset}{r}$

(4) $\ddot{\emptyset} = -\frac{1}{2} r \rho \dot{\emptyset}^2 \left(\frac{A_s C_d}{m_s}\right)$

where v_r and $v_\emptyset$ are the radial and tangential velocity components, $\dot{v}_r$ and $\ddot{\emptyset}$ are the radial and azimuthal accelerations, respectively. A_s, C_d and m_s are, respectively, the projected area in the direction of motion, drag coefficient and mass of the spacecraft. ρ is the altitude-dependent atmospheric density, obtained from the Naval Research Laboratory Mass Spectrometer and Incoherent Scatter Extended (NRLMSISE) model [19]. To achieve long-duration orbital decay trajectories (that aligns closely with historical decay records of LEO objects) we applied a drag normalization coefficient (DNC) to the radial velocity component. The DNC is expressed as

(5) $\boldsymbol{\gamma}_{mod} = \frac{\Delta r_{act}}{\Delta r_{est}} = \frac{r_{at} - r_{af}}{r_{et} - r_{ef}}$

where Δr_{act} is the difference between the actual positions at time t (r_{at}), and some future time f (r_{af}), whereas Δr_{est} is the difference between the estimated positions r_{et} (r_{ef}) at the respective times $t(f)$. The goal of EDAC is to drive towards a unitary value of γ_{mod} (i.e, $\gamma_{mod} \sim 1$).

Applying DNC is important because simplified spherical coordinate drag models tend to over- or under-estimate long-term orbital decay when using nominal aerodynamic coefficients alone. In LEO, unmodelled effects such as attitude variations, complex geometry, atmospheric composition uncertainty, and along-track averaging tend to accumulate over thousands of orbits. The DNC acts as a physically motivated calibration factor that absorbs these unresolved processes without altering the governing dynamics. This approach is suitable for long-duration decay studies where reproducing observed semi-major axis evolution is more critical than resolving short-period oscillations. It also provides a realistic, validated bridge between simplified physics and historical orbital decay records.

This form of γ_{mod} (equation 5) have been previously used to simulate the orbital decay of selected LEO objects for long- and short-term regimes (e.g., [18]). However, the resulting γ_{mod} value sometimes require some adjustments to achieve a good drag estimate. The trends in the simulated mean height and orbit decay rate (ODR) have shown that γ_{mod} significantly depends on

Materials Research Proceedings 69 (2026) 1131-1139 https://doi.org/10.21741/9781644904251-195

solar activity and the spacecraft's orbital and ballistic parameters. To achieve an improved γ_{mod}, we leveraged these observed trends to develop and implement the equation for the DNC (γ_{mod}) in the long-term orbital decay simulations. The dimensionless normalization coefficient (γ_{mod}) that scales a spacecraft's drag-driven decay rate $\dot{\alpha}$ to a known reference condition based on the influencing factors of ballistic coefficients $B = A_s C_d/m_s$, atmospheric density $\rho(h)$ at the satellite altitude h and orbital eccentricity of the spacecraft can be expressed as:

$$(6) \quad \gamma_{mod}(h_p, B, e) = \frac{\dot{\alpha}(h_p,B,e)}{\dot{\alpha}(h_{ref},B_{ref},0)} \approx \left(\frac{B}{B_{ref}}\right).\left(\frac{\rho(h_p)}{\rho(h_{ref})}\right).\left(\frac{1-e}{1-e_{ref}}\right)$$

B_{ref}, h_{ref} and e_{ref} are the reference values for B, h and e, respectively. Our current implementation of the EDAC model assumes a satellite in a near-circular orbit where e ~ 0 such that the eccentricity factor, [(1-e)/(1-e$_{ref}$)], in equation 6 can be ignored. The mean effective atmospheric density of the spacecraft ($\bar{\rho}_{eff}$) at the spacecraft location can be used in place of the density at reference height ($\rho(h_{ref})$), which can be expressed as:

$$(7) \quad \bar{\rho}_{eff} = \frac{2(\sqrt{a_0}-\sqrt{a_1})}{B\sqrt{GM_e}(t_1-t_0)}$$

We selected 6 catalogued debris for this investigation, based on height (typically LEO) and the ability to be measured from the ground using the satellite laser ranging (SLR) technique via retro-reflectors. The orbital and ballistic parameters are provided in Table 1. All the listed objects have near circular orbits so that $a \sim r$ as noted above. Their historical orbital (and ballistic) data were obtained from a comprehensive satellite catalogue (https://in-the-sky.org/) and ESA's DISCOSweb (https://discosweb.esoc.esa.int/). The objects' drag coefficients (C_d) were based on the shape-dependent recommendations contained in [20-22]. Solar-geophysical indices for the solar radio flux (*F10.7*) and geomagnetic *Ap* are from GFZ Helmholtz Centre for Geosciences database (https://kp.gfz.de/en/data) and were used as inputs to the NRLMSISE to obtain the spacecraft local time (SLT) density profiles. Implicit in the reminder of this text is that the F10.7 is in solar flux units (1 sfu = 10^{-22} Watts per square meter per Hertz (W/m^2/Hz)) and Ap is in units of 2 nanoTesla (nT).

By incorporating Equation 6 with the appropriate space weather (density) and reference spacecraft parameters our drag model generates a suitable γ_{mod} for the long-duration propagation of a specific object's orbit. Table 2 shows the resulting γ_{mod} associated with each object. Using γ_{mod}, we simulated 6-month orbit decay evolution of the LEO objects (due to atmospheric drag effect) from January to June 2025.

Table 2: The γ_{mod} normalisation coefficient and the associated reference object parameters

Results and discussion

Estimation of long-term aerodynamic drag effect

Figure 1 shows the actual mean height (*h-act*) obtained from the object's historical data and the simulated mean heights (*h-sim*) of satellites GFO, OICETS, ASAP-S, HELIOS, RESURS and SOHLA along with their corresponding orbit decay rates (ODR_act, ODR_sim), modeled as a function of the observed solar-geophysical indices during Jan-Jun 2025. The historical orbital data showed that the objects were orbiting Earth at the mean height of 478.1, 527.1, 532.46, 618.8, 625.12 and 655.8 km, respectively, on 1 January. Their respective actual and simulated mean heights (*h-act* and *h-sim*) after six months (on 30 June) are provided in Table 3. Their actual total orbit deviations (TOD_act) are 23.15, 12.7, 6.5, 2.8, 1.6, and 2.3 km, respectively, while their respective simulated total orbit deviations (TOD_sim) were 23.2, 13.3, 7, 2.8, 1.7, and 2.3 km, respectively. These values correspond to the standard deviation (σ) of 0.03, 0.25, 0.24, 0.02, 0.05 and 0.02 km, respectively, and a corresponding percentage error (δ) of 0.13. 1.93, 3.56, 0.89, 3.32 and 0.88%.

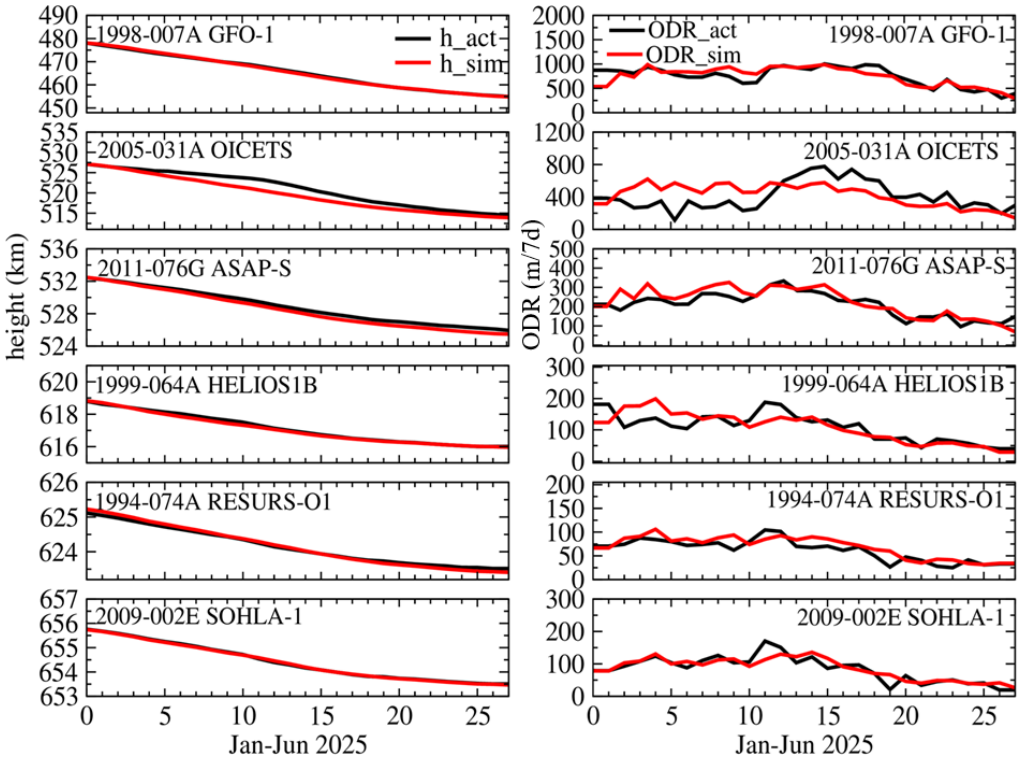

Fig. 1: Actual mean height (h-act) obtained from the object's historical data and the simulated mean heights (h-sim) of GFO, OICETS, ASAP-S, HELIOS, RESURS and SOHLA and their corresponding orbit decay rates (ODR_act, ODR_sim) during January - June 20025. The x-axes timelines are in weeks.

Materials Research Proceedings 69 (2026) 1131-1139 https://doi.org/10.21741/9781644904251-195

Table 3: The actual and simulated mean heights of the objects during Jan-Jun 2025

	Catalogued Object	**Actual mean *h* (km)**			**Simulated h-OSI (km)**	
	LEO Object	01.01.2025	30.06.2025	TOD	30.06.2024	TOD
1	1998-007A GFO-1	478.07	454.92	23.15	454.86	23.21
2	2005-031A OICETS	527.10	514.40	12.70	513.90	13.20
3	2011-076G ASAP-S	532.46	525.95	6.51	525.47	6.99
4	1999-064A HELIOS-1B	618.80	616.01	2.79	615.96	2.84
5	1994-074A RESURS	625.12	623.52	1.60	623.41	1.71
6	2009-002E SOHLA-1	655.76	653.51	2.25	653.47	2.29

In the present analysis, the mean σ and δ were 0.102 km and 1.79%, respectively. Four spacecraft show very small δ (0.13% (GFO), 0.89% (HELIOS), 0.88% (SOHLA), 1.93% (OICETS)), which are good fits for long-term decay modeling, whereas two spacecraft (having δ ≈ 3.56% (ASAP-S) and 3.32% (RESURS)) showed significantly larger deviations. There was also a very close agreement between the actual and simulated decay of three of the objects with low σ values of 0.02 (SOHLA), 0.03 (GFO) and 0.02 (HELIOS). The observed deviations in the *h-sim* and ODR_sim may be due to factors not well represented in the model such as poorly resolved normalization coefficients, unspecified differences in attitude or drag area histories, change in material or surface properties (affecting accommodation coefficients), questionable estimated mass or orientation assumptions (e.g., [1,8,23,24]). Nevertheless, the simulated mean altitudes (*h-sim*) and simulated orbital decay rates (ODR_sim) agree well with the historical orbital data of the objects and can be considered acceptable for mission purposes (such as lifetime planning and debris mitigation).

Prediction and validation of drag-induced orbital decay

We applied our model to predict the orbit decay of three LEO objects using NASA's estimate of solar-geophysical activity for the 25th solar cycle. (https://www.nasa.gov/solar-cycle-progression-and-forecast/). The predicted solar-geophysical indices (*F10.7* and *Ap*) represent the smoothed values for 13 months, based on a best estimate given as the 50th percentile value, along with the statistical 95th and 5th percentiles. The orbital decay was simulated according to the estimated levels of the indices and range of predicted values for each object. Figure 2 shows the model-based prediction of orbital decay evolution associated with the observed solar-geophysical indices for Jan-Mar 2025 and the predicted activity for Apr-July 2025. Details of the predicted decay are provided in Table 4. Based on the levels of estimated indices, the range of simulated mean height of the objects were 525.8 - 529.7, 617.51 - 618.25 and 716.89 - 717.71 km, respectively.

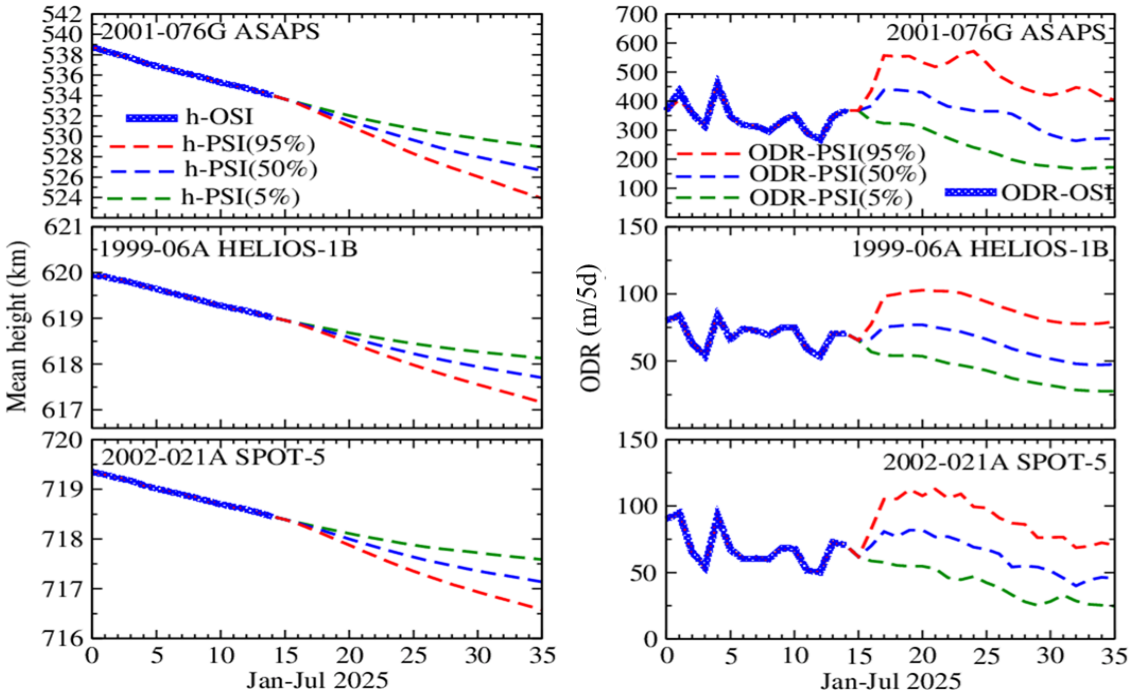

Fig. 2: The observed/predicted mean height (h) and orbit day rate (ODR) of 3 LEO objects, associated with the observed solar-geophysical indices (OSI) for Jan-Mar 2025 and the predicted solar-geophysical indices (PSI) for Apr-July 2025. The thick blue lines are the observed values, whereas the green, blue and red dashed lines are the predicted values.

Table 4: Predicted mean heights of the objects

	Mean height (*h*) analysis						
	Catalogued LEO object	**h-OSI (km)**			**predicted h-PSI (km)**		
	LEO object	**01.01.25**	**31.03.25 (ACT)**	**31.03.25 (SIML)**	**30.04.2025** F10.7=161.97 Ap=14.5	**31.05.2025** F10.7=179.47 Ap=14.77	**30.06.2025** F10.7=177.4 Ap=15.0
1	2011-076G ASAPS	538.77	533.52	534.01	531.31±0.58	529.31±1.32	527.75±1.95
2	1999-064A HELIOS-1B	619.93	619.02	619.02	618.54±0.12	618.17±0.26	617.88±0.37
3	2002-021A SPOT-5	719.34	718.46	718.45	717.95±0.13	717.58±0.28	717.30±0.41

To validate the predicted regime, we obtained and show in Fig. 3 and Table 5 the historical orbital data of the objects during Jan-Jun 2025. The actual heights of the objects at the end of June were 525.16, 617.11 and 717.52 km, respectively, which indicates that the actual mean heights of two (ASAP-S and HELIOS) of the objects lie slightly outside their error bar. This scenario may be unrelated to the model performance but on the predicted solar-geophysical indices for the interval. The predicted mean *F10.7*/*Ap* for April, May and June were 162/14.5, 179.5/14.8 and 177.4/15, respectively, while the respective observed mean values were 162.3/17.6, 135.3/17.3 and 131.3/20.5. The obvious difference between the predicted versus observed regimes is that the predicted values for *F10.7* were higher during the 3-month interval in contrast to the *Ap* predictions, which were lower than observed. Nonetheless, the predicted estimates were within an acceptable range and can potentially provide a testbed for the model improvement. As the results presented here are still in their preliminary stage, it would be premature to draw conclusions regarding the computational limitations of the model. However, the results of the model can be improved by; (i) diagnoses of observed outliers through the inspection of parameters such as attitude or area history, possible mass changes and exposure to uncaptured solar energetic events, (ii) use of precise orbit determination (POD) and accelerometer data (where available) to estimate satellite-specific drag coefficients, (iii) replacing a single global coefficient with a parametric

Materials Research Proceedings 69 (2026) 1131-1139 https://doi.org/10.21741/9781644904251-195

normalization or applying piecewise calibrations across altitude bands, and (iv) validating the approach using cross-validation and providing operational procedures for periodic recalibration after major solar events (e.g., [1,25,26]). Also, orbit propagation and/or prediction longer than 6-month duration (as done here) may require further refinement of the normalisation coefficients used here to conclusively assess the model's stability and predictive accuracy over the extended timescales that are typical of long-term orbit prediction.

Conclusion

In this work, we simulated (and predicted) the orbital decay evolution of LEO debris with varying ballistic coefficients, as a function of solar-geophysical indices, using the ephemeris data-assisted calibration (EDAC) adapted model. The comparison between the actual and simulated decays yielded standard deviations (σ) ranging from 0.02 km to 0.25 km and percentage errors (δ) between 0.13% and 3.56%. These low deviations indicate strong consistency between the observed and modeled orbital decays, demonstrating the model's high suitability for long- and medium-term orbital prediction and decay trend estimation. The small dispersion of errors across spacecraft with different ballistic properties further suggests that the normalization coefficient effectively captures the altitude-dependent drag variability. Minor residuals were likely attributable to unmodeled spacecraft-specific parameters such as attitude, surface characteristics, or temporal density variations. The model's validation with independent data confirmed its predictive reliability and establishes a robust framework for further refinement. Overall, the performance of the model is good and consistent, supporting its application to both predictive and analytical orbit-decay studies.

Acknowledgements
This work was supported by the Impulsprojekt Orbitale Nachhaltigkeit (ION) of the German Aerospace Center (DLR). Authors acknowledge the data providers whose data were used for this work. The objects' mass, effective projected area, and shape were obtained from ESA DISCOSWeb. Their historical orbital data were obtained from In-the-sky.org satellite catalogue. The observed Ap and F10.7 were obtained from the database GFZ Helmholtz Centre for Geosciences, Germany and the predicted indices were obtained from NASA's estimate of the solar activity estimate for the 25th solar cycle (see, https://www.nasa.gov/solar-cycle-progression-and-forecast/).

Keywords: Lunar Constellation, Constellation Reconfiguration, Multi-Objective Optimization

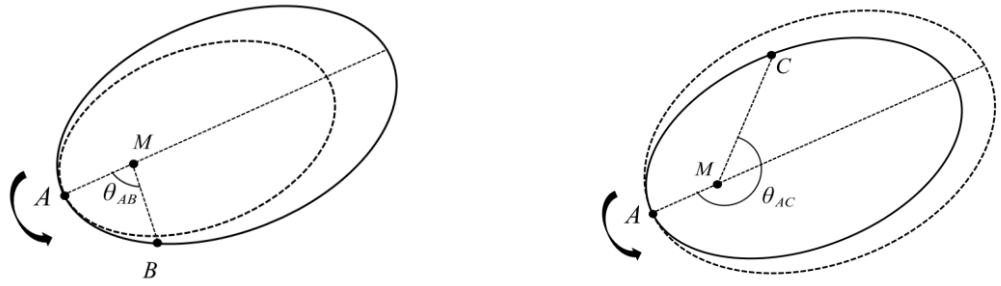
Abstract. The Lunar Navigation Satellite System (LNSS) is a critical initiative in response to the current surge in international lunar exploration. Compared to Global Navigation Satellite Systems (GNSS), the development of LNSS involves significantly higher costs and longer deployment cycles. As a result, optimizing constellation design to maximize the use of limited resources has become a popular topic. This work adopts two constellation reconfiguration strategies and a multi-objective optimization approach to extend the target area from the lunar South Pole to the whole Southern Hemisphere. First, Hohmann-type phasing maneuvers are applied to in-orbit satellites, with optimization of both fuel consumption and maneuver time, resulting in a notable improvement in dual coverage performance over the South Hemisphere. Second, new satellites are introduced to restore high-quality service in the South Pole region. Simulation results of coverage and navigation performance at the lunar South Pole confirm the effectiveness of the final constellation scheme.

Introduction

In 2005, NASA proposed six lunar communication architectures, regarding the resource-rich lunar south pole as the first exploration target [1]. In recent years, many studies have focused on the configuration design of lunar constellations. For example, Circi et al. used Halo orbits around L1 and L2 libration points to build a lunar constellation [2]. Zanotti et al. performed a multi-objective optimization of lunar orbits, targeting both low-altitude orbital missions and surface operations near the lunar South Pole [3].

The deployment of medium and large constellations usually involves reconfiguration operations, which are mainly applied in two scenarios. The first application scenario occurs when a satellite experiences an anomaly or a loss of functionality. Ferringer et al. simulated two failure scenarios and employed an evolutionary algorithm to optimize the reconfiguration process [4]. Arnas and Linares proposed a reconfiguration strategy considering the constraint of minimum inter-satellite safety distance [5]. The second scenario is the phased constellation deployment. Oliver et al. employed an Auction algorithm to derive the optimal assignment of satellites [6]. Alexandra et al. explored the design of a reconfigurable Earth observation satellite constellation, significantly improving detection rates for ground events [7].

In previous research, satellite constellations targeting the lunar South Pole have been optimized and analyzed [8]. This paper first presents the phase maneuvering methods, then the optimization models for two reconfiguration phases, followed by the results and conclusions.



Orbital Phasing Maneuver

The first-phase reconfiguration is intended only as a temporary response to the urgent navigation demands in the Southern Hemisphere. Therefore, only orbital phase is adjusted. A Hohmann-type

Materials Research Proceedings 69 (2026) 1140-1145 https://doi.org/10.21741/9781644904251-196

phasing maneuver is employed, including a sub- and a super-synchronous transfer, illustrated respectively in Fig. 1(a) and Fig. 1(b).

(a) *Sub-synchronous transfer* (b) *Super-synchronous transfer*

Figure 1: Phasing maneuver strategies. M denotes the Moon, A represents the perilune, and B and C indicate the target positions.

When the phase angle between the target position and the perilune satisfies $\theta_{AB} \leq 180°$, the sub-synchronous transfer is performed. The satellite enters a transfer orbit with lower attitude applying an impulse in the direction opposite the velocity at the perilune. After completing an integer number of revolutions, the satellite returns to original orbit using an equal impulse. Define t_{AB} as the time taken to move from A to B along the original orbit. Then the period of the transfer orbit can be calculated by

$$T_{sub} = T_0 - \frac{\Delta t_{AB}}{W} \tag{1}$$

where T_0 presents the period of the original orbit, and W represents the number of revolutions in the transfer orbit. The total velocity increment Δv_1 of two maneuvers can be given by

$$\Delta v_1 = 2|v_{Asub} - v_{A0}| \tag{2}$$

where v_{Asub} and v_{A0} represent the velocities of the perilune in the transfer orbit and the original orbit, respectively. The total duration of the transfer process is

$$\Delta t_1 = W \cdot T_{tran1} \tag{3}$$

When the phase angle satisfies $\theta_{AC} > 180°$, the super-synchronous transfer is employed. In this case, the satellite requires an accelerating impulse to change to a higher-altitude transfer orbit. Define t_{AC} as the time taken to move from A to C along the original orbit. Then, the period of the transfer orbit is

$$T_{super} = \frac{W+1}{W} T_0 - \frac{\Delta t_{AC}}{W} \tag{4}$$

The velocity increment Δv_2 and transfer duration Δt_2 can be determined in the same way as the previous case.

Materials Research Proceedings 69 (2026) 1140-1145 https://doi.org/10.21741/9781644904251-196

Optimization Model

Optimization Variables.

In the initial step of the reconfiguration, only the phases need to be adjusted. Therefore, the optimization variables and their bounds are

$$\begin{aligned} &x_{\mathrm{SH1}} = (\theta_i, W_i)^T, i = 1,2,\cdots, N_{\mathrm{SP}}, \\ &x_{\mathrm{SH1}lb} = (0° \times N_{\mathrm{SP}}, 1 \times N_{\mathrm{SP}})^T, x_{\mathrm{SH1}hb} = (360° \times N_{\mathrm{SP}}, 3 \times N_{\mathrm{SP}})^T \end{aligned} \tag{5}$$

where N_{SP} denotes the number of satellites in previous research [8].

In the second phase, the optimization focuses on orbital parameters of the new satellites. Consequently, both the orbital inclinations $incline_i$ and eccentricities e_i are considered as independent variables, and the allowable range for the perigee arguments ω_i is extended.

$$\begin{aligned} &x_{\mathrm{SH2}} = (incline_i, e_i, \omega_i, \Omega_i, \theta_i)^T, i = 1,2, \\ &x_{\mathrm{SH2}lb} = (0° \times N_{\mathrm{SH}}, 1 \times N_{\mathrm{SH}})^T, x_{\mathrm{SH2}hb} = (360° \times N_{\mathrm{SH}}, 3 \times N_{\mathrm{SH}})^T \end{aligned} \tag{6}$$

where Ω_i and θ_i represent the right ascension of the ascending node and the true anomaly, respectively.

Objective Functions.

Two coverage performance metrics $Cov2_i$, $Cov4_i$, and two navigation performance metrics $PerHDOP_i$, $PerGDOP_i$ are applied. Denote SP as the region spanning latitudes 70°S to 90°S, while SH as the region from 0°S to 70°S. In the phasing maneuver stage, the fuel consumption and reconfiguration time are also included as optimization objectives. As a result, there are seven optimization objectives for the first phase: $Cov4_{\mathrm{SP}}$, $PerHDOP_{\mathrm{SP}}$, $PerGDOP_{\mathrm{SP}}$, $Cov2_{\mathrm{SH}}$, $Cov4_{\mathrm{SH}}$, $\sum \Delta v_i$, $\max(\Delta t_i)$. The objective functions for the second phase are $Cov4_{\mathrm{SP}}$, $PerHDOP_{\mathrm{SP}}$, $PerGDOP_{\mathrm{SP}}$, $Cov2_{\mathrm{SH}}$, $Cov4_{\mathrm{SH}}$, $PerHDOP_{\mathrm{SH}}$.

Results

The optimization is based on two constellation schemes designed for lunar SP region in previous work, whose performance metrics are listed in Table 1.

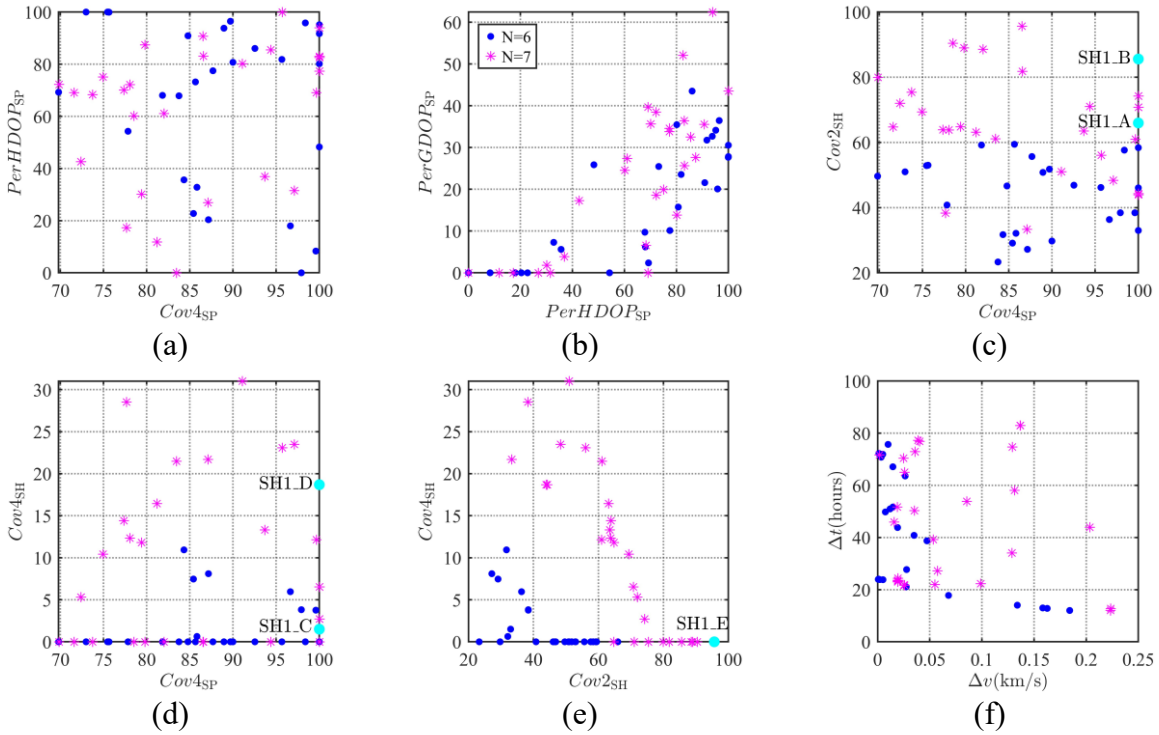
Table 1: Performance metrics of constellation schemes targeting South Pole

Schemes	$Cov4_{\mathrm{SP}}$	$PerHDOP_{\mathrm{SP}}$	$PerGDOP_{\mathrm{SP}}$	$Cov2_{\mathrm{SH}}$	$Cov4_{\mathrm{SH}}$
SP_E	100%	91.03%	49.02%	61.23%	0%
SP_F	100%	94.91%	67.53%	80.73%	0%

The NSGA-II (Elitist Non-dominated Sorting Genetic Algorithm) method is used to optimize the model in last section. The sub-Pareto fronts are shown in Fig. 2. Compared to Table 1, most of the solutions in Fig. 2(a) and Fig. 2(b) no longer satisfy the continuous four-fold coverage over SP. Additionally, the navigation performance exhibit significant degradation. Solutions SH1_A and SH1_B in Fig. 2(c) achieve the highest $Cov2_{\mathrm{SH}}$ while maintaining 100% $Cov4_{\mathrm{SP}}$. However, the improvement in $Cov2_{\mathrm{SH}}$ compared to SP_E and SP_F is marginal, and the $PerGDOP_{\mathrm{SP}}$ deteriorates by over 15%. Similarly, solutions SH1_C and SH1_D in Fig. 2(d) reach the highest $Cov4_{\mathrm{SH}}$ while also ensuring 100% $Cov4_{\mathrm{SP}}$. But their $Cov2_{\mathrm{SH}}$ drops by more than 28%, and the navigation performances for SP are severely compromised. It is evident that none of these four representative points can be considered as the final solutions. Fig. 2(e) illustrates an inverse correlation between $Cov2_{\mathrm{SH}}$ and $Cov4_{\mathrm{SH}}$. Dual coverage is the most urgent requirement in the first

Materials Research Proceedings 69 (2026) 1140-1145 https://doi.org/10.21741/9781644904251-196

stage, so solution SH1_E with the highest $Cov2_{SH}$ is selected. As shown in Fig. 2(f), the velocity increment remains below 0.25 km/s, and the maximum maneuver duration does not exceed 83 hours, which is a positive outcome in terms of both efficiency and energy consumption.



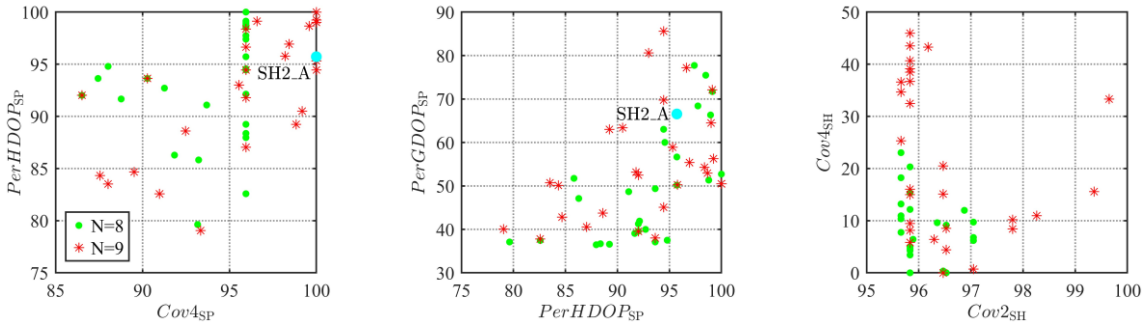


Figure 2: The Optimization Pareto fronts of the first stage of reconfiguration. N represents the number of the satellites.

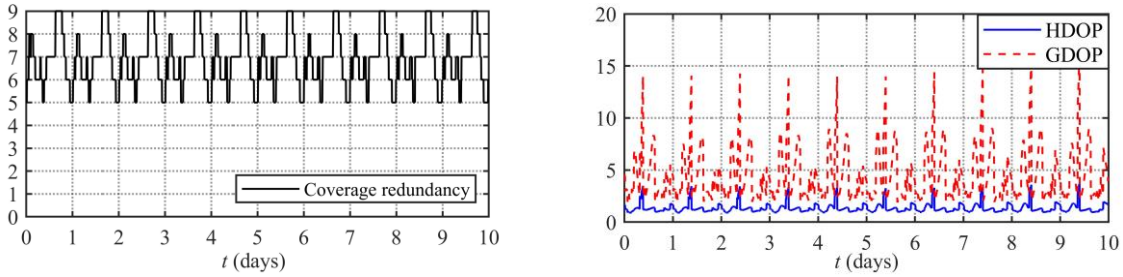
The performance metrics of solution SH1_E $Cov4_{SP}$, $PerHDOP_{SP}$, $PerGDOP_{SP}$, and $Cov2_{SH}$ are 86.52%, 90.74%, 35.53%, and 95.66%, respectively. It can be observed that SH1_E exhibits performance decline over the SP region compared to SP_F. Therefore, in the second phase, the new satellites are added to restore the performance in SP regions. The second sub-Pareto fronts are illustrated in the Fig. 3. As seen in Fig. 3(a) and Fig. 3(b), significant improvements are observed in the performances for SP region. According to Fig. 3(c), the $Cov2_{SH}$ of all solutions maintains no lower than 95.66%. By comparing five candidate solutions satisfying 100% $Cov4_{SP}$ and better $PerHDOP_{SP}$ than SP_F, scheme SH2_A with highest $PerGDOP_{SP}$ and $PerHDOP_{SH}$ is chosen as the final solution.



To evaluate the service capability, the coverage and navigation performance at the South Pole are shown in Fig. 4. From Fig. 4(a), it can be seen that the coverage redundancy at the south pole always exceeds five-fold, which implies superior navigation performance. This is further validated by Fig. 4(b). During the 10-day simulation period, the HDOP at the south pole remains below 5, while the GDOP stays below 10 for the most of time. These values indicate that scheme SH2_A can provide precise navigation support for most lunar missions at South Pole.

Figure 4: Coverage and navigation performance of SH2_A at South Pole. The simulation time is chosen as 10 days.

Conclusion

Based on the constellation schemes targeting the South Pole, this work applies the reconfiguration to extend the service area to the entire Southern Hemisphere. In the first stage, Hohmann-type phasing maneuvers are employed to adjust the phases of in-orbit satellites, with optimization for minimizing fuel and time consumption. Selected scheme SH1_E is able to achieve over 95% dual coverage across the Southern Hemisphere. In the second stage, one to two new satellites in non-frozen orbits are deployed to restore continuous four-fold coverage over the South Pole region.

Abstract. This study presents a comprehensive analysis of tether-assisted hitchhiking, an innovative propellant less technique that leverages momentum exchange through deployable tethers for asteroid and comet missions. Seven advanced materials are analyzed using the Space Hitchhike Equation framework, with multi-hop degradation modeling across radiation, thermal cycling, and micrometeoroid impacts. Results show that CNT150 provides 10.4 km/s ΔV capability, while Zylon offers near-term mission readiness at 1.9 km/s. Mission scenarios from Near-Earth Object tours (2 km/s) to Kuiper Belt exploration (10 km/s) validate scalability, demonstrating mass efficiency improvements over chemical propulsion.

Introduction

Conventional orbital maneuvering fundamentally relies on the rocket equation, where propellant mass fraction dominates mission architecture. For multi-target exploration requiring cumulative $\Delta V > 10$ km/s, propellant mass exceeds 90% of initial spacecraft mass, severely limiting payload capacity and mission scope. Space hitchhiking introduces a paradigmatic shift: momentum exchange with celestial bodies through temporary mechanical coupling via deployable tethers eliminates propellant dependency entirely[1]. During close approach to an asteroid or comet, a spacecraft deploys a high-strength tether that grapples the target body. Controlled differential velocity between spacecraft and body generates a tension force that decelerates the spacecraft thanks to tether retrieval. Elastic energy storage in the tether material is subsequently converted to electrical energy via a regenerative braking system, enabling propellantless ΔV accumulation across multiple encounters. Tether technology heritage includes several flight demonstrations: TSS-1, SEDS-1/2, YES2. However, these systems focused on single-use Earth-centric operations with Kevlar-class materials[2]. Recent advances in carbon nanotube (CNT) synthesis enable fiber production with tensile strengths exceeding 100 GPa in laboratory settings, though scalability challenges persist. While previous research has explored individual aspects of tether-based propulsion, no prior work comprehensively addresses the integration of multi-hop mission architectures with cumulative degradation modeling, regenerative energy harvesting systems, material trade-space analysis spanning candidates from TRL 4 through TRL 9[3], [4], and outer Solar System mission feasibility assessment. This study provides a comprehensive assessment of these aspects through physics-based modeling and performance simulation across mission scenarios ranging from Near-Earth Objects to Kuiper Belt Objects.

Methodology

For this analysis, a uniform tether geometry is assumed, with L = 1000 m and A = 1×10^{-5} m² (1 cm² cross-section) across all materials, resulting in material-specific tether masses ranging from 13.5 kg (CNT-fiber) to 22.0 kg (Graphene), for the baseline 500 kg spacecraft configuration. The fundamental governing equation for achievable ΔV derives from energy conservation during tether-assisted braking. The analysis framework was implemented in Python using a modular library architecture, with numerical computations performed via *NumPy* and results visualized through *Matplotlib*. The code base includes dedicated modules for material characterization, tether dynamics, PMSG performance modeling, and degradation analysis across multi-hop mission profiles. For a spacecraft of mass m_0 (excluding tether) coupled via tether of mass m_t to an asteroid of mass $M_a \gg (m_0 + m_t)$:

$$\Delta V = \sqrt{\frac{\sigma}{\rho}} \cdot \sqrt{1 - \left(\frac{m_0}{M}\right)^2}. \quad (1)$$

where σ is material tensile strength [Pa], ρ is density [kg/m³], M = $m_0 + m_t$ is total system mass, and the term $\sqrt{\frac{\sigma}{\rho}}$ represents material-specific velocity—the theoretical maximum ΔV achievable as $m_t \to \infty$ [1]. During braking, kinetic energy converts to elastic potential energy stored uniformly across tether length L. For a uniform tether under maximum allowable stress σ_{max}/SF (SF = safety factor = 2.0)[5], integration yields Eq. 1. The mass efficiency factor in the Eq. 2

$$\eta_m = \sqrt{1 - \left(\frac{m_0}{M}\right)^2}. \quad (2)$$

quantifies the fraction of material-specific velocity achievable for a given tether-to-spacecraft mass ratio. Optimal performance occurs when $m_t \approx m_0$, yielding $\eta_m = 0.87$ (87% efficiency).
Seven candidate materials spanning TRL 4-9 were analyzed:

Table 1. Materials description and properties. [5], [6], [9], [10], [11], [12], [13], [14], [15].

Material	σ [GPa]	ρ [kg/m³]	ΔV_{max} [km/s]	TRL
Kevlar-49	3.0	1440	1.44	9
Zylon	5.8	1560	1.93	8
Graphene	3.54	1500	1.54	4
CNT-fiber	8.8	1450	2.46	6
MWNT	35	1450	4.91	5
SWNT	85	1400	7.79	4
CNT150	150	1400	10.35	4

- *Flight-Ready Materials*: Kevlar-49 represents baseline technology with extensive space heritage but limited ΔV capability (1.44 km/s). Zylon offers 34% performance improvement (1.93 km/s) with demonstrated Mars mission applications (airbag systems), positioning it as optimal near-term candidate. [7]
- *Developmental Materials*: Commercial CNT-fiber (TRL 6) offers intermediate performance between polymer and advanced nanotube options, achieving 2.46 km/s with 1 km production capability—sufficient for demonstration missions. Multi-wall (MWNT) and single-wall (SWNT) nanotubes provide 4.91 km/s and 7.79 km/s respectively, enabling Main Belt and

Materials Research Proceedings 69 (2026) 1146-1152 https://doi.org/10.21741/9781644904251-197

Centaur exploration but requiring production scalability development (current: 100 m and 10 m lengths) [8], [9].

CNT150 represents a laboratory-scale achievement with 150 GPa tensile strength in 1-meter samples, offering 10.35 km/s capability sufficient for Kuiper Belt missions. However, its TRL 4 status necessitates a 15–20-year development timeline[11]. A Permanent Magnet Synchronous Generator (PMSG) has been selected for kinetic energy conversion based on several advantages: elimination of excitation power requirements through permanent magnet design, high efficiency (92-97%), vacuum compatibility, and compact architecture with specific power of 50-100 W/kg for space-rated systems. The linear regenerative configuration with an insulated tether equipped with permanent magnets provides superior thermal management for critical high-ΔV maneuvers compared to induction-based alternatives. The generator produces back electromotive force opposing rotation, which creates electromagnetic braking torque[12]. The resulting power output scales with both stator current and angular velocity. Energy losses occur across multiple subsystems: copper losses in generator windings dominate at 40-50% of total dissipation due to resistive heating, iron losses contribute 10-20% through hysteresis and eddy currents, mechanical losses remain negligible (<1%) in vacuum, and power electronics inverter losses from switching transitions and conduction resistance account for 15-25%. The cascade of component efficiencies—generator (95%), inverter (97%), and energy storage (98%)—yields an overall system efficiency of 90.2%. Tether lifetime in multi-hop missions requires degradation analysis:

- *Radiation Exposure*: Cumulative dose varies by trajectory—Main Belt: 2 Mrad over 20 hops; Jupiter region: 10 Mrad (exceeds CNT tolerance limit of 10 Mrad but within Kevlar's 200 Mrad). Strength retention is modeled as in the Eq. 3:

$$\sigma(D) = \sigma_0 e^{-\frac{D}{D_0}}. \quad (3)$$

where D_0 is characteristic damage dose [19], [20].

- *Thermal Cycling*: Each hop induces thermal transient from ambient (300 K) to peak (400-600 K depending on braking duration and material). Polymer degradation: Kevlar retains 60% strength after 100 cycles; Zylon: 74%; CNT-fiber: 90%.
- *Micrometeoroid Impact*: modeled with probabilistic model in the Eq. 4

$$P_{impact}(t) = 1 - e^{-\lambda A t}. \quad (4)$$

where $\lambda = 10^{-6}$ m^{-2}yr^{-1} (Main Belt flux), A is the tether cross-sectional area [21].

Over a 20-year mission duration, impact probability is approximately 65% for Main Belt operations, compared with around 12% for Centaur and Kuiper Belt trajectories. Fig. 1 reveals a stark performance dichotomy. Polymer materials exhibit catastrophic UV-driven degradation, collapsing to <30% retention after 1-2 hops—rendering them non-viable for multi-hop architectures. In contrast, advanced CNT materials (MWNT, SWNT, CNT150) display gradual, predictable degradation at rates 6-7× slower, maintaining >60% strength retention over 15-20 hops. This fundamental material boundary defines the transition from single-encounter demonstrations to sustained deep-space exploration campaigns.

Materials Research Proceedings 69 (2026) 1146-1152 https://doi.org/10.21741/9781644904251-197

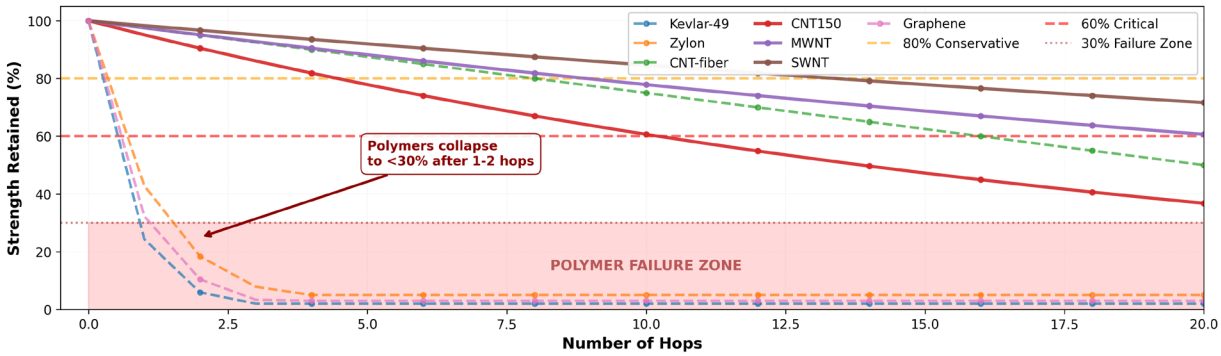

Fig. 1: Multi-hop degradation analysis.

Results

Fig. 2 presents Eq.1 performance across the mass ratio spectrum. CNT150 maintains >10 km/s capability until $m_0/M < 0.3$, while Kevlar-49 achieves ~ 1.44 km/s only for $m_0/M<0.5$.

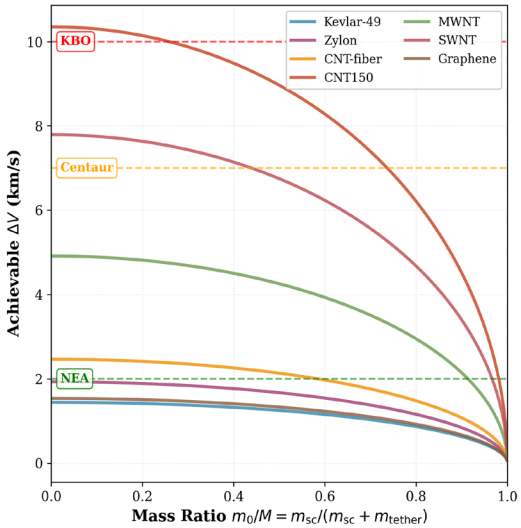

Fig. 2: Space Hitchhike Equation: achievable ΔV capabilities vs. mass ratio m_0/M for all materials, showing mission target thresholds (NEA, MBA, Centaur, KBO).

The computational analysis evaluates seven tether materials across 20 sequential hitchhike maneuvers, incorporating progressive strength degradation from radiation (dose-dependent exponential decay), UV exposure, thermal cycling, and micrometeoroid impacts. [15]
To be conservative, for each hop *i*, the strength retention factor, SRF_i, defined in Eq. 5

$$SRF_i(material) = min(SRF_{rad}, SRF_{UV}, SRF_{thermal}, SRF_{mmod}). \quad (5)$$

determines the degraded tensile strength, $\sigma_{degraded_i}$,

$$\sigma_{degraded_i} = \sigma_0 \times SRF_i. \quad (6)$$

which feeds into Eq.1 to calculate the available ΔV_i as

$$\Delta V_i = \sqrt{\frac{\sigma_{degraded_i}}{\rho}} \times \sqrt{\left[1 - \left(\frac{m_0}{M}\right)^2\right]}. \quad (7)$$

Cumulative ΔV budgets emerge from summation:

$$\Delta V_{total} = \sum_i^n \Delta V_i \, . \quad (8)$$

Results reveal critical material-dependent limitations driven by UV radiation: high-performance polymers (Kevlar, Zylon, Graphene) exhibit few or none viable hops due to catastrophic strength

Materials Research Proceedings 69 (2026) 1146-1152 https://doi.org/10.21741/9781644904251-197

loss (>50%) within the first hop cycle, despite adequate initial ΔV capacity (1.4-1.9 km/s). CNT-based materials demonstrate superior survivability [16]: CNT150 achieves 43.5 km/s cumulative over 20 hops (99+ hop theoretical maximum), MWNT delivers 24.2 km/s (22 hop limit), and SWNT provides 30.8 km/s (99+ hops), with radiation damage as the dominant long-term failure mechanism (D_{50} = 4-8 Mrad)[16].

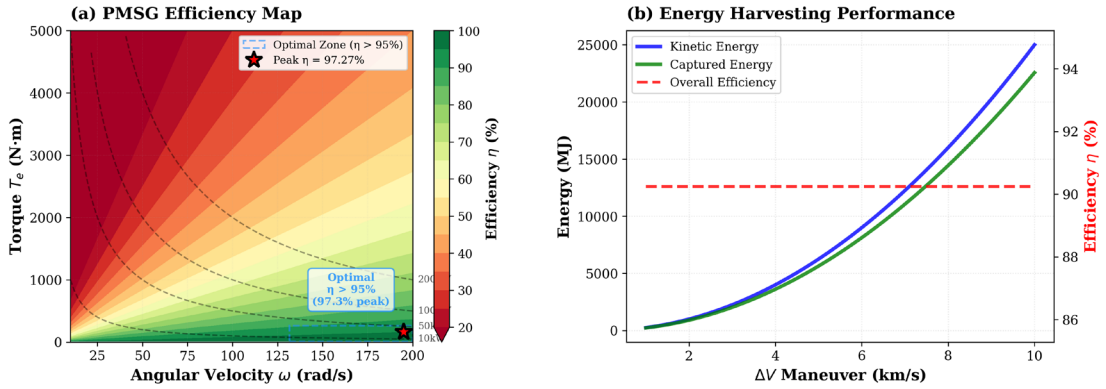

Fig. 3: PMSG regenerative braking system performance.

PMSG efficiency mapping identifies an optimal operating region at 125-200 rad/s and 200-1200 N·m (blue dashed zone, Fig. 3a), achieving peak efficiency of 97.3% with η > 95% throughout. Low-speed (<50 rad/s) and high-torque (>3000 N·m) regimes exhibit <60% efficiency due to fixed iron losses and excessive copper losses dominating, respectively. Energy harvesting maintains 90.2% overall efficiency across 1-10 km/s ΔV range, with captured energy scaling quadratically. The power-time trade-off demonstrates that extended braking strategies address both thermal management and mission operational requirements simultaneously, offering design flexibility across the mission complexity spectrum. TRL-performance scatter in Fig. 4 reveals critical trade-space: Kevlar-49, at TRL 9, offers immediate flight readiness, but its 1.4 km/s capability limits missions to NEA-class targets. Zylon (TRL 8, with 1.9 km/s capability) supports extension to MBA scenarios with minimal development risk. CNT-fiber (TRL 6, 2.5 km/s) requires 5-7 year maturation but enables comprehensive NEA campaigns. Advanced CNT materials (SWNT, CNT150) provide >7 km/s for Centaur/KBO missions but necessitate 10-20 year development timelines [3], [4], [17].

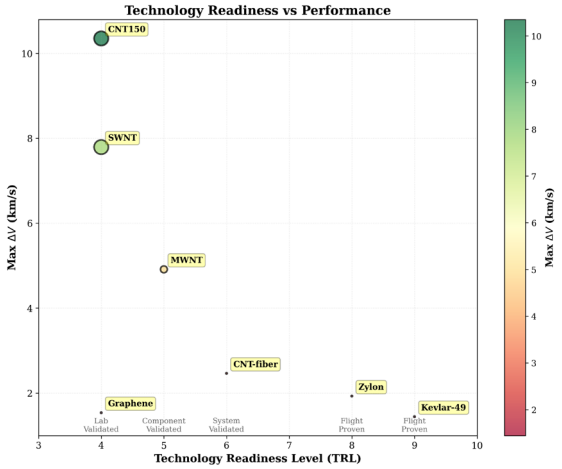

Fig.4: Technology readiness vs. performance: TRL assessment mapped against maximum achievable ΔV, with bubble size indicating max hops before 60% strength degradation threshold.

Conclusion

This analysis demonstrates that tether-assisted hitchhiking enables propellantless multi-target exploration through momentum exchange, with material selection critically determining mission scope. Flight-ready polymers (Kevlar, Zylon) support Near-Earth Object campaigns but exhibit UV-dominated degradation, limiting operational lifetime to <10 hops. CNT-based architectures unlock Main Belt and outer Solar System exploration with cumulative ΔV budgets exceeding 40 km/s over 20 hops, though thermal management and radiation tolerance remain critical design constraints. The identified TRL-performance trade-space provides mission planners with quantitative criteria for material selection aligned with scientific objectives, development timelines, and risk tolerance. Progressive PMSG efficiency validates the regenerative energy harvesting approach, establishing hitchhiking as a scalable paradigm for sustainable, long-duration exploration architectures that transcend conventional propellant limitations.

A Compensation Strategy for Cases of Divergence in Angle of Arrival Measurements Due to Satellite Attitude

Marcello ASCIOLLA[1,a *], Angela CRATERE[1,b] and Francesco DELL'OLIO[1,c]

[1]Politecnico di Bari, Via Orabona 4, 70126, Bari, Italy

[a]m.asciolla@phd.poliba.it, [b]a.cratere@phd.poliba.it, [c]francesco.dellolio@poliba.it

Keywords: Angle of Arrival (AOA), Attitude Determination and Control System (ADCS), Attitude, Cramér-Rao Lower Bound (CRLB), Error Divergence, Error Compensation, Error Modelling, Satellite, Space Systems

Abstract. The study is on satellite systems for localization purposes. The platform of interest is a satellite system equipped with antenna array payload able to perform Angle of Arrival (AOA) measurements. The framework is on the possible interaction and mutual influence between two subsystems: the Attitude Determination and Control System (ADCS) and a payload composed of 3D antenna arrays. The paper wants to investigate the effects of the attitude of the satellite on the payload measurement and it focuses on the propagation of the attitude errors on the payload measurement error. In particular, it has been observed that in some relative configurations it is possible to have an unwanted divergence of the measurements: its prediction and compensation is of crucial interest both for Earth scanning operations and interplanetary missions. The methodology follows the analytical formulation of the problem of geolocation, through the measurement equation and performance metrics based on Cramér Rao Lower Bound (CRLB) for its variance. Then, combining the attitude of the satellite with the relative position of the emitter of signal with respect to the satellite platform, the reveal of cases of divergence is exposed. The novelty of the study is on the proposal of a scheme of compensation for such cases of divergence in order to obtain a reliable measurement considering only the data available onboard. The study is of interest for a set of future algorithms for miniaturized payload systems composed of sensors based on antenna arrays. Potential target satellite missions are on, but not limited to, search and rescue, telecommunication, and spectrum monitoring of jamming signals for civil aviation in E1/L1 GNSS band. The exemplary use-case scenario presented in the study involves an emitter of electromagnetic waves on the surface of the Earth and a satellite system with tri-axial antenna array as sensing equipment. Despite the toy model of the study is on Earth missions, the approach and results are generalizable and of interest also for any manned and unmanned interplanetary missions that have to deal with the influence of ADCS on 3D antenna array payloads.

Mathematical Model for Satellite-Based Geolocation

The starting point of the study is the problem of the geolocation of the position of a source of electromagnetic waves $\mathbf{x}_E$ by a satellite platform placed in $\mathbf{x}_S$ with Angle of Arrival (AOA) technology [1].

In order to perform this operation, the onboard algorithm must perform the workflow depicted in Figure 1; the operations are based on common representation of data in astrodynamics [2].

Materials Research Proceedings 69 (2026) 1153-1157 https://doi.org/10.21741/9781644904251-198

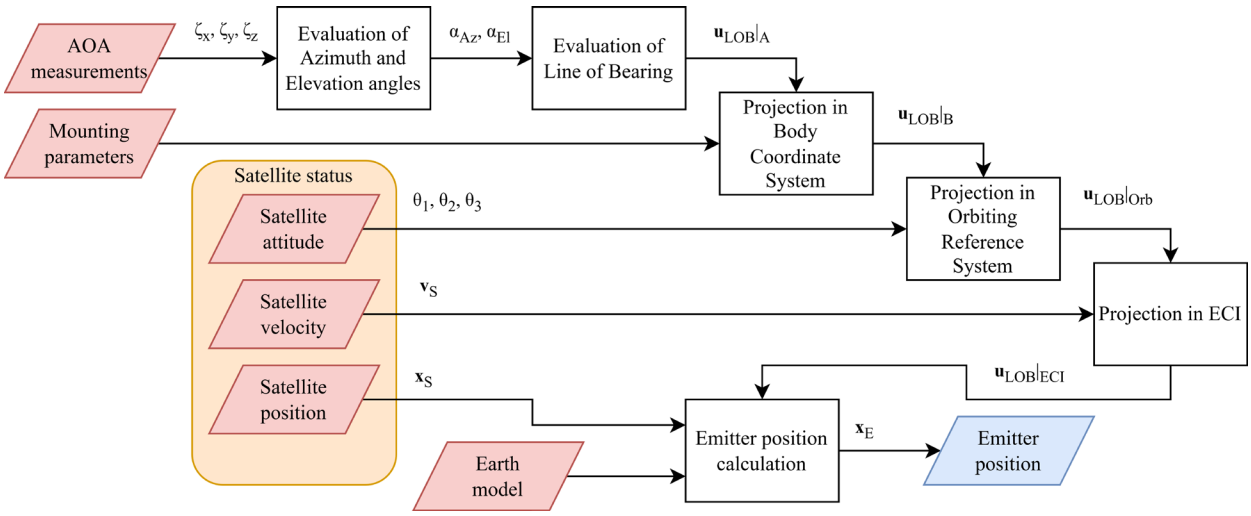

Figure 1 – Scheme of geolocation of the position an electromagnetic emitter of signal x_E from a satellite platform placed in x_S.

Each sensing array calculates its bearing angle ζ_x, ζ_y, ζ_z, which geometrically can be defined as the dot product between the Line of Bearing (LOB) $\mathbf{u}_{LOB}$ and the unit vectors of the arrays $\mathbf{u}_{Ar,x}$, $\mathbf{u}_{Ar,y}$, $\mathbf{u}_{Ar,z}$ as shown in (1).

$$\begin{cases} \cos(\zeta_x) = \mathbf{u}_{LOB} \cdot \mathbf{u}_{Ar,x} \\ \cos(\zeta_y) = \mathbf{u}_{LOB} \cdot \mathbf{u}_{Ar,y} \\ \cos(\zeta_z) = \mathbf{u}_{LOB} \cdot \mathbf{u}_{Ar,z} \end{cases} \tag{1}$$

Introducing [3] a local spherical coordinate system x_A, y_A, z_A, it is possible to define the (1) in terms of Azimuth angle α_{Az} and Elevation angle α_{El} as shown in (2).

$$\begin{cases} \cos(\zeta_x) = \mathbf{u}_{LOB}|_A \cdot \mathbf{u}_{Ar,x}|_A = \begin{pmatrix} \cos(\alpha_{Az})\cos(\alpha_{El}) \\ \sin(\alpha_{Az})\cos(\alpha_{El}) \\ \sin(\alpha_{El}) \end{pmatrix} \cdot \begin{pmatrix} 1 \\ 0 \\ 0 \end{pmatrix} = \cos(\alpha_{Az})\cos(\alpha_{El}) \\ \cos(\zeta_y) = \mathbf{u}_{LOB}|_A \cdot \mathbf{u}_{Ar,y}|_A = \begin{pmatrix} \cos(\alpha_{Az})\cos(\alpha_{El}) \\ \sin(\alpha_{Az})\cos(\alpha_{El}) \\ \sin(\alpha_{El}) \end{pmatrix} \cdot \begin{pmatrix} 0 \\ 1 \\ 0 \end{pmatrix} = \sin(\alpha_{Az})\cos(\alpha_{El}) \\ \cos(\zeta_z) = \mathbf{u}_{LOB}|_A \cdot \mathbf{u}_{Ar,z}|_A = \begin{pmatrix} \cos(\alpha_{Az})\cos(\alpha_{El}) \\ \sin(\alpha_{Az})\cos(\alpha_{El}) \\ \sin(\alpha_{El}) \end{pmatrix} \cdot \begin{pmatrix} 0 \\ 0 \\ 1 \end{pmatrix} = \sin(\alpha_{El}) \end{cases} \tag{2}$$

Unreliable Measurement and Attitude Role

A measurement of a broadside angle $\hat{\zeta}$ for a linear antenna array can be unreliable when the variance $\sigma_{\hat{\zeta}}^2$, predicted through the Cramér-Rao Lower Bound [4] and reported in (3), diverges.

$$\sigma_{\hat{\zeta}}^2 = \frac{12}{(2\pi)^2 SNR \frac{(M+1)}{(M-1)} M \left(\frac{fL}{c}\right)^2 \sin^2(\zeta)} \tag{3}$$

Materials Research Proceedings 69 (2026) 1153-1157 https://doi.org/10.21741/9781644904251-198

In the model SNR denotes the Signal-to-Noise ratio, c the speed of propagation of the signal, f the frequency of the signal. M and L denote the number of antenna elements and the length of the antenna array along the considered direction.

The divergence condition is $\sigma_{\hat{\zeta}}^2 \to \infty$ which corresponds to $1/\sin^2(\zeta) \to \infty$ or, equivalently, to $\sin(\zeta) \to 0$ and $\zeta \to 0 + k\pi$ with $k \in \mathbb{Z}$. Operatively, for models reported in (1) and (2), the condition of divergence written as $\cos(\zeta) \to \pm 1$ is of interest.

Given a certain relative configuration between the satellite position $\mathbf{x}_S$ and emitter position $\mathbf{x}_E$, this divergence can occur because the antenna array axis can be aligned to the LOB because of the satellite attitude, so it is possible to assume $\zeta = (\theta_1, \theta_2, \theta_3)$ as a first attempt of abstract model, where θ_1, θ_2, θ_3 denote the attitude angles of roll, pitch, and yaw of the satellite.

In particular, when $\hat{\zeta}_x$ results unreliable, then $\cos(\hat{\alpha}_{Az})\cos(\hat{\alpha}_{El}) \to \pm 1$ or, equivalently, $\hat{\alpha}_{Az} \to k_1\pi \cup \hat{\alpha}_{El} \to k_2\pi$ with $k_1, k_2 \in \mathbb{Z}$.

When $\hat{\zeta}_y$ results unreliable, then $\sin(\hat{\alpha}_{Az})\cos(\hat{\alpha}_{El}) \to \pm 1$ or, equivalently, $\hat{\alpha}_{Az} \to \frac{\pi}{2} + k_1\pi \cup \hat{\alpha}_{El} \to k_2\pi$ with $k_1, k_2 \in \mathbb{Z}$.

When $\hat{\zeta}_z$ results unreliable, then $\sin(\hat{\alpha}_{El}) \to \pm 1$ or, equivalently, $\hat{\alpha}_{El} \to \frac{\pi}{2} + k\pi$ with $k \in \mathbb{Z}$.

Possible Estimations of Azimuth and Elevation Angles

From the representation of data in (2) it is possible to conclude that for each pair of broadside angles an estimation of the Azimuth and Elevation angles is possible.

Given the measurements $\hat{\zeta}_x$ and $\hat{\zeta}_y$, the corresponding Azimuth and Elevation angles, denoted here with $\hat{\alpha}_{Az;x-y}$ and $\hat{\alpha}_{El;x-y}$ can be estimated through the ones reported in (4).

$$\begin{cases} \hat{\alpha}_{Az;x-y}(\hat{\zeta}_x, \hat{\zeta}_y) = \operatorname{atan2}\left(\cos(\hat{\zeta}_y), \cos(\hat{\zeta}_x)\right) \\ \hat{\alpha}_{El;x-y}(\hat{\zeta}_x, \hat{\zeta}_y) = \arccos\sqrt{\cos^2(\hat{\zeta}_x) + \cos^2(\hat{\zeta}_y)} \end{cases} \tag{4}$$

Given the measurements $\hat{\zeta}_x$ and $\hat{\zeta}_z$, the corresponding Azimuth and Elevation angles, denoted here with $\hat{\alpha}_{Az;x-z}$ and $\hat{\alpha}_{El;x-z}$ can be estimated through the ones reported in (5).

$$\begin{cases} \hat{\alpha}_{Az;x-z}(\hat{\zeta}_x, \hat{\zeta}_z) = \arccos\left(\dfrac{\cos(\hat{\zeta}_x)}{\cos\left(\arcsin\left(\cos(\hat{\zeta}_z)\right)\right)}\right) \\ \hat{\alpha}_{El;x-z}(\hat{\zeta}_z) = \arcsin(\hat{\zeta}_z) \end{cases} \tag{5}$$

Given the measurements $\hat{\zeta}_y$ and $\hat{\zeta}_z$, the corresponding Azimuth and Elevation angles, denoted here with $\hat{\alpha}_{Az;y-z}$ and $\hat{\alpha}_{El;y-z}$ can be estimated through the ones reported in (6).

$$\begin{cases} \hat{\alpha}_{Az;y-z}(\hat{\zeta}_y, \hat{\zeta}_z) = \arcsin\left(\dfrac{\cos(\hat{\zeta}_y)}{\cos\left(\arcsin\left(\cos(\hat{\zeta}_z)\right)\right)}\right) \\ \hat{\alpha}_{El;y-z}(\hat{\zeta}_y) = \arcsin(\hat{\zeta}_z) \end{cases} \tag{6}$$

Fusion of the Measurements in a Linear Model

When all the three measurements $\hat{\zeta}_x$, $\hat{\zeta}_y$, $\hat{\zeta}_z$ are reliable, then, in principle, it is possible to fuse all the estimations (4), (5), and (6). For simplicity and demonstrative purposes, in this paper a linear model with weights $w_{Az;x-y}$, $w_{Az;x-z}$, $w_{Az;y-z}$, $w_{El;x-y}$, $w_{El;x-z}$, and $w_{El;y-z}$ is assumed, as in (7).

Materials Research Proceedings 69 (2026) 1153-1157 https://doi.org/10.21741/9781644904251-198

$$\begin{cases} \hat{\alpha}_{\mathrm{Az}}(\hat{\zeta}_x, \hat{\zeta}_y, \hat{\zeta}_z) = w_{\mathrm{Az;x-y}}\hat{\alpha}_{\mathrm{Az;x-y}}(\hat{\zeta}_{\mathrm{x}}, \hat{\zeta}_y) + w_{\mathrm{Az;x-z}}\hat{\alpha}_{\mathrm{Az;x-z}}(\hat{\zeta}_{\mathrm{x}}, \hat{\zeta}_z) \\ \qquad\qquad + w_{\mathrm{Az;y-z}}\hat{\alpha}_{\mathrm{Az;y-z}}(\hat{\zeta}_y, \hat{\zeta}_z) \\ \hat{\alpha}_{\mathrm{El}}(\hat{\zeta}_x, \hat{\zeta}_y, \hat{\zeta}_z) = w_{\mathrm{El;x-y}}\hat{\alpha}_{\mathrm{El;x-y}}(\hat{\zeta}_{\mathrm{x}}, \hat{\zeta}_y) + w_{\mathrm{El;x-z}}\hat{\alpha}_{\mathrm{El;x-z}}(\hat{\zeta}_z) + w_{\mathrm{El;y-z}}\hat{\alpha}_{\mathrm{El;y-z}}(\hat{\zeta}_z) \end{cases} \tag{7}$$

The set of conditions on the weights are reported in (8).

$$\begin{cases} w_{\mathrm{Az;x-y}} + w_{\mathrm{Az;x-z}} + w_{\mathrm{Az;y-z}} = 1 \\ w_{\mathrm{El;x-y}} + w_{\mathrm{El;x-z}} + w_{\mathrm{El;y-z}} = 1 \\ 0 \le w_{\mathrm{Az;x-y}} \le 1 \\ 0 \le w_{\mathrm{Az;x-z}} \le 1 \\ 0 \le w_{\mathrm{Az;y-z}} \le 1 \\ 0 \le w_{\mathrm{El;x-y}} \le 1 \\ 0 \le w_{\mathrm{El;x-z}} \le 1 \\ 0 \le w_{\mathrm{El;y-z}} \le 1 \end{cases} \tag{8}$$

The reader can notice that $\hat{\alpha}_{\mathrm{El;x-z}}(\hat{\zeta}_z) = \hat{\alpha}_{\mathrm{El;y-z}}(\hat{\zeta}_z) = \hat{\alpha}_{\mathrm{El;z}}(\hat{\zeta}_z)$, so it is possible to consider $w_{\mathrm{El;x-z}} = w_{\mathrm{El;y-z}} = w_{\mathrm{El;z}}$, then the second equation of (7) can be rewritten as reported in (9).

$$\begin{cases} \hat{\alpha}_{\mathrm{Az}}(\hat{\zeta}_x, \hat{\zeta}_y, \hat{\zeta}_z) = w_{\mathrm{Az;x-y}}\hat{\alpha}_{\mathrm{Az;x-y}}(\hat{\zeta}_{\mathrm{x}}, \hat{\zeta}_y) + w_{\mathrm{Az;x-z}}\hat{\alpha}_{\mathrm{Az;x-z}}(\hat{\zeta}_{\mathrm{x}}, \hat{\zeta}_z) \\ \qquad\qquad + w_{\mathrm{Az;y-z}}\hat{\alpha}_{\mathrm{Az;y-z}}(\hat{\zeta}_y, \hat{\zeta}_z) \\ \hat{\alpha}_{\mathrm{El}}(\hat{\zeta}_x, \hat{\zeta}_y, \hat{\zeta}_z) = w_{\mathrm{El;x-y}}\hat{\alpha}_{\mathrm{El;x-y}}(\hat{\zeta}_{\mathrm{x}}, \hat{\zeta}_y) + 2w_{\mathrm{El;z}}\hat{\alpha}_{\mathrm{El;z}}(\hat{\zeta}_z) \end{cases} \tag{9}$$

An architectural representation of the linear fusion strategy of the model (9) is reported in Figure 2.

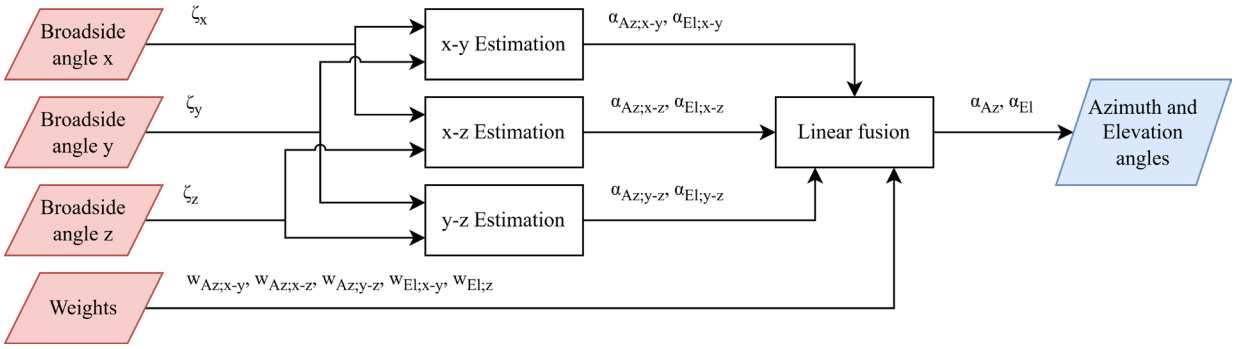

Figure 2 – Scheme of linear fusion of the measurements with weights for the calculation of Azimuth angle α_{Az} and Elevation angle α_{El}.

Management of Unreliable Measurements

Considering that an estimation of Azimuth angle and Elevation angle can be obtained even if one of the three broadside angles is unreliable, then it is possible to develop a simple scheme of reliability analysis with the selection of weights for the fusion of the measurements as reported in Figure 3. More generally, it is also possible to conceive the scheme considering the estimation of the position of the emitter of the signal as additional feedback information: in this latter case, the reliability analysis is performed considering the relative position between the satellite platform and the emitter of signal $\mathbf{x}_{\mathrm{E}} - \mathbf{x}_{\mathrm{S}}$ and the full state of the satellite.

Materials Research Proceedings 69 (2026) 1153-1157 https://doi.org/10.21741/9781644904251-198

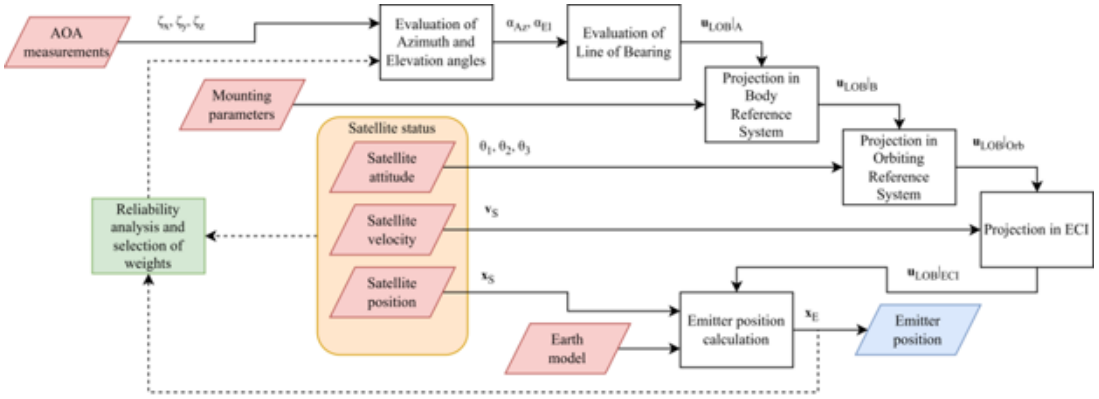

Figure 3 – Scheme of geolocation of the position an electromagnetic emitter of signal x_E from a satellite platform placed in x_S with a scheme of reliability analysis of the measurements and selection of weights for the fusion of the measurements.

Conclusions

The study presents a first level of theoretical analysis of cases of divergence of the dispersion of the measurements in space-based geolocation applications with tri-axial antenna arrays with AOA technology. The model shows that for this payload it is possible to predict and overcome the phenomenon of the divergence of the dispersion of the measurement if the current state of the satellite is available. Despite the study is restricted to a linear fusion model, an overall reliable measurement has been obtained and a compensation scheme has been presented. The validation of the method, its simulation and experimental implementation are left for future investigations.

Keywords: Angle of Arrival (AOA), Cramér-Rao Lower Bound (CRLB), Dilution of Precision (DOP), LEO satellites, multi-constellation, Radio Frequency Interference (RFI), RF emissions monitoring, space systems, Time Difference of Arrival (TDOA)

Abstract. The deployment of small Low Earth Orbit (LEO) satellites equipped with radio-frequency (RF) tracking sensors marks a transformative shift in global, space-based RF emissions monitoring. Leveraging cost-effective software-defined radio (SDR) technology and advanced micro-antenna arrays, these satellites – organized into tandems or clusters – can efficiently scan the Earth's surface. Their payload can generate Time Difference of Arrival (TDOA) or Angle of Arrival (AOA) observables that can be used to accurately detect and locate RF emitters. Applications range from identifying known distress signals for search and rescue operations to detecting unknown Radio Frequency Interference (RFI) sources that may disrupt protected bands, such as GNSS. Currently operational LEO satellite constellations already offer such data acquisition, with commercial providers offering varying performances based on the number of deployed satellites and revisit times. To achieve unparalleled monitoring coverage and responsiveness, this paper introduces the innovative concept of a multi-constellation approach, where a centralized RF monitoring service provider accesses data from multiple constellations. The cost-benefit of this more expensive solution hinges not on the sum of individual constellation capabilities but on the potential to capitalize on additional multi-constellation opportunistic events, termed 'collisions.' These occur when satellites from different constellations form new clusters, allowing simultaneous observation of the same area and enabling additional TDOA or AOA measurements not associated to a single constellation. The effectiveness of these collisions depends on relative geometry and other critical performance indicators, and not all events can be considered advantageous for a target RF detection and localization scenario. This paper develops a methodology to establish metrics that quantify the occurrence and utility of such interactions, providing collision frequency data. The methodology involves an analytical description of satellite constellations with varying orbit sizes, considering their relative kinematics to a reference signal emitter on Earth's surface, the Cramér-Rao Lower Bound (CRLB), Dilution of Precision (DOP), and incorporating constraints on the Line of Sight (LOS). Case studies in LEO mission applications, exemplary of search and rescue operations and spectrum monitoring in the E1/L1 GNSS frequency bands, are discussed. The proposed solution offers a crucial tool for monitoring service providers to evaluate the advantages of multi-constellation data access, assess the expected number of beneficial collisions, and optimize sensor acquisition scheduling to maximize multi-constellation RF detection and localization accuracy.

Reference Context of the Study

The context of the study is within the macroscopic area related to the evaluation of the set of conditions that can guarantee a combined measurement for a set of constellations of satellites. For simplicity, the study is confined to a simpler case of two constellations $\mathcal{C}_1$ and $\mathcal{C}_2$. Each constellation is also supposed to be, more specifically, a cluster of satellites that orbit very close to each other: given two satellites $\mathbf{x}_{S_1} \in \mathcal{C}_1$ and $\mathbf{x}_{S_2} \in \mathcal{C}_2$, their distance is small compared to the total lengths $\mathcal{L}_{S_1}$ and $\mathcal{L}_{S_2}$ of their orbits, so condition $\|\mathbf{x}_{S_1} - \mathbf{x}_{S_2}\| \ll \mathcal{L}_{S_1} \cup \|\mathbf{x}_{S_1} - \mathbf{x}_{S_2}\| \ll \mathcal{L}_{S_2}$ holds for each couple of satellites within the same cluster.

The objective of the problem is to evaluate when the two constellations $\mathcal{C}_1$ and $\mathcal{C}_2$ are close enough to perform a combined measurement.

Without loss of generality and to have a first simpler approach to the problem, it is supposed that each constellation is composed of one single satellite, which is a representative for the whole cluster. The actors of the problem are then satellites $\mathbf{x}_{S_1} \in \mathcal{C}_1$ and $\mathbf{x}_{S_2} \in \mathcal{C}_2$

Each single satellite is supposed to have a generic payload composed of antenna array able to perform measurement with Angle of Arrival (AOA) technology and the combined presence of at least two satellites can perform a Time Difference of Arrival (TDOA) measurement [1].

These measurements can be used to geolocate an emitter of electromagnetic waves placed in $\mathbf{x}_E$ on the surface of the Earth for search and rescue operations or spectrum monitoring of jamming signals.

Relative Geometry and Intersection Points

Orbital kinematics of the satellites that orbit the Earth follow elliptic orbits that can be described by orbital parameters [2]: the semi-major axis a, the eccentricity e, the inclination i, the right ascension of the ascending node Ω, the argument of perigee ω, and the true anomaly ν. The true anomaly is the only parameter that depends on the time t, so $\nu = \nu(t)$.

For circular orbits $e = 0$, $\omega = 0$, and the semi-major axis is replaced by the radius of the orbit $a = r$. Given this further assumption, then $\mathbf{x}_{S_1}(r_1, i_1, \Omega_1, \nu_1(t))$ and $\mathbf{x}_{S_2}(r_2, i_2, \Omega_2, \nu_2(t))$.

In order to predict the moments in which a combined measurement is possible, a higher level of abstraction is required. More generally, for a satellite S it is possible to say that a circular orbit, described by a closed curve γ_S, lies completely in an orbital plane π_S.

By definition, an orbital plane π_S contains both the orbit γ_S and the centre of mass of the planet, which for the Earth is denoted by $\mathbf{x}_\oplus$ in this study.

Then, the intersection of the planes $\pi_{S_1} \cap \pi_{S_2}$ gives the line l_{S_1,S_2} in which the combined measurement of the two constellations $\mathcal{C}_1$ and $\mathcal{C}_2$ is supposed to be possible.

The set of points of the intersections I between this line and the orbits, formally

$$\begin{aligned} I &= \{\mathbf{x} \in \mathbb{R}^3 | (l_{S_1,S_2} \cap \gamma_{S_1}) \vee (l_{S_1,S_2} \cap \gamma_{S_2})\} \\ &= \{\mathbf{x} \in \mathbb{R}^3 | ((\pi_{S_1} \cap \pi_{S_2}) \cap \gamma_{S_1}) \vee ((\pi_{S_1} \cap \pi_{S_2}) \cap \gamma_{S_2})\} \end{aligned} \quad (1)$$

are of interest. If the orbital planes are not parallel $\pi_{S_1} \nparallel \pi_{S_2}$, the set of points I is finite and, in particular, it has two points (denoted here as A and B) for each orbit, $I = \{\mathbf{x}_{1,A}, \mathbf{x}_{1,B}, \mathbf{x}_{2,A}, \mathbf{x}_{2,B}\}$. Equivalently, this means that for each couple of orbital planes, two geometrical values of the true anomaly can be identified for each satellite; here, for two satellites S_1 and S_2 they are denoted with $\nu_{1,A}$, $\nu_{1,B}$, $\nu_{2,A}$, and $\nu_{2,B}$.

Materials Research Proceedings 69 (2026) 1158-1163 https://doi.org/10.21741/9781644904251-199

Intervals at Intersection Points

The position of each circular orbit is periodic with a period $T_k = 2\pi\sqrt{\frac{r_k^3}{\mu_\oplus}}$ with $k = 1,2$, where $\mu_\oplus$ is the standard gravitational parameter of the Earth. So also the passage of the satellites in each one of the intersection points is periodic with period T, so $\nu_{1,\mathrm{A}}(t) = \nu_{1,\mathrm{A}}(t + n_1T_1)$, $\nu_{1,\mathrm{B}}(t) = \nu_{1,\mathrm{B}}(t + n_1T_1)$, $\nu_{2,\mathrm{A}}(t) = \nu_{2,\mathrm{A}}(t + n_2T_2)$, $\nu_{2,\mathrm{B}}(t) = \nu_{2,\mathrm{B}}(t + n_2T_2)$ with $n_1, n_2 \in \mathbb{N}$.

A true anomaly of intersection $\nu_\mathrm{I} = \{\nu \in \gamma | \nu = \nu_\mathrm{A} \vee \nu = \nu_\mathrm{B}\}$ can be defined and considered to avoid the duplicated representation. In this representation, the periodicity is half of the orbital period: $\nu_{1,\mathrm{I}}(t) = \nu_{1,\mathrm{I}}(t + n_1T_1/2)$ and $\nu_{2,\mathrm{I}}(t) = \nu_{2,\mathrm{I}}(t + n_2T_2/2)$ with $n_1, n_2 \in \mathbb{N}$.

A measurement exists when the emitter of signal is within the line of sight of the satellite. Considering the geometry reported in Figure 1, the interval of true anomaly of visibility $\Delta\nu_\mathrm{v}$ can be calculated as in (2), where $R_\oplus$ is the radius of the Earth, assumed to be spherical for simplicity.

$$\Delta\nu_{\mathrm{v},k} = 2\arccos\left(\frac{R_\oplus}{r_k}\right), \quad k = 1,2 \tag{2}$$

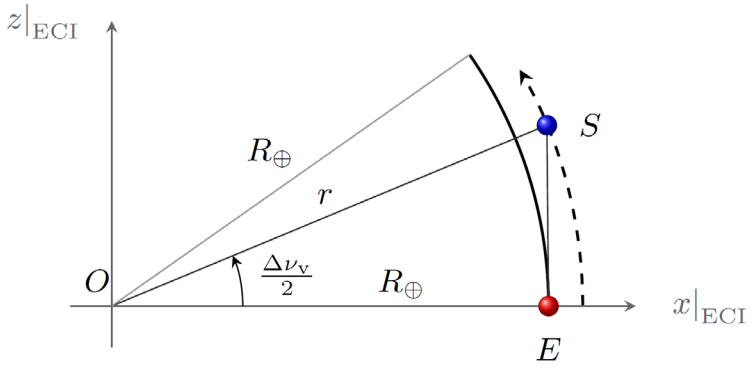

Figure 1 – Reference geometry to calculate the true anomaly of visibility from the Earth radius and satellite orbit radius.

The interval of time visibility ΔT_v is then

$$\Delta T_{\mathrm{v},k} = \frac{\Delta\nu_{\mathrm{v},k}T_k}{2\pi} = \frac{\arccos\left(\frac{R_\oplus}{r_k}\right)T_k}{\pi} = 2\arccos\left(\frac{R_\oplus}{r_k}\right)\sqrt{\frac{r_k^3}{\mu_\oplus}}, \quad k = 1,2. \tag{3}$$

The passage of the satellites at the intersection points can be modeled with a train of rectangular pulses f_1 and f_2 with periodicities $T_1/2$ and $T_2/2$, and widths $\Delta T_{\mathrm{v},1}$ and $\Delta T_{\mathrm{v},2}$, as shown in (4); $t_{0,1}$ and $t_{0,2}$ represent the initial starting times.

$$f_{\mathrm{v},k}(t) = \sum_{j=1}^{\infty}\Pi\left(\frac{\left(t - t_{0,k}\right) - j\frac{T_k}{2}}{\Delta T_{\mathrm{v},k}}\right) = \sum_{j=1}^{\infty}\Pi\left(\frac{\left(t - t_{0,k}\right)\sqrt{\frac{\mu_\oplus}{r_k^3}} - j\pi}{2\arccos\left(\frac{R_\oplus}{r_k}\right)}\right), \quad k = 1,2. \tag{4}$$

Superposition of Intervals

Once the intersection intervals have been defined and modelled it is possible to check their superposition in a certain instant of time.

Given starting instant of time $t_\mathrm{Start} = t_0 + nT$ with $n \in \mathbb{N}$ and ending instant of time $t_\mathrm{End} = t_0 + nT + \Delta T_\mathrm{v}$ with $n \in \mathbb{N}$, then the active interval for a satellite S can be defined as $I_{\mathrm{Act,S}}(n) = [t_\mathrm{Start}(n), t_\mathrm{End}(n)[$ with $n \in \mathbb{N}$; for satellites S_1 and S_2 they are as reported in (5).

Materials Research Proceedings 69 (2026) 1158-1163 https://doi.org/10.21741/9781644904251-199

$$\begin{aligned} I_{\mathrm{Act,S_1}}(n_1) &= \left[t_{0,1} + n_1 T_1\,, t_{0,1} + n_1 T_1 + \Delta T_{\mathrm{v},1}\right[\quad n_1 \in \mathbb{N} \\ I_{\mathrm{Act,S_2}}(n_2) &= \left[t_{0,2} + n_2 T_2\,, t_{0,2} + n_2 T_2 + \Delta T_{\mathrm{v},2}\right[\quad n_2 \in \mathbb{N} \end{aligned} \tag{5}$$

Formally, the set $\mathcal{T}_{\mathrm{Sup}}$ of instants of time of superposition of the intervals can be written as $\mathcal{T}_{\mathrm{Sup}} = \left\{t \in \mathbb{R}_{>0} \middle| \left(t \in I_{\mathrm{Act,S_1}}\right) \wedge \left(t \in I_{\mathrm{Act,S_2}}\right)\right\}$. Because the train of pulses defined in (4) have values of 1 if the interval is active and 0 if the interval is not active, so formally $f_{\mathrm{v},1}\left(t \in I_{\mathrm{Act,S_1}}\right) = 1$ and $f_{\mathrm{v},2}\left(t \in I_{\mathrm{Act,S_2}}\right) = 1$, then from an intuitive point of view, the set $\mathcal{T}_{\mathrm{Sup}}$ can be obtained evaluating the domain of the product function $f_{\mathrm{v},1} f_{\mathrm{v},2}$. To check if a superposition between two active intervals exists, the following situation must happen: both of the starting instants of time $t_{\mathrm{Start},1}$ and $t_{\mathrm{Start},2}$ must happen before of both the ending instants of time $t_{\mathrm{End},1}$ and $t_{\mathrm{End},2}$. This can be written formally as in (6).

$$\max\left(t_{\mathrm{Start},1}(n_1), t_{\mathrm{Start},2}(n_2)\right) < \min\left(t_{\mathrm{End},1}(n_1), t_{\mathrm{End},2}(n_2)\right), \quad n_1, n_2 \in \mathbb{N} \tag{6}$$

Counting the Intersections and Frequency of Collisions

Given the expected ending of the missions of a constellation in $T_{\mathrm{End},\mathcal{C}}$, then the scanning of the superposition of the intervals can happen within a maximum instant of time $T_{\mathrm{Max}} = \min\left(T_{\mathrm{End},\mathcal{C}_1}, T_{\mathrm{End},\mathcal{C}_2}\right)$, because it is supposed that it is not possible to exploit a combined measurement after the end of one of the two missions. From the evaluation of T_{Max}, then it is possible to obtain the total number of intervals for the satellites with $N_1 = 2\left(T_{\mathrm{Max}} - t_{0,1}\right)/T_1$ and $N_2 = 2\left(T_{\mathrm{Max}} - t_{0,2}\right)/T_2$.

With the aid of the condition in (6), it is possible to build an algorithm to predict and count the number of events with the aid of a counter N_{Events}, here denoted as collisions between constellations. When the total number of events have been calculated, then the frequency of collisions $f_c = N_{\mathrm{Events}}/T_{\mathrm{Max}}$ can be calculated. The metrics $f_c(\mathcal{C}_1, \mathcal{C}_1)$ can be useful to evaluate if two constellations $\mathcal{C}_1$ and $\mathcal{C}_2$ can be operatively exploited to perform combined measurements.

It is possible to filter the total number of events evaluating the quality of the collision with respect to local metrics, such as the position dilution of precision $PDOP$, which depends on the distribution of the satellites $\mathbf{x}_{\mathrm{S_1}}$, $\mathbf{x}_{\mathrm{S_2}}$ with respect to a local emitter of signal $\mathbf{x}_{\mathrm{E}}$. Furthermore, models for the variances of the measurements are required, which commonly can be estimated through the Cramér-Rao Lower Bound (CRLB); in particular, for two satellites, the variances of AOA $\sigma^2_{\mathrm{AOA},1}$, $\sigma^2_{\mathrm{AOA},2}$, and TDOA σ^2_{TDOA} can be employed. The details of the models are beyond the purposes of the study, dedicated literature on the topic can be found in [3], [4], [5], [6], [7].

Functional dependence is then in the form

$$PDOP = f\left(\mathbf{x}_{\mathrm{S_1}}, \mathbf{x}_{\mathrm{S_1}}, \mathbf{x}_{\mathrm{E}}, \sigma^2_{\mathrm{AOA},1}, \sigma^2_{\mathrm{AOA},2}, \sigma^2_{\mathrm{TDOA}}\right) \tag{7}$$

The algorithm is presented in Table 1.

Materials Research Proceedings 69 (2026) 1158-1163 https://doi.org/10.21741/9781644904251-199

Conclusions

The study presents a first level of theoretical analysis on the conditions that guarantee the possibility to perform combined measurements for multi-constellation systems, useful for space-based geolocation applications. Despite the study is restricted to two-constellation case and to satellites confined in a circular orbit, a first attempt of a formal framework to model and to build an operative algorithm to check and count the opportunities of such events, here denoted as collisions between constellations, has been obtained. The generalization of the model, e.g. to accommodate multiple constellations and elliptic orbits, its numerical simulation, and the validation of the approach in real-case operative scenarios are left for future investigations.

Credits

Activities of formal analysis and development of models and methods have been performed by the Politecnico di Bari. Motivations and possible application to real-case operative scenarios have been offered by the gentle consultancy of the EC Joint Research Center.

Keywords: Electron Beam Powder Bed Fusion, Open Source

Abstract. Electron Beam Powder Bed Fusion (E-PBF) enables the production of high-performance components by processing reactive alloys under vacuum with controlled microstructures. However, innovation in beam path development has been limited by proprietary software environments. This work introduces OBPlanner, an open-source Python package for slicing and generating beam path strategies for E-PBF. The framework supports spot and line melting, contouring, and localized preheating within a unified workflow and outputs paths in the open Open Beam Format (OBF) used by Freemelt systems. By enabling transparent and reproducible process strategy development, OBPlanner lowers the barrier to experimentation and accelerates open innovation in E-PBF research.

Introduction

Yet another 3D printing slicer? Why?

A fair question. While the market is saturated with commercial and open-source slicers, most are developed for polymer or laser-based additive manufacturing (AM) systems. These typically rely on simple path-planning routines that combine contour scanning with ordered infill lines (hatching). In contrast, Electron Beam Powder Bed Fusion (E-PBF) operates under a fundamentally different regime. The electron beam is magnetically controlled and contains no moving mechanical parts, allowing it to traverse the powder bed with exceptional speed and precision. This makes it possible to employ not only traditional line-based melting but also spot melting, where discrete points are rapidly melted and thermally managed across the layer [1].

Such unconventional beam path strategies offer new opportunities to control thermal gradients, tailor microstructures, and reduce distortion in high-performance alloys such as Ti-6Al-4V and nickel-based superalloys [1]. However, systematic exploration of these strategies has been hindered by proprietary software environments. Most existing E-PBF systems provide only a small set of predefined melting patterns, limiting researchers' ability to design, test, and share new process routes. This restricts reproducibility and slows innovation in a field that thrives on experimental creativity.

To address these limitations, we introduce OBPlanner [2], an open-source Python framework supporting spot and line melting, contouring, and local preheating. By enabling transparent, modifiable beam-path generation in the Open Beam Format (OBF), OBPlanner empowers researchers to experiment, share, and innovate in E-PBF strategy design.

Background and Related work

E-PBF is an AM process that uses a focused electron beam to selectively melt metallic powder under vacuum. Unlike laser-based systems, E-PBF employs electromagnetic lenses for beam deflection, providing non-mechanical, near-instantaneous control of beam position, focus, and power. This enables microsecond beam jumps and dynamic modulation of energy input, making

E-PBF uniquely suited for advanced scan strategies such as discrete spot melting [1]. E-PBF builds typically combine several sequential heating stages to ensure process stability: spatter-safe preheating to minimize particle ejection, jump-safe preheating to stabilize the bed before melting, melting for material consolidation, and heat-balance heating to maintain interlayer temperature uniformity [1]. Recent research has shown that smart planning and thermal control enables microstructure engineering through beam path design, where variations in dwell time, overlap, or scan order can drastically affect local cooling rates and solidification behavior [3], [4], [5], [6]. In addition, studies have shown that ordered and random spot strategies can be used to promote different grain formation and reduce cracking demonstrating that beam motion itself can serve as a powerful process variable [6].

Recent developments in open-architecture research platforms, such as Freemelt's OBP [7] (instructions on how the beam should behave within a specific sequence in a layer) and OBF [8] (overall build process instructions). These open standards provide the foundation for programmable beam control, adaptive scanning, and microstructure-on-demand manufacturing. While these formats exist, there is a lack of open, easily extendable, and modifiable tools for creating such files.

The OBPlanner framework

The OBPlanner framework provides a modular, open-source environment for generating OBP and OBF files. Its architecture is founded on transparency and extensibility, enabling full access to each stage of beam-path generation, from geometric slicing to energy input specifications. At its core, OBPlanner combines two primary inputs: a user-defined JSON configuration file and a sliced 3D model. The configuration file defines which process strategies to apply, including parameters such as beam power, dwell time, and point spacing, while the sliced geometry constrains the beam path to the desired part contours. The output is written in the Open Beam Format (OBF), directly executable on Freemelt systems.

OBPlanner's software structure is organized around two major classes:

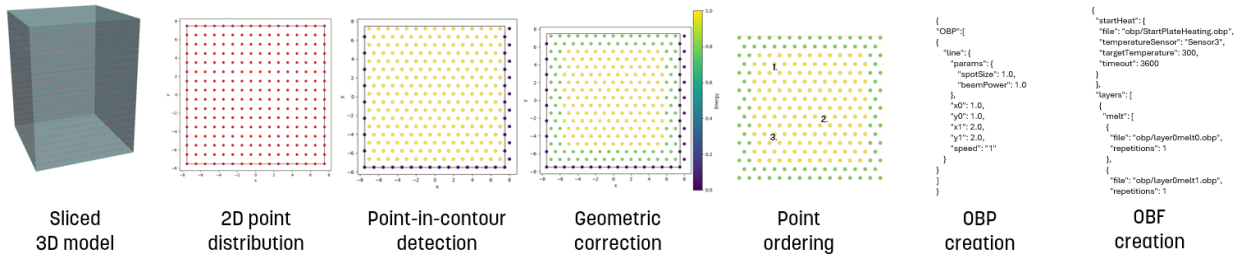
- Strategy: represents a process step, combining a pattern, beam parameters, and an execution movement strategy. Each strategy belongs to one of four categories (spatter-safe, jump-safe, melting, and heat-balance) and defines how energy is distributed across the layer.
- Pattern: generates the spatial distribution of exposure points according to a user-selected layout (square, triangular, HCP, or FCC). The pattern module governs spacing, rotation, and offset between layers, effectively defining the scan geometry.

This object-oriented design ensures that each function is self-contained yet interoperable, allowing users to extend or replace modules independently. For example, new pattern generators or ordering algorithms can be implemented by subclassing existing templates without modifying the rest of the code. This modularity makes OBPlanner both a practical research tool and a foundation for future adaptive process-control systems.

Computational Workflow

OBPlanner converts the combination of geometric and process definitions into ordered beam commands through six main stages (Figure 1):

Materials Research Proceedings 69 (2026) 1165-1170 https://doi.org/10.21741/9781644904251-200



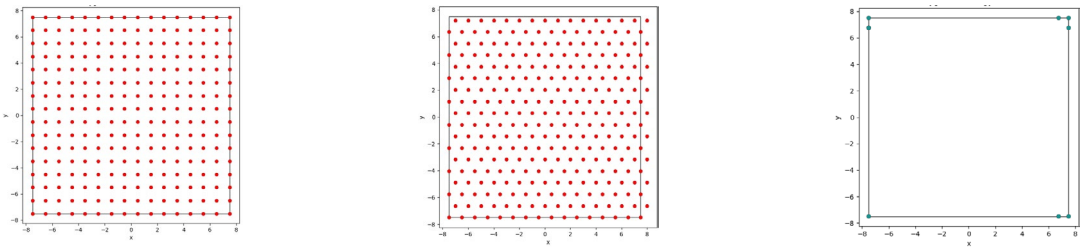


Figure 1. Overview of the OBPlanner workflow.

Sliced model input: The framework imports a sliced 3MF file containing the layer boundaries. This slicing can be performed using an external tool or with the py3mf_slicer Python package [9], which was developed in parallel with this work.
Point distribution: Candidate exposure points are generated according to the selected pattern type, with user-defined spacing and optional rotation between layers. Various filling strategies can be applied, including square and triangular fills, or contour-only exposure (see Figure 2). The package also supports advanced three-dimensional filling patterns, such as hexagonal and face-centered cubic (FCC) arrangements, which enable efficient 3D point packing.
Point-in-contour detection: The generated points are filtered using geometric inclusion tests to retain only those within the part contour. An optional offset parameter can be applied to modify the effective boundary size. This is useful, for example, when compensating for expected swelling during melting or when performing localized preheating slightly beyond the melt area.
Point-in-contour detection: Filter points using geometric inclusion tests to retain only those inside the part contour. In this step an offset setting can be applied to change the size of the boundary, this may be useful e.g. if the user expects swelling during melt or want to du local preheating a little bigger than the melt area.
Geometric correction: The local energy input can be adjusted to account for geometric features such as thin walls, edges, or overhangs, allowing targeted compensation for regions that require additional or reduced heat input.
Point ordering: The valid points are then arranged into optimized beam trajectories—such as random or ordered spot sequences, lines, or contour-following paths, according to user input (see Figure 3.). The code structure is intentionally modular, allowing users to easily integrate and test new path-planning strategies.
OBP/OBF creation: Finally, the ordered point data are converted into Open Beam Path (OBP) files containing position, power, and timing information. These are then assembled into a complete Open Beam Format (OBF) structure, ready for execution on compatible E-PBF systems.

Materials Research Proceedings 69 (2026) 1165-1170 https://doi.org/10.21741/9781644904251-200

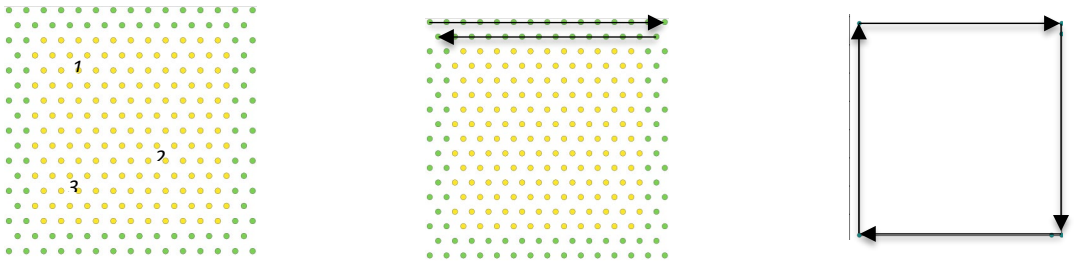

Figure 3. Example of different point ordering methods, (a) random spots, (b) connection of points to a snake line pattern, and (c) contour lines.

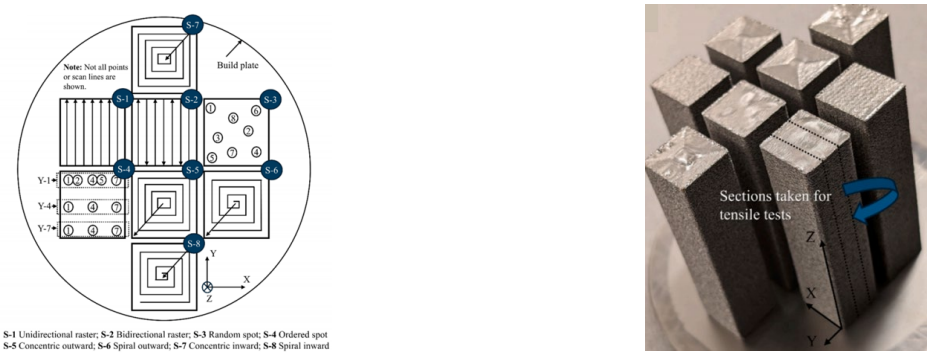

At runtime, OBPlanner reads the JSON configuration, initializes the output directory, and sequentially processes each layer according to the defined strategy hierarchy. For each strategy, the framework generates the spatial pattern, performs contour filtering, applies compensation (if defined), and exports ordered OBP elements. Additional OBF files and scripts (such as a lua script which controls what happens in the machine) are automatically generated to ensure full compatibility with Freemelt's open-architecture control environment.

Because every core operation is encapsulated in modular Python classes, OBPlanner can easily be extended with new patterns, compensation models, or adaptive algorithms. This flexibility encourages experimentation with feedback-based control, where beam parameters evolve dynamically in response to in-situ sensing or simulated temperature fields. By unifying these elements into a transparent and reproducible framework, OBPlanner bridges geometric design, thermal management, and process strategy. It provides a practical foundation for data-driven research on how beam path design influences local energy input, solidification behavior, and ultimately, microstructure formation in E-PBF.

Demonstration and usage

The OBPlanner package has been implemented and used to design and execute a wide range of beam path strategies for process evaluation and material development using a Freemelt ONE system. Its flexibility allows users to explore how variations in beam motion, energy distribution, and sequencing affect the resulting microstructures and material properties.

In the first demonstration, the package was used to generate eight distinct scan strategies for simple cubic samples. These included raster, spiral, concentric, and spot-based melting patterns. Each strategy produced a unique combination of thermal history and solidification behavior, resulting in visibly different microstructural morphologies and mechanical responses. The comparison between these strategies revealed that microstructure evolution in E-PBF is highly sensitive to local energy input and remelting cycles, showing that beam path design can be used as a deliberate control parameter for tailoring properties. The full study is presented in [6], see Figure 4.

(a) *(b)*

Figure 4. Test case one, (a) show the different strategies used for the cubes, (b) shows the printed specimens. Figure adapted from [6].

In the second case, the package was used to fabricate a scaled-down sand screen component representative of an industrial part, see Figure 5. Here, OBPlanner enabled the assignment of different scan strategies to specific regions of the geometry. The inner core was built with a raster strategy for uniform structure, while the outer rim employed a random spot strategy to increase hardness. The resulting component exhibited distinct microstructures and property gradients, demonstrating how spatially varying beam control can be used to locally tune mechanical performance within a single component [6].

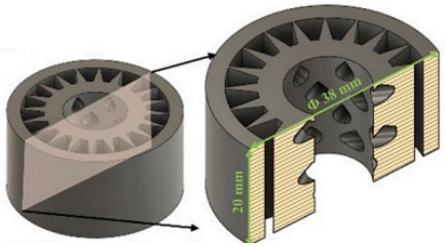

Figure 5. Sand screen component where one setting is applied on the outer ring and one is applied at the core structure. Figure adapted from [6].

Discussion and Outlook

The development of OBPlanner represents an important step toward openness and reproducibility in E-PBF research. By exposing the entire beam-path generation pipeline, from geometric slicing to executable beam commands, the framework gives researchers full control over parameters that are typically hidden in proprietary software. This transparency enables systematic investigation of how beam motion, energy input, and process strategy influence microstructure evolution and material performance. A central strength of OBPlanner is its accessibility and possibility to easy modify the process. All process definitions for the input is stored in human-readable JSON format and exported through the standardized OBF, allowing experiments to be easily replicated and shared across research groups. This open data structure supports the establishment of shared benchmarks for process parameters, thermal conditions, and resulting microstructures, facilitating truly comparable studies in E-PBF.

The framework's modular Python design also promotes collaborative research and education. It lowers the barrier for implementing custom scan patterns, compensation models, or control algorithms, making it a valuable platform for both industrial process development and academic instruction on beam-path design and solidification phenomena. While highly flexible, the current version remains focused on static, pre-defined strategies and relies on serial geometry operations. Future developments aim to integrate thermal simulation, process monitoring, and in-situ

feedback, enabling adaptive, closed-loop beam control. Such advancements would connect path planning directly with real-time process data, bridging the gap between design, monitoring, and microstructure control.

In summary, OBPlanner transforms beam-path generation in E-PBF from a closed, prescriptive task into an open, programmable, and reproducible research environment. By promoting transparency and collaboration, it provides a foundation for data-driven process optimization, functionally graded material design, and ultimately, microstructure-on-demand manufacturing.

Keywords: Carrera Unified Formulation (CUF), Low-Velocity Impact, Higher-Order Structural Modeling, Continuum Damage Mechanics, Delamination

Abstract. Numerical simulations are an essential tool for predicting structural response under low-velocity impact and for damage evolution. The present work investigates the low-velocity impact (LVI) response of composite laminate plates by applying the Carrera Unified Formulation (CUF) for structural modelling combined with a fully three-dimensional (3D) Hashin failure criterion for damage evaluation. Previous studies have employed two-dimensional (2D) Hashin criteria, combined with cohesive zone models, to detect intralaminar and interlaminar damage. However, such approaches neglect out-of-plane stress components, which are critical in impact scenarios. The methodology discussed overcomes this limitation by adopting the 3D Hashin criterion within each ply, thereby allowing all six stress components to be included and providing a more accurate prediction of intralaminar damage and interlaminar delamination activation. The numerical model is developed within the CUF framework, using higher-order structural theories based on Lagrange polynomial expansions and a layer-wise representation through the laminate thickness. The results highlight the accuracy of the proposed approach and its computational cost advantages.

Introduction

Impact response is one of the most critical loading cases for the lightweight, layered structures widely used in aerospace. LVI, in particular, are localized events that can introduce intralaminar and interlaminar damage that is difficult to detect visually. As a consequence, the residual strength of the structure is reduced. Numerical simulation helps reduce costly testing and enables rapid sensitivity studies to optimize the design. This, in turn, allows prediction of damage scenarios and stiffness degradation over time. Computational approaches for damage simulation are generally divided into two main categories. Discrete damage models, such as those based on cohesive zone methods (CZM) [1], provide detailed damage representation but are often computationally demanding. As an alternative, the continuum framework employed in [2] facilitates efficient damage simulation with reduced numerical overhead. This study is motivated by the need for a fast, computationally efficient tool to analyze impacts on composite structures. The advantages of using the Carrera Unified Formulation (CUF) in this context lie in achieving 3D fidelity at reduced computational cost. By coupling CUF with explicit dynamics and progressive damage models, it is possible to obtain a rapid, robust, and accurate simulation tool for impact problems.

Structural theories and damage model

The structural theories adopted in this paper are based on the Carrera Unified Formulation (CUF) [3], which employs higher-order Lagrange polynomial expansions and yields a layer-wise representation through the laminate thickness. CUF enables the derivation of 1D and 2D theories thanks to a compact notation by representing the displacement fields, over the cross-section for

Materials Research Proceedings 69 (2026) 1171-1175 https://doi.org/10.21741/9781644904251-201

beams and through the thickness for plates and shells, as basic functions whose type and order are arbitrary. The three-dimensional displacements in the layer-wise 2D model adopted in this work can be expressed as:

$$u(x,y,z) = F_\tau(z)N_i(x,y)u_{\tau i}, \qquad \tau = 1,\dots,M, \qquad i = 1,\dots,N \tag{1}$$

That is, as the product of nodal displacements $u_{\tau i}$ for the expansion function $F_\tau(z)$ of M terms, which approximates the kinematics through the thickness of the plate, and for the 2D shape function $N_i(x,y)$.

The damage model [4,5] is divided into a criterion for which the damage is activated and a model for the evolution of this damage. The 3D Hashin criterion, which accounts for failure in both fibers and matrix, predicts damage initiation under compression and tension. Here, the 3D Hashin model is adopted for fiber tension and matrix and fiber compression. Only for matrix compression, the Puck criterion [6] is considered. Once the criterion for initiating failure is triggered, the subsequent progression of the damage follows a linear pattern, with the material stiffness decreasing until final failure. Using a unified subscript $P \in \{ft, fc, mt, mc\}$ to represent the four modes of damage, d_P is a parameter governing the evolution of damage in each mode. The constitutive elastic stress-strain relation during the damage evolution can be written as:

$$\sigma = C_{dam}\epsilon \tag{2}$$

where C_{dam} is the stiffness matrix in the damage state, function of damage parameters d_P.

Numerical examples

The first numerical example presents a multibody analysis of a spherical impactor (diameter 16 mm) striking a square, linearly elastic composite plate with a side length of 100 mm. The composite is modeled as a quasi-isotropic laminate with a stacking sequence $[90/45/0/-45]_{2s}$ and a total thickness of 2 mm. The material system is IM7/8552 CFRP; see Ref. [7], Table 1, for material properties. The plate is fully clamped along its edges, and the impactor hits the center with an initial velocity of 5 m/s.

Different CUF models are employed, characterized by increasing orders of Lagrange expansion through the thickness, denoted CUF-LE*x*, where *x* is the expansion order. In addition, a CUF model with multiple linear expansions per ply (CUF-3LE1/ply) is examined. Model details are provided in Model 1 (Table 1).

Figures 1 and 2 show the stress distributions from the CUF models near the center of the plate, benchmarked against a standard ABAQUS 3D FEA [7]. The numerical results indicate that in-plane stresses predicted by CUF are in excellent agreement with the ABAQUS solution (Fig. 1). By contrast, the interlaminar shear stresses (Fig. 2) are more challenging and require either higher-order through-thickness expansions or multiple linear expansions per ply to be captured accurately.

Materials Research Proceedings 69 (2026) 1171-1175 https://doi.org/10.21741/9781644904251-201

CUF- 260Q9/LE2	260 Q9 (1 LE2/ply)	77,832

Table 1: Model information

The second numerical study considers the impact of a rigid sphere on a circular composite plate with a stacking sequence of $[0/90]_{2s}$ and ply thickness 0.25 mm. The plate radius is 37.5 mm, thickness 2 mm, and is clamped at its boundary. The material is HTS40/9772 unidirectional CFRP. The impactor has a diameter of 15 mm, initial velocity 3.83 m/s, and kinetic energy 7.35 J. Delamination is modeled with cohesive elements inserted between adjacent plies. Material properties and cohesive parameters are taken from [7].

A mesh-convergence study on the peak impact force (Fig. 3) was performed using the same CUF LE2 expansion and varying in-plane discretizations of 132, 192, and 260 Q9 elements; see Model 2 in Table 1 for model and DOF details. The 192 Q9 mesh was chosen for subsequent analyses with different expansions. Force–time curves were denoised with MATLAB's smooth (centered moving average) using spans of 10–15%. Damage-variable contour maps for the 192 Q9–LE3 model are shown in Fig. 4, and the predicted inter-ply delamination is reported in Fig. 5 for each of the seven cohesive interfaces. The cohesive law triggers delamination once a relative displacement threshold is exceeded [8,9]. Experimental [10] and numerical results are compared.

Conclusions

In this study, the layer-wise 2D-CUF framework for impact analysis was extended from 2D damage criteria [11] to the 3D Hashin criterion, while retaining mixed-mode cohesive elements to model delamination. The proposed approach matches numerical and experimental results. The simulations indicate widespread, saturated matrix damage, while fiber damage remains partially unsaturated (see Fig. 4).

The 3D interlaminar stresses help calculate the extent and morphology of delamination, which more closely aligns with reference results [10]. In fact, slight back-face delamination is also

captured. Overall, the methodology resolves both intralaminar and interlaminar damage while preserving computational efficiency, as the present approach requires a fraction of 3D FEM DOF.

Keywords: Aerospace Structures, CUF, Higher-Order Theories, Neural Networks

Abstract. This study introduces a Machine Learning (ML) framework to assess the accuracy of higher-order structural theories for aerospace structures. Stiffened panels are modeled using one-dimensional elements and analyzed using refined theories based on the Carrera Unified Formulation (CUF). To evaluate accuracy, the framework compares the average error of the first ten natural frequencies with that of a reference model. An ML tool automatically predicts this error and identifies the most relevant generalized variables for each structural configuration. The dataset used to train the ML tool is generated using CUF and includes material properties, geometry, and the structural theory generalized variables. To process this information, two types of Neural Networks (NN) are employed: a Convolutional Neural Network (CNN) extracts geometric features from cross-section images, e.g., number and position of stiffeners, and a Deep Neural Network (DNN) combines these features with material and geometric data to predict the accuracy of each theory. As a result, the framework effectively predicts the most accurate and computationally efficient theories and their associated generalized variables.

Introduction

In structural mechanics, creating accurate reduced models is crucial to lowering the computational complexity of 3D analyses. Since they have fewer degrees of freedom than 3D models, 1D and 2D theories are frequently employed. However, depending on the specific problem, the accuracy of these theories can vary significantly. Classical theories such as the Euler–Bernoulli Beam Theory (EBBT) [1] and the Timoshenko Beam Theory (TBT) [2,3] are often unable to capture complex behaviors such as material anisotropy, shear deformability, or warping effects. To overcome these limitations, higher-order theories (HOT) [4,5] have been developed to address more complex structural problems, including composites [6] and thick beams [7, 8]. The Carrera Unified Formulation (CUF) [9] provides a general and systematic framework for defining structural theories of any order. The Axiomatic/Asymptotic Method (AAM) [10] can be applied to determine the most influential unknowns in higher-order theories, enabling the selection of the most efficient theory for a given problem. However, AAM requires multiple evaluations of generalized variables, leading to high computational costs. In recent years, Machine Learning (ML) techniques [11] have attracted increasing attention in structural mechanics and finite element analysis due to their predictive capabilities and reduced computational time. Their applications include stress prediction, structural health monitoring, and topology optimization. The present paper combines a fully connected Deep Neural Network (DNN) and a Convolutional Neural Network (CNN) to reduce the computational cost of AAM and improve the accuracy of error prediction. The proposed framework extends the authors' previous works [12,13] to stiffened structures for aerospace applications.

CUF and FEM Formulations

The reference system adopted for beam structures is shown in Fig. 1. Here, the x-z plane lies on the cross-section Ω.

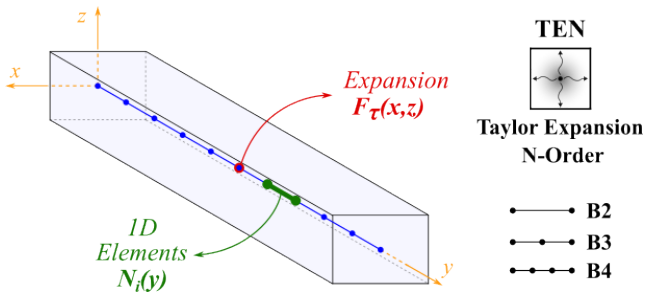

Figure 1: Reference coordinate system for beam models

The displacement field for beams can be expressed as:

$$\boldsymbol{u}(x,y,z) = N_i F_\tau(x,z)\boldsymbol{u}_{\tau i} \tag{1}$$

Where F_τ is the expansion function; τ=1,…, M, and M is the number of expansion terms. N_i is the shape function; $i = 1, \ldots, N_n$, where N_n is the number of FE nodes. $\boldsymbol{u}_{\tau i}$ is the vector of the nodal unknowns. For 1D theories, the expansion function F_τ acts on the cross-section x-z, while the shape function along the beam axis. For a second-order beam theory, the displacement field is:

$$\begin{aligned} u_x &= u_{x_1} + xu_{x_2} + zu_{x_3} + x^2u_{x_4} + xzu_{x_5} + z^2u_{x_6} \\ u_y &= u_{y_1} + xu_{y_2} + zu_{y_3} + x^2u_{y_4} + xzu_{y_5} + z^2u_{y_6} \\ u_z &= u_{z_1} + xu_{z_2} + zu_{z_3} + x^2u_{z_4} + xzu_{z_5} + z^2u_{z_6} \end{aligned} \tag{2}$$

With a total of eighteen nodal displacement variables. The Principle of Virtual Displacements is used to derive the governing equations for the free vibration problem,

$$\delta L_{int} = \delta L_{ext} - \delta L_{ine} \tag{3}$$

The work done by internal forces is δL_{int}, by external forces is δL_{ext}, and by inertial forces is δL_{ine}. In this free-vibration case, the governing equation is the following:

$$\delta \boldsymbol{u}_{sj}: \quad \boldsymbol{m}_{\tau sij}\ddot{\boldsymbol{u}}_{\tau i} + \boldsymbol{k}_{\tau sij}\boldsymbol{u}_{\tau i} = 0 \tag{4}$$

$\boldsymbol{k}_{\tau sji}$ and $\boldsymbol{m}_{\tau sji}$ are the 3x3 Fundamental Nuclei (FN), for the stiffness and mass matrix, respectively. By solving the eigenvalue problem, natural frequencies, ω_n, and modal shapes are obtained:

$$(\boldsymbol{K} - \omega_n^2\boldsymbol{M})\boldsymbol{U} = 0 \tag{5}$$

Neural Networks

The Neural Network (NN) has two components. The first is a CNN that takes as input real-scale images of the beam cross-sections used for training. The CNN, which works as a feature extractor, uses Sobel and Laplace filters to extract valuable geometric information from the images. For each structural case, the CNN output vector is concatenated with a vector containing the specific structural theory used, the slenderness ratio (L/h), and the beam material. Each structural theory is encoded as a sequence of 0s and 1s, where 1 represents an active generalized variable, e.g.,

Materials Research Proceedings 69 (2026) 1176-1180 https://doi.org/10.21741/9781644904251-202

$$u_x = u_{x_1} + xu_{x_2} + x^2u_{x_4} + z^2u_{x_6} = [1\ 1\ 0\ 1\ 0\ 1] \quad (6)$$

The resulting arrays are fed into a DNN trained on the average error of the first 10 natural frequencies with respect to the reference fourth-order theory for each structural case computed by AAM. The trained NN predicts the accuracy of a kinematic theory for a generic structural case, taking as inputs the image of the cross-section, the L/h ratio, and the beam material, see Fig. 2.

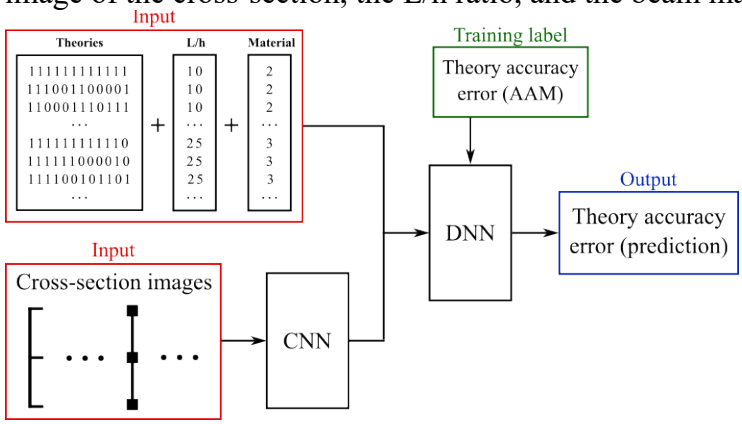

Figure 2: NN architecture

Numerical Results

The dataset consists of 1080 structural cases, each computed using AAM. Each AAM analysis comprises 4096 FEM modal analyses. To train the DNN, only 10% of these analyses were randomly selected and used. The results shown hereafter refer to two different beams, both clamped-free and made of titanium. The material properties are: E=115 GPa, ν=0.33, ρ=4500 kg/m^3. The first, whose cross-section is shown in Fig. 3, is a stiffened spar included in the network training. The length L is equal to 10m, the height of the cross section is 1m, the sides of the three equally spaced squared stiffeners are 4 cm, while the thickness of the web is 2 mm. The Best Theory Diagrams (BTD) computed by AAM and DNN are shown in Fig. 4, while Tables 1 and 2 report the best theories and their accuracies, from AAM and DNN, respectively. In these tables, the black triangle indicates that the generalized variable is active. The network's predictive capabilities were analyzed by testing different beams not used during network training. A stiffened spar not involved in the network training is shown in Fig. 5, with a length L of 8 m, a height "h" of the cross-section of 1 m, and the side of the squared stringer is 4 cm. The web thickness is 2 mm. The stringers are not equally spaced, with the middle stringer located at h/3 from the bottom of the cross-section. Figure 6 shows the BTD for this structural case, while Tables 3 and 4 report the best theories and their accuracies.

Conclusion

This work presents a methodology and a tool for the accuracy estimation of a beam theory and its generalized variables for a given problem. In addition, it assesses the minimum number of DOF required to obtain that level of accuracy. The proposed methodology uses NN to correlate structural theories, geometries, materials, and accuracy. The results show a strong correlation between AAM results and DNN predictions for the beams included in the network's training set. For those not included in the training, the results remain excellent for accuracy prediction, while the correlation slightly decreases for predicting the best theories. The results indicate that, in both cases, achieving errors below 10% requires at least two parabolic terms, while errors under 1% can only be ensured by using the complete parabolic expansion along with two or three additional higher-order terms. The results are highly problem-dependent, as the specific higher-order terms involved vary from case to case.

Abstract. This work presents an adaptive multi-fidelity framework for uncertainty quantification in defect-tolerant composite structures. The approach couples the Carrera Unified Formulation (CUF) for generating consistent low- and high-fidelity structural theories with an adaptive Gaussian Process Regression (GPR) surrogate that learns their correlation. High-fidelity simulations are selectively activated in regions of high uncertainty, minimizing computational cost while preserving accuracy. The framework enables probabilistic estimation of stresses and failure indices with confidence intervals and is validated against 3D Abaqus benchmarks.

Introduction

The increasing demand for lightweight and high-performance structures has driven the adoption of advanced composite materials, with manufacturing techniques like Automated Fiber Placement (AFP) enabling highly optimized and complex designs [1-2]. However, the reliability of these components is often compromised by the interplay of manufacturing defects, such as gaps, overlaps and fiber misalignment, and inherent material and load variability [3]. Designing defect and damage-tolerant components therefore requires a rigorous quantification of how these uncertainties shape local stress fields and drive damage evolution, including crack propagation. Traditional deterministic or single fidelity models are either prohibitively expensive for comprehensive probabilistic analysis or too simplistic to capture the governing physics, leaving a critical gap in robust composite design methodologies.

This work proposes a novel Multi-Fidelity (MF) probabilistic framework to overcome these limitations. The methodology is built upon the Carrera Unified Formulation (CUF) [4], which provides a consistent hierarchical basis for generating both computationally efficient Equivalent Single-Layer (ESL) models and highly accurate Layer-Wise (LW) models. An adaptive Gaussian Process Regression (GPR) [5-6] surrogate learns the correlation between these fidelity levels, drastically reducing the need for expensive High-Fidelity (HF) simulations. This intelligent learning process actively queries new HF data only in regions of high predictive uncertainty, maximizing information gain while minimizing computational cost. The conceptual workflow of this adaptive framework is illustrated in Fig. 1. This integrated framework enables an efficient and accurate uncertainty quantification for damage onset assessment, allowing for the direct calculation of key probabilistic metrics such as through-the-thickness stress profiles with confidence intervals, probability distributions of critical failure indices, and the overall probability of failure. To ensure methodological rigor, the framework's predictions are validated against benchmark analyses using high-fidelity 3D models in Abaqus.

Furthermore, the framework extends to progressive damage [7] prediction by combining Low-Fidelity (LF) and high-fidelity models along the damage evolution path. The LF model efficiently captures the global structural response and damage progression, while the adaptive learning strategy selectively deploys HF simulations when approaching critical failure thresholds. A separable GPR surrogate corrects the entire damage history, enabling accurate reconstruction of high-fidelity crack-growth curves across the uncertainty space with minimal computational cost.

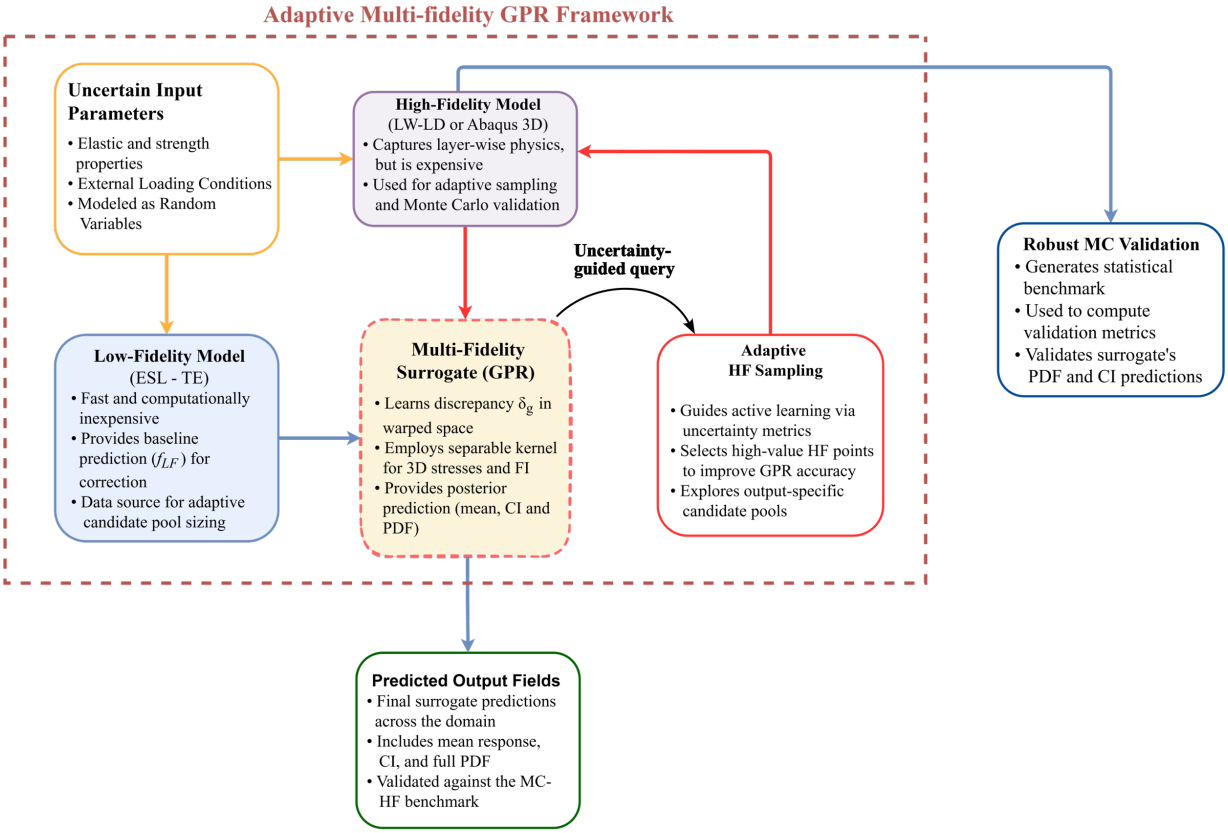

Figure 1. Adaptive multi-fidelity GPR framework combining low-fidelity predictions with selective high-fidelity corrections to provide probabilistic failure and stress predictions validated by Monte Carlo.

Unified finite elements

In this work, CUF formalism is used to implement 2D FE. The 3D displacement field can be expressed using arbitrary through-the-thickness expansion functions $\boldsymbol{F_\tau(z)}$ as follows:

$$\boldsymbol{u}(x,y,z) = F_\tau(z)\boldsymbol{u}_\tau(x,y).\ \tau = 1,\dots,M \tag{1}$$

The symbol M represents the number of expansion terms, and $\boldsymbol{u}_\tau(x,y)$ represents the vector containing the generalized displacements, with τ indicating summation. Examining multi-layered structures typically employs either an Equivalent-Single-Layer (ESL) or Layer-Wise (LW) approach. In this manuscript, ESL models utilize Taylor polynomials represented by $F_\tau(z)$; while LW employs Lagrange polynomials over individual layers and ensures the continuity of displacements at layer interfaces. Utilizing the FE and shape functions $N_i(x,y)$, the displacement field becomes:

$$\boldsymbol{u}(x,y,z) = N_i(x,y)F_\tau(z)\boldsymbol{q}_{\tau i}(x,y).\ i = 1,\dots,N_n \tag{2}$$

Materials Research Proceedings 69 (2026) 1181-1186 https://doi.org/10.21741/9781644904251-203

In Eq. (2), $\boldsymbol{q}_{\tau i}$ are the unknown nodal variables, with N_n denoting the number of nodes per element. This work employs 2D nine-node quadratic elements for the in-plane discretization.

The governing equations are derived using the Principle of Virtual Displacements (PVD), which asserts that the virtual variation of internal strain energy, $\delta\mathcal{L}_{int}$, equals the virtual work of external forces, $\delta\mathcal{L}_{ext}$, minus inertia forces, $\delta\mathcal{L}_{ine}$. Specifically, $\delta\mathcal{L}_{int}$ can be written as:

$$\delta\mathcal{L}_{int} = \delta\boldsymbol{q}_{sj}^{T}\left[\int_{V}\boldsymbol{D}^{T}(N_jF_s)\,\widetilde{\boldsymbol{C}}\boldsymbol{D}(N_iF_\tau)\,dV\right]\boldsymbol{q}_{\tau i} = \delta\boldsymbol{q}_{sj}^{T}\boldsymbol{k}_{0}^{ij\tau s}\boldsymbol{q}_{\tau i}, \tag{3}$$

where $\boldsymbol{k}_0^{ij\tau s}$ is the 3 × 3 Fundamental Nucleus (FN) of the stiffness matrix, invariant regardless of 2D shape function order and through-the-thickness expansion. $\boldsymbol{D}(\cdot)$ is the differential operator matrix with geometric relations, and $\widetilde{\boldsymbol{C}}$ is the material stiffness matrix in the global reference frame, i.e., $\widetilde{\boldsymbol{C}} = \boldsymbol{T}(x,y)^{T}\boldsymbol{C}\boldsymbol{T}(x,y)$. The global stiffness matrix, $\boldsymbol{K}$**,** is obtained by iterating over FN's with indices i, j, τ and s to compute element-level matrices, which are then assembled for the global structure.

MF - GPR framework

The approach integrates GPR with a multi-fidelity strategy combining LF (ESL) and HF (LW) simulations. Uncertainties stem from material properties and applied loads, as well as potential manufacturing defects such as fiber misalignments, gaps, overlaps, and resin-rich zones. Random samples are generated using Latin Hypercube Sampling (LHS) to ensure uniform coverage of the input space. GPR models the relationship between input parameters **x** and outputs f(**x**) as a Gaussian Process (GP) defined by a mean function μ(x) and a covariance function κ(x, x′):

$$f(x) \sim \mathcal{GP}(\mu(x), \kappa(x,x')) \tag{4}$$

$$\kappa(x,x') = \sigma_f^2 \exp\left(-\frac{\|x-x'\|^2}{2l^2}\right) \tag{5}$$

where σ_f^2 and l the kernel variance and length scale for each output. Using training data (X, y), the GP predicts outputs at new points by combining the mean and variance derived from the model. The multi-fidelity framework accounts for the discrepancy between low- and high-fidelity simulations. The high-fidelity response $\hat{f}_{HF}(x)$ is expressed as:

$$\hat{f}_{HF}(x) = f_{LF}(x) + \Delta(x) \tag{6}$$

where f_{LF} is the LF response and $\Delta(x)$ is the discrepancy between LF and HF modeled as a GP. This formulation enables accurate and efficient structural predictions under uncertainties by merging LF trends with corrections derived from high-fidelity data.

Damage model

The Hashin 3D criterion predicts the onset of fiber and matrix failure under tension and compression by evaluating stresses in three dimensions. When any failure index reaches unity, the corresponding damage mode is activated, initiating stiffness degradation through an evolution law. Hashin 3D criterion is adopted to evaluate three failure modes: fiber tension, fiber compression, and matrix compression.

$$F_{ft} = \left(\frac{\sigma_{11}}{X_T}\right)^2 + \alpha_f\left[\left(\frac{\sigma_{12}}{S_{12}}\right)^2 + \left(\frac{\sigma_{13}}{S_{13}}\right)^2\right]$$

Materials Research Proceedings 69 (2026) 1181-1186 https://doi.org/10.21741/9781644904251-203

$$F_{mt} = \left(\frac{\sigma_{22}+\sigma_{33}}{Y_T}\right)^2 + \frac{1}{S_{23}^2}(\sigma_{23}^2 - \sigma_{22}\sigma_{33}) + \left(\frac{\sigma_{12}}{S_{12}}\right)^2 + \left(\frac{\sigma_{13}}{S_{13}}\right)^2$$

$$F_{fc} = \left(\frac{\sigma_{11}}{X_C}\right)^2$$

F quantify the failure, the first subscript indicates whether the failure concerns the matrix (M) or the fiber (F), while the second whether it is tensile (T) or compressive (C). X is the strength of the fiber, if compressive X_C if traction X_T. S_{12}, S_{13} and S_{23} are the shear strengths. Y_T is the tensile strength of the matrix.

Only for matrix compression is considered the Puck criterion according to which the fracture of the matrix is due to stress σ_{nn}, σ_{nl}, σ_{nl}, which are respectively the normal, longitudinal shear and transverse stresses to the fracture plane.

$$F_{mc} = \left(\frac{\sigma_{nt}}{S_{23}^A - \eta_{nt}\sigma_{nn}}\right)^2 + \left(\frac{\sigma_{nl}}{S_{13} - \eta_{nl}\sigma_{nn}}\right)^2$$

η_{nt} and η_{nl} characterize the internal friction of the material while S_{23}^A is the transverse shear strength in the fracture plane.

Once the criterion for the initiation of failure is triggered, the progression of the damage is governed by a linear pattern of damage evolution, so that the stiffness of the material decreases until the final failure. The linear model is based on the equivalent displacements δ_{eq}. Using a unified subscript $P \in \{ft, fc, mt, mc\}$ to represent the four modes of damage, a parameter for the evolution of the damage is defined for each mode d_P,

$$d_p = \frac{\delta_{eq}^u(\delta_{eq} - \delta_{eq}^0)}{\delta_{eq}(\delta_{eq}^u - \delta_{eq}^0)}$$

$\delta_{eq}^0 = \delta_{eq,F=1}$ is the equivalent displacement at the beginning of the damage, while δ_{eq}^u is at the final failure.

The constitutive elastic stress-strain relation during the damage evolution can be written as

$$\sigma = C_{dam}\epsilon$$

where C_{dam} is the stiffness matrix in the damage state, function of damage parameters d_P.

Results

The case study analyzes a composite open-hole plate under tensile loading using the proposed multi-fidelity (MF) framework. The configuration follows a benchmark from Ref. [8] with a symmetric $[45°/90°/-45°/0°]_{3s}$ laminate. Material and load properties are modeled as normal or uniform random variables. LF analyses use an ESL-TE1 model, while HF analyses employ an LW model with one LD1 expansion per ply. Figures 2 and 3 show the probabilistic distributions of the Fiber Tension (FT) and delamination failure indices across the laminate thickness, comparing low-, high-, and multi-fidelity models with their 90% confidence intervals. The MF predictions accurately reproduce the HF trends with a fraction of the computational cost.

Materials Research Proceedings 69 (2026) 1181-1186 https://doi.org/10.21741/9781644904251-203

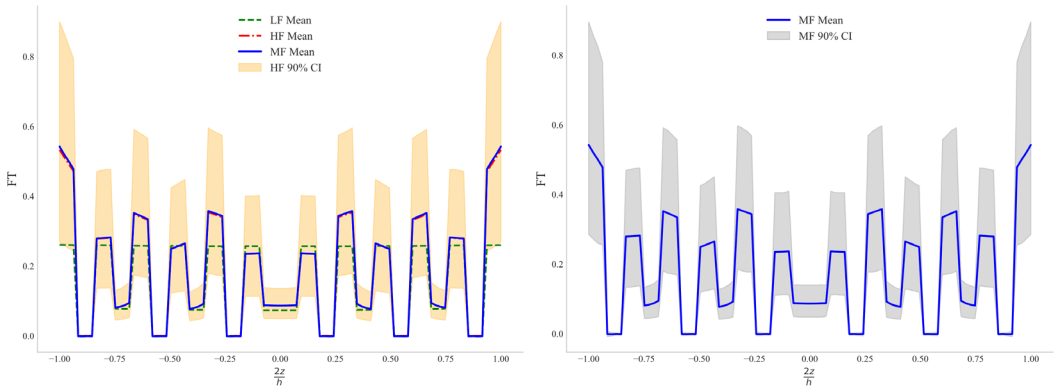

Figure 2. Fiber Tension (FT) failure index through the laminate thickness obtained from LF, HF, and MF models with corresponding 90% confidence intervals.

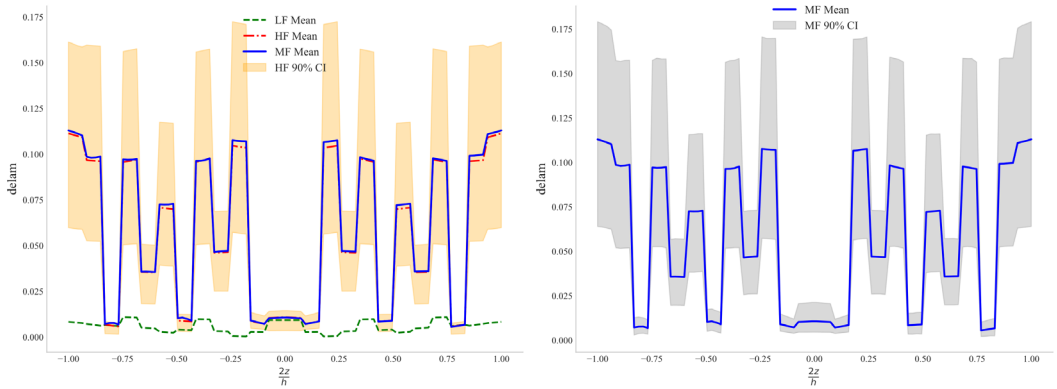

Figure 3. Delamination failure index through the laminate thickness obtained from LF, HF, and MF models with corresponding 90% confidence intervals.

Figure 4 presents the stress–strain response of a composite single element under tension with a symmetric laminate stacking sequence $\theta = [45,90,-45,0]^{\circ}_{4s}$. The uncertainties are applied to the material properties and strength allowables. The MF surrogate accurately reconstructs the high-fidelity (HF) reference using only a limited number of HF simulations (~10%), achieving close agreement with the deterministic curve and providing 90% confidence bounds on the predicted stress field.

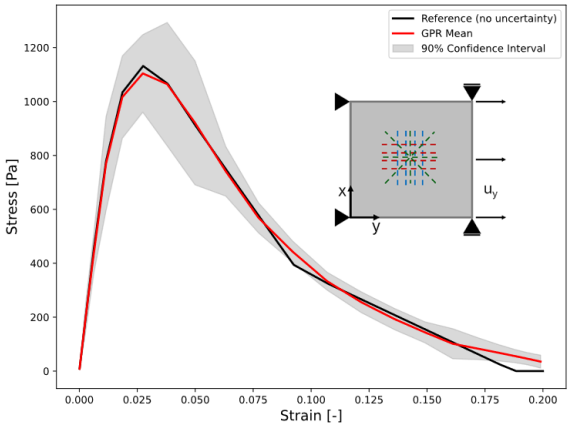

Figure 4. Multi-fidelity stress-strain curve under uncertainties

Conclusions

The proposed adaptive multi-fidelity framework effectively combines CUF-based structural models with Gaussian Process Regression to quantify the impact of material and manufacturing uncertainties on composite failure. By integrating low- and high-fidelity analyses within an active learning strategy, it achieves high accuracy with a fraction of the computational cost. These results demonstrate its potential for Reliability-Based Design Optimization (RBDO) of lightweight composite structures [9].

Abstract. Composite materials are widely used in the engineering field due to their valuable specific properties and the adaptability of fiber orientation and lay-up to specific load conditions. The tailorability of composite materials is increased with Variable Angle Tows (VAT) composite materials, in which fiber deposition can follow a curved path. These properties lead to a higher anisotropy, and non-linear analyses are required to ensure a good description of the behaviour. The study focuses on the post-buckling configuration of the VAT model and examines the impact of curved fiber paths. The analyses are conducted to compare high-order theory for describing the nonlinear behaviour of the VAT composite structure. Additionally, the post-buckling shape of VAT plates is thoroughly explored, leading to the selection of the most accurate model for characterizing plate behaviour.

Introduction

Composite materials present valuable properties, such as high specific strength and stiffness, thermal stability, and the adaptability of lamination and lay-up to manage the mechanical and thermal properties of the structure [1]. Thanks to advanced manufacturing techniques, the capabilities of the constant-stiffness composite laminate are enhanced by the introduction of Variable Angle Tow (VAT) composite materials, which have been developed in recent years [2]. The VATs are characterized by the curvilinear path of the reinforced fibers. Consequently, the properties of VATs vary continuously within each lamina, depending on the curvature imposed on the fibers, opening a vast range of possibilities for the adaptability of the structures to the specific load conditions [3]. Due to their high tailoring capability, VATs are mainly studied in the field of optimization to adapt fiber orientation to different loads or geometric configurations.

Additionally, the remarkable stability under thermal and high-temperature conditions enables the use of this class of material in applications where temperature is a primary load factor. Among the key concerns in VAT plate analysis, thermal stability is a focal point, as demonstrated in [4]. Furthermore, this class of materials, which has been extensively studied in the field of linear or linearized analysis under mechanical and thermal loads, lacks studies in the nonlinear thermal field. The reported tailoring capabilities are suitable for adapting the fiber deposition to the load distribution. However, the post-buckling and high-deflection configurations can be significantly affected by the curved deposition. Under variation in the applied temperature, the presence of curved fibers can lead to unexpected phenomena, and nonlinear investigations are necessary to ensure a correct level of confidence in the results.

This paper utilizes the Carrera Unified Formulation (CUF) to develop a high-order plate theory within the finite element method framework, offering novel insights into the intricate three-dimensional phenomena exhibited by VAT structures [5]. The governing equations are obtained from the Principle of Virtual Displacement (PVD), and the nonlinear problem is solved through

Materials Research Proceedings 69 (2026) 1187-1191 https://doi.org/10.21741/9781644904251-204

the Newton-Raphson procedure in conjunction with the arc-length constraint. The geometrical nonlinearity is described using the full Green-Lagrange strain tensor, and its accuracy is compared with that of the simplified von Kármán nonlinearities model. The analyses adopt a layer-wise approach, and a comparison to the equivalent single-layer model is also presented. It is demonstrated that the layer-wise model in combination with high-order theories provides an accurate description of the through-the-thickness primary unknowns, facilitating a detailed analysis of nonlinear thermal stresses within the component.

Non-linear thermal formulation

The thermo-mechanical field is expressed in a decoupled approach where the unknowns of the problem are the displacement components, which are expressed through the CUF and FEM as the combination of nodal displacements $\boldsymbol{q}_{i\tau}$, shape functions $\boldsymbol{N}_i(x,y)$, and expansion functions $\boldsymbol{F}_\tau(z)$, as reported in Eq. (1). More details about CUF can be found in [6].

$$\boldsymbol{u}(x,y,z) = \boldsymbol{F}_\tau(z)\,\boldsymbol{u}_\tau(x,y) = \boldsymbol{F}_\tau(z)\boldsymbol{N}_i(x,y)\,\boldsymbol{q}_{i\tau} \quad \tau = 1,2,\dots,M \quad i = 1,2,\dots,N_n \qquad (1)$$

Where the double indices mean sum, M and N_n are the number of expansion terms and the number of nodes respectively.

The VAT orientation is considered to vary linearly, following the notation by G*ü*rdal et al. [7]; the lamination is denoted as $[\Phi < T_0, T_1 >]$, where Φ is the reference system rotation angle from the x-axis, T_0 and T_1 are the fiber orientations in the center and at the edge of the plate, respectively.

It is possible to describe the strain and the stresses as the sum of the mechanical linear and non-linear terms and the thermal component, as reported in Eq.s (2), (3), where the nonlinearities are incorporated in the formulation using the full Green-Lagrange strain tensor, see [8].

$$\boldsymbol{\varepsilon} = \boldsymbol{\varepsilon}_m + \boldsymbol{\varepsilon}_\theta = (\boldsymbol{b}_l + \boldsymbol{b}_{nl})\boldsymbol{u} - \boldsymbol{\alpha}\,\Delta T \qquad (2)$$

$$\boldsymbol{\sigma} = \boldsymbol{C}\,\boldsymbol{\varepsilon} = \boldsymbol{C}[(\boldsymbol{b}_l + \boldsymbol{b}_{nl})\,\boldsymbol{u} - \boldsymbol{\alpha}\,\Delta T] = \boldsymbol{\sigma}_l + \boldsymbol{\sigma}_{nl} - \boldsymbol{\beta}\Delta T \qquad (3)$$

Where the vector $\boldsymbol{\beta}$ is the thermo-mechanical coupling coefficient. Due to the presence of VAT the fiber orientation vary from a point to another and consequently matrix $\boldsymbol{C}$ becomes a function of the position, $\boldsymbol{C}(x, \mathrm{y})$ as well as vector $\boldsymbol{\beta}\,(x,y)$.

The governing equations are obtained though the PVD as reported in Eq.s (4), (5).

$$\delta L_{int} = \int_V \delta\boldsymbol{\varepsilon}^T\boldsymbol{\sigma} = \int_V \delta\boldsymbol{\varepsilon}_m^T\boldsymbol{C}\boldsymbol{\varepsilon}_m dV - \int_V \delta\boldsymbol{\varepsilon}_m^T\,\boldsymbol{\beta}\Delta T\,dV = \delta\boldsymbol{q}^T\,\boldsymbol{K}_s\boldsymbol{q} - \delta\boldsymbol{q}^T\,\boldsymbol{F}_\theta = 0 \qquad (4)$$

$$\delta\boldsymbol{q} : \boldsymbol{K}_S\,\boldsymbol{q} - \boldsymbol{F}_\theta = 0 \qquad (5)$$

Where $\boldsymbol{K}_S$ is the secant stiffness matrix which depends only on the mechanical components and $\boldsymbol{F}_\theta$ is the nonlinear vector of thermal loads. Eq. (5) describes a nonlinear set of equations, and it is necessary to solve it in an iterative procedure. To use the Newton-Raphson method, the residual nodal force vector is defined as in Eq. (6). Furthermore, it is necessary to linearize the equation through a Taylor expansion about the known solution as reported in Eq. (7).

$$\boldsymbol{\varphi}_{res} = \boldsymbol{K}_S\,\boldsymbol{q} - \boldsymbol{F}_\theta \qquad (6)$$

$$\boldsymbol{\varphi}_{res}(\boldsymbol{q}+\delta\boldsymbol{q}, \Delta T + \delta\Delta T) = \boldsymbol{\varphi}_{res}(\boldsymbol{q}, \Delta T) + \left.\frac{\partial\boldsymbol{\varphi}_{res}}{\partial\boldsymbol{q}}\right|_q \delta\boldsymbol{q} + \left.\frac{\partial\boldsymbol{\varphi}_{res}}{\partial\Delta T}\right|_{\Delta T} \delta\lambda(\Delta T)_{ref} = 0 \qquad (7)$$

Materials Research Proceedings 69 (2026) 1187-1191 https://doi.org/10.21741/9781644904251-204

From Eq. (7) it is possible to define the tangent stiffness matrix as $\boldsymbol{K}_T = \frac{\partial \boldsymbol{\varphi}_{res}}{\partial \boldsymbol{q}}\Big|_q$ and the tangent load vector as $\widetilde{\boldsymbol{F}}_\theta = -\frac{\partial \boldsymbol{\varphi}_{res}}{\partial \Delta T}\Big|_{\Delta T} (\Delta T)_{ref}$ which is composed of a linear and a nonlinear part. Substituting these definitions into Eq. (7) it is possible to write Eq.s (8) and (9).

$$\boldsymbol{\varphi}_{res}(\boldsymbol{q} + \delta\boldsymbol{q}, \Delta T + \delta\Delta T) = \boldsymbol{\varphi}_{res}(\boldsymbol{q}, \Delta T) + \boldsymbol{K}_T\delta\boldsymbol{q} - \left(\widetilde{\boldsymbol{F}}_{l_\theta} + \widetilde{\boldsymbol{F}}_{nl_\theta}\right)\delta\lambda = 0 \quad (8)$$

$$\boldsymbol{K}_T\delta\boldsymbol{q} = \widetilde{\boldsymbol{F}}_\theta\delta\lambda - \boldsymbol{\varphi}_{res}(\boldsymbol{q}, \Delta T) \quad (9)$$

Here, the loading scaling parameter is introduced as a new variable; as a result, a constraint equation is needed to close the problem. The obtained system can be written as in Eq. (10).

$$\begin{cases} \boldsymbol{K}_T\delta\boldsymbol{q} = \widetilde{\boldsymbol{F}}_\theta\delta\lambda - \boldsymbol{\varphi}_{res} \\ c(\delta\boldsymbol{q}, \delta\lambda) = 0 \end{cases} \quad (10)$$

The path following method is adopted, where it is possible to act on both $\delta\boldsymbol{q}$ and $\delta\lambda$, see [9].

Numerical results

The study is conducted on a rectangular plate with lamination $[90 \pm < 60, 90 >]_{2s}$. The plate edges are $a = 300$ mm and $b = 150$ mm with a thickness of 1.0176 mm. The material properties are E_1=181GPa, E_2= E_3=10.27GPa, G_{12}= G_{13}=7.17GPa ν_{12}= 0.28, $\alpha_1 = -0.11$ x $10^{-6}/°C$, $\alpha_2 = \alpha_3 = 25.2$ x $10^{-6}/°C$. The plate is subjected to uniform thermal load. The edges are fixed against normal displacements, and they are allowed to translate in the tangential direction. A convergence analysis is conducted on the plate, for which a mesh of 5 x 10 Q9 elements is selected. A validation is presented in Fig. 1 comparing the displacement in the center of the plate. Present results are obtained with LE2 and TE2 models and are compared to reference [10].

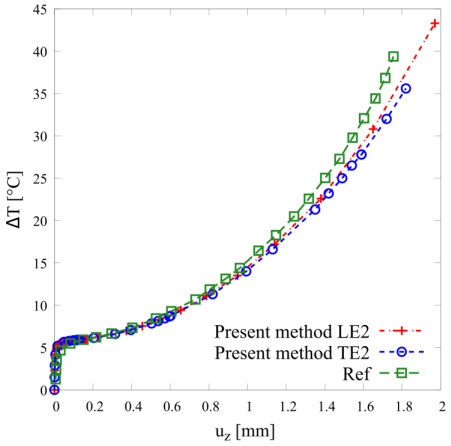

Figure 1: Displacement obtained through present method LE2 and TE2 compared to the reference [10].

From Fig. 1 it is possible to say that the displacements are in close agreement with the reference, which model is based on von Kármán-type nonlinearities and the Rayleigh-Ritz energy method. The discrepancy between the two results may be attributable to the differing formulations of the problem. In the present work the analysis is conducted to an higher level of temperature where the equilibrium curve change in shape due to the change of the post-buckling shape. From Fig. 2 it is possible to note the primary buckling and the secondary buckling of the plate.

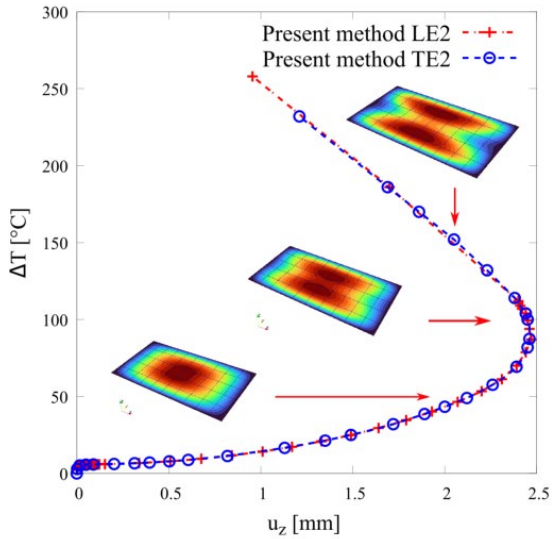

Figure 2: Displacement equilibrium curve obtained though the present method TE2 and LE2

Figure 3 shows the stress distribution for σ_x and σ_z along the thickness of the plate in Point A (75, 30) mm, considering the center of the plate as the origin of the reference system The results obtained demonstrate that, in the case of out-of-plane stresses, the interlaminar continuity is not guaranteed by the Taylor mode. Moreover, it is evident that a discrepancy in the results is present even when in-plane stresses are taken into consideration.

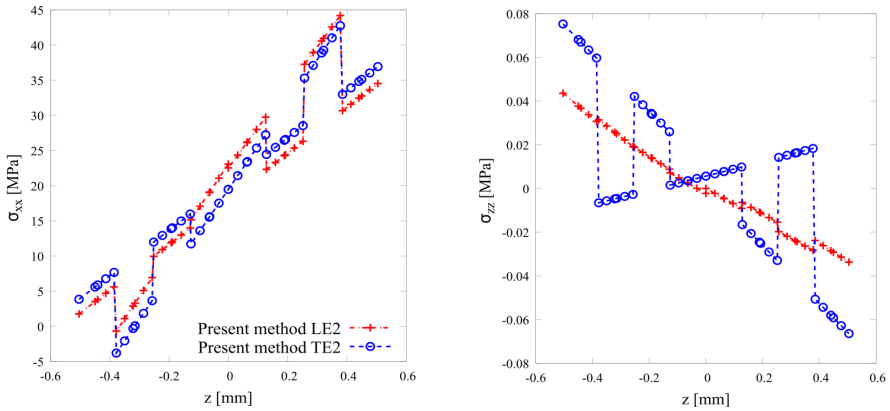

Figure 3: Stress distribution along the thickness Point A (75,30) mm. Comparison between LE2 and TE2 models.

Conclusions

The present work aims to show a nonlinear formulation for the post-buckling configuration of a rectangular plate made of a variable angle tow composite material. The governing equations are obtained from the principle of virtual displacement, and a comparison is conducted between the Lagrange and Taylor models for displacements and stresses. The findings indicate that the displacement description is accurate, even when the Taylor model is taken into consideration. However, to achieve optimal stress results, it is necessary to employ a Lagrange model in conjunction with the Layer wise description.

Keywords: Composite Aircraft Wings, Doublet Lattice Method (DLM), Finite Element Method (FEM), Aeroelastic Analysis, Neural Networks, Carrera Unified Formulation (CUF), Parametric Modeling, Global-Local Optimization

Abstract. This work presents a multiscale, global/local optimization framework for composite aircraft wings that integrates aeroelastic, strength, and stability constraints. Global-level analyses, including static aeroelasticity and flutter using the Doublet Lattice Method, provide the boundary conditions for local high-fidelity model based on the Carrera Unified Formulation. A neural-network surrogate enables rapid strength assessments, while a parametric FEM model supports geometry and thickness optimization. The framework establishes an efficient hierarchical methodology for integrating aeroelastic and structural design of composite wings.

Introduction

The structural optimization of composite aircraft wings remains a critical challenge in aerospace engineering due to the interplay between aeroelastic effects, buckling phenomena, and failure mechanisms at the ply level [1]. While global optimization frameworks efficiently handle stiffness and weight minimization, they often neglect the detailed stress fields and failure onset in layered composites. Conversely, local high-fidelity models capture these phenomena but are computationally prohibitive and rarely integrated into iterative optimization loops.

Recent advances in composite optimization have explored a wide range of formulations, from classical stacking-sequence and fiber-angle optimization [2,3] to topology-based approaches and reliability-based design optimization [4]. However, these methods typically operate at a single scale, limiting their capability to simultaneously address global performance metrics and local stress constraints. The multiscale nature of composite structures where interactions at lower scales influence the structural response at the macroscale, has motivated the development of hierarchical strategies capable of coupling global efficiency with local accuracy. Within this context, global/local frameworks have emerged as a promising approach, enabling the transfer of information from a global-level model to refined local domains [5,6]. The Carrera Unified Formulation (CUF) [7] offers an ideal foundation for this purpose, as it allows the automatic generation of refined structural theories, including higher-order shear deformation and Layer-Wise (LW) descriptions. By embedding CUF-based local analyses within a global optimization loop, a multiscale methodology can be established that preserves computational efficiency without compromising the accuracy of capturing the 3D stress field.

Methodology

This work introduces a hierarchical global-local optimization framework that overcomes this gap, enabling minimum-mass design of composite wing structures under aeroelastic, buckling, and strength constraints. The global level relies on a fully parametric Finite Element Model (FEM), where geometric and thickness parameters are treated as design variables. Static aeroelastic loads and flutter boundaries are computed via the Doublet Lattice Method (DLM) [8], while structural stability is ensured through eigenvalue buckling analysis. All global analyses are automated through Patran Command Language (PCL) scripting and run in NASTRAN via MATLAB-controlled workflows, supporting efficient design-space exploration.

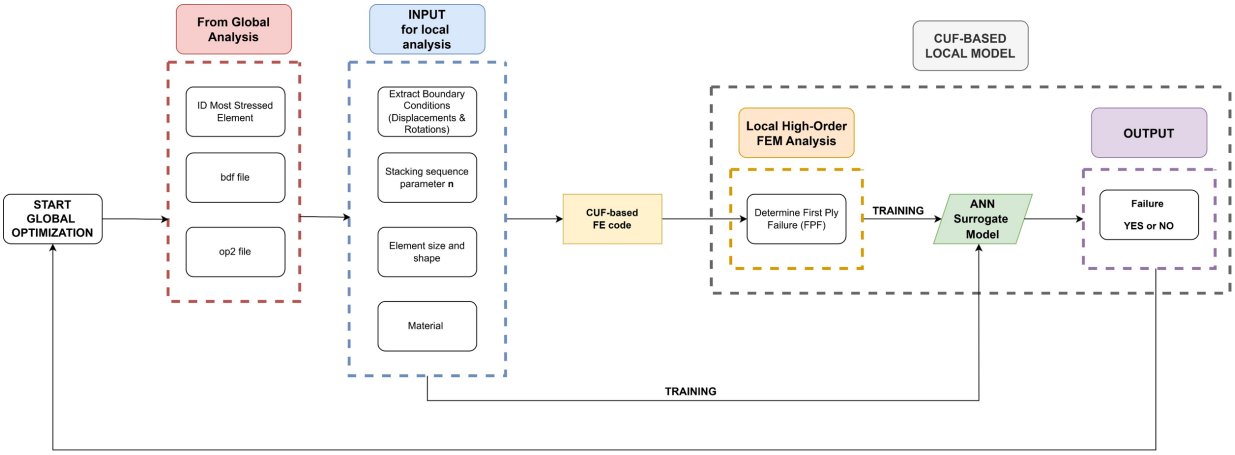

Figure 1. CUF-based local model integrated into the global optimization loop. Boundary conditions and laminate properties from the most stressed global element are used to perform high-fidelity CUF simulations. The results feed a neural network surrogate that predicts damage onset based on the 3D Hashin criterion.

The novelty of the framework lies in its local analysis strategy, which aims to provide accurate prediction of failure onset without compromising computational efficiency. A high-order two-dimensional Layerwise formulation based on the CUF is employed to capture the full three-dimensional stress distribution across the laminate thickness. Damage initiation is assessed via the 3D Hashin criterion, focusing on the most heavily stressed element of the global FEM model. The CUF model for the local domain adopts a displacement-based formulation, where only translational Degrees of Freedom (DOFs) are considered. Since the global model provides both translations $\left(\boldsymbol{u_x^0}, \boldsymbol{u_y^0}, \boldsymbol{u_z^0}\right)$ and rotations $\left(\boldsymbol{\theta_x^0}, \boldsymbol{\theta_y^0}, \boldsymbol{\theta_z^0}\right)$, a conversion procedure is required to express the latter as equivalent displacements. The Reissner–Mindlin displacement field in Eq. 1 is used to compute translational boundary displacements of the local model, written as:

$$u_x(x,y,z) = u_x^0(x,y) + z\theta_y^0(x,y) - y\theta_z^0(x,y)$$

$$u_y(x,y,z) = u_y^0(x,y) - z\theta_x^0(x,y) + x\theta_z^0(x,y) \quad (1)$$

$$u_z(x,y,z) = u_z^0(x,y) - y\theta_x^0(x,y) + x\theta_y^0(x,y)$$

Because repeated local evaluations using CUF-based models can be computationally expensive [9-10], a neural network-based surrogate model is trained to replace them within the optimization loop. The surrogate is constructed by sampling boundary conditions and material/laminate parameters, including stacking sequences and fiber properties, through Latin Hypercube Sampling.

Materials Research Proceedings 69 (2026) 1192-1197 https://doi.org/10.21741/9781644904251-205

Each configuration is simulated with high-fidelity CUF-based FE analysis and labeled according to the 3D Hashin criterion. The accumulated dataset is then used to train a neural network classifier. After testing several architectures involving principal component analysis (PCA), L2-regularized cross-entropy loss, and varying hidden-layer depths, the final network features three hidden layers (50, 30, and 10 neurons) trained via scaled conjugate gradient descent. Once trained, the surrogate enables real-time failure predictions based on the displacement field extracted from the global FEM model, as illustrated in Figure 1.

The optimization problem minimizes the structural mass, with constraints on buckling margin, flutter speed, and strength compliance. Colony Optimization (MIDACO) [11], based on Ant Colony Optimization, is used to explore the mixed-variable design space. At each iteration, the global model is updated, structural responses are computed, and the surrogate-based local model evaluates failure onset at the critical locations. The overall framework is presented in Figure 2. A representative composite wingbox configuration is optimized to demonstrate the methodology.

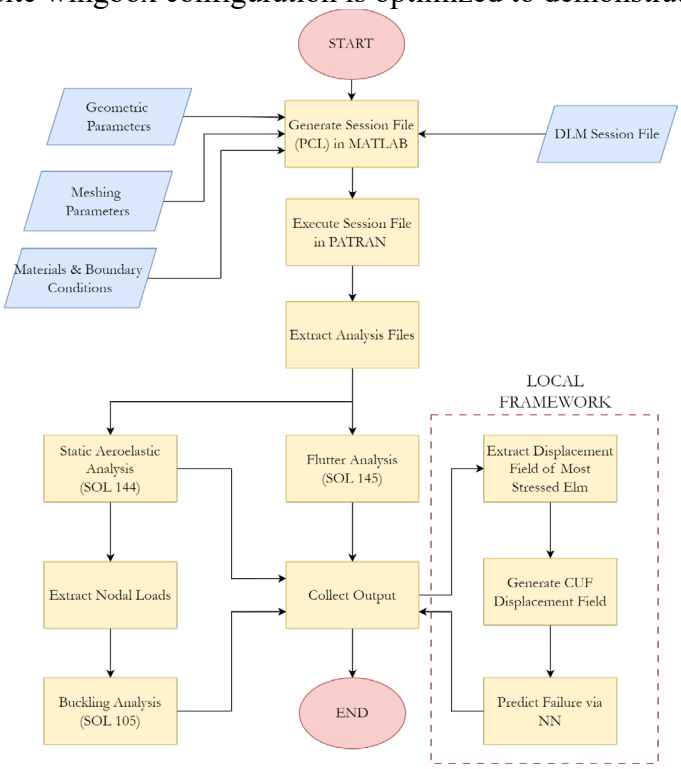

Figure 2. Workflow of the proposed global-local approach

Results and Verification

The optimization framework considers a semi-span composite wing box representative of a regional aircraft configuration. The model includes front and rear spars, ribs, stringers, and laminated skins. Design variables involve geometric parameters such as spar positions and stiffener spacing together with thicknesses of the structural components and ply orientations. The objective is to minimize the total structural mass subject to constraints on strength, stiffness, buckling, and dynamic behavior. Continuous and discrete variables are optimized simultaneously to achieve an efficient structural layout that satisfies all mechanical requirements.

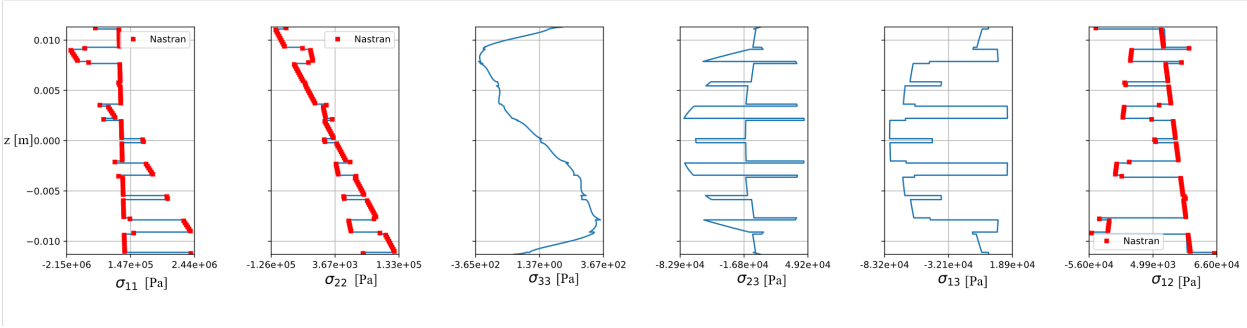

Figure 3. Local CUF-LW analysis of finite element ID 100 extracted from the global 2D finite element wing-box model. The through-thickness stress distributions $(\boldsymbol{\sigma_{11}, \sigma_{22}, \sigma_{33}, \sigma_{23}, \sigma_{13}, \sigma_{12}})$*are shown, comparing the present CUF-based results with the Nastran reference solutions for the in-plane stresses.*

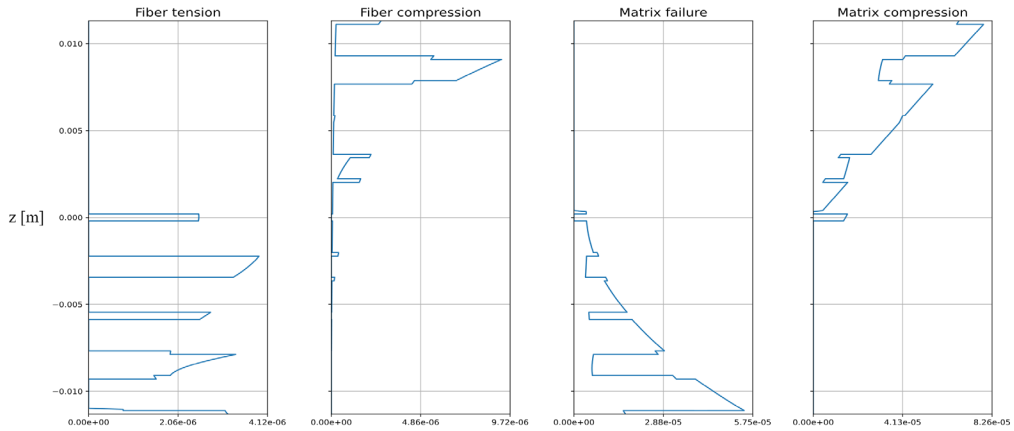

Figure 4. Through-thickness distribution of Hashin failure indices obtained from the local CUF-LW.

The structural constraints related to strength are evaluated through a global–local coupling procedure described, where local CUF-LW analyses are performed on the most stressed element identified in the global 2D wing-box model. Figure 3 shows the through-thickness stress distributions obtained from the local model, where the in-plane components are compared with the Nastran 2D global FE model, while the out-of-plane stresses are computed exclusively by the LW formulation. Figure 4 presents the corresponding Hashin failure indices for fiber tension, fiber compression, matrix tension, and matrix compression, which are used to evaluate the strength constraints within the optimization framework.

Additional verification analyses were carried out with the global optimization framework, which was executed for 300 iterations. The convergence of the objective function, the best feasible objective, and the aggregate constraint violation are depicted in Figure 5.

Materials Research Proceedings 69 (2026) 1192-1197 https://doi.org/10.21741/9781644904251-205

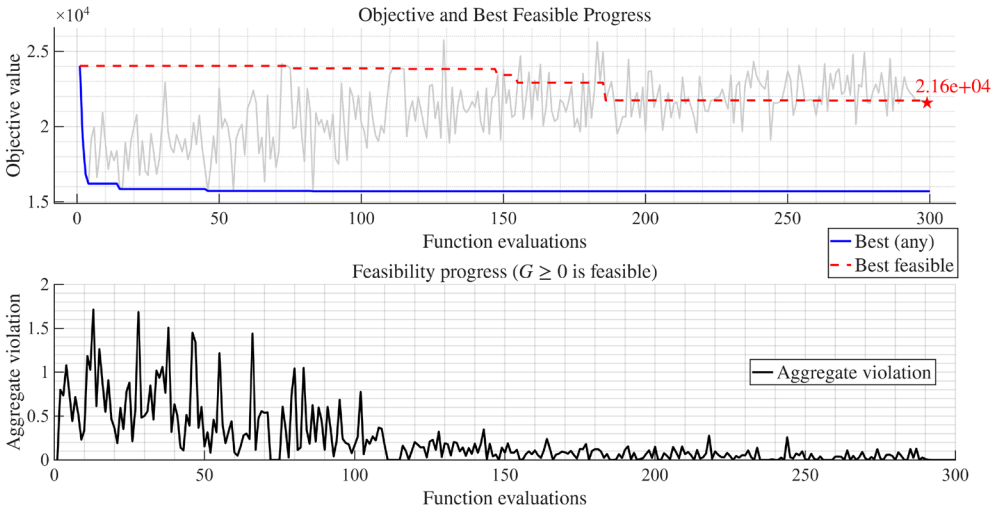

Figure 5 Convergence of objective function and aggregate violation

The optimized distribution of the design variables reflects a configuration consistent with the expected aeroelastic loading of a wing. The front and rear spar locations were adjusted toward the mid-chord region to efficiently react the maximum aerodynamic bending and torsional loads, providing an effective load path between the upper and lower skins. The relatively high skin thicknesses, particularly in the upper panel, correspond to regions of dominant compressive bending stresses, while thinner lower skins are associated with tensile-dominated regions. The spars and ribs exhibit moderately increased ply counts to enhance torsional stiffness and suppress local buckling, ensuring stability under combined bending and shear. In contrast, several beam-type components such as stringers and spar caps converge toward their lower bounds, indicating that their stiffness contribution beyond a certain threshold does not yield additional mass savings. Overall, the optimized configuration demonstrates a rational balance between stiffness, weight, and aeroelastic performance, with the structural reinforcements concentrated in load-critical regions.

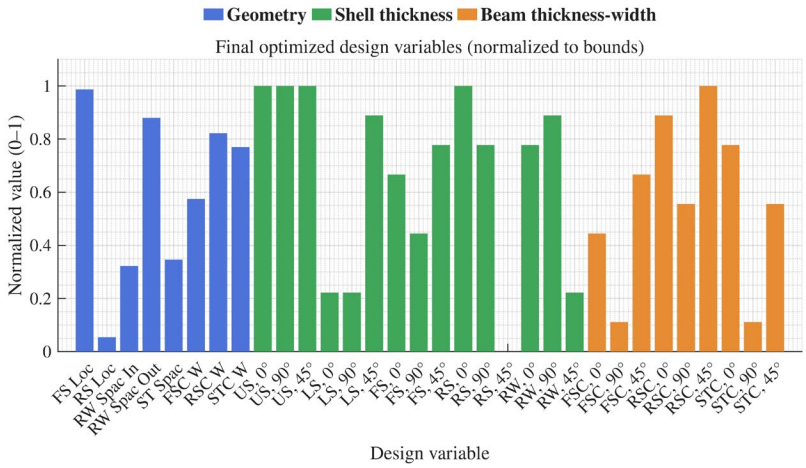

Figure 6 Final normalized values of the design variables obtained from the global optimization framework. Bars are color-coded by category: geometry (blue), shell thickness (green), and beam thickness-width (orange).

Conclusions

This research advances current methodologies by embedding surrogate-based local strength evaluations into a multiscale optimization process. The framework bridges efficient global-level aeroelastic design with detailed laminate-level failure modeling, providing a viable strategy for future composite wing development. Ongoing work will extend the approach to full aeroelastic tailoring and stacking sequence optimization for high-aspect-ratio wings.

Keywords: Turbine Blade, Trailing Edge, Rotating, Heat Transfer, Pin-Fins, Ribs

Abstract. The current work conducts an experimental investigation of the heat transfer performance in a rib-pin composite trapezoidal channel. The channel employs ribs and pin-fins as turbulators, with the ribs arranged in two distinct configurations: forward-swept and backward-swept. The inlet Reynolds number (Re) and rotation number (Ro) respectively vary between 8000 and 24000 and from 0 to 0.83. The results indicate that under static conditions, forward-swept ribs enhance local heat transfer, but they provide no improvement in overall heat transfer within the low-radius region. Under rotating conditions, the heat transfer disparity between the leading and trailing walls progressively diminishes with increasing radius. When using backward-swept ribs, buoyancy forces influence the size of separation vortices induced by the ribs, which in turn reduces the overall heat transfer efficiency under rotation, especially when Ro > 0.5. This study demonstrates that in the trailing edge channel of turbine blades with lateral slots, within the commonly employed range of rotation numbers (Ro = 0 ~ 0.5), backward-swept ribs are more effective when combined with pin-fins, enabling optimal heat transfer performance.

Introduction

The continuous advancement of aero-engine technology is primarily marked by the progressive increase in turbine inlet temperature (TIT). High-performance aero-engines typically operate with TIT exceeding 2000 ℃, surpassing the thermal resistance capabilities of current high temperature alloys. Consequently, effective cooling strategies for turbine blades become indispensable [1]. The fundamental approach to turbine blade cooling involves introducing cooling air into internal channels to remove heat from the inner wall surfaces. Concurrently, a fraction of the cooling air is ejected through small holes on the blade surface, forming an insulating air film that covers the exterior and separates the metallic structure from the high-temperature gases. Due to the narrow and long geometric characteristics of the trailing edge of the turbine blade, the arrangement of internal turbulators is restricted [2]. Moreover, the lateral slots intensifies the flow loss of the cooling air [3]. All these factors jointly make the internal cooling of the trailing edge a weak link. Hence, achieving efficient cooling within the trailing edge is of critical importance for improving the overall thermal reliability of the blade cooling system.

The most commonly employed cooling enhancement structure in the trailing edge channel of turbine blades is the pin-fins [4], as it serves the dual purpose of enhancing turbulence intensity and maintaining structural integrity. Early research primarily concentrated on the arrangement [5,6], cross-sectional shape [7,8], and geometric characteristics [9,10] of pin-fins. Later, some researchers introduced ribs into the internal cooling design of the trailing edge to mitigate the high flow resistance associated with traditional pin-fins arrays [11], which led to a growing interest in investigating the heat transfer mechanisms of hybrid configurations combining ribs and turbulators

[12,13]. Nevertheless, the integration of ribs and pin-fins remains somewhat empirical, and the coupling mechanisms under rotating conditions are still insufficiently explored.

This study experimentally examines the heat transfer mechanisms influenced by two different rib configurations under rotating conditions in a rib-pin composite channel, offering valuable insights for engineering applications to effectively leverage the individual advantages of ribs and pin-fins, thereby enabling more rational design of trailing edge cooling schemes.

Test Section and Measurement Method

The experimental facility comprises a power module, an air supply module, a support module, and a temperature measurement module, as shown in Fig. 1. The power module is centred around a 30 kW electric motor that drives the rotating shaft via a belt transmission system. The air source module provides compressed air at a maximum pressure of 0.8 MPa, serving as the coolant. The support module ensures stable mechanical support for the entire rotating assembly. In the temperature measurement module, the ADAM-4018 data acquisition module converts thermocouple signals from the test section into digital signals, which are then transmitted through a slip ring to the ADAM-4520 communication module. Subsequently, the RS-232 interface of the ADAM-4520 module transfers the data to the host computer for real-time monitoring and analysis. The test section is primarily composed of an aluminium cylinder, nylon frameworks, copper plate-based temperature measurement units, turbulators (including ribs and pin-fins), as shown in Fig. 2. The copper plate method [14] is employed as the measurement method. The fundamental principle of this method involves embedding copper plates within the nylon skeleton of the channel and applying thin-film heaters to the rear surfaces of the copper plates for controlled heating. Moreover, thermocouples are inserted into blind holes located on the back side of the copper plates to monitor their temperature (Fig 2(f)). Due to the high thermal conductivity of copper (approximately 400 W/(m·K)), the lumped parameter method can be applied, allowing the assumption that the temperature measured by the thermocouples accurately represents the temperature at the interface between the copper plates and the cooling air.

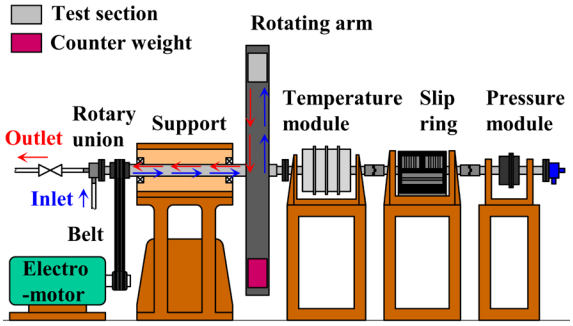

Fig. 1. Schematic illustration of the experimental facility configuration.

Data Reduction

The convective heat transfer coefficient (h) and the Nusselt number (Nu) on the wall of the channel are calculated using Eq. (1) and (2), respectively.

$$h = \frac{Q_{net}}{A\left(t_w - t_b\right)} \tag{1}$$

$$Nu = \frac{hD_h}{\lambda} \tag{2}$$

Materials Research Proceedings 69 (2026) 1198-1203 https://doi.org/10.21741/9781644904251-206

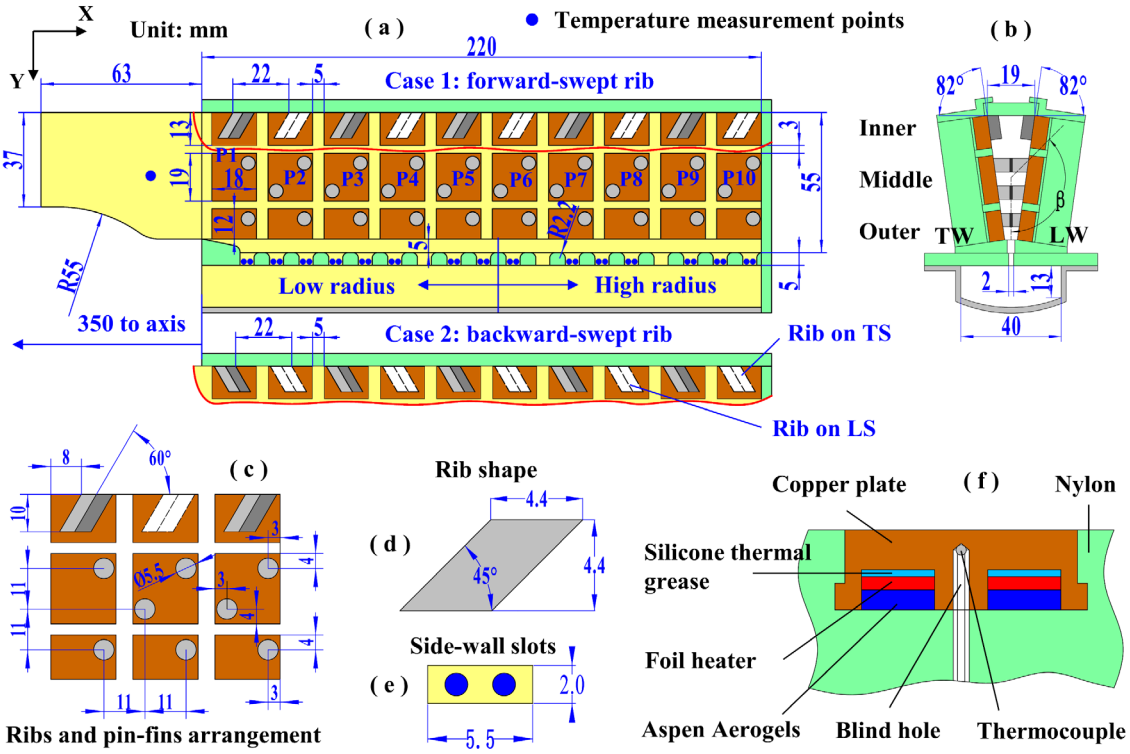

Fig. 2. Schematic illustration of the overall structure of the test section and the distribution pattern of turbulators within the channel.

Here, Q_{net} denotes the net heat flux applied to the copper plates, A represents the contact area between each copper plate and the cooling air, t_w indicates the temperature of the copper plate, t_b refers to the local mean bulk temperature, D_h signifies the hydraulic diameter at the channel inlet, and λ stands for the thermal conductivity of the cooling air.

The definition of net heat flux is as follows:

$$Q_{net} = I^2R - Q_{loss} = I^2R - \alpha\left(T_w - T_e\right) \tag{3}$$

$$\alpha = \frac{\left(I^2R\right)_{cond}}{T_w - T_e} \tag{4}$$

Here, α denotes the heat loss coefficient, which must be determined via a calibration experiment conducted in the absence of convective heat transfer. This experiment involves measuring the heat conducted to the surrounding environment ($\left(I^2R\right)_{cond}$), the wall temperature of the copper plate (T_w), and the ambient temperature (T_e).

The remaining dimensionless parameters to be controlled during the experiment are as follows:

$$Re = \frac{\rho_{in} U D_h}{\mu} = \frac{\dot{m}_{in} D_h}{\mu A_{in}} \tag{5}$$

$$Ro = \frac{\Omega D_h}{U} = \frac{\Omega \rho A_{in} D_h}{\dot{m}_{in}} \tag{6}$$

$$DR = \frac{\overline{T_w} - T_{in}}{\overline{T_w}} \tag{7}$$

Here, $\dot{m}_{in}$, μ, and ρ denote the inlet mass flow rate of the test section, the dynamic viscosity of the cooling air, and the coolant density, respectively. D_h and A_{in} represent the hydraulic diameter and the cross-sectional area at the inlet of the test section, respectively. Ω refers to the rotational speed,

Materials Research Proceedings 69 (2026) 1198-1203 https://doi.org/10.21741/9781644904251-206

T_w is the area-averaged wall temperature of the copper plates, and T_{in} denotes the inlet temperature. The range of experimental operating conditions for this study is presented in Table 1.

Table 1 Work conditions

Parameters	Values
Reynolds number (Re)	8000 ~ 24000
Rotation number (Ro)	0 ~ 0.83
Density ratio (DR)	0.07 ~ 0.14
Rotational speed [rpm]	0 ~ 800 (interval 100)
Back pressure [kPa]	around 500
Positional coordinates of the copper plates	X/D_h = 0.66, 1.78, 2.91, 4.03, 5.15, 6.27, 7.39, 8.51, 9.63, 10.75

Results and Discussion

The heat transfer characteristics of two configurations are examined under both static and rotating conditions. Under static conditions, the forward-swept rib scheme (Case 1) generated significantly larger separation vortices compared to the backward-swept rib scheme (Case 2). This resulted in a tortuous heat transfer distribution pattern in the inner region of Case 1, whereas such a phenomenon is absent in Case 2. However, in the low-radius middle and outer regions (Fig. 3(c)~(f)), heat transfer in Case 2 is stronger than in Case 1, indicating that the separation vortex induced by the forward-swept ribs under static conditions adversely affects spanwise heat transfer in adjacent regions, thereby diminishing the effectiveness of the pin-fins.

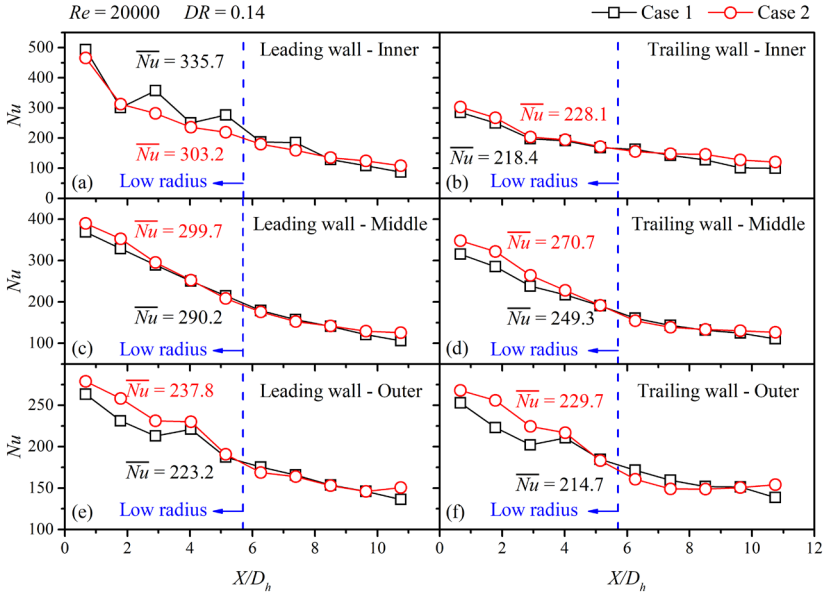

Fig. 3 Heat transfer distribution in the stationary channel under two different rib configurations.

Under rotating conditions, the differences in heat transfer distribution between the two configurations are minimal at low Ro. Overall, the effect of Re on rotational heat transfer can be decoupled, and heat transfer in the low-radius region exhibits greater sensitivity to rotation. A comparison of Fig. 4 and Fig. 5 reveals that, although the backward-swept rib channel shows a relatively small difference in heat transfer between the leading and trailing walls under rotating conditions, its heat transfer level declines significantly when Ro > 0.5, with a reduction exceeding 20%. This behaviour is attributed to the lower flow resistance of the backward-swept rib configuration, which allows a larger portion of cooling air to reach the high-radius region even under static conditions. At high Ro, the separation vortices generated by these ribs in the high-

Materials Research Proceedings 69 (2026) 1198-1203 https://doi.org/10.21741/9781644904251-206

radius downstream area are elongated due to the progressively increasing buoyancy force. This enlargement of the vortices adversely affects the heat transfer performance.

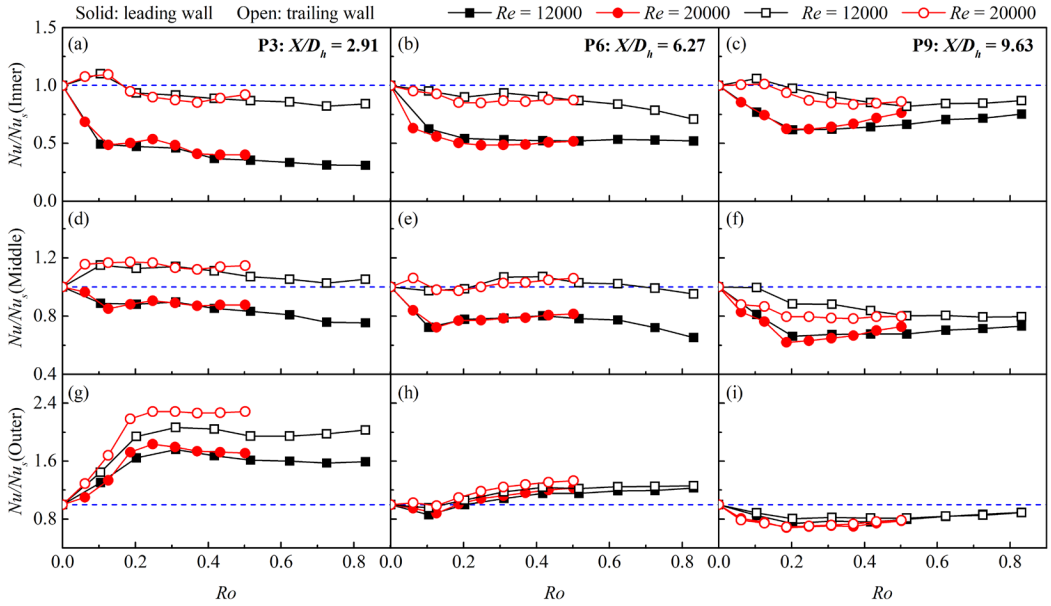

Fig. 4 Rotational heat transfer distribution in the channel with forward-swept ribs (Case 1).

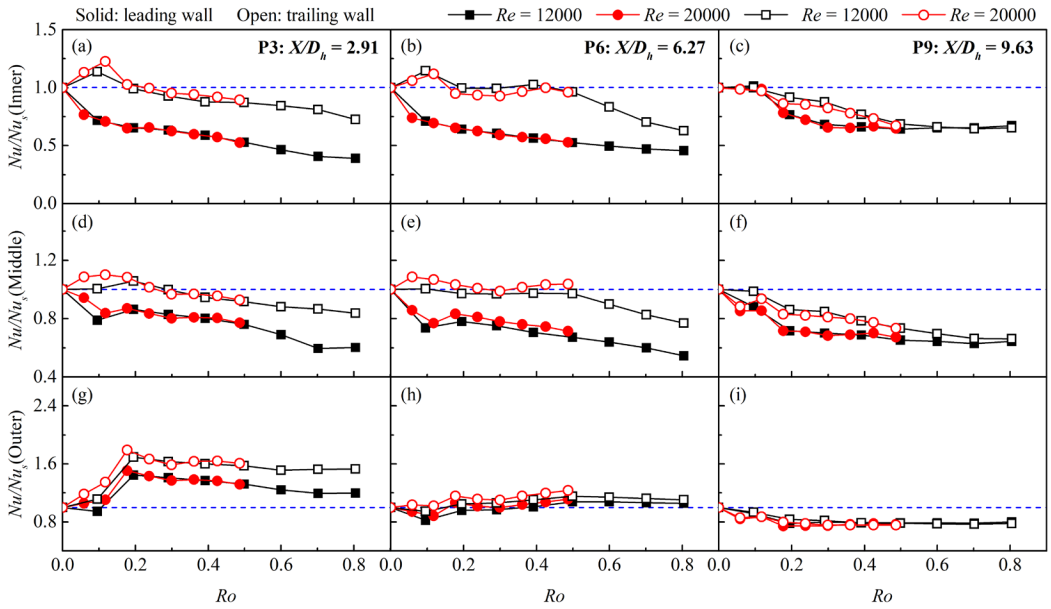

Fig. 5 Rotational heat transfer distribution in the channel with backward-swept ribs (Case 2).

Conclusion

Experimental investigations into the rotating heat transfer mechanisms of two rib-pin composite trapezoidal channels demonstrate that the coupling effect between ribs and pin-fins is primarily manifested through the separation vortices induced by the ribs. During rotation, the buoyancy force at the high-radius zone exerts a significant influence on the heat transfer distribution. The forward-swept rib configuration enhances local heat transfer. However, its adverse impact on heat transfer in adjacent regions is non-negligible. For operating conditions with Ro < 0.5, the backward-swept rib configuration is preferred. Otherwise, the forward-swept configuration becomes more advantageous.

Keywords: Compression After Impact, Delamination, Composite Structures, Low Velocity Impact

Abstract. Composite materials possess excellent properties in terms of their high strength and stiffness. The use of CFRPs composites in aerospace and space applications is increasing exponentially due to their superior properties and usage in primary structures. Such structures because of their nature, if get impacted by external projectiles or debris can develop barely visible impact damage developing delamination within themselves. These delaminations become catastrophic when faced with additional compressive loads. These kinds of events are called compression after impact [CAI] events, and they are very critical for aerospace structures. These problems are solved by structural engineers either by experimentation or conducting computational studies by using commercially available tools or in-house developed codes. The experimental evaluation of CAI is quite expensive while the computational approach makes it a reasonable choice for engineers. In this study, the CAI event is computationally evaluated using commercially available ABAQUS software. Continuum shell modeling is utilized to make the geometry following the ASTM D7137 and Airbus AITM 1-0010 standard. Boundary conditions were provided according to the standard to mimic the failure behavior. Unidirectional AS4/8552 pre-preg material and its properties were used as material property. Structures with predefined delamination, which mimics impact events, were evaluated in this research and found that the simulated results were within ±10% difference, showing that Abaqus simulation helps researchers minimize experimental cost and can increase diversity in the profile of the results and composite laminates for CAI events. Local, mixed, and global buckling plays a critical role in CAI events.

Introduction

Composite materials are widely used in all engineering applications ranging from commercial structures to advanced aerospace / space structures including deep space exploration rovers. Their higher specific strength and stiffness make them distinctive in terms of their selection to their metallic counterpart. Despite their unique properties, their usage must be evaluated carefully because their failure mechanisms are different than that of metals [1]. Fiber breakage, matrix cracking, delamination, fiber kinking, in-plane and out of plane buckling are a few different failure mechanisms among many which used to happen in composites [2,3]. The behavior of composites towards damage also varies according to different loading scenarios. Tensile failure is different than that of compressive failure, impact loading is also different whenever categorized under high or low velocity impact loadings.

Low velocity impact (LVI) in composites needs to be evaluated critically. These kinds of impacts can damage the structures internally without leaving any traces on the surface. LVI are more critical for aerospace structures and their applications [3-5]. Externally the surface looks as

Materials Research Proceedings 69 (2026) 1204-1209 https://doi.org/10.21741/9781644904251-207

clean as pristine but internally the damage has already happened. The LVI can be categorized where the effect is minimum unless crack growth takes place further that can be classified as barely visible impact damages (BVID). The term BVID is well known in composite/aerospace structure community. These BVIDs, because of low velocity impacts become even more critical if followed by compressive load which is usually called compression after impact (CAI) event [6-9].

CAI events have been investigated experimentally and computationally in an extensive way by different researchers in the aerospace community [10,11]. Experimentally it is extremely expensive, the best approach is to use commercially available tools and mimic those events computationally [12] and get reliable results. Among the available different tools, Abaqus is selected, being extensively used by the aerospace community and big companies.

In this computational work, the attempt was made to evaluate composite based structures for compression after impact events computationally by using commercially available software. The assumption was made that impact has happened already and investigated structure has already developed delamination with in it having different shapes. Afterwards compressive loads applied computationally and compared with available experimental data to validate.

Methodology

In this research, the commercially available FEM tool Abaqus is utilized for computational modelling of specimens. Within software Abaqus/Explicit module is utilized by adopting Continuum shell methodology technique. The FEM model is splitted into different zones. The area of interest, the central region is modelled by ply by ply or different laminates while the outer region is modelled by singly continuum shell elements by providing combined properties in the system. Unidirectional AS4/8552 pre-preg material and its properties were used as material property. Five diverse kinds of laminates were simulated as used by NASA and other researchers earlier in their research [13-15].

Table 1: Laminates as available in reference [9].

Laminate	# plies	t [mm]	Lay-up
181	16	2.944	[45, -45, 0, 45, 45, -45, -45, 90]s
181T	20	3.68	[45, -45, 0, 45, -45, 90, 45, -45, 45, -45]s
252	24	4.416	[45, 0, -45, 90, 45, 0, -45, 90, 45, 0, -45, 90]s
351	24	4.416	[45, 0, -45, 0, 45, 0, -45, 90, 45, 90, -45, 0]s
361	34	6.256	[45, 0, -45, 0, -45, 45, 0, -45, 90, 45, 45, 90, -45, 0]s

Different number of plies are there for different configurations. The ply properties were taken from earlier research available at [13]. Table is attached for reference here. In this research, meshing was done according to need, where we have more stress concentrations, there we have provided refine mesh while on the part with least interest, coarse mesh was provided as shown in figure 1. Boundary conditions and geometry configurations were provided as per ASTM standard D7137 and Airbus standard AITM 1-0010 [14,16]. Interested regions were modelled with finer mesh and multiple sub-laminates, while upper and lower parts were modelled with one element though the thickness of laminates.

Materials Research Proceedings 69 (2026) 1204-1209 https://doi.org/10.21741/9781644904251-207

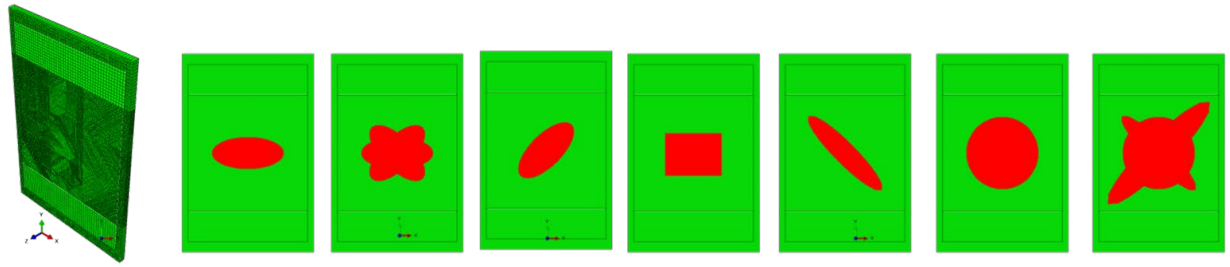

*Figure 1: FEM modelling in Abaqus (100 mm * 150 mm coupon size with central zone having finer mesh) and Different delamination's profiles in Abaqus for FEM.*

Multiple shapes were selected to provide delamination to mimic real time impact event within the laminate. These delamination's includes but not limited to Circle, Oval and Rectangular shapes. These delamination's were provided at various locations through the thickness of laminates. With these delamination's, the effect of delamination was studied with shape and location. For delamination behavior, Abaqus/explicit Cohesive zone modelling approach based on Surface based criterion were utilized. In comparison to Cohesive element approach, it was easier to define cohesive surface criterion and no of elements also reduced by its usage. After initiation, propagation was done by B-K law as available in Abaqus software.

Results and Discussion

Continuum shell modelling was adopted in this research by providing delamination at various locations with different shapes according to literature. Different delaminations and their different areas resulted in reduction in strength differently. Oval, circle, and square shapes with same areas resulted in different strength reduction as can be seen in figure 2 especially when the delamination was provided only one end and then on both end after third ply in series.

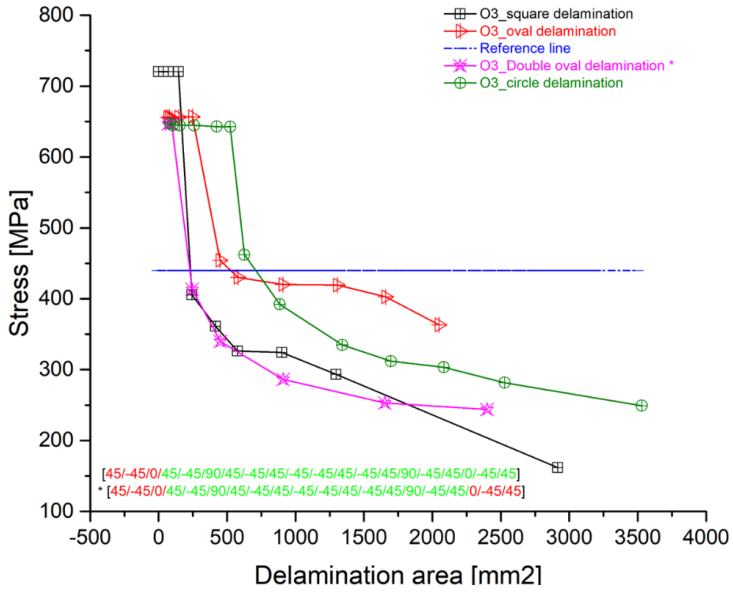

Figure 2: Reduction due to delamination area.

Afterwards multiple delamination's were provided to check how it affects the damage behavior. This multiple delamination was sorted out based on extensive literature [10-13] which suggests how strain energy is being accumulated and ply clustering plays a critical role in that. In addition

Materials Research Proceedings 69 (2026) 1204-1209 https://doi.org/10.21741/9781644904251-207

to this compression after an impact event initial depth of indent is the point where delamination moves towards the end, starting from back end delaminated piles.

The delamination can be seen in figure 3 below where it can be seen how the delamination propagates within the laminate after CAI loads.

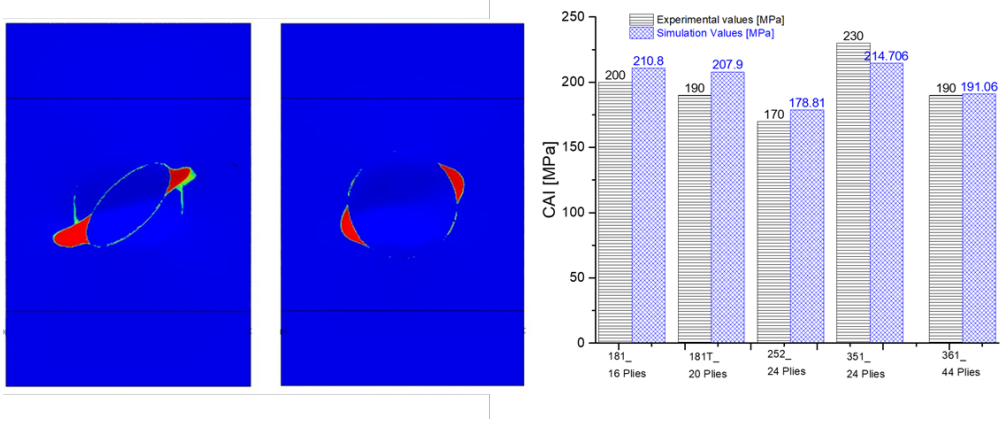

Figure 3: Delamination propagation in post-processor and Strength reduction due to delamination for different laminates (Experimental values taken from references [13,15,17]).

After applying multiple combinations for provided 5 different sets of plies, the analyses resulted in overpredicting most of the configurations by 5 to 10% while few of them resulted in under-prediction but all CAI simulated events resulted in ±10% of experimental known values from literature [15]. When laminate is thick its underpredict, while for thin laminate having ply less than 24, behavior shows over prediction. The interaction properties defined within the Abaqus also influenced the damage behavior.

In the figure 3, experimented values from reference [13,15] and simulated values, all are within ±10% variation. These results after further evaluation can be implemented to further unknown configurations and can get prediction without performing expensive experimentations. The buckling behavior observed in thin and thick laminates were also different.

Conclusion

Composite materials having exceptional engineering properties fail in a unique way which is different than that of conventional metals. These structures when used for aerospace applications need further care. They need to be evaluated critically if they are subjected to compressive load after an impact event, because internal delamination led to catastrophic effect. Structures with predefined delamination, which mimics impact events, evaluated in this research and found that simulated results were within ±10% difference, showing that Abaqus simulation help researchers to minimize experimental cost and can increase diversity in outcome and composite laminates profile for CAI events. Local, mixed, and global buckling plays a critical role in CAI events. This research is still going on by evaluating different delamination's profile by comparing real-time CSCAN data.

Keywords: Ultra-Thin Structures; One-Dimensional Refined Model; Carrera Unified Formulation; Failure Analysis

Abstract. This study investigates the failure of ultra-thin deployable composite structures. The analysis focuses on a laminated tape spring composed of three layers of glass fibre and carbon fibre reinforced polymers, subjected to opposing bending moments at its ends. The Carrera Unified Formulation (CUF) is employed for the numerical analysis within a geometrically nonlinear framework. This approach enables the accurate evaluation of the complete three-dimensional (3D) stress state at each equilibrium configuration. The Hashin 3D criterion is then applied to compute failure indices, allowing for the identification of critical points along the nonlinear equilibrium path. The results conclusively identify the mid-span section as the most critical region, with matrix-dominated failure modes being predominant.

Introduction

Deployable structures have gained prominence in space engineering due to their ability to reduce significantly mass, volume, and cost [1]. Typically fabricated from thin or ultra-thin materials, these structures are extensively used in applications such as satellite antennas [2]. Tape springs represent the most common type of deployable boom. While traditionally metallic, recent designs increasingly employ carbon fibre-reinforced plastic (CFRP) to achieve superior stiffness-to-mass ratios. These structures demand advanced analyses due to their nonlinear mechanical behaviour, including large deformations coupled with local and global instabilities, which can produce damages [3, 4]. Material nonlinearities present additional complexities, particularly when modelling composite or elastomeric components, where an accurate failure prediction is crucial and due to their propensity for multifaceted failure modes, making high-fidelity modelling both essential and challenging.

This study focuses on the accurate evaluation of three-dimensional (3D) stress fields and the failure mechanisms in space deployable structures by calculating the failure indices within the geometrical nonlinear framework. This study employs the one-dimensional version of Carrera Unified Formulation (CUF) [5, 6] for the structural modelling. CUF framework decomposes the three-dimensional displacement field into axial and cross-sectional components, enabling the implementation of higher-order theories that accurately capture cross-sectional deformation patterns. Specifically, Lagrange polynomial expansions are utilized to represent the kinematics. This refined beam formulation provides significant computational advantages over conventional 2D and 3D finite element approaches, particularly in terms of solution efficiency. The methodology maintains 3D solution accuracy while substantially reducing computational costs.

Materials Research Proceedings 69 (2026) 1210-1214 https://doi.org/10.21741/9781644904251-208

CUF has been recently adopted for calculating the nonlinear behaviour of deployable space structures [7, 8].

This paper is organized as follows: (a) Section *Methodology* introduces the principles of CUF in the nonlinear scenario; (b) Section *Numerical Results* presents the main outcomes; and (c) Section *Conclusions* summarizes the key findings of the study.

Methodology

According to the CUF, the 3D displacement field can be expressed in the following unified form:

$$\mathbf{u}(x,y,z) = F_\tau(x,z)\mathbf{u}_\tau, \qquad \tau = 1,2,\dots,M \tag{1}$$

where $\mathbf{u}$ denotes the displacement vector with components defined in the global reference system (x,y,z). $F_\tau(x,z)$ represent the cross-sectional functions in-plane coordinates (x,z), τ is the summation index, and M is the number of terms used in the cross-sectional displacement expansion. In the present work, quadratic Lagrange polynomials (L9) are adopted to approximate the kinematic field; further details can be found in [5]. The use of Lagrange polynomials enables the discretization of complex cross-sectional geometries.

To approximate the displacement field along the beam axis, the Finite Element Method (FEM) is employed. Thus, the displacement vector $\mathbf{u}_\tau(y)$ may be now expressed as:

$$\mathbf{u}(x,y,z) = N_i(y)F_\tau(x,z)\mathbf{u}_{\tau i}, \qquad i = 1,2,\dots,N_n \tag{2}$$

where $N_i(y)$ denotes the i-th one-dimensional shape function, i indicates summation, and N_n is the number of finite element nodes per element, whereas $\mathbf{u}_{\tau i}$ is the vector of nodal parameters. In this formulation, one-dimensional finite Lagrangian elements are used along the y-axis.

Finally, the stress $\boldsymbol{\sigma}$ and strain $\boldsymbol{\epsilon}$ components are expressed in vectorial form as:

$$\boldsymbol{\sigma} = \{\sigma_{xx}\ \sigma_{yy}\ \sigma_{zz}\ \sigma_{yz}\ \sigma_{xz}\ \sigma_{xy}\}^T, \quad \boldsymbol{\epsilon} = \{\epsilon_{xx}\ \epsilon_{yy}\ \epsilon_{zz}\ \epsilon_{yz}\ \epsilon_{xz}\ \epsilon_{xy}\}^T \tag{3}$$

Regarding the geometric relations, the Green–Lagrange nonlinear strain components can be written as

$$\boldsymbol{\epsilon} = \boldsymbol{\epsilon}_l + \boldsymbol{\epsilon}_{nl} = (\mathbf{b}_l + \mathbf{b}_{nl})\mathbf{u} \tag{4}$$

where $\boldsymbol{\epsilon}_l$ and $\boldsymbol{\epsilon}_{nl}$ denote the linear and nonlinear strain components, respectively. The 6×3 linear and nonlinear differential operators, $\mathbf{b}_l$ and $\mathbf{b}_{nl}$, are defined in detail in [9]. As far as the constitutive relation is concerned, linear elastic structures are considered in this work. Consequently, the constitutive relation reads as:

$$\boldsymbol{\sigma}^k = \mathbf{C}^k\boldsymbol{\epsilon}^k \tag{5}$$

where $\mathbf{C}^k$ is the material elastic matrix of the k-th layer, whose explicit form can be found in [5].

In this study, the 3D Hashin failure criterion [10] is employed to assess material failure. This criterion identifies the predominant failure mode at the ply level based on the local stress state. Four distinct failure indices are considered: Fiber Tension (FT), Fiber Compression (FC), Matrix Tension (MT), and Matrix Compression (MC).

Numerical results

The analysed tape spring has a length of L = 577 (mm), a thickness of t = 80 (ìm), a radius of r = 11.25 (mm), and a subtended angle of α = 90°, see Fig. 1. The structure is simply supported and subjected to two applied moments at its ends. The boom consists of three layers made of Carbon

Materials Research Proceedings 69 (2026) 1210-1214 https://doi.org/10.21741/9781644904251-208

Fiber (CF) and Glass Fiber Plain Weave (GFPW), as shown in Fig. 1 and detailed in Tables 1 and 2, [11]. Its stacking sequence is [±45GFPW/0CF/±45GFPW]°.

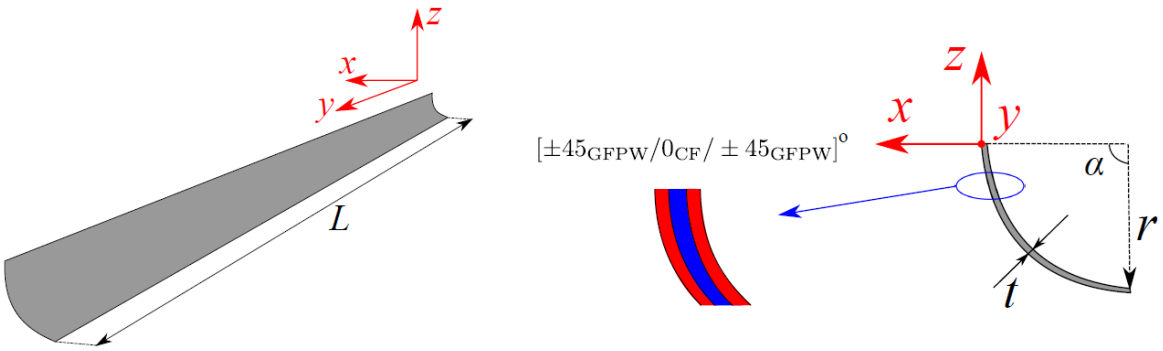

Figure 1: Geometrical details and stacking sequence of the tape-spring boom.

Table 1: Material characteristics of the tape-spring.

	E_1(GPa)	E_2(GPa)	G_{12}(GPa)	ν_{12}(-)	t(μm)
CF	128	6.5	7.6	0.32	
GFPW	23.8	23.8	3.3	0.17	

Table 2: Strength parameters for CF and GFPW in the tape-spring. Values in (MPa).

	X_T	X_C	Y_T	Y_C	S_{XY}	S_{XZ}	S_{XZ}
CF	2700	1650	55	225	100	100	32.26
GFPW	452.37	312.37	452.37	312.69	69.76	69.76	44.83

The structural model developed within CUF framework discretizes the cross-section into 30 L9 subdomains, enabling a piecewise parabolic approximation of the cross-sectional displacement field. Along the beam axis, two linear and eighteen cubic finite elements are employed, resulting in a total of 25,137 degrees of freedom (DOFs).

Figure 2 shows the equilibrium curve as a function of the angle θ, with the definitions of θ and the moment M provided for completeness. Point C (at $\theta = 6.8°$) marks the equilibrium state where the MC failure index reaches a critical value. A detailed distribution of the MC failure index at the equilibrium configuration C is provided in Fig. 3 (a). The plot clearly illustrates the variation of each failure index across the laminate's thickness at the mid-span. Fig. 3 (b) makes a comparison between configurations C and D.

Finally, Table 3 summarizes the maximum values of the four failure indices at the location of peak stress concentration for equilibrium states A, B, C, and D (see Fig. 2), along with their corresponding angles θ. All four failure indices reach their maximum values at the mid-span section, even though at distinct locations through the thickness. Specifically, the critical points for FT, MT, and MC are located within the GFWP layers, whereas the critical point for FC lies in the CF layer.

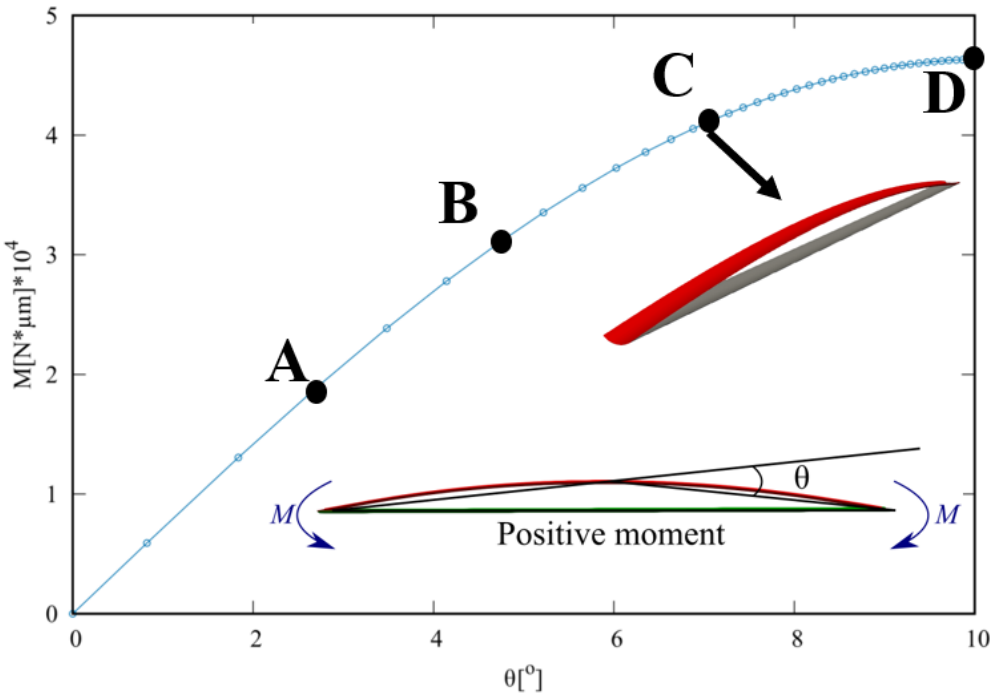

Figure 2: Equilibrium curve for the tape-spring boom.

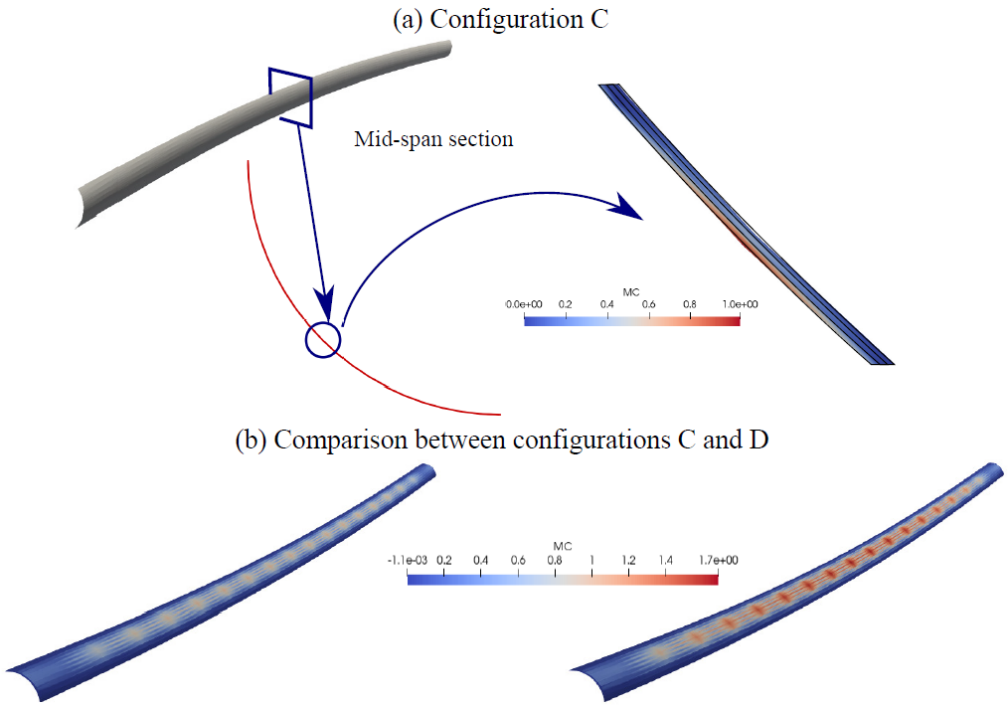

Figure 3: Failure indices for the equilibrium states C and D.

The results indicate that the structure may be susceptible to damage initiation even at relatively low angles of deformation. Among the considered failure indices, FT and FC, and MT are the least critical, whereas MC is significantly higher. The MC index, in particular, exhibits the most severe values, confirming it as the dominant failure mechanism. This analysis further reveals that the GFWP layers are the most prone to damage. Notably, the critical values for MC are reached during the nonlinear regime of the structural response.

Table 3: Failure indices for equilibrium points A, B, C, and D. (The locations are given in mm).

Configuration	θ[°]	FT (-0.0125,*L*/2,0)	FC (-3.51,*L*/2,-8.34)	MT (-4.22,*L*/2,8.94)	MC (-0.0125,*L*/2,-8.37)
A	2.7	0.000	0.000	0.010	0.16
B	4.7	0.002	0.000	0.026	0.44
C	6.8	0.006	0.002	0.031	1.03
D	9.9	0.009	0.002	0.050	1.69

Conclusions

This work has investigated the nonlinear behaviour of a tape-spring boom using a one-dimensional CUF framework. The Hashin 3D failure criterion was employed to assess the structure's failure state at various equilibrium points. It is important to note that the current model assumes a pristine, linear-elastic material response and does not incorporate damage progression. This simplification, the results clearly identify the mid-span region as the most critical area. Furthermore, the GFRP layers are identified as the most susceptible to damage initiation. Future work will focus on extending this analysis to include progressive failure modelling to accurately simulate damage initiation and evolution.

Keywords: Virtual Manufacturing, Carrera Unified Formulation, Multi-Field Model, Thermo-Chemo-Mechanical Analysis

Abstract. This work presents a multifield simulation approach using a higher-order one-dimensional model derived within the Carrera Unified Formulation framework to assess the impact of curing on the composite part's performance. The proposed approach enables coupled thermo-chemo-mechanical simulation and the simultaneous evaluation of temperature, degree of cure, process-induced deformations, and residual stresses in time and space. The advantage of this model is that it can generate a three-dimensional representation of the part while keeping computational cost low. Typical composite configurations in the aeronautical field, such as sandwich and stiffened structures, are analyzed. The results demonstrate the capability of the present numerical tool to simulate the behavior of the composite part during the process.

Introduction

The growing use of composite materials in the aerospace industry, owing to their excellent mechanical properties and high strength-to-weight ratio, has generated considerable interest in their curing processes. The complexity of the process and the stringent manufacturing specifications required to achieve high product quality have necessitated numerical modeling for the accurate and rapid study of the thermo-chemo-mechanical behavior of the composite part [1]. In recent years, more complex structural configurations, such as sandwich panels, have been increasingly used due to the excellent compromise between lightness and mechanical performance [2]. However, the presence of heterogeneous materials and complex interfaces makes the curing process even more challenging, requiring advanced numerical models that can realistically capture the three-dimensional distributions of temperature, degree of cure, and deformations.

The autoclave curing process is characterized by complex, coupled thermal, chemical, and mechanical interactions, further complicating its numerical simulation. The strong temperature and degree-of-cure gradients that develop within the laminate can lead to process-induced defects, such as residual stresses, warpage, and spring-in angles, which may significantly affect the final mechanical performance of the component [3,4]. In this context, numerical tools based on the finite element method (FEM) can be used to predict thermochemical behavior and process-induced defects; however, the inherently three-dimensional nature of the problem requires the use of solid elements, which significantly increases computational costs. For this reason, this work uses higher-order 1D models based on the Carrera Unified Formulation (CUF) [5] and finite elements to solve the coupled thermo-chemo-mechanical problem. In previous work, CUF-based models have been used to determine spring-in angles and stresses in L-shaped parts. Still, they have not accounted for the three-dimensional effects of thermal and chemical phenomena [6]. This variability is now introduced, enabling a more accurate solution for the part's temperature, degree of cure, and

mechanical deformation. This work considers a typical aeronautical configuration of a stiffened honeycomb sandwich structure.

Thermo-chemo-mechanical model

To accurately describe the curing process, the thermochemical behavior of the composite is modeled using the 3D heat-conduction equation, coupled with the kinetic model governing the resin curing reaction [7]. The heat transfer equation is expressed as:

$$\rho C_p \frac{\partial T}{\partial t} = \nabla \cdot (\boldsymbol{\kappa} \nabla T) + \rho H_r \frac{d\alpha}{dt} \tag{1}$$

where ρ is the density, C_p is the specific heat and $\boldsymbol{\kappa}$ is the thermal conductivity tensor. $\partial T/\partial t$ and $d\alpha/dt$ are the two time derivatives of temperature and degree of cure, respectively, and ∇T is the gradient of temperature. H_r is the effective total heat of reaction. Curing kinetics depend on material type and are typically described by Arrhenius-type equations. For AS4 carbon fiber reinforced Hexcel 8552 resin, the cure rate is [8]:

$$\begin{aligned} &\frac{d\alpha}{dt} = \frac{K\alpha^m(1-\alpha^n)}{1+e^{C[\alpha-(\alpha_{C0}+\alpha_{CT}T)]}} \\ &K = Ae^{\frac{-\Delta E}{RT}} \end{aligned} \tag{2}$$

where A is the pre-exponential coefficient, ΔE is the activation energy, R is the universal gas constant, and the others are constant fitting parameters. The experimentally fitted cure kinetic parameters are given in [8].

During curing, the resin's mechanical properties and volumetric cure shrinkage depend on both the instantaneous temperature and the degree of cure. The fiber properties, on the other hand, are assumed to be constant and independent of the cure. Consequently, the composite's mechanical properties evolve in time and space in response to the local thermochemical behaviour. Micromechanical models, such as those presented in [8], are employed to relate the fiber and matrix properties and to derive the lamina's effective mechanical properties, thermal expansion coefficients, and cure shrinkage. The evolution of these quantities is then incorporated into the mechanical analysis to calculate the stiffness matrix and the external force vector, as described in [6].

Therefore, to solve for the unknown displacement field $\boldsymbol{u}$, a linear static mechanical equation is solved [6]:

$$\boldsymbol{k}_{uu}\boldsymbol{u} = \boldsymbol{p}_u \tag{3}$$

where $\boldsymbol{k}_{uu}$ is the [3x3] fundamental nucleus of the stiffness matrix, and $\boldsymbol{p}_u$ is the fundamental nucleus of the vector of external loads represented by the shrinkage and thermal strains. In this paper, the thermo-chemo-mechanical problem is solved using a higher-order 1D model based on CUF and finite elements. This model assumes that the displacement, temperature, and degree-of-cure fields in the cross-section are expressed as expansions of two-dimensional Lagrange functions. At the same time, along the y-axis of the beam, they are approximated using FEM, i.e., they can be written as:

$$\begin{aligned} \boldsymbol{u} &= N_i(y)F_\tau(x,z)\boldsymbol{u}_{i\tau}, \qquad \tau = 1,\dots,M; i = 1,\dots,N \\ T &= N_i(y)F_\tau(x,z)T_{i\tau}, \qquad \tau = 1,\dots,M; i = 1,\dots,N \\ \alpha &= N_i(y)F_\tau(x,z)\alpha_{i\tau}, \qquad \tau = 1,\dots,M; i = 1,\dots,N \end{aligned} \tag{4}$$

where $F_\tau(x,z)$ is the expansion function over the cross-section, $N_i(y)$ are the shape functions, and $\boldsymbol{u}_{i\tau}$, $T_{i\tau}$, and $\alpha_{i\tau}$ are the nodal unknowns of the displacement field, temperature, and degree of cure. M is the number of terms of the expansion function, and N is the number of nodes of the

Materials Research Proceedings 69 (2026) 1215-1219 https://doi.org/10.21741/9781644904251-209

finite element. By expressing the unknowns in terms of the CUF and finite elements and substituting them into the thermo-chemo-mechanical equations, the resulting system is obtained:

$$\begin{bmatrix} 0 & 0 & 0 \\ 0 & D_T & D_{T\alpha} \\ 0 & 0 & D_\alpha \end{bmatrix} \begin{Bmatrix} \dot{\boldsymbol{u}} \\ \dot{T} \\ \dot{\alpha} \end{Bmatrix} + \begin{bmatrix} \boldsymbol{k}_{uu} & 0 & 0 \\ 0 & K_T & 0 \\ 0 & 0 & 0 \end{bmatrix} \begin{Bmatrix} \boldsymbol{u} \\ T \\ \alpha \end{Bmatrix} = \begin{Bmatrix} \boldsymbol{p}_u \\ p_T \\ p_\alpha \end{Bmatrix} \tag{5}$$

whose terms are written as fundamental nuclei [5]. The problem is partially coupled, since thermal and chemical phenomena influence mechanics but not vice versa. Because the thermochemical problem requires more iterations than the mechanical problem, the heat-transfer and cure-kinetics equations are solved first using the Newmark method [9], yielding a 3D solution for temperature and degree of cure. Starting from the solution of α, the mechanical properties of the composite are evaluated and used as input for the mechanical analysis. The mechanical problem is solved iteratively using a CHILE approach [10,6]. In this way, an accurate solution can be obtained while limiting analysis time and computational costs.

Results

The higher-order 1D model introduced in this work is used to investigate the thermochemical behavior and process-induced deformations of a substructure representative of a stiffened honeycomb fuselage structure studied in [8]. The structure consists of two 12-layer AS4/8552 composite skins with symmetrical lamination $[45/90/-45/0/45/90]_s$. Between the two skins, there is a thick HEXCEL HRP-3/16-8.0 honeycomb core. The reinforcement, located on the top surface at the center of the sandwich panel, is a pre-cured resin-transfer molded J-frame. The tool used is made of aluminum, while the tool/part interface is simulated using a shear layer. All details on the materials used, geometric dimensions, and boundary conditions are given in [8]. In the reference, some properties of the composite and J-frame are temperature-dependent, whereas in this work, they are assumed constant and calculated using the maximum curing-cycle temperature. The curing cycle used in the numerical simulation is the one that most accurately reproduces the autoclave temperature measured experimentally in [8]. It involves two holding temperatures at 107 °C and 177 °C for 100 min and 116 min, respectively. The two heating ramps have heating rates of 1.85 °C/min and 0.7 °C/min, and a cooling rate of 2.3 °C/min. The FEM model consists of 3 quadratic beam elements, while 140 Lagrange elements with nine nodes (140L9) are used in the cross-section. The total number of degrees of freedom is 22085.

Figure 1 shows the temperature and degree of cure at the same points considered in [8], i.e., at the tool/part interface, on the top surface of the sandwich panel, and on the J-shaped reinforcement. A good match is obtained between the temperature obtained from the CUF model and those reported in the literature. Significant temperature and degree-of-cure gradients develop across the thickness of the sandwich panel due to the low thermal conductivity of the core. These variations can promote the formation of high residual stresses and induce deformations.

Figure 2 shows the 3D deformation of the structure along the z-axis after tool removal. The structure exhibits warpage in the x–z plane. In the top plot of Fig. 2, the predicted warpage along the x-axis is compared with the fitted experimental results for three specimens reported in [8], showing good agreement.

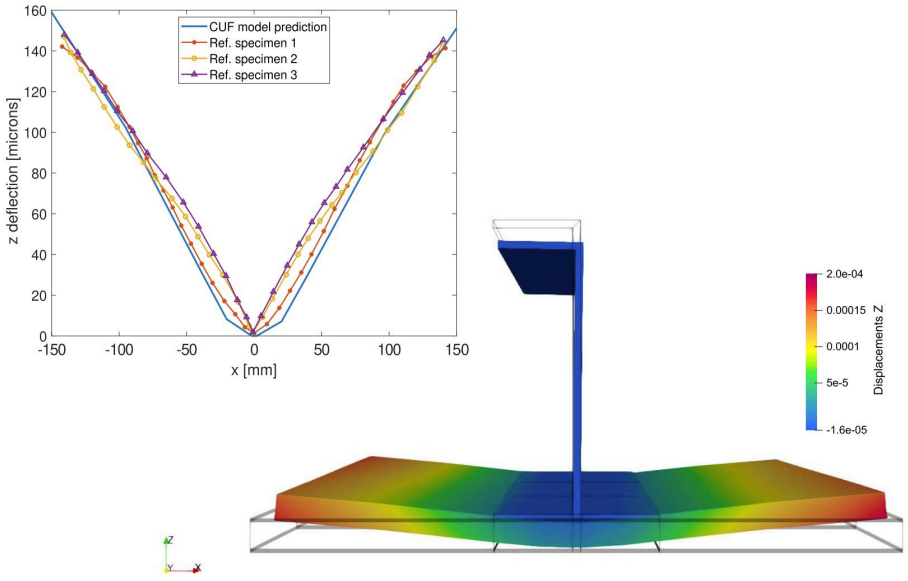

Figure 2: 3D distribution of the displacement in the z-direction (in mm) and comparison between the CUF model prediction and the experimental reference data taken from [8] of the warpage along the x-axis

Conclusion

This paper presents a numerical simulation to solve the coupled thermo-chemo-mechanical problem associated with the curing process of composite materials. The proposed model uses 1D finite elements along the beam axis and in the cross-section, higher-order distributions of temperature, degree of cure, and displacements using the Carrera Unified Formulation. The

advantage of the CUF model is that it can obtain 3D solutions for temperature, degree of cure, and displacements while maintaining a 1D formulation at low computational cost. A stiffened honeycomb sandwich panel is analyzed to validate the proposed numerical model. Comparing temperature measurements at different points on the part with the experimental data in the literature shows good agreement, confirming the accuracy of this approach.

Keywords: Multi-Fidelity Surrogate Models, Gaussian Process Regression, Bayesian Optimization, Carrera Unified Formulation, Process-Induced Deformations, Composite Design

Abstract. This work presents a multi-fidelity machine learning strategy for efficiently modeling the mechanical response of composite laminates during curing. A Gaussian Process Regression (GPR) framework is adopted to link the laminate stiffness parameters (B_{11}, D_{22}) to the stress component σ_{xx}, combining data from numerical models of different accuracy. High- and low-fidelity datasets are generated using Layer-Wise (LW) and Equivalent Single Layer (ESL) theories derived from the Carrera Unified Formulation (CUF) and finite-element analysis. The proposed approach employs Bayesian Optimization to adaptively select the most informative high-fidelity samples, thereby achieving accurate predictions at reduced computational cost. The model's predictive validity for stress distributions is demonstrated for L-shaped cross-ply composite laminates.

Introduction

Process-induced deformations and residual-stress development in composite laminates during curing pose significant challenges for ensuring structural performance and dimensional reliability in aerospace components [1]. Low-fidelity models provide fast, cost-effective estimates of deformation and stress distributions but often fail to capture detailed thickness variations. Conversely, high-fidelity simulations can resolve detailed stress fields across the laminate thickness but are computationally expensive, limiting their practicality for extensive design exploration of more complex part geometries.

For these reasons, there is growing interest in developing multifidelity simulation tools to analyze the composite manufacturing process [2]. The objective of this work is to minimize reliance on high-fidelity simulations by utilizing lower-fidelity data to train a surrogate model that accurately predicts stresses in composite components.

To bridge this gap, we propose a multi-fidelity surrogate modeling framework that combines two fidelity tiers: Equivalent Single Layer (ESL) theories and Layer-Wise (LW) simulations based on the Carrera Unified Formulation (CUF) [3]. A probabilistic surrogate model is then constructed using a Gaussian Process Regression (GPR) [2]. Two laminate stiffness parameters ($\mathbf{B_{11}}$, $\mathbf{D_{22}}$), derived from classical lamination theory, serve as GPR inputs and are mapped to the target stress. Bayesian Optimization (BO) is employed to allocate high-fidelity simulations to regions of high predictive uncertainty selectively.

Materials Research Proceedings 69 (2026) 1220-1224 https://doi.org/10.21741/9781644904251-210

The effectiveness of the ML method is evaluated by predicting the stress $\boldsymbol{\sigma_{xx}}$ in L-shaped laminates made of AS4/8552 material.

Methodology

A multi-fidelity Gaussian Process Regression (GPR) framework was developed to model the relationship between laminate stiffness parameters B_{11} and D_{22} and the simulated stress component σ_{xx}. The goal was to quantify the amount of high-fidelity (HF) data required to achieve accurate predictions when abundant low-fidelity (LF) data are available. The GPR approach was chosen for its ability to provide both a mean prediction and an uncertainty estimate, enabling the model to use Bayesian optimization (BO) to identify regions where substitutive HF data would be most beneficial for improving model accuracy. The LF and HF datasets share the same inputs but differ in accuracy and computational cost. LF simulations are faster but less accurate, whereas HF simulations are more representative of the physical system but more computationally expensive to generate.

The distinction between fidelity levels arises from the structural modeling approach used to compute the training data. The high-fidelity (HF) data were obtained using Layer-Wise (LW) models, in which an independent kinematic expansion is used to describe each composite layer. This formulation enables a detailed through-thickness description, yielding a piecewise linear displacement field and a more accurate representation of interlaminar stress distributions. Conversely, the low-fidelity (LF) data are generated from Equivalent Single Layer (ESL) models, in which all layers share a single global kinematic expansion in the thickness direction. While each ply still retains its own material properties, the through-thickness displacement field in ESL models is linear and continuous. Both the ESL and LW datasets were generated using a higher-order model based on the Carrera Unified Formulation (CUF) combined with the finite element method (FEM) [4].

To appropriately represent the difference in accuracy between the two data sources, each fidelity level was assigned its own noise value (α). The noise term quantifies the uncertainty the model ascribes to each data point; larger values indicate that the model should place less trust in the data. Because LF simulations are less precise compared to HF simulations, the LF points were intentionally assigned higher noise levels. The optimal noise configuration was identified through a grid search over possible LF/HF combinations, ensuring that the LF-only model captures the general trends in the data without being overly optimistic. Once the baseline noise levels were established, the GPR model was iteratively trained using a composite kernel designed to capture both linear and nonlinear relationships between the stiffness parameters and stress response. The kernel combined a linear term, a Radial Basis Function (RBF), and a Rational Quadratic (RQ) component, along with a small fixed white noise term for numerical stability:

$$k(x,x') = C_1^2(x \cdot x') + C_2^2 RBF(L_1) + C_3^2 RationalQuadratic(\alpha, L_2) + C_4^2 WhiteNoise \quad (1)$$

$$k(x,x') = C_1^2(x \cdot x') + C_2^2\, exp\left(-\frac{\|x-x'\|^2}{2L_1^2}\right) + C_3^2\left(1+\frac{\|x-x'\|^2}{2\alpha L_2^2}\right)^{-\alpha} + C_4^2\delta(x,x') \quad (2)$$

where:

C_1^2 = Signal variance associated with the linear term
C_2^2 = Signal variance associated with the RBF term
L_1 = Characteristic length scale of the RBF term
C_3^2 = Signal variance of the RQ term
α = Shape parameter of the RQ term
L_2 = Length scale of the RQ term

Materials Research Proceedings 69 (2026) 1220-1224 https://doi.org/10.21741/9781644904251-210

C_4^2 = Noise variance
$\delta(x, x')$ = Kronecker delta function

Next, a BO framework was employed to determine which LF data points should be replaced with HF values to maximize model performance. The acquisition function utilized to accomplish this task was Expected Improvement (EI):

$$EI(x) = (\mu(x) - f^* - \xi)\Phi(z) + \sigma(x)\phi(z) \quad (3)$$

and

$$z = \frac{\mu(x) - f^* - \xi}{\sigma(x)} \quad (4)$$

where:
$\mu(x)$= Predicted mean of the Gaussian Process at candidate point x
$\sigma(x)$= Predicted standard deviation (uncertainty) of the Gaussian Process at x
f^*= Current best observed value of the objective function (here, validation R^2)
ξ= Small positive constant that controls exploration–exploitation balance
$\Phi(z)$= Cumulative distribution function (CDF) of the standard normal distribution
$\phi(z)$= Probability density function (PDF) of the standard normal distribution

At each iteration, BO ranks all candidate LF points by their potential contribution to model improvement. The LF samples with the greatest expected improvement are then replaced by their HF counterparts, and the GPR is retrained using the same kernel and noise configuration. This iterative substitution continues until the validation accuracy converges or all available HF data are used.

Results

The proposed approach was applied to an L-shaped composite structure comprising eight plies of unidirectional AS4/8552 material mounted on an Invar tool. The geometry, material properties, and curing cycle adopted are described in detail in [3]. Finite Element (FE) simulations based on the CUF higher-order model were conducted for all 256 possible cross-ply stacking sequences, employing both ESL and LW theories. The total degrees of freedom of the LW and ESL models of the L-shape structure were 21861 and 7455, respectively. The resulting dataset for the GPR analysis comprised 174 training points and 84 validation points. Initially, the GPR model was trained solely on the LF (ESL-based) dataset. In subsequent iterations, however, the 10 LF points with the greatest expected improvement are replaced with their corresponding HF counterparts. In Fig. 1 the updated GPR surface is evaluated over a grid to visualize how the predicted surface evolved as more HF data points are incorporated.

Materials Research Proceedings 69 (2026) 1220-1224 https://doi.org/10.21741/9781644904251-210

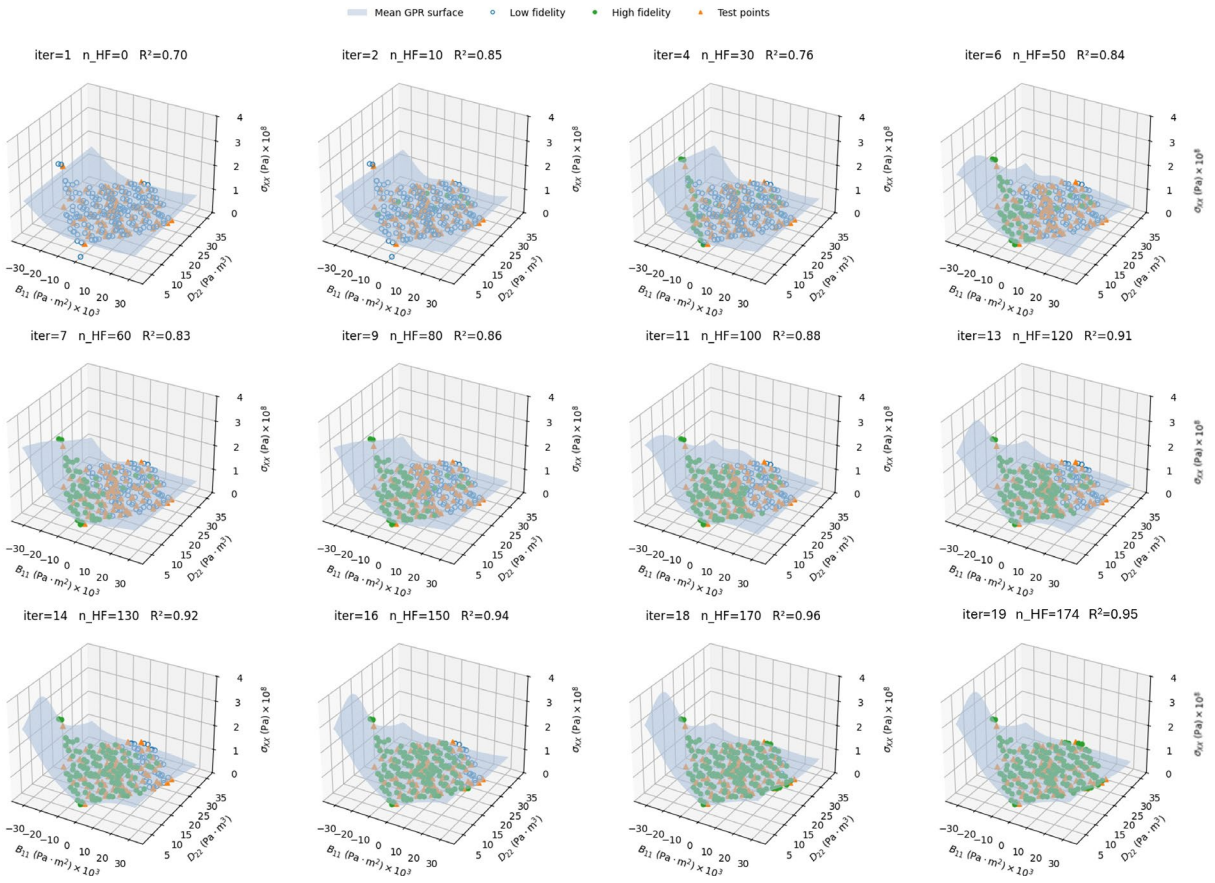

Figure 1: Evolution of the predicted GPR surface over the input parameter grid as high-fidelity data points $\boldsymbol{n_{HF}}$ are progressively incorporated

These results show the progressive refinement of the multi-fidelity GPR model as LF data points are gradually replaced with HF values. The term n_{HF} is representative of the number of HF points at a given iteration. At iteration 1 (iter = 1), the model trained only on LF data achieves a moderate accuracy (R^2 = 0.70), capturing general trends but missing finer variations in the 3D space. As additional HF points are incorporated, the predicted surface becomes smoother and more physically consistent with the observation data, and the validation accuracy steadily improves from roughly R^2 = 0.70 to R^2 = 0.95 by the final iteration. This also demonstrates that, within six iterations, the model increased accuracy by 14% and maintained that level for the remaining iterations. This means that, very quickly, it is possible to create an accurate machine learning model by replacing only 50 HF points (~29% of the total LF data). The results in Fig. 2 illustrate how the model evolves as HF data are selectively introduced through BO. At iteration 1, the GPR surface relies solely on LF data, producing a smooth but relatively uncertain trend with a moderate accuracy of R^2 = 0.70. By iteration 6, several strategically chosen LF points have been replaced by their HF counterparts, tightening the 95% confidence band and improving correlation to R^2 = 0.84. Evidence that the model is learning the actual stress distribution more effectively. Finally, at iteration 14, with 130 HF points now in training, the model achieves R^2 = 0.92, with the predictive surface aligning closely with the HF validation points and uncertainty collapsing in multiple zones of the domain.

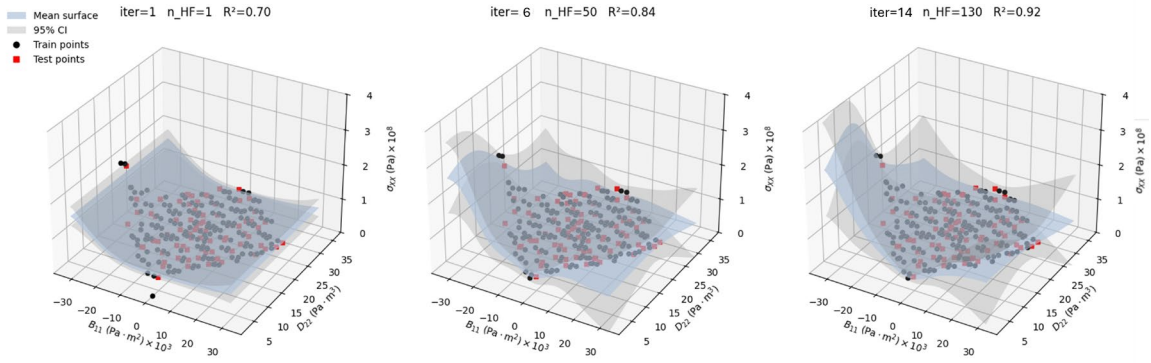

Figure 2: Multi-fidelity GPR predictive surface with iterative replacement of low-fidelity (LF) points by high-fidelity (HF) points, and comparison with the 95% confidence bands

Conclusion

In this work, a multi-fidelity GPR framework was applied to predict the stress field in composite laminates by combining data from models of different fidelity. The approach integrates low-fidelity (ESL) and high-fidelity (LW) simulations, formulated within the Carrera Unified Formulation (CUF), and solved using finite-element analysis. The results obtained for the L-shaped AS4/8552 composite structure show that, through Bayesian Optimization, a limited number of HF samples are sufficient to improve prediction accuracy significantly. After only a few iterations, the model achieved an accuracy $\mathbf{R^2}$ of 0.95, demonstrating that selective replacement of LF data is an effective strategy for balancing computational costs and accuracy.

Keywords: Testing in Aerospace, Eulerian Video Magnification, Video Processing, Finite Element Method, Modal Analysis

Abstract. This study presents a low-cost, non-contact experimental approach for structural dynamic testing of simplified aerospace components using Eulerian Video Magnification (EVM). Vibrations induced by a shaker are captured at 120 frames per second (fps), processed through a custom Python EVM algorithm, and compared with Finite Element (FEM) and analytical models. Results showed frequency deviations below 2% between EVM and FEM, validating the method's accuracy. The approach demonstrates that meaningful modal data can be obtained with consumer-grade equipment, enabling affordable, accessible, and non-invasive modal analysis for aerospace applications.

Introduction

Experimental Modal Analysis (EMA) is a key technique in structural dynamics used to determine the natural frequencies and mode shapes of mechanical and aerospace systems [1]. Conventional EMA approaches typically depend on costly and intrusive equipment, such as accelerometers, laser vibrometers, or high-speed cameras [2]. In this study, it is introduced and validated a low-cost, non-invasive experimental method that employs Eulerian Video Magnification (EVM) [3] using standard smartphone camera recordings to extract the vibrational characteristics of a simplified aerospace structure. EVM is a computational technique capable of amplifying subtle variations in motion and color within standard video recordings, analyzing pixel intensity variations over time, and applying temporal filtering to enhance imperceptible signals such as small vibrations or physiological changes. The method revealed versatility in applications, including the visualization of human pulse and the magnification of minute structural movements, marking a significant advancement in video-based motion analysis. This method is evaluated against both numerical (FEM) and theoretical analyses, providing a three-tier validation framework that integrates cost-effectiveness, computational modeling, and analytical accuracy. The study focuses on the dynamic characterization of a simplified structure (Fig. 1) through a detailed comparison between a numerical reference model and the results obtained from accessible measurement instruments. The structure is a simple beam-based model representative of aerospace components, excited by a shaker to produce broadband vibrations within the target frequency range, resulting in subtle oscillations that are often imperceptible to the human eye.

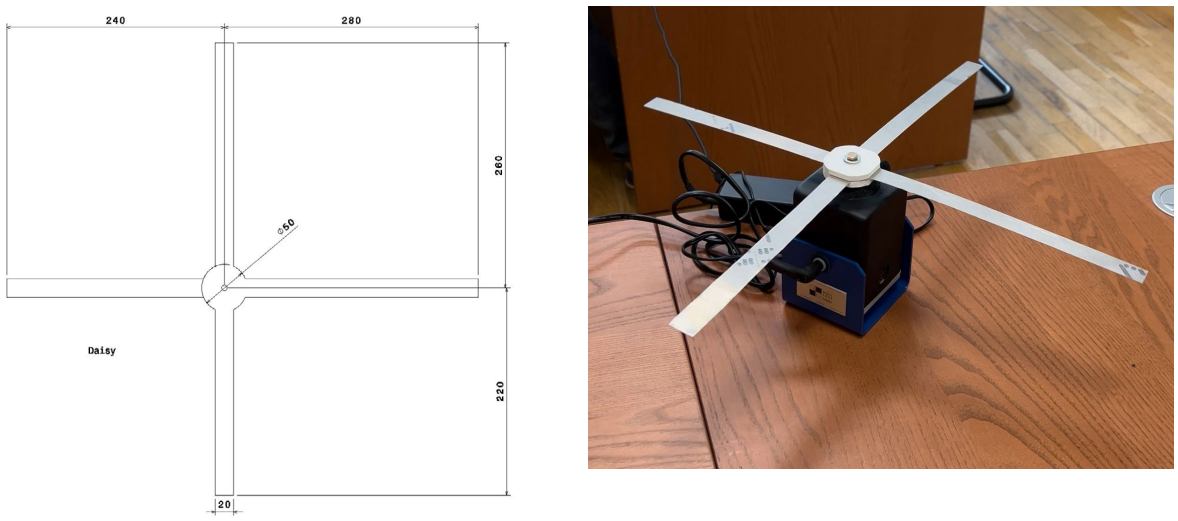

Figure 1 – Structure drawing (on left) and Experimental set-up (on right)

Methodology

To record these vibrations, an accessible approach is employed: a standard smartphone configured to capture video at 120 frames per second (fps). According to the Nyquist criterion, this sampling rate enables the detection of vibration frequencies up to 60 Hz, which is sufficient to capture the low-frequency vibration modes characteristic of the studied structure. Dedicated video recordings are obtained for the first and second vibration modes of each beam, ensuring full coverage of the relevant modal responses. This instrumental choice highlights the practicality of performing advanced dynamic analyses without relying on costly or specialized equipment [3]. Videos are recorded at both 60 frames per second (fps) and 120 fps using commercially available smartphones. A custom Python-based implementation of Eulerian Video Magnification is developed to process the video footage and extract the subtle motions associated with structural vibrations. The algorithm decomposes each video frame into multiple spatial scales using Gaussian and Laplacian pyramids, allowing the isolation of subtle motion components at different resolutions. Temporal intensity variations of pixels are then analyzed and filtered through a Butterworth bandpass filter, designed according to specified frequency bounds (low and high cutoffs) relative to the video frame rate. This enables selective amplification of vibrations within the frequency range of interest. For each pyramid level and color channel, temporal signals are detrended and transformed via Fast Fourier Transform (FFT) to identify dominant vibration frequencies and their spectral power. The filtered temporal signals are subsequently multiplied by a user-defined amplification factor, enhancing the magnitude of motion corresponding to the selected frequencies. The amplified Laplacian pyramid is then reconstructed into full-resolution frames, and the magnified video is saved in standard format. The code supports both grayscale and color processing, resizing videos to manageable dimensions (e.g., 640×360) for computational efficiency. It includes automatic frame reading, Laplacian pyramid generation, frequency-domain analysis, and result visualization through saved spectral plots. The resulting amplified videos allow for qualitative visualization and quantitative extraction of the mode shapes using frame differencing and pixel-based motion tracking techniques. In order to complement the experimental investigation and enable quantitative validation of the proposed method, a Finite Element Model (FEM) of the simplified structure is developed. The model serves as a theoretical benchmark for comparison with the experimental EVM results. The structure represents a simplified configuration of typical aerospace components, such as turbine blades.

Materials Research Proceedings 69 (2026) 1225-1228 https://doi.org/10.21741/9781644904251-211

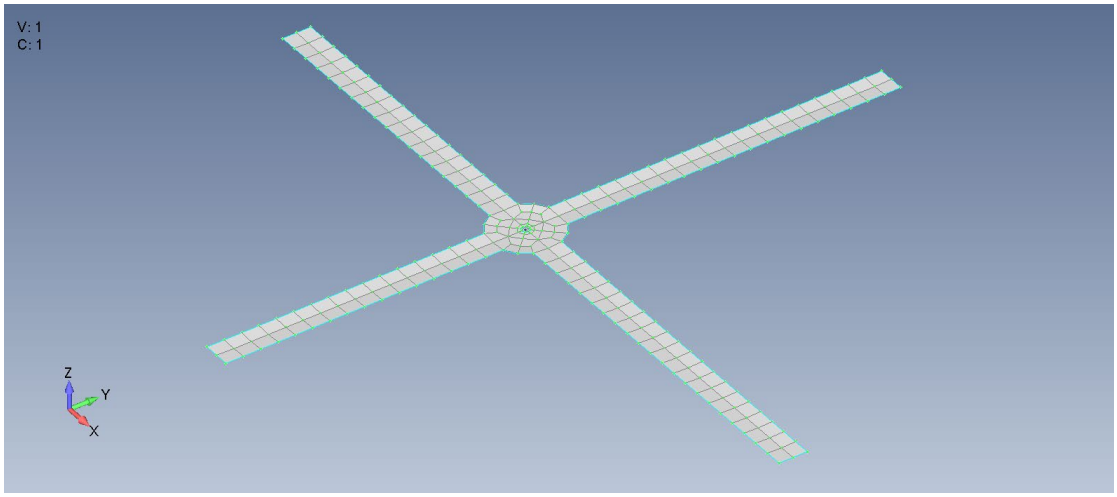

Figure 2 – FE Model of the Structure

The simulation used the SOL 103 solution for Normal Modes/Eigenvalue analysis [4]. The material properties are defined for Aluminum 3003 (Annealed Wrought). The model utilized SHELL elements and is constrained with a "Fixed" boundary condition at the center to simulate real conditions. Nastran input details included coordinate definitions and the EIGRL parameter to request the first 10 modes. The FEM successfully allowed for the determination of the frequencies and mode shapes of the first two vibration modes for each beam (petal) of the structure, providing the numerical benchmark for experimental comparison. The experimental setup is designed for efficiency and low cost. The simplified structure, representing aerospace components, is placed in the setup (Fig. 1). The structure is excited horizontally by a shaker, generating broadband vibrations within the target frequency range. These induced oscillations are described as subtle, often imperceptible to the human eye [1][5].

Results

The validation of the proposed approach relies on comparing the numerical (FEM) and experimental (EVM) results, supported by a theoretical analytical reference [6].The findings demonstrated high consistency across the estimated modal frequencies. For the first two vibration modes of the four analyzed beams, the frequency differences between EVM and FEM results are minimal.

Table 1 - Numerical-EVM Experimental Tests

Test	FPS	Beam	Mode	Freq. [Hz]	Num. Freq. [Hz]	EVM Freq. [Hz]	Err. % Num.	Err. % EVM
REC_001	120	1	1	6	5.47	6.03	9.69	0.5
REC_002	120	2	1	7	6.39	7.12	9.55	1.71
REC_003	120	3	1	8	7.74	8.14	3.36	1.75
REC_004	120	4	1	9	9.31	9.12	3.33	1.33
REC_005	120	1	2	35	34.18	35.4	2.4	1.14
REC_006	120	2	2	41	39.95	41.55	2.63	1.34
REC_007	120	3	2	49	47.72	49.64	2.68	1.31
REC_008	120	4	2	59	58.03	59.7	1.67	1.19

Conclusion

The EVM technique proved capable of handling moderate noise and suboptimal video resolution—factors typically expected to limit performance in high-precision applications. A key

contribution of this study is the demonstration that meaningful modal data can be extracted using ubiquitous and inexpensive hardware, such as smartphones, when combined with modern video processing techniques. This significantly lowers the entry barrier to experimental modal analysis, opening the door to practical applications in low-resource testing environments and preliminary engineering investigations.

Future work will focus on extending the proposed EVM-based approach to maintenance and testing activities in aerospace applications. In particular, the goal is to develop an integrated, video-based monitoring framework capable of supporting maintenance operations and in-field structural assessments with minimal instrumentation and setup complexity.

Abstract. Additive manufacturing (AM), particularly fused deposition modelling (FDM), enables the precise fabrication of lattice structures with minimal material waste. This study investigates four polylactic acid (PLA) lattice geometries fabricated via FDM: two conventional body-centered cubic (BCC) configurations, BCC1.5 and BCC2, and two wavy-BCC (WBCC) counterparts, WBCC1.5 and WBCC2. The structures differ in strut diameter, set at either 1.5 mm or 2 mm, respectively. Each configuration was tested under identical low-velocity impact conditions using a 2 kg hemispherical impactor dropped from a height of 200 mm. The dimensionless index, D^*, was employed to relate the local indentation depth to the global maximum displacement. Results confirmed that BCC1.5 and WBCC1.5 exhibited higher energy dissipation (ED). Conversely, BCC2 and WBCC2 showed lower ED than their counterparts with smaller strut diameters. Notably, BCC2 yielded slightly lower ED than WBCC2 – yet with reduced indentation depth – indicating more favorable local deformation behavior.

Introduction

Cellular solids are a class of materials that continue to attract significant interest within the scientific community, due to their exceptional combination of low weight and excellent mechanical performance. These materials are frequently employed in sectors such as aerospace, automotive, and biomedical engineering [1]. Within this broad category, lattice structures – defined by the spatial repetition of unit cells organized in regular periodic patterns [2] – have demonstrated relevance for applications involving energy absorption [3].

Among lattice structures, the body-centered cubic (BCC) represents one of the most extensively studied topologies due to its favourable strength-to-weight ratio, and the relative simplicity with which it can be manufactured using both conventional and advanced techniques [4,5]. The latter are closely aligned with the principles of Industry 4.0, which integrates smart manufacturing and data for adaptive production [6]. In this regard, the rapid development of additive manufacturing (AM) technologies – ranging from powder bed fusion [7] to the fused deposition modelling (FDM) techniques – have further enhanced the feasibility of producing topology-optimized geometries [8] with high precision and minimal material waste.

While BCC structures have been extensively characterized in terms of their quasi-static mechanical response (e.g., see [9] and [10]), emerging research suggests that geometric

Materials Research Proceedings 69 (2026) 1229-1234 https://doi.org/10.21741/9781644904251-212

modifications at the strut level can alter their global mechanical behavior. In this context, a modified BCC configuration has been introduced, featuring sinusoidal waviness along the struts [11]. This configuration, known as the wavy-BCC (WBCC), is based on the geometrical concept illustrated in Fig. 1. Particularly, it is characterized by curved struts defined by a non-zero amplitude a. The parameters Φ and L denote the strut's diameter and the characteristic side length of the unit cell, respectively.

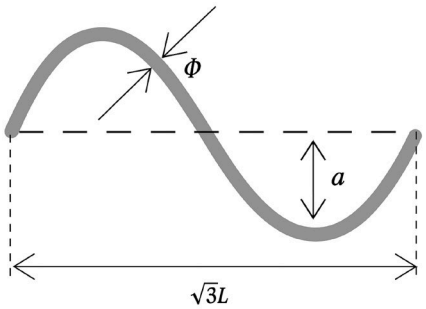

Fig. 1 Geometrical concept of strut waviness

Conversely, in explicit analyses, their local response may differ depending on the impact point. For this reason, a dimensionless index (D^*) [12] was previously defined to quantify the local indentation depth ($\bar{d}$) induced by the impact in relation to the global maximum displacement (δ_{max}), under a controlled drop height of 150 mm, in polylactic acid (PLA)-based lattices.

$$D^* = \frac{\bar{d}}{\delta_{max}} \quad \text{where} \quad \bar{d} = \frac{d_1 + d_2}{2}, \qquad \delta_{max} > 0 \tag{1}$$

In Eq. (1), d_1 and d_2 are the indentation depth values at the impact point, experimentally measured using a depth gauge in two perpendicular directions. Since the probe tip remains stationary and only the supporting base is repositioned along two perpendicular directions, both measurements refer to the same physical location. This accounts for surface irregularities resulting from the AM process.

Thus, the primary objective of this experimental campaign is to assess which BCC and WBCC structures, under the established impact conditions, demonstrate a lower energy dissipation (ED). This assessment is based on the hypothesis that increasing the strut diameter Φ from 1.50 mm to 2.00 mm may improve the structure's ability to withstand impact loads without undergoing catastrophic failure, thereby ensuring an efficient and stable energy response. This implies a higher fraction of energy stored elastically and released after impact, indicating improved structural resilience.

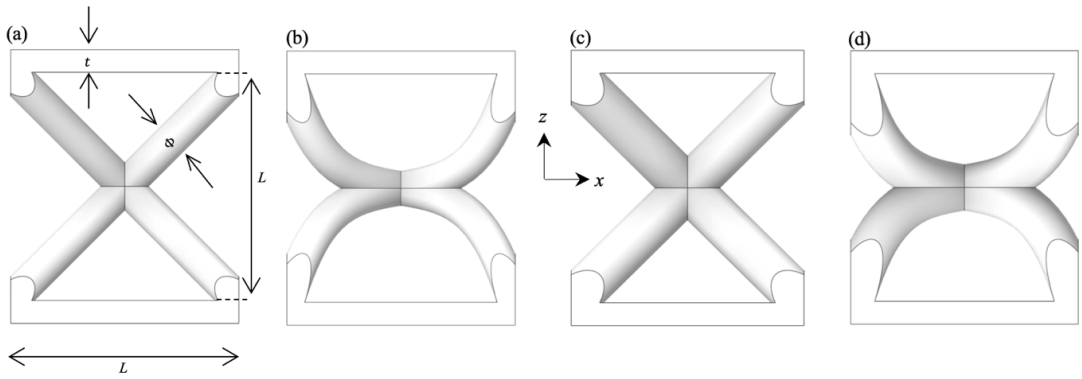
Experimental Setup and Results

The PLA periodic lattice specimens were manufactured at the Laboratory of Mechanical and Aerospace Engineering of the Kore University of Enna, Italy, using the Flashforge Adventurer M5 Pro 3D printer, following the ASTM D7136 [13] standard. To assess the mechanical properties of PLA, three additional dog-bone specimens were previously fabricated according to [14], with an average mass of 8.70 g (SD = 0.017 g). The tests yielded a Young's modulus (E) of 2427.67 MPa (SD = 19.75 MPa) and a maximum stress (σ_{max}) of 15.17 MPa (SD = 0.15 MPa).

The nominal dimensions of the BCC/WBCC samples along the x-y plane are 150 × 100 mm. Four lattice configurations were investigated, including BCC1.5 and WBCC1.5, featuring Φ = 1.5 mm, and BCC2 and WBCC2, with Φ = 2 mm. For each configuration, five samples were produced, resulting in a total of twenty specimens. All configurations feature top and bottom skins with a thickness of t = 1 mm and share the same nominal unit cell size (L = 10 mm), which enables the

Materials Research Proceedings 69 (2026) 1229-1234 https://doi.org/10.21741/9781644904251-212

impactor to strike the region between four nodes. For the WBCC categories, a was set at 1.5 mm. These dimensions were selected based on the manufacturing capabilities of the 3D printer and were defined according to practical constraints rather than through an optimization procedure. Fig. 2 shows a representation of the BCC1.5 (a), WBCC1.5 (b), BCC2 (c), and WBCC2 (d) unit cells.



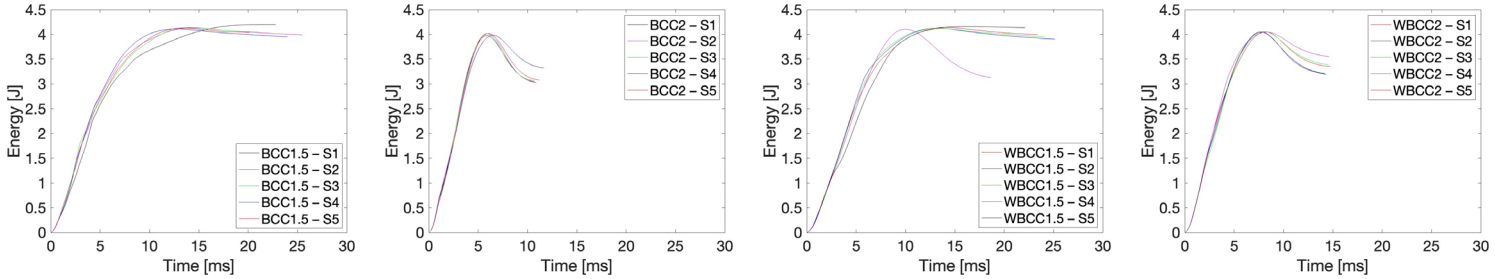


Fig. 2 Front view of the (a) BCC1.5, (b) WBCC1.5, (c) BCC2, (d) WBCC2 single-unit CAD models

The low-velocity impact tests were conducted at the Analysis and Advanced Materials for Structural Design (AMADE) research group at the University of Girona, Spain, utilizing a CEAST Fractovis Plus machine. All tests were conducted under identical conditions, employing a 2 kg hemispherical mass (Ø16 mm) dropped from a height of 200 mm, corresponding to an impact velocity of 1.98 m/s. After each individual test, dent depths d_1 and d_2 were measured using the Mitutoyo 547-217S ABS digital depth gauge to compute the D^* index.

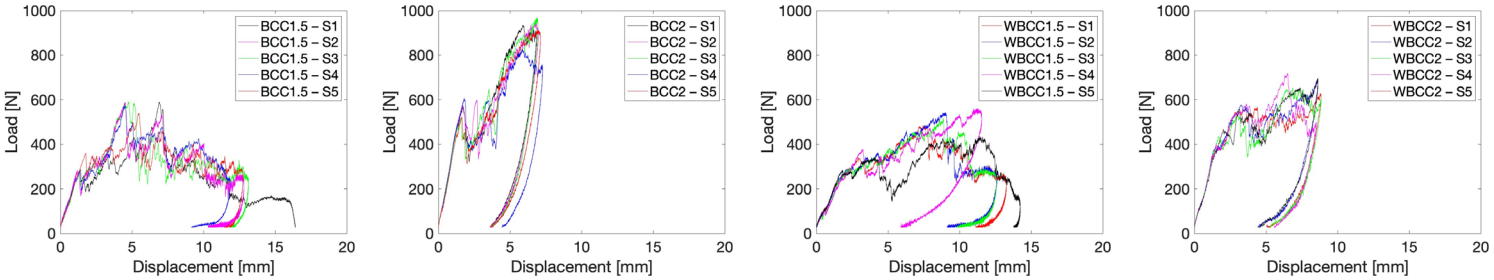

Figure 3 presents the energy-time and load-displacement diagrams for each configuration, whereas the averaged maximum values of each output are summarized in Table 1. Here, F_{mean}, δ_{mean}, $\bar{d}_{mean}$, ED_{mean}, and D^*_{mean} represent the mean values of the maximum load (F_{max}), δ_{max}, $\bar{d}$, ED, and D^* over all tested specimens within each sample category.

Table 1 Mean experimental values of $\boldsymbol{F_{max}}$, $\boldsymbol{\delta_{max}}$, $\boldsymbol{\bar{d}}$, $\boldsymbol{ED}$ and $\boldsymbol{D^*}$ after impact on each sample category

Sample Category	$F_{mean} \pm SD$ [N]	$\delta_{mean} \pm SD$ [mm]	$\bar{d}_{mean} \pm SD$ [mm]	$ED_{mean} \pm SD$ [J]	$D^*_{mean} \pm SD$
BCC1.5	577.02 ± 21.65	13.39 ± 1.75	7.33 ± 0.32	4.04 ± 0.09	0.55 ± 0.18
BCC2	918.68 ± 54.33	7.03 ± 0.17	2.05 ± 0.12	3.09 ± 0.12	0.29 ± 0.01
WBCC1.5	509.41 ± 49.62	12.85 ± 0.99	6.38 ± 2.22	3.82 ± 0.40	0.50 ± 0.16
WBCC2	679.55 ± 36.17	8.70 ± 0.14	2.73 ± 0.30	3.33 ± 0.14	0.31 ± 0.03

(a) (b) (c) (d)

(e) (f) (g) (h)

Fig. 3 Energy-time diagrams for BCC1.5 (a), BCC2 (b), WBCC1.5 (c) and WBCC2 (d) configurations; load-displacement diagrams for BCC1.5 (e), BCC2 (f), WBCC1.5 (g) and WBCC2 (h) configurations

According to Table 1, BCC2 exhibits the highest mean peak force (918.68 ± 54.33 N), while WBCC1.5 shows the lowest (509.41± 49.62 N). BCC1.5 reaches the highest δ_{max} (13.39 ± 1.75 mm), whereas BCC2 has the lowest (7.03 ± 0.17 mm). Similarly, BCC1.5 shows the largest $\bar{d}$ values (7.33 ± 0.32 mm), and BCC2 the smallest (2.05 ± 0.12 mm). ED_{mean} is highest in BCC1.5 (4.04 ± 0.09 J) and lowest in BCC2 (3.09 ± 0.12 J).

The BCC1.5 configuration – Figure 3(a) – recorded the highest ED_{mean} value, as the specimens exhibited low load-bearing capacity. Regarding the WBCC1.5 configuration – Fig. 3(c) – only one specimen (WBCC1.5 – S4) did not exhibit a failure mechanism. Fig. 4 presents a top-view comparison between specimen WBCC1.5 – S4 (a), and specimen WBCC1.5 – S1 (b), randomly selected among those presenting visible damage. The BCC2 and WBCC2 configurations demonstrated structurally efficient behavior, as evidenced by a clear plateau region in the energy-time domain – see Fig. 3(b) and 3(d). Notably, none of the tested specimens exhibited skin perforation. It is also worth noting that Fig. 3(e) and 3(g) reflect larger displacements, which are indeed associated with higher ED values. However, this does not apply to sample WBCC1.5 – S4, which showed lower displacement than the other specimens. Conversely, Fig. 3(f) and 3(h), representing the BCC2 and WBCC2 configurations, exhibit a more regular and progressive load-displacement behavior, with well-defined peak loads followed by gradual post-peak softening. These differences suggest that the higher ED observed in BCC1.5 and WBCC1.5 specimens is likely the result of sudden failure propagation rather than a more progressive damage, likely linked to a single failure mechanism. These observations are consistent with D^*, whose highest values were recorded for BCC1.5 (0.55 ± 0.18) and WBCC1.5 (0.50 ± 0.16).

Conclusions

In this experimental study, four PLA periodic lattice structures were subjected to low-velocity impact tests. A 2 kg mass was released from a height of 200 mm to evaluate which configuration exhibited lower ED. Despite BCC1.5 exhibiting the highest mean ED, its structural performance was poor due to sudden failure after impact. Similar behavior was observed in WBCC1.5, although only one out of five specimens showed minor denting. The increase in strut diameter in BCC2 and WBCC2 resulted in a general reduction in ED, likely due to the greater stiffness associated with the increased material volume. Notably, WBCC2 showed a 7.8% higher ED_{mean} and a 33.17% increase in $\bar{d}_{mean}$ compared to BCC2. This level of deformation may be considered acceptable in applications where limited localized damage is permissible. Conversely, BCC2 remains the optimal choice where even minimal indentations are critical.

Nevertheless, this study is subject to certain limitations. Firstly, only a single drop height was considered, limiting the validity of the results to the specific experimental conditions adopted. Moreover, the analysis was based on a limited sample size, with five specimens tested per configuration. Future work will examine alternative geometric configurations, including variations in skin thickness, as well as modified experimental conditions in which the impact load is applied directly to a node rather than in the area defined by four nodes.

Overall, the findings highlight the complex interplay between ED and geometric design in lattice structures under low-velocity impact, revealing how certain configurations may lead to sudden failure. The results provide valuable insights for the tailored design in applications where specific trade-offs between ED and structural preservation are required.

Keywords: Finite Element Method, Higher-Order Theories, Kinematic Models, Unified Formulation, Node-Dependent Kinematics

Abstract. This paper introduces enhanced two-dimensional finite elements based on a node dependent kinematics method, which allows each node to adopt a unique thickness expansion. A key innovation of the proposed approach is the ability to independently select models for each of the three displacement variables, employing both Taylor-based and Legendre-based expansions for the cross-section. The formulation is developed within the framework of the Carrera Unified Formulation, which separates the three-dimensional displacement field into in-plane and cross-sectional components. The method is validated for a free-edge problem by comparison with results from the literature and highly refined benchmark solutions. The findings show that the optimal computational model for balancing accuracy and efficiency is problem specific.

Introduction

Laminated composite structures are extensively used in the aerospace and automotive industries for their lightweight and high-performance properties. However, their material inhomogeneity can cause complex behaviours, such as free-edge effects (i.e., stress concentrations at layer interfaces near discontinuities) that often serve as initiation sites for damage [1]. Refined theories, including those by Carrera based on Reissner's Mixed Variational Theorem and the Principle of Virtual Displacements (PVD) within the CUF framework [2, 3, 4], have improved upon classical models. Most existing studies use the Equivalent Single Layer (ESL) approach, which simplifies modelling by using variables independent of the number of layers. For more detailed and accurate stress analysis, the Layer-Wise (LW) approach is preferred, assigning separate variables to each layer.

While refined models improve accuracy, they also increase computational costs, especially when involving local phenomena like delamination [5]. To address this, hybrid modelling strategies have been developed, applying high-fidelity models only in critical regions and lower-fidelity models elsewhere, reducing computational load with minimal loss of accuracy. However, implementing such global–local approaches is complex, and numerous methods for integrating different structural theories have been proposed, as reviewed by Noor [6]. This work presents enhanced 2D finite elements based on the Node-Dependent Kinematics (NDK) method [7], which allows each node to adopt different section expansions and enables independent modelling of displacement variables without special coupling. As usual, the Lagrange (LW) and Taylor (ESL) polynomials are adopted as structural theories. The first step is the development of a unified method that isolates contributions of individual terms and avoids reformulating equations for each new theory, thereby balancing accuracy and computational efficiency. Building on Carrera's work [8, 9], the approach combines ESL and LW models within a consistent framework. The second step exploits the hierarchical nature of CUF to incorporate thickness-wise descriptions, assigning different structural theories to each node. Originally applied to plates and recently extended to plates [10], the NDK method provides flexibility in combining low- to high-order theories in 2D problems.

Structure of the work. This paper is organized as follows. Section *Theoretical formulation* discusses the principles of the Unified Formulation and the mathematical details of the Node-Dependent Kinematics (NDK) approach, including the governing equations. Section *Numerical results* presents the outcomes for out-of-plane stresses. Finally, Section *Conclusions* summarizes the key findings of the work.

Theoretical formulation

In classical elasticity, the stress tensor, $\boldsymbol{\sigma}_k$, and the strain tensor, $\boldsymbol{\epsilon}_k$, can be conveniently expressed in vector form as:

$$\boldsymbol{\sigma}^k = \left\{\sigma_{xx}^k\ \sigma_{yy}^k\ \sigma_{zz}^k\ \sigma_{yz}^k\ \sigma_{xz}^k\ \sigma_{xy}^k\right\}^T, \quad \boldsymbol{\epsilon}^k = \left\{\epsilon_{xx}^k\ \epsilon_{yy}^k\ \epsilon_{zz}^k\ \epsilon_{yz}^k\ \epsilon_{xz}^k\ \epsilon_{xy}^k\right\}^T \tag{1}$$

The geometric relationships between strains and displacements are defined as:

$$\boldsymbol{\epsilon}^k = \mathbf{D}\mathbf{u}^k \tag{2}$$

where $\mathbf{D}$ is the matrix of differential operators, valid under the assumption of small displacements and small rotations [3]. For linear elastic orthotropic materials, the constitutive relation is given by

$$\boldsymbol{\sigma}^k = \mathbf{C}^k\boldsymbol{\epsilon}^k \tag{3}$$

where $\mathbf{C}^k$ denotes the matrix of material coefficients (see [11] for details).

Unified formulation. In this method, the concept of the Unified formulation and the FE method are used together. Furthermore, every FE node possesses its unique set of structural theories, and each displacement component can use a different theory. These concepts can be summarized mathematically as follows for the real system:

$$\begin{aligned} u_x^k(x,y,z) &= N_i(x,y)F_{u_x\tau}^{ki}(z)q_{x\tau i}^k,\ \ \tau = 1,\dots,M_{u_x}; i = 1,\dots,N_n \\ u_y^k(x,y,z) &= N_i(x,y)F_{u_y\tau}^{ki}(z)q_{y\tau i}^k,\ \ \tau = 1,\dots,M_{u_y}; i = 1,\dots,N_n \\ u_z^k(x,y,z) &= N_i(x,y)F_{u_z\tau}^{ki}(z)q_{z\tau i}^k,\ \ \tau = 1,\dots,M_{u_z}; i = 1,\dots,N_n \end{aligned} \tag{4}$$

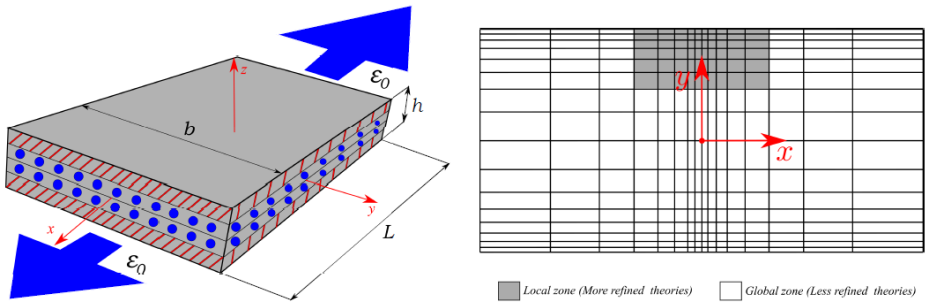
where $F_{u_x\tau}^{ki}$, $F_{u_y\tau}^{ki}$, and $F_{u_z\tau}^{ki}$ denote the expansion functions associated with the generalized displacements $q_{x\tau i}^k$, $q_{y\tau i}^k$, and $q_{z\tau i}^k$, respectively. The index τ indicates summation, while M_{u_x}, M_{u_y}, and M_{u_z} represent the number of expansion terms for each displacement component. In this paper, seven-node Lagrange (LE7) expansions and Taylor functions are used. Moreover, N_i denotes the shape functions, with the repeated subscript i implying summation, and N_n the number of shape functions per element. For the numerical assessments carried out in this study, the classical nine-node Lagrangian element (Q9) is employed [11]. In the case of the virtual system, the indices i and τ are replaced by j and s, respectively.

Governing equations. By using the Principle of the Virtual Displacements:

$$\begin{aligned} &\delta L_{int} = \delta L_{ext} = \\ &\int_{Vk}\left(\delta\epsilon_{xx}^k\sigma_{xx}^k + \delta\epsilon_{yy}^k\sigma_{yy}^k + \delta\epsilon_{zz}^k\sigma_{zz}^k + \delta\epsilon_{yz}^k\sigma_{yz}^k + \delta\epsilon_{xz}^k\sigma_{xz}^k + \delta\epsilon_{zz}^k\sigma_{zz}^k\right)\mathrm{d}V^k = \\ &\delta u_x^k P_{u_x}^k + \delta u_y^k P_{u_y}^k + \delta u_z^k P_{u_z}^k \end{aligned} \tag{5}$$

It is possible to obtain three governing equations for each virtual displacement:

Materials Research Proceedings 69 (2026) 1235-1239 https://doi.org/10.21741/9781644904251-213



$$\begin{aligned}
\delta q^k_{x_{sj}}&: K^k_{u_x u_x s\tau ji} q^k_{x_{\tau i}} + K^k_{u_x u_y s\tau ji} q^k_{y_{\tau i}} + K^k_{u_x u_z s\tau ji} q^k_{z_{\tau i}} = P^k_{u_x sj} \\
\delta q^k_{y_{sj}}&: K^k_{u_y u_x s\tau ji} q^k_{x_{\tau i}} + K^k_{u_y u_y s\tau ji} q^k_{y_{\tau i}} + K^k_{u_y u_z s\tau ji} q^k_{z_{\tau i}} = P^k_{u_y sj} \\
\delta q^k_{z_{sj}}&: K^k_{u_z u_x s\tau ji} q^k_{x_{\tau i}} + K^k_{u_z u_y s\tau ji} q^k_{y_{\tau i}} + K^k_{u_z u_z s\tau ji} q^k_{z_{\tau i}} = P^k_{u_z sj}
\end{aligned} \tag{6}$$

The fundamental nuclei for the load vector are written in the followings:

$$\begin{aligned}
P^k_{u_x sj} &= N_j F^{kj}_{u_x \tau} P^k_{u_x} \\
P^k_{u_y sj} &= N_j F^{kj}_{u_y \tau} P^k_{u_y} \\
P^k_{u_z sj} &= N_j F^{kj}_{u_z \tau} P^k_{u_z}
\end{aligned} \tag{7}$$

Assembly. This work employs an innovative formulation of the Fundamental Nucleus (FN) that represents a significant departure from conventional CUF implementations. The key advancement lies in the treatment of FN components $K^k_{u_m u_l s\tau ji}$ and $P^k_{u_m sj}$ as single scalar elements rather than the traditional 3×3 matrix structure. The explicit expressions of $K^k_{u_m u_l s\tau ji}$ are not explicitly given for the sake of brevity. This streamlined approach requires only nine independent scalar parameters for complete stiffness characterization (and three for the load array), offering substantial computational advantages. The new formulation provides important theoretical and practical benefits compared to standard CUF implementations [2, 3]. Most notably, it eliminates the constraint requiring all variables to share the same expansion theory, a limitation that often forces unnecessary computational overhead in conventional approaches. See also [8,9]. The assembly across all displacement components, FE nodes, and elements results in the problem: $\mathbf{KU} = \mathbf{P}$.

Numerical results

(a) *Geometrical properties* (b) *NDK mesh*

Figure 1: Four-Layer composite plate. The study case is taken from [12] and [4].

The study investigates the free-edge behaviour of a symmetric composite plate (see Fig. 1a) with rectangular surface measuring L = 40 [mm], b = 20 [mm], and a thickness of h = 5 [mm]. The laminate has a stacking sequence of [45◦/−45◦]s, and its material properties are E_1 = 137.9 [GPa], $E_2 = E_3$ = 14.5 [GPa], $\nu_{12} = \nu_{13} = \nu_{23}$ = 0.21, and $G_{12} = G_{13} = \nu_{23}$ = 5.9[GPa]. The analysis, based on the works of Robbins and Reddy [12] and Scano et al. [4], applies a uniform axial strain ϵ_0 along the x-axis by imposing end displacements u at $x = \pm$L/2. This loading condition induces a constant strain field in the central region of the plate, provided that the plate length L is sufficiently large compared to the edge perturbed zones. In this problem, a finer mesh is required near the free edge; therefore, a non-uniformly distributed 16 × 16 finite element mesh is adopted. Figure 1b illustrates the mesh configuration, highlighting the local region with 208 FE nodes and the global region with 881 FE nodes, where more refined and less refined theories are employed, respectively. Shear, σ_{xz}, and transverse, σ_{zz}, stresses are calculated along the thickness of the plate near the

Materials Research Proceedings 69 (2026) 1235-1239 https://doi.org/10.21741/9781644904251-213

free-edge (at y/b = 0.998) in mid-plate (at x = 0). The results are reported in a scaled form as follows

$$\bar{\sigma}_{xz} = \frac{\sigma_{xz}}{\epsilon_0}, \quad \bar{\sigma}_{zz} = \frac{\sigma_{zz}}{\epsilon_0} \tag{9}$$

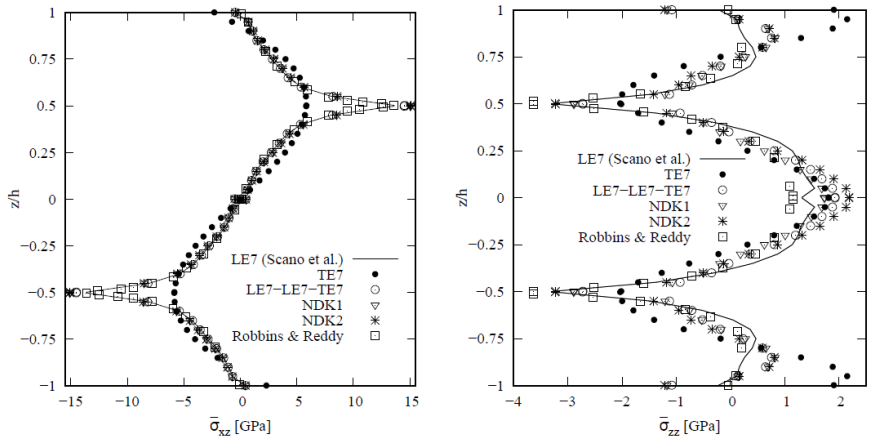


Table 1 presents the characteristics of the Unified Formulation models, including the adopted theories, the number of Degrees of Freedom (DOF), the corresponding DOF reduction, and the naming convention. Shear and transverse stresses along the thickness are studied, as displayed in Figs. 2a and 2b, respectively.

Table 1: Unified formulation models used for the angle-ply [45◦/−45◦]$_s$ laminate.

Global Model	Local Model	DOF	DOF Reduction [%]	Theory Definition
LE7-LE7-LE7	LE7-LE7-LE7	81675	—[a]	LE7 (Scano et al.)
TE7-TE7-TE7	TE7-TE7-TE7	26136	68.00	TE7
LE7-LE7-TE7	LE7-LE7-TE7	63162	22.67	LE7-LE7-TE7
TE2-TE2-TE2	LE7-LE7-TE7	19993	75.52	NDK1
TE1-TE1-TE2	LE7-LE7-TE7	18231	77.68	NDK2

(a): Taken as the reference solution.

The analysis reveals that lower-order models are sufficient for accurately representing the majority of the plate. However, when evaluating out-of-plane stresses, higher-order LW models are required to obtain accurate results for the u_x and u_y displacement components. Additionally, the two proposed NDK models demonstrate high efficiency, showing strong agreement with the reference results while achieving a degree-of-freedom reduction of over 75%, which is greater than that achieved with the TE7 model.

Conclusions

The present work introduces an improved method for the analysis of two-dimensional structures within the framework of the CUF. The method is obtained by reformulating the traditional CUF approach and reorganizing the assembly of the FE matrices. The proposed framework relies on two main features: (1) Different expansions can be adopted for each displacement variable; in particular, Taylor- and Legendre-based expansions are employed. (2) The NDK approach is incorporated, allowing the adoption of a different model at each finite element node.

The paper demonstrates that the proposed method effectively joins different types of expansions and polynomial orders, allowing a significant reduction in the degrees of freedom through an accurate selection of expansions for each finite element node. It also enables the application of local kinematic refinements without altering the finite element mesh. Future work will focus on extending this approach to shell formulations and multifield analyses.

Abstract. A global optimization framework with global–local verification is developed for composite wings by coupling a NASTRAN-based global finite element model with Carrera Unified Formulation (CUF)-based high-order local analyses. The proposed methodology enables the minimization of structural weight under stress and buckling constraints, while identifying critical zones of interest for multi-fidelity and hierarchical strategy. The global model based on first-order shear deformation theory identifies the critical regions where the CUF Equivalent Single Layer and Layer-Wise refinements should be introduced to provide detailed local buckling and stress analyses. This integrated global-local framework enables adaptive local fidelity global-local analysis, improving margins of accuracy while mapping the accessible design space and maintaining computational efficiency.

Introduction

The optimization of composite aircraft wings has long been a key challenge in aerospace structural design. Classical approaches have focused on minimizing mass or maximizing stiffness by tailoring stacking sequences and fiber orientations, often under constraints on strength, buckling, and aeroelastic performance [1–3]. These methods, implemented within commercial Finite Element (FE) solvers, have proven effective for global-level optimization but are typically limited by simplified structural theories, which are unable to represent local behaviors, especially in regions of complex stress or instability. In this regard, refined structural theories based on the Carrera Unified Formulation (CUF) [4] have been developed. CUF provides a hierarchical framework capable of generating both Equivalent Single Layer (ESL) and Layer-Wise (LW) FE formulations with Node-Dependent Kinematic (NDK). This enables an accurate representation of transverse shear effects, local buckling, and through-the-thickness stress distributions, which are critical in composite structures. CUF-based analyses have been successfully applied to a wide range of problems, including failure onset, progressive failure, and nonlinear postbuckling behavior, offering substantial improvements in accuracy over models based on Classical Laminated Plate Theory (CLPT) or First-Order Shear Deformation Theory (FSDT).

Recent studies have explored global–local strategies that combine the efficiency of global FE models with the accuracy of CUF-based structural theories [5–6]. The global model captures the overall behavior of the structure and provides the boundary conditions for high-fidelity CUF submodels, enabling precise local stress evaluations where complex stress or instability phenomena occur. When integrated with an optimization process, this approach allows adaptive fidelity across automatically detected zone of interests (ZOI), ensuring accuracy only where needed while preserving computational efficiency [7]. The present work extends this concept to a fully integrated global–local analysis framework that couples NASTRAN global optimization analyses with CUF-based refinements for the weight optimization of composite wings under stress and buckling constraints.

Methodology

The framework developed in this work is presented in Figure 1. Its objective is to minimize structural weight while satisfying stress and buckling constraints, enabling automatic Global–Local (G–L) refinement on ZOIs. The approach integrates commercial and high-fidelity numerical tools, leveraging automatic multi-fidelity, multi-model and hierarchical strategy analysis for margin verification.

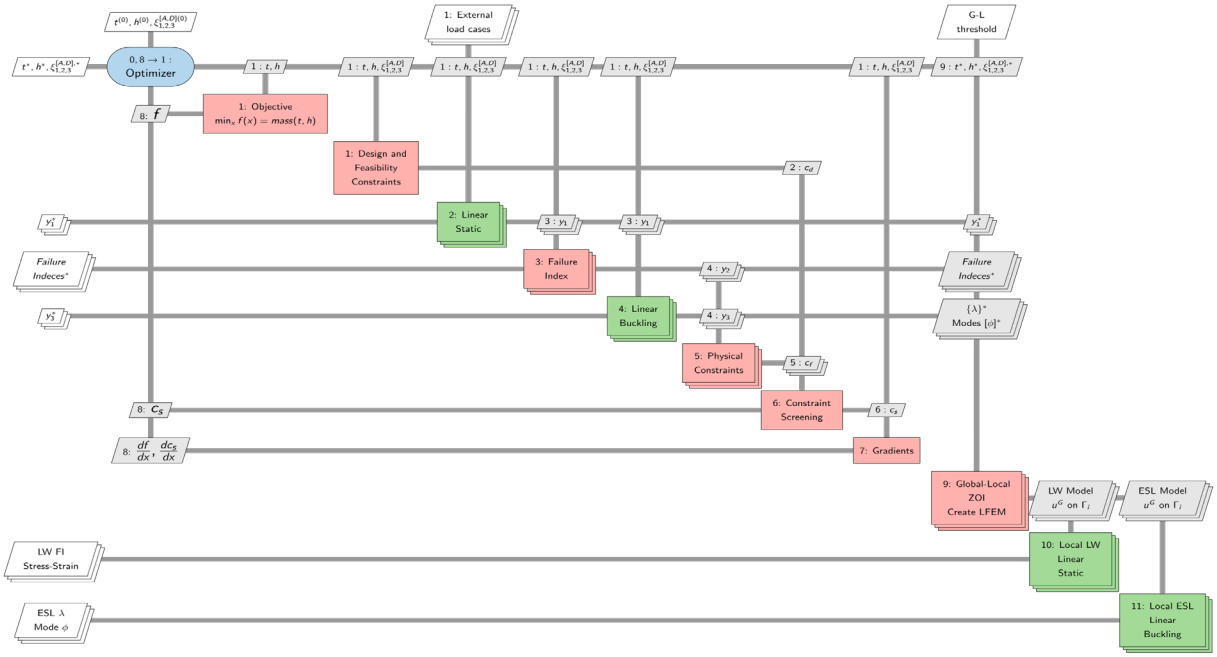

Figure 1- xDSM diagram of the novel global optimization framework with automatic global–local high-fidelity margins verification for composite structures.

In Figure 1, blocks along the diagonal represent processes, whereas off-diagonal blocks indicate the information exchanged among processes. Red blocks denote generic processes and green ones refer to FE and CUF solvers. Parallelograms represent data inputs and outputs; vertical lines indicate data-input and horizontal lines data-output. Stacked blocks denote parallel execution, and asterisks identifies optimal values.

Optimization Framework. First, a global FE model of the entire structure is built in NASTRAN using classical CQUAD4 shell elements based on FSDT. This global model serves as a computationally efficient baseline for the iterative optimization process using lamination parameters strategy [8–10]. The global optimization employs lamination parameters to map discrete stacking sequences into a continuous domain, enabling gradient-based SUMT optimization in NASTRAN MSCADS [11]. Design variables include laminate thicknesses, lamination parameters, and component shapes, while constraints comprise Angle-Minus-Loaded

(AML) failure indices [12-13], buckling loads, and laminate design and feasibility conditions [14-15]. Boundary conditions and multiple load cases are simultaneously applied to an idealized global model.

Global–Local Coupling. Second, once converged, the optimized model is automatically transferred to the G–L stage, which identifies ZOIs, extracts boundary conditions, approximates stacking sequences by minimizing AML values and ply-volume fractions using precomputed lookup tables, and generates corresponding high-fidelity CUF models.

Identification of Critical Regions. Third, ZOIs are selected through threshold criteria on AML failure indices for strength-critical elements and on global buckling-load factors followed by normalized buckling-mode displacement for buckling-critical panels. These metrics determine which regions require high-fidelity CUF analyses to verify margins and adjust the design, directly influencing final structural weight.

Local Analysis. Fourth, high-fidelity analyses are performed using the CUF, in the most critical subregions (ZOIs), allowing for an accurate evaluation of local stress and buckling behavior with an integrated G-L analysis. In the local CUF models, stress and strain distributions through the thickness, interlaminar behavior, and local buckling eigenmodes are evaluated for accurate failure-mechanism characterization.

The CUF model for the local domain adopts a displacement-based formulation, where only translational Degrees of Freedom (DOFs) are considered. Since the global model provides both translations $\left(\boldsymbol{u_x^0}, \boldsymbol{u_y^0}, \boldsymbol{u_z^0}\right)$ and rotations $\left(\boldsymbol{\theta_x^0}, \boldsymbol{\theta_y^0}, \boldsymbol{\theta_z^0}\right)$, a conversion procedure is required to express the latter as equivalent displacements. The Reissner–Mindlin displacement field in Eq. 1 is used to compute translational boundary displacements of the local model, written as:

$$\begin{aligned} u_x(x,y,z) &= u_x^0(x,y) + z\theta_y^0(x,y) - y\theta_z^0(x,y) \\ u_y(x,y,z) &= u_y^0(x,y) - z\theta_x^0(x,y) + x\theta_z^0(x,y) \\ u_z(x,y,z) &= u_z^0(x,y) - y\theta_x^0(x,y) + x\theta_y^0(x,y) \end{aligned} \tag{1}$$

The graphical representation of these transformations is shown in Fig. 2.

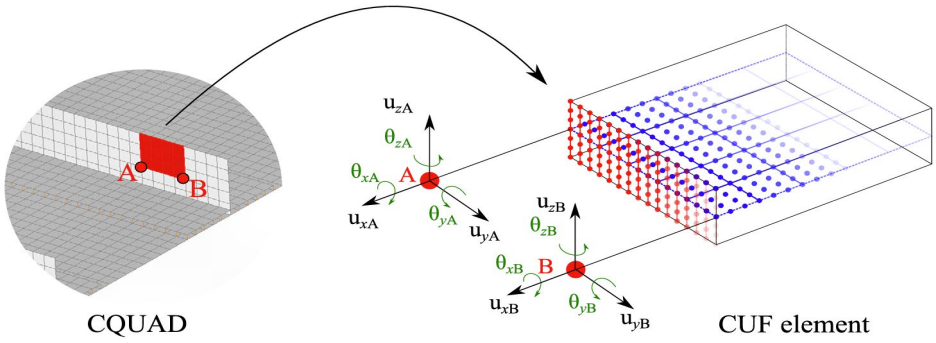

Figure 2. Schematic representation of the procedure adopted to transfer the rotational degrees of freedom from the global model into displacement-based boundary conditions for the local model.

In addition to the Element-Wise (EW) coupling strategy described above, a Patch-Wise (PW) formulation has been implemented to improve the accuracy of the boundary condition transfer between global and local models. In the EW approach, translational and rotational quantities are extracted from a single CQUAD4 element of the global model and employed to define the boundary displacements of the local CUF domain. Conversely, in the PW formulation, the interface displacements are evaluated over a larger region. This extended interpolation domain allows the contribution of all involved global nodes to be considered, resulting in smoother and

Materials Research Proceedings 69 (2026) 1240-1245 https://doi.org/10.21741/9781644904251-214

more consistent boundary conditions for the local problem. The PW procedure refines the displacement field without altering the geometry of the local region, providing higher fidelity in the transfer of boundary information. This enhancement leads to more accurate local stress predictions between the global and CUF-based submodels, particularly in zones characterized by high stress gradients or local instabilities.

Results

To demonstrate the proposed framework, a simplified composite wingbox segment was modeled in NASTRAN to represent a highly loaded wing section. The model consists of ten ribs (nine bays), two spars, and upper and lower reinforced skins with five blade-shaped stringers each. The main dimensions are 6.48 m span, 1.44 m chord, and 0.29 m height. The upper and lower skins are subdivided into 54 panels, and the spars into 9 panels, all designed as symmetric and balanced laminates. Stringer webs and feet are divided into nine segments with constant lamination parameters; only thicknesses and geometries are optimized. The stringers use a constant AML parameter of –10%, representing a "hard" laminate [12–13].

Material properties correspond to Hexcel 8552 IM7 unidirectional prepreg [16], using low-temperature dry (LTD) elastic data and open-hole tension/compression (OHT/OHC) allowable considering environmental variability.

The optimization problem comprises 1,072 design variables (thicknesses, lamination parameters, stringer shapes) and 3,554 constraints related to AML failure indices, buckling loads, and laminate feasibility. Two load cases, +2.5 G and –1.0 G, are applied by scaling the nominal distributed pressure and tip loads. Boundary conditions include a clamped root, 12,081 Pa pressure on the upper skin, and tip loads of 193,047 N and –581,201 Nm, representing the running loads of the adjacent wing segment for a MTOW of 62,500 kg.

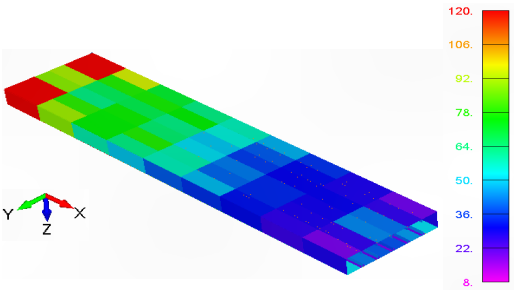

Figure 3. Optimized ply count.

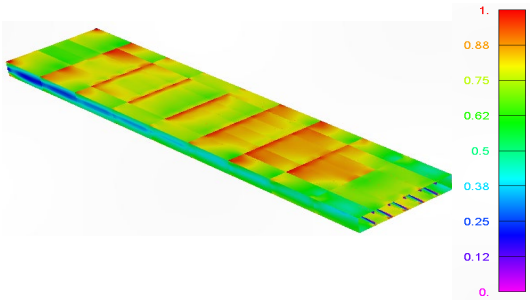

Figure 4. AML failure index.

As shown in Fig. 3, the optimization yields the number of layers, and Fig. 4 presents the corresponding AML failure indices. The optimized lamination parameters for each laminate— not shown here—contain information on fiber fractions for each lamination direction and the homogenized characteristics of the idealized optimal laminate using FSDT. This information is used to approximate stacking sequences by minimizing AML values and ply-volume fractions using precomputed lookup tables, as explained in the Methodology.

A higher number of layers improves the likelihood of obtaining a close approximation between the lamination parameters from continuous optimization and the discrete stacking sequence with similar characteristics. However, deriving an equivalent stacking sequence from idealized lamination parameters inherently introduces deviations. The effect of these deviations can be quantified by replacing panels represented by lamination parameters with discrete approximations that satisfy laminate-formation constraints and evaluating the model again.

Materials Research Proceedings 69 (2026) 1240-1245 https://doi.org/10.21741/9781644904251-214

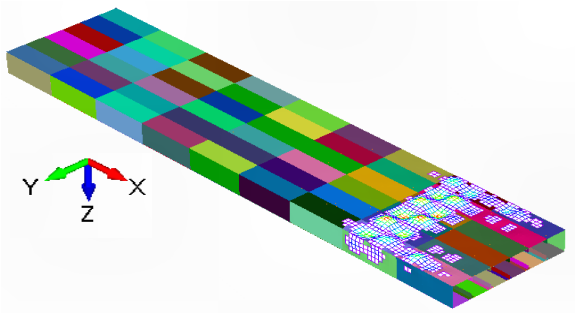

Figure 5. ZOI detection for buckled panels (5% threshold).

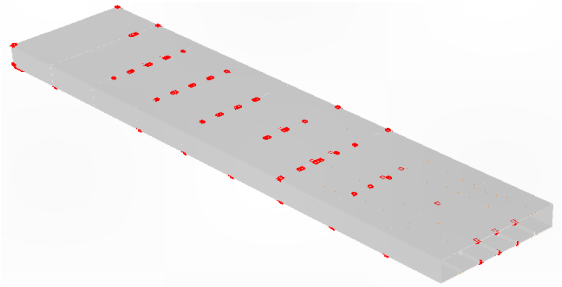

Figure 6. ZOI detection for LW stress analysis (1% FI threshold).

In this work, the G–L phase detected 25 panels out of 216 for CUF ESL buckling analysis above a 5% modal displacement threshold (Figure 5), and 191 ZOIs out of 18,900 elements for CUF LW stress analysis using a 1% AML failure index threshold (Figure 6). As an example, a critical panel with 28 layers exhibited differences of approximately 2.7% in critical buckling and 2.6% in the critical failure-index element.

Conclusions

The proposed framework integrates NASTRAN global analyses with CUF-based local refinements through a hierarchical two-level strategy for composite wing optimization. ESL models are used for local buckling assessment, while LW formulations enable detailed ply-level stress evaluation. The coupling between commercial and in-house solvers is fully automated thought ZOI detection, approximation from laminate variables to discrete stacking sequence while ensuring adaptive local fidelity during the design process. This multi-fidelity and hierarchical approach enhance constraint margins verification at two levels of local scale, explore the feasible design space with greater confidence, and maintains computational efficiency. The framework's modular architecture and high degree of automation make it suitable for integration into industrial design environments.

Acknowledgments

Keywords: Buckling Mode-Switching, Composite Laminates, Compression, Digital Image Correlation

Abstract. This study experimentally investigates the effect of low-cycle fatigue loading on the evolution of buckling modes in a specimen consisting of a composite skin and four metallic stringers. The specimen was designed to achieve multiple stable configurations under compression through a tailored lay-up configuration that enables bucking to initiate in the thinner region and subsequently expand to the thicker region. The results indicate that the designed specimen was able of switching among different buckling modes under low-cycle fatigue loading. However, the skin-stringer separation was observed during high-amplitude fatigue loading.

Introduction

To meet the ambitious targets for clean aviation, weight reduction and efficiency increase are essential in structural design. Fibre reinforced composite materials are used in thin-walled aeronautical structures like wings and fuselages due to their light weight. By nature, they are susceptible to buckle under in-service loads, which can induce significant non-linear deformation and potentially complex failure mechanisms [1]. Consequently, a conservative no-buckling approach is often considered in the design phase. However, if buckling and post-buckling behaviour are allowed, provided they remain controlled, predictable, and confined to the elastic region, significant weight reduction can be achieved, even under fatigue loading. Furthermore, the potential to switch among different buckling modes could enable multiple stable configurations in aeronautical structures. Currently, there is a limited understanding on how aeronautical composite structures behave under fatigue loading with repeated buckling mode switches.

Buckling-driven composite design concepts for structural multi-stability are investigated in the NABUCCO project [2]. Studies to support such design concepts have been reported: Zhang and Bisagni [3] applied local displacement constraints to a simplified wing box, achieving changes in stiffness and buckling modes with redistributed load for twisting control; Gutiérrez Álvarez and Bisagni [4] combined mechanical and thermal loading in a flat, four-edge-clamped panel, which enabled buckling and subsequent mode switching under compression and heating; Bisagni and Gigliotti [2,5] designed multi-stiffness laminates with different number of plies and varying layups in local regions, which achieves changes in axial stiffness through local buckling at specific locations.

To further explore whether structural multi-stability induced by buckling can be controlled within the elastic region during repeated mode switching, this study investigates the post-buckling behaviour of a multi-stable stiffened specimen, achieved through a tailored layup configuration, under low-cycle fatigue loading.

Design, manufacturing and testing

As a preliminary study, the multi-stable design should be capable of switching among different buckling modes under compression and be suitable for easy hand laminating. To this end, a panel was designed from IM7/8552 material, incorporating four metallic stringers to create three distinct

Materials Research Proceedings 69 (2026) 1246-1249 https://doi.org/10.21741/9781644904251-215

regions. The geometry of the design is detailed in Fig. 1. The central region (Region 1) is stacked in a sequence of [0/90/0], while the layup of the two lateral regions (Region 2) is [0/90/0/90/0]. The composite plate has a ply thickness of 0.125 mm, and the stringers are 1.5 mm thick. Buckling is expected to firstly occur in the thin region and subsequently expand to the thick region, enabling mode switching as the compressive load increases. Four aluminium 6061 T6 stringers were bonded to the composite plate. The top and bottom of the specimen were potted in metal-filled casting resin tabs.

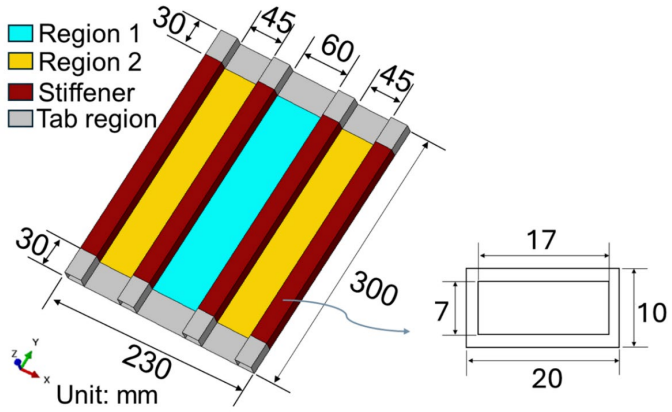

Fig. 1 Geometry of the multi-stable stiffened specimen.

A series of static tests were conducted to establish a baseline for the buckling and post-buckling behaviour of the specimen prior to fatigue testing. The tests were performed to different maximum loads, ranging from 3 kN to ~ 46 kN. During these tests, two digital cameras were positioned in front of the specimen to measure full-field deformation using digital image correlation (DIC) techniques, as shown in Fig. 2. The surface of the composite specimen was painted with a speckled pattern to assist DIC measurements. Then, a fatigue load profile was applied with a frequency of 1 Hz and a load ratio of 0.1. Each loading block consisted of approximately 10000 cycles at a constant amplitude. In total, four load blocks were applied with increasing maximum cyclic loads: Load Block 1 - 10 kN, Load Block 2 - 20 kN, Load Block 3 - 30 kN, Load Block 4 - 40 kN. To enable DIC image acquisition, the fatigue loading was interrupted every 1000 cycles to perform a static test at a loading rate of 10 kN/min.

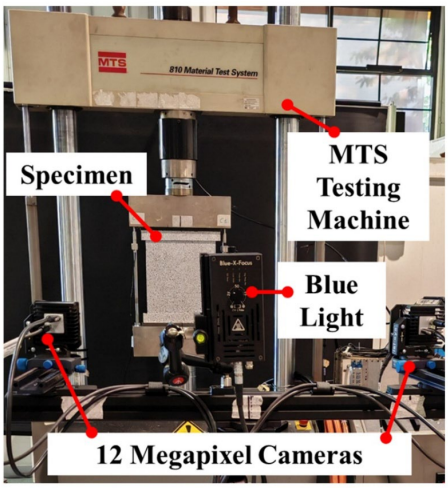

Fig. 2 Experimental set-up.

Materials Research Proceedings 69 (2026) 1246-1249 https://doi.org/10.21741/9781644904251-215

Results

The designed specimen exhibited a linear force-displacement relationship in the post-buckling regime under static loading, as shown in Fig. 3(a), which represents the final static test conducted prior to fatigue loading. The evolution of the buckling modes began in Region 1 with three half-waves and subsequently expanded to Region 2, forming a six half-wave pattern (Fig. 3(b)). As the applied force increased from 20 kN to 30 kN, the number of half-waves in the central region transitioned from three to four (Fig. 3(b)).

Fig. 4 presents the out-of-plane deformation fields of the specimen under a static load equivalent to the maximum cyclic load, both initially (0 cycle) and after 10000 cycles of Load Blocks 1-3. During Load Block 1, bucking primarily occurred in the central region with three half-waves, similar to the static baseline shown in Fig. 3. The low-cycle fatigue loading up to 10000 cycles evidently has a negligible effect on the post-buckling behaviour at this low load amplitude. When the maximum cyclic load was increased to 20 kN in Load Block 2, the buckling mode in the central region switched from three to four half-waves. This mode transition occurred at a static load higher than 20 kN. In Load Block 3, the buckling mode frequently changed between four and five half-waves in the central region. Meanwhile, visible local debonding between the composite skin and the stringers was observed at the top of the specimen. At the early stage of Load Block 4, local debonding propagated across the entire width of the specimen.

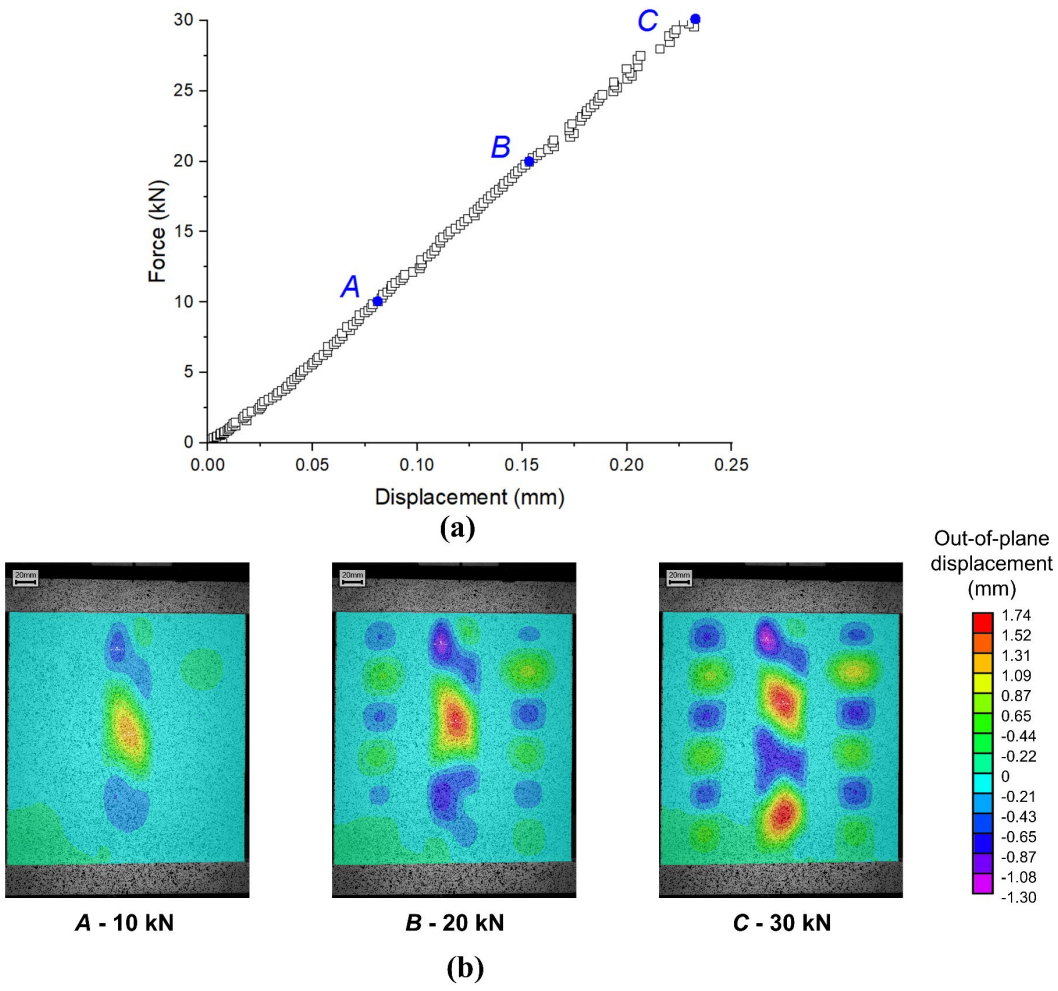

Fig. 3 Force-displacement response of the static test up to 30 kN (a), and evolution of buckling modes (b).

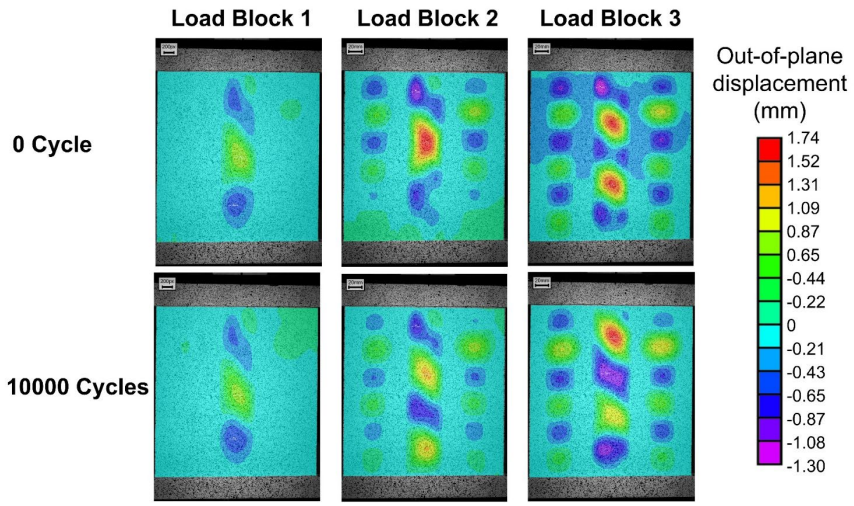

Fig. 4 Post-buckling mode at the maximum load of Blocks 1-3 at 0 and 10000 cycles.

Summary

Experimental work was carried out to design, manufacture and test a stiffened specimen with composite skin and metallic stringers under both static and fatigue loading conditions. The specimen was designed with variations in skin thickness, enabling to switch among different buckling modes as compressive load increases. Under low-cycle fatigue loading, the buckling mode in the central region changed as the load amplitude increased: it remained unchanged during the fatigue with 10 kN maximum load, transitioned from three to four half-waves during fatigue up to 20 kN, and switched frequently between four and five half-waves during fatigue up to 30 kN. Furthermore, local debonding between the composite skin and the stringers was observed under high-amplitude fatigue loading.

Abstract. The space industry continuously seeks lighter and higher-performance materials to improve the efficiency and reliability of spacecraft structures. This is particularly true for deployable boom structures, slender elements stowed during launch and extended in orbit to support antennas, solar panels, or sensors, where minimizing mass while maintaining sufficient stiffness and strength is essential for successful deployment and long-term stability. This study investigates the potential of incorporating carbon nanotubes (CNTs) into conventional carbon fiber reinforced polymers (CFRPs) for future application in deployable booms. Composite laminates were fabricated and characterized through tensile and column bending tests to evaluate their mechanical performance. The resulting material properties were then used in a buckling analysis of deployable booms, as buckling represents a critical design factor. The outcomes aim to assess whether CNT-enhanced CFRPs are a viable option for manufacturing next-generation space deployable boom structures.

Introduction

Advances in aerospace technology are driving spacecraft toward larger sizes and increasingly complex architectures. At the same time, the limited payload volume and mass capacity of launch vehicles pose significant challenges for integrating large-scale components such as solar sails, deep-space antennas, and high-capacity solar arrays. Space deployable structures offer an effective solution, allowing these components to be compactly stowed during launch and reliably deployed in orbit. Deployable booms can be efficiently stowed through coiling or folding and, once deployed, serve as structural elements in various space systems, including parabolic mesh antennas, solar sails, probes, and docking systems. Booms are typically classified based on the geometry of their cross-section; this work focuses on collapsible tubular masts (CTMs) with a double-omega cross-section [1]. The current trend in boom design is toward ultra-thin laminated composite materials, which provide high stiffness and strength at low mass while allowing for large deformations [2]. Booms manufactured from these composites have been fabricated and characterized experimentally [3], and the effects of ply number, fiber content, and fiber modulus on buckling behavior have been studied using free-end loading tests [4]. To date, laminates reinforced solely with continuous fibers have been employed, while the potential of hybrid composites, in which the polymer matrix is reinforced with both long fibers and carbon nanotubes (CNTs), remains largely unexplored. Such materials offer promising opportunities to enhance mechanical performance and enable multifunctional capabilities [5,6]. This study addresses this gap by manufacturing and mechanically characterizing CNT-reinforced CFRP laminates, which are subsequently used in finite element simulations to assess buckling behavior of a collapsible tubular mast (CTM), which is a critical design criterion for deployable structures.

Materials and method

The material used is a based-spread tow carbon fiber reinforced polymer (CFRP). The reinforcement consists in TeXtreme 43 PW HS40 fabric. Before being woven, HS40 12K tows have been flattened by means of an airflow method to become spread [7]. The matrix is the bicomponent aerospace grade epoxy resin CYCOM®823 RTM. Two layers of spread tow plain weave fabric are embedded in an epoxy matrix with [0/90] lamination sequence and out-of-phase configuration [8]. Carbon nanotubes were added at a concentration of 0.7% of the total weight, dispersed in the resin using the centrifugal mixer/defuser THINKY MIXER ARE-250, as it's experienced to be the maximum concentration for mechanical properties improvement. The laminates for sample preparation are fabricated through vacuum bagging technique and pressed with a hydraulic hot press, with a pressure of 2.38 bar, to get lower thickness and facilitate nanotubes dispersion. Tensile tests are conducted on five samples of composite materials to measure the A_{11} and A_{12} components of their global stiffness matrix. Tensile tests are carried out using an AGS-X series Shimadzu machine with a tensile clamping. The experimental set-up and the tested specimen comply with ASTM d3039 [9], using a 10KN load cell and performing the test at 2 mm/min. The longitudinal and transversal strain, ϵ_1 and ϵ_2, respectively, are measured using a Digital Image Correlation (DIC) system. This optical equipment consists in a stereo camera system, able to observe micro displacements on the sample. An acquisition frequency of 4 Hz was selected. Then the A_{11} and A_{12} components are computed according to the followings:

$$A_{11} = \frac{F}{w}\frac{\epsilon_1}{\epsilon_1^2-\epsilon_2^2}\ ; \tag{1}$$

$$A_{12} = -\frac{\epsilon_2}{\epsilon_1}A_{11}\ ; \tag{2}$$

where w is the width of the sample.

To determine the bending properties of thin composite laminates, the Column Bending Test (CBT) method was adopted. Juan M. Fernandez et al. presented and validated the CBT mechanism design, optimized for thin-walled samples [10]. It consists in a counterweight-balanced CBT fixture adapted to the tensile test machine: bringing the pin close to each other, a bending behavior on the specimens is inducted. During the test, the curvature of the coupons has been approximated to a semi-circumference as Milinda et al. have already experienced to be a good choice for properties evaluation [11].

Material properties calibration

To populate the ABD matrix components which cannot be directly evaluated experimentally, the CLT has been used. Particularly, the experimental outcomes are used as reference for calibrating properties of the single phase in an iterative analysis such that the analytical results coming from the CLT best matched with the data from experiments. To obtain optimized values, a particle swarm optimizer (PSO) was implemented in Matlab. The cost function that compares experimental outcomes with properties coming from CLT is:

$$J = \left(\frac{A_{11}^{exp}-A_{11}^{CLT}}{A_{11}^{exp}}\right)^2 + \left(\frac{A_{12}^{exp}-A_{12}^{CLT}}{A_{12}^{exp}}\right)^2 + \left(\frac{D_{11}^{exp}-D_{11}^{CLT}}{D_{11}^{exp}}\right)^2\ ; \tag{3}$$

Here, normalized residuals were considered to give the same weight to each term in the evaluation of the minimum value of the cost function [12]. The calibration determined the complete global stiffness matrix of the composite material.

Materials Research Proceedings 69 (2026) 1250-1254 https://doi.org/10.21741/9781644904251-216

Buckling numerical model

The boom is modeled as two Ω-shaped shells, each 70 cm in length. The shells are bonded by interposing a ply that simulates the adhesive layer between their flat regions, while tie constraints are defined between each flat region and the adhesive. Multi-Point Constraints (MPCs) are applied to link the nodes at the tip and root cross-sections to reference points (RPs) located at the center of each cross-section. The RP at the boom root is fully constrained, whereas the RP at the boom tip is constrained in the x- and y-translations and in the x-, y-, and z-rotations. The load is a compressive load applied at the boom tip. The boom is discretized using S4R elements, which are 4-node, doubly curved thin shell elements with reduced integration and hourglass control. The simulation consists of a preliminary linear buckling analysis followed by a nonlinear Riks analysis [13,14]. The critical load and the deformed shapes corresponding to the first three buckling modes obtained from the linear buckling analysis are used to introduce initial geometric imperfections in the subsequent nonlinear analysis. The imperfections are scaled relative to the laminate thickness, with amplitudes of 1%, 0.5%, and 0.25% for the first, second, and third modes, respectively.

Material characterization results

Experimental tests allowed us to determine 3 of the components of the global stiffness matrix of the material.

$$A_{11} = 10607\ N/mm \tag{4}$$

$$A_{12} = 167.79\ N/mm \tag{5}$$

$$D_{11} = 7.86\ Nmm \tag{6}$$

While from properties calibration, the resulting ABD stiffness matrix is:

$$A_{0/90} = \begin{Bmatrix} 8511 & 81.53 & 0 \\ 81.53 & 8511 & 0 \\ 0 & 0 & 154.9 \end{Bmatrix}\ N/mm \tag{7}$$

$$D_{0/90} = \begin{Bmatrix} 8.819 & 0.049 & 0 \\ 0.049 & 1.407 & 0 \\ 0 & 0 & 0.093 \end{Bmatrix}\ Nmm \tag{8}$$

While matrix B results null due to lamination sequence.

Buckling numerical model

A mesh sensitivity analysis was performed through linear buckling simulations, determining asymptotic behaviour at 520 N starting from 20400 elements for each boom half and 1200 elements for each adhesive layer. The first three buckling modes, shown in Fig.1, results very close to each other, highlighting a local collapse at the boom root for a critical load of 518.9 N. This behaviour is replicated by the non-linear analysis, in which the boom shows a bulging effect near the root, determining buckling occurrence at critical load. A global and top side views are reported in Fig.2, to better explain the structural response to the compressive load.

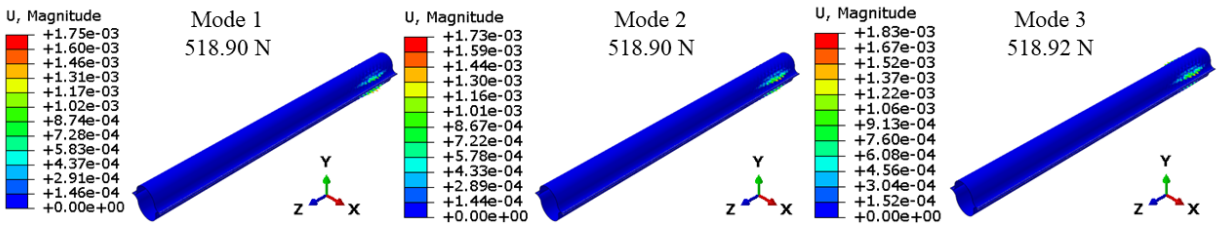

Figure. 1 Critical load of the first three buckling modes

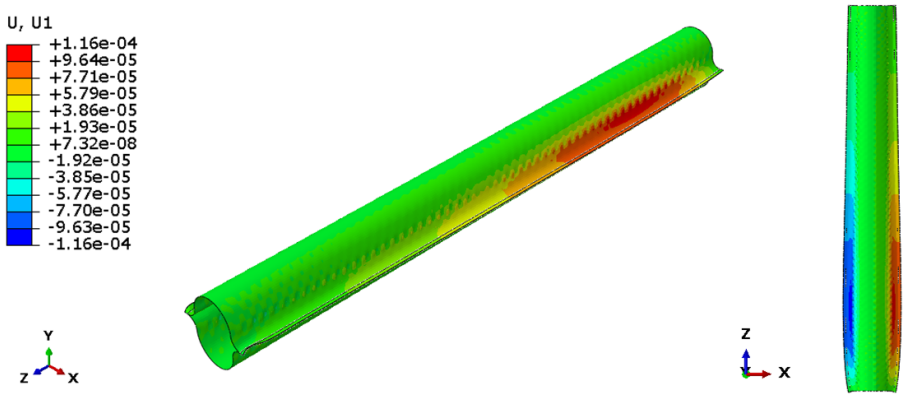

Figure. 2 Global (left side) and top (right side) view of the non-linear buckling outcome.

Conclusions

In this work, the mechanical characteristics of an ultra-thin composite material are determined, and the buckling behavior of a CTM boom is analyzed. Firstly, the composite material is selected and characterized through experimental tensile and bending tests. Specifically, an optimization process is performed to determine the ABD matrix providing reliable properties of such thin material. The second part of the study is focused on the numerical simulation of the buckling test. The aim was to realize a model that accurately describes the behavior of these ultra-thin structures under axial compression, accounting on reliable material properties. This work represents an initial step in the exploration of CNT-reinforced deployable composites. Beyond potential mechanical improvements, the introduction of CNTs could enable multifunctional capabilities, such as enhanced electrical conductivity, thermal management, or sensing, which warrant further investigation in future studies.

Keywords: Abrasion, Lunar Dust, Regolith, Taber Abraser, Grit Feeder, Wear Index

Abstract Abrasion caused by lunar regolith is a critical challenge for future exploration missions. The highly angular, sharp-edged particles of lunar dust can severely degrade mechanical systems, protective fabrics, and structural materials. This study focuses on the laboratory characterization of material degradation under three-body abrasion, which accurately represents the abrasive conditions caused by lunar regolith. Using a Taber Abraser equipped with a Grit Feeder and LHS-1 lunar highland simulant, the research compares the abrasion behavior of fiber-reinforced composites and polyethylene-based materials. By defining a Dust Wear Index (DWI) in terms of mass and thickness loss due to abrasion, the study establishes a framework for evaluating abrasion resistance of both classes of materials.

Introduction

The renewed global interest in lunar exploration, driven by programs such as NASA's Artemis and the development of permanent surface habitats is leading to new challenges in material engineering. Among these, lunar dust (i.e. regolith) remains one of the most mission-limiting factors. Its sharp, irregular particles adhere to surfaces establishing an abrasion mechanism followed by surface wear [1] as reported since the Apollo missions. Prolonged exposure can compromise the performance of materials used in life-support systems, seals, visors, and spacesuits [2,3].

Understanding and mitigating regolith-induced abrasion is thus essential to ensure astronaut safety, operational reliability, and lunar infrastructures sustainability. As future missions foresee prolonged surface operations [4], a systematic investigation of material degradation under realistic regolith–surface interaction scenarios becomes critical.

This study addresses the issue through controlled laboratory tests simulating three-body abrasion, a wear mechanism that best represents the lunar operating scenario [5]. By reproducing the interaction between regolith particles and material surfaces, it aims identifying suitable materials for lunar applications and to develop a quantitative Dust Wear Index (DWI) as a benchmark for abrasion resistance [6].

Materials and methods

Specimens

Specimens are square shaped measuring 10x10 cm with variable thickness in the range of mm, as this parameter is not critical for the test. Two material categories were tested: composite samples and polymer-based ones.

Content from this work may be used under the terms of the Creative Commons Attribution 3.0 license. Any further distribution of this work must maintain attribution to the author(s) and the title of the work, journal citation and DOI. Published under license by Materials Research Forum LLC.

Composites are realized starting from fiber fabric layers impregnated with epoxy resin Prime 37 with a mixing ratio of parts A to B of 100:29. The layers consist in a quasi-isotropic balanced layup sequence.

The curing process lasts 7 hours and occurs at a temperature of 65°C reached via a ramp of 4°C per minute, the specimen is placed in a vacuum bag inside a vacuum oven.
The Carbon/epoxy plate is manufactured using a 12K Prochima Carbon fiber fabric C-420/D, its fiber volume fraction is verified with a Thermogravimetric analysis to be 48.83%.

A second Carbon/epoxy plate, identical to the first one, is realized and then subjected to a chemical recycling treatment (solvolysis process) based on sulfuric acid at a concentration of 18.3 mol/l [7]. Its fiber volume fraction is verified with a Thermogravimetric analysis to be 55.58%.

The Glass/epoxy plate meets the same requirements of the Carbon/epoxy plates and underwent an additional 30 minutes post-curing phase to further relieve residual stresses.

Polymer based samples are manufactured starting from ultra-high modulus Polyethylene powder Aldrich. Samples are both in pure form and filled with 5% and 10% Biolit regolith simulant by weight. Biolite is a ultrafine basalt powder extracted from sites in Oberdorf, Austria [8].

The pure powder is placed in a metallic mold and then in a vacuum oven for 90 minutes at a temperature of 180°C while the filled ones were kept in the oven for 180 minutes at 220°C and 230°C. A higher temperature than that used for pure polyethylene samples was required to ensure proper mixing of Biolit and polyethylene.

Test methodology

All abrasion tests were carried out using a Taber Abraser (Model 5135) equipped with a Grit Feeder (Model 255) [9]. This configuration allows continuous and uniform deposition of abrasive particles between rotating wheels and specimen surface, thus reproducing three-body abrasion conditions.

The abrasive medium employed was LHS-1 (Lunar Highlands Simulant), it was oven-dried following the NASA standard [10] and sieved to ensure a representative grain size distribution of lunar regolith [11].

Before abrasion testing all specimens underwent a pre-conditioning phase in accordance with ASTM F510M-20 standard and a pre-characterization process in terms of mass, thickness and surface conditions. Mass was measured using a high-precision analytical balance (accuracy ± 0.1 mg), thickness using a digital micrometer (accuracy ± 1μm) and surface morphology was examined with an optical microscope. The thickness of each specimen was measured at five fixed points to account for possible non-uniformity.

The procedure is built starting from ASTM F510M-20 standard and consists of two sequential phases: reference and test, both lasting 1000 Taber cycles at 72 rpm.

In the *reference phase* specimens were abraded only with S-39 leather wheels without the introduction of regolith to quantify the wear only produced by the wheel–surface mechanical interaction.

In the *test phase*, the same setup was repeated with the Grit Feeder activated (feed rate set to 100), dispensing sieved LHS-1 on the specimen. The simulant particles act as the third body between the specimen and the surface, reproducing the lunar three-body abrasion mechanism.
After each phase, the specimens were cleaned with compressed air to remove residual dust.

Mass and thickness variations obtained in the reference phase are subtracted from the corresponding values measured after the test phase, where both wheels and regolith are present. This superposition of effects enables the isolation of the net contribution of regolith particles to the total abrasion, independent of the baseline mechanical wear.

Mass measurements exhibited a standard deviation less than 1 mg while thickness ones are reported using the standard error of the mean (SEM) as the representative uncertainty. The SEM

Materials Research Proceedings 69 (2026) 1255-1259 https://doi.org/10.21741/9781644904251-217

was computed to quantify the average thickness loss, over the five points, due to regolith abrasion for each specimen.

Based on the results, two *Dust Wear Indexes (DWI)* were defined as dimensionless quantities quantifying material degradation, expressed both in terms of mass by eq. 1 and thickness loss by eq. 2 allowing comparation of different materials.

$$DWI_m = \left|\frac{m_{pre\,ref} - m_{post\,ref}}{m_{pre\,test} - m_{post\,test}}\right| \cdot \frac{1}{N} \quad (1)$$

$$DWI_t = \left|\frac{t_{pre\,ref} - t_{post\,ref}}{t_{pre\,test} - t_{post\,test}}\right| \cdot \frac{1}{N} \quad (2)$$

Results and discussion

Composite specimens exhibited measurable mass and thickness loss after the standard test, confirming regolith's abrasive potential. Among the tested composites Carbon/epoxy showed the highest abrasion resistance, with minimal mass loss and moderate thickness one. Glass/ epoxy displayed intermediate performance, with localized thickness loss while recycled Carbon/epoxy was the most affected, showing the major mass and thickness losses. All results are shown in table 1.

A Differential Scanning Calorimetry analysis (DSC) was conducted on both the Carbon/epoxy and the recycled Carbon/epoxy plates, it revealed that the recycled plate underwent a less complete curing process showing residual polymerization. This highlights the key role of the curing cycle for composites, as improper curing can lead to a weaker matrix and increased susceptibility to abrasion.

Pure Polyethylene samples and filled ones behaved differently from composites. A mass gain occurred due to dust particles penetration in the porous surface of the specimens; the more the filler, the more the mass gain. This behavior was confirmed by the optical microscope analysis that shows dust particles entrapment on the specimens' surface.

The Dust Wear Index (DWI) provides a quantitative measure of materials' response to regolith-induced abrasion.

Since the DWI is inversely proportional to the measured losses during the test, lower DWI values indicate that the regolith exerts a stronger abrasive action on that material while higher DWI values correspond to a minor surface degradation.

However, in the case of polyethylene-based specimens, the interpretation of the DWI must be treated with caution. The combined action of two phenomena can be observed, on one hand the abrasive mechanism while on the other hand the penetration of regolith into surface porosities, which leads to an increase in the sample mass. Those two mechanisms need to be further addressed to better understand their combined action.

The observed mass gain and apparent lower DWI values do not reflect higher abrasion resistance but rather the penetration and entrapment of dust particles within the porous polymer surface.

This behavior results in apparent negative mass losses, the corresponding DWIs are mainly indicative of dust accumulation rather than true mechanical protection against regolith abrasion. A similar consideration can be applied to thickness measurements.

Conclusions and future perspectives

The present study establishes a reproducible and standardized approach for assessing abrasion resistance of materials under lunar-like dust exposure.

Future research can expand this framework by testing under extended cycles to simulate prolonged missions, implementing thermal–vacuum conditions and exposure to ionizing radiations to replicate lunar atmospheric conditions and day–night temperature fluctuations, considering combined environmental factors and integrating the Dust Wear Index into design requirements.

Ultimately, understanding regolith-induced abrasion is not only a tribological issue but a crucial factor for the sustainability and safety of long-term lunar operations. Continued experimental research will enable the selection and engineering of materials capable of withstanding the unique challenges of the lunar environment.

Abstract. This work presents the development of a novel platinum wire Resistance Temperature Detector (RTD) designed for operation in the harsh Martian environment, within the "Space It Up" initiative. The current datasets of the Martian atmosphere measured parameters are limited in spatial and temporal coverage, highlighting the need for high-precision, robust sensors that can fill this gap. For this reason, accurate temperature measurements are essential to improve atmospheric models and support future human exploration missions and habitat design on Mars that require accurate thermal control. The proposed RTD uses a 700 mm length platinum wire of 60 μm diameter with a parylene insulation coating and a four-wire configuration. The preliminary designed sensor supporting structure has been produced using different Additive Manufacturing (AM) techniques, to enhance structural optimization through lightweight supports. Two prototypes have been developed and taken into consideration in this study: one in titanium via Direct Metal Laser Sintering (DMLS) and one in nanoceramic resin via Stereolithography (SLA). Due to the absence of geometric validation for the titanium specimen, the nanoceramic prototype demonstrated comparatively better structural geometry, as confirmed by FEM analyses and vibration testing. Also, to reduce production costs, AM techniques were selected after comparing different fabrication approaches. The sensor is suitable for integration into future rover, lander, and Entry-Descent-Landing (EDL) systems for Mars missions. As part of the characterization process, environmental qualification will be carried out through thermal-vacuum, calibration, and dust resistance tests.

Introduction

Human exploration of Mars requires in-depth knowledge of the Martian environment in order to accurately assess risks and operating conditions and, in general, to adequately prepare future missions to the Red Planet. Several atmospheric reference models are currently available [1,2], but the need to improve atmospheric measurements on Mars remains critical: current general circulation models rely on exiguous in situ datasets limited to specific locations and sometimes cannot be generalized to the entire planet due to local variations that come from altitude of the site, the presence of phenomena such as dust devils, the seasonality and the longitude and latitude. In order to effectively support future human exploration missions, particularly those aiming at the

Materials Research Proceedings 69 (2026) 1260-1265 https://doi.org/10.21741/9781644904251-218

construction of human habitats, it is therefore necessary to expand and refine the in situ database of atmospheric parameters. An in-depth understanding of the environment could be a key resource for scientific activities such as boundary layer characterization, dust vortex studies, extended monitoring for integration into Martian global climate models, and it is also necessary to provide accurate and effective thermal control that is capable of handling the difficulties presented by future human systems.

Within the Space It Up initiative, a consortium funded by the Italian Space Agency (ASI) and the Ministry of University and Research (MUR), aimed at promoting innovation and collaboration in the field of space technologies, a specific research project is devoted to the "Development of prototypes for analysis of the external environment of potential extraterrestrial habitats". In this framework, a temperature sensor is specifically developed for collecting measurements during the atmospheric descent in the Martian atmosphere and for temperature evolution during surface operations.

Project requirement and operating environment

Mars has an extremely hostile and peculiar environment: the atmosphere is composed mainly of carbon dioxide (CO_2) with traces of other gases (N_2, Ar, O_2, CO, H_2O, NO), at very low pressures (approximately 70 - 1400 Pa), the environment is also characterised by a high presence of erosive dust, which can compromise the functioning of instruments, and by strong temperature gradients (from ~140 K to ~250 K) [1,2].

A sensor designed to operate in such conditions must guarantee high accuracy, rapid response and mechanical robustness. These requirements guided the definition of the design specifications and performance characteristics of the device, which include resistance to thermal shock, vibrations and, eventually, dust impacts and deposits.

Sensor design

The present study introduces a new platinum wire resistance temperature detector (RTD) design that is specifically studied to operate in the harsh Martian atmosphere. It represents the evolution of previous instruments, such as HASI TEM (Huygens Atmospheric Structure Instrument) from the Huygens mission [3], and MarsTem from ExoMars 2016 DREAMS package [4].

The new design is based on a high-purity platinum sensing element (99.9998% Pt) configured as a wire, a technologically advanced solution that offers high precision and stability. The structures of previous sensors were complex: HASI TEM used a platinum-rhodium structure with a glass coating [3], manufactured using high-precision techniques available at the time of its development, while MarsTEM used a monolithic titanium structure, carved from a single block. While these solutions demonstrated excellent compatibility with the project specifications and performance objectives, their implementation led to considerably high manufacturing costs, primarily due to the complexity of the fabrication processes and the precision required.

To achieve a balance between performance and manufacturability, this work explored the use of Additive Manufacturing (AM) techniques, which allow greater geometric freedom and rapid prototyping, with the added advantage of being able to use low-cost materials such as polymers and ceramics.

The sensor is based on a 700 mm long annealed platinum wire with a diameter of 60 μm, including the parylene coating of 0.01 mm thickness intertwined on a supporting structure. The coating guarantees electrical insulation from the metallic support, protects the sensitive element from external agents, assuring also chemical stability, and mechanical protection and thus increases reliability; still under investigation is the use of a noncoated wire in order to decrease further the time response of the sensor. The expected performance includes an accuracy of 0.2 K and a resolution of 0.05 K over the range of 150–300 K. The overall dimensions are approximately 75 × 20 × 25 mm^3, with a total mass of ~10 g for the titanium prototype and ~2 g for the

Materials Research Proceedings 69 (2026) 1260-1265 https://doi.org/10.21741/9781644904251-218

nanoceramic one, making it suitable for deployment on ground stations, rovers, and Entry-Descent-Landing (EDL) modules. The reading circuit configuration includes a four-wire setup, eliminating the interference caused by cable resistance to ensure high precision, and the possibility of post processing corrections. Specific shielded space-grade cables are employed, while a pulsed current of 1 mA is used to limit the phenomenon of self-heating. The sensor is designed to operate in wind speeds ranging from 0 to 50 m/s, and under pressures between 50 and 1500 Pa.

Mechanical design and additive manufacturing

The structure is designed to expose the sensing element to the atmospheric flow while minimizing spurious heat inputs, thereby ensuring a rapid response time. Several models were developed to optimize the RTD support structure and minimize both mass and manufacturing costs. Consequently, AM techniques were selected, as they provide high geometric freedom and allow the fabrication of complex prototypes [5].

Two main variants of the support structure were produced:

1. a titanium structure manufactured by Direct Metal Laser Sintering (DMLS)
2. a nanoceramic resin structure printed via Stereolithography (SLA), developed on the basis of the results present in the Master's thesis by Tonelli (2025) [Structural Design and Numerical–Experimental Validation of a 3D Printed Nanoceramic Structure for a Thermometer for Planetary Exploration, University of Padua].

The titanium version, conceived as an initial reference prototype, lacked sufficient geometric resolution to accurately reproduce the fine details conceived in the design. This was mainly due to the limited precision of the DMLS laser beam (±0.2 mm). As a result, several important features were not properly formed, including Ø 0.30 mm holes which were completely absent; threaded holes (M1.2), which proved difficult to tap due to their small size and the material hardness; and notches intended to the wire support, which could not be fabricated as their diameter (Ø 0.07 mm) was below the achievable resolution of the laser beam (Fig.1). Further optimisation will therefore be required to fully validate this manufacturing route. For future developments, it will be necessary to collaborate with a manufacturer equipped with a higher-precision laser system or willing to perform additional post-processing operations to achieve the required dimensional accuracy. The titanium prototype was not subjected to functional testing for the time of the study, but it is currently under test.

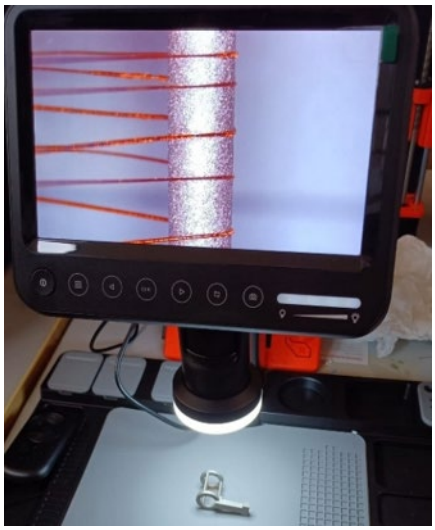

Fig. 1: Titanium prototype. Detail on the absence of the notches for the wire support

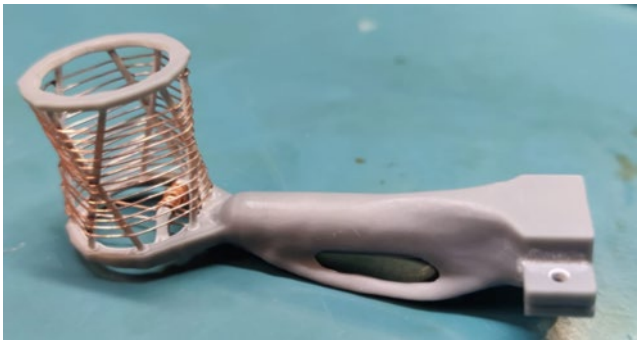

Fig. 2: ThermaDM570 material prototype

On the other hand, the nanoceramic resin prototype (Fig. 2) demonstrated superior performance in terms of geometric accuracy, design flexibility, and thermal insulation. The Therma DM570 material, which is a composite made of a polymeric matrix reinforced with nanometric ceramic particles, is compatible with SLA photopolymerization processes and characterised by low thermal conductivity (≈ 0.54 W/m·K at 30°C), density of 1730 kg/m³, Young's modulus of 6340 MPa, and tensile strength of 56 MPa after UV and thermal post-curing, was used for this specimen [6]. These properties make the material suitable for RTD structure, thanks to its low density, stiffness ratio and reduced heat transfer to the sensing element.

The mechanical design was conceived with the application of topology optimisation (TO) [7] using the finite element method (FEM) with the objective of compliance minimization, starting from the design of DREAMS MarsTem. The objective was to minimise mass while preserving the structural robustness required to withstand the launch loads, enforcing a minimum natural frequency of 100 Hz. For reference, the Falcon Heavy launcher loads were taken into consideration [8]. The resulting geometry achieved a more efficient structure and improved thermal isolation compared to the titanium version [6,9].

The numerical–experimental validation involved an extensive comparison between FEM analyses and laboratory tests, including tensile tests on post-cured resin specimens to characterise the mechanical properties, and vibration tests on 4:1 and 6:1 scale prototypes printed via Multi Jet Fusion (MJF) PA12 [10], using an electrodynamic shaker to evaluate the modal response and validate the numerical models. The scale prototypes were conceived to fully validate the models with minor influence of the measuring accelerometer mass. The results show (Fig. 3) a close correspondence between numerical and experimental data, with frequency discrepancies below 5%, validating the FEM model adopted in the real scale structure [11]. The structure proves to be adequate for the launch environment, with a worst case of 2 for the safety margins.

The only limitation observed concerns the anisotropic behaviour of the nanoceramic material in the printing directions (taken into account in the numerical validation): this could be mitigated through optimisation of printing parameters and post-curing cycles. Since the ThermaDM570 is conceived for high-temperature and high-pressure applications [6], it is essential to assess the performance of the nanoceramic resin under different thermal cycles, especially in low-temperature and low-pressure environments, such as those found on Mars.

Overall, the prototype of nanoceramic resin combines good mechanical performance, excellent thermal insulation, lightness and compatibility with high-precision additive manufacturing techniques to provide a technologically advanced and promising solution.

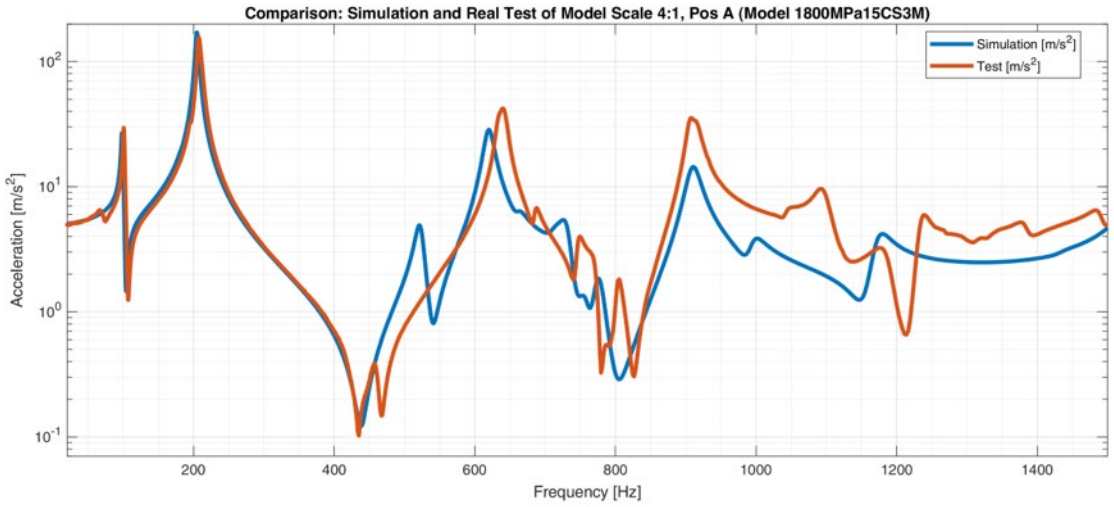

Fig. 3: Comparison between simulation and vibration test of model scale 4:1

Future developments

The following steps involve the production of a titanium version of the supporting structure of the sensing element (i.e. Pt wire) of the thermometer using higher precision additive manufacturing, followed by vibration and functional validation tests. In addition, thermal-vacuum tests and thermal cycling on the nanoceramic resin will be required to evaluate its behaviour under the Martian extreme environmental conditions. Accuracy, calibration, thermal shock, and dust resistance tests will also be necessary to reproduce Martian operating conditions. The experiments will be carried out in terrestrial analogue environments, such as the Moroccan Desert, or in specialized Martian simulation facilities, like the one at Aarhus University. Other test campaigns will include wind tunnel experiments to assess the sensor's survivability under Martian wind conditions and to evaluate the dynamic response of the sensor (e.g. time response).

Conclusions

Rapid prototyping has already been proven to be effective in the production of low-cost designs, even in space [12] and in addition it has shown significant advantages when it comes to geometric freedom, weight savings and time to develop.

More optimisation studies will still be needed, particularly on thermo-fluid dynamics and sensor response under extreme operating conditions for space qualification. Prototype validation goes on, and new configurations of the supporting frame are planned to be developed and tested. The scientific and engineering impact of the project lies in the possibility of obtaining lighter, and more adaptable temperature sensors, contributing to the advancement of measurement technologies for planetary exploration.

Keywords: Structural Health Monitoring (SHM), Flexible Sensors, Radiation Shielding

Abstract. This work investigates a novel class of multifunctional poly(vinyl alcohol) (PVA) gels incorporating multi-walled carbon nanotubes (MWCNTs) for combined radiation shielding and strain-sensing applications. The proposed PVA/MWCNT gels, crosslinked with boric acid, offer high flexibility, conductivity, and mechanical robustness. MWCNT dispersion was optimized by analyzing sedimentation behavior as a function of sonication temperature and PVA concentration. Experimental characterization, including compression tests (–60 °C to +60 °C) and tensile–impedance coupling, demonstrated excellent electromechanical stability. These findings confirm the suitability of PVA/MWCNT gels for flexible, radiation-resistant SHM sensors in space structures.

Introduction

Flexible, durable, and conductive materials have played a crucial role in the development of Structural Health Monitoring (SHM) systems [1]. Traditionally, they have been employed as strain sensors to track the mechanical deformation of structures under load, enabling the early detection of potential threats to structural integrity [2-4]. In the space sector, SHM techniques are widely used to monitor primary structures such as satellite solar panels and antennas. Strain sensors are typically fabricated by embedding conductive materials, such as carbon nanotubes (CNTs), graphene, metal powders, and conductive polymers, within the matrix of elastomers [5, 6]. This approach enables elastomer-based sensors to achieve significant stretchability while maintaining good electrical conductivity. However, the practical use of elastomers in space applications remains challenging because of their sensitivity to the harsh radiative environment.

In addition to elastomers, conductive gels heve also attracted considerable interest as alternative strain-sensing materials [7]. Due to their high water content, softness, and tissue-like mechanical properties, gels can conform to complex surfaces and detect even subtle deformations. Moreover, their conductivity, which can be further enhanced by incorporating conductive fillers, makes them suitable for flexible and stretchable sensor systems.

Results from the PErsonalized Robotics as SErvice Oriented applications (PERSEO) project have demonstrated that liquid water is highly effective in mitigating radiation damage in space environments [8]. Among the various candidate materials for radiation shielding, gels have gained particular attention in the medical and pharmaceutical fields due to their high water content, which provides superior shielding performance compared to conventional polymers. Being intrinsically rich in hydrogen, an essential element for attenuating ionizing radiation such as neutrons and protons, water-based gels represent a promising solution for multifunctional systems. Therefore,

Materials Research Proceedings 69 (2026) 1266-1271 https://doi.org/10.21741/9781644904251-219

incorporating gels into SHM systems could simultaneously enable strain sensing and passive radiation shielding.

In this work, we propose a novel class of multifunctional gels designed for simultaneous radiation shielding and strain sensing applications. The gels are based on a polyvinyl alcohol (PVA) matrix incorporating 0.5, 1.0, and 2.0 wt% multi-walled carbon nanotubes (MWCNTs), which act as conductive fillers to enhance both mechanical robustness and electrical conductivity. Dispersion quality of MWCNTs was optimized by analyzing sedimentation times as function of sonication temperature and PVA concentration. The aqueous PVA–MWCNTs dispersions were then chemically crosslinked with boric acid (BA), aiming to leverage the well-established neutron absorption capabilities of the ^{10}B isotope for shielding applications [9]. To validate their multifunctionality, both experimental and numerical investigations were conducted. Compression tests across the temperature range typical of satellites (–60 °C to +60 °C) were performed using dynamic mechanical analysis, while quasi-static tensile tests coupled with impedance monitoring were used to evaluate electromechanical stability. Finally, radiation transport simulations using the On-Line Tool for the Assessment of Radiation in Space (OLTARIS) tool confirmed the gels' potential as lightweight shielding materials. These findings open new avenues for the development of smart, adaptive materials capable of withstanding extreme environments while providing real-time structural monitoring.

Fabrication of PVA/BA gels

The following materials were obtained from Sigma-Aldrich: poly(vinyl alcohol) (PVA, Mw = 30,000 Da, ρ = 1.3 g/cm³, product no. 8438680100), boric acid (BA, product no. B0394), and ethanol (ρ = 0.790 g/cm³ at 20 °C, product no. 02860-1L). Pristine multi-walled carbon nanotubes (MWCNTs, NC7000 series) supplied by Nanocyl S.A. (Belgium) were used as nanofillers in the gel matrix.

The dispersion of MWCNTs in water was optimized using poly(vinyl alcohol) (PVA) as dispersing agent. 0.03g of MWCNTs were dispersed in ultrapure water (12 mL) containing different PVA concentrations. The suspensions were magnetically stirred and sonicated for 1 hour at 60 °C. The investigated PVA-to-MWCNT weight ratios were 4:1 (denoted as PVA 1 wt%), 12:1 (PVA 3 wt%), 20:1 (PVA 5 wt%), 32:1 (PVA 8 wt%), 40:1 (PVA 10 wt%) and 60:1 (PVA 15 wt%). Sedimentation tests revealed that dispersions below 5 wt% PVA were unstable, while 5 - 15 wt% PVA at 60 °C ensured homogeneous, long-lasting dispersions. Further optimization identified 8 wt% PVA as the optimal concentration, maintaining full stability for at least eight days. After dispersing the MWCNTs in ultrapure water using the optimized PVA concentration, the PVA/BA–MWCNT gels were synthesized by chemical crosslinking. A 30 wt% aqueous PVA–MWCNT solution was prepared by magnetic stirring at 80 °C for 1 hour. Separately, a 10 wt/vol% boric acid (BA) stock solution in ethanol was prepared under the same conditions. Crosslinking was initiated by adding the BA solution to the PVA dispersion to obtain a final BA concentration of 4 wt/vol%. The resulting mixtures were cast into glass molds and conditioned in a climate chamber at 30 °C and 50% relative humidity for 48 hours.

Compressive behavior

Dynamic mechanical analysis (DMA) of PVA/BA–MWCNT gels revealed a strong dependence of viscoelastic behavior on MWCNT concentration (Fig. 1). The pristine gel showed the lowest storage modulus (Fig. 1a), indicating a weak polymer network. Introducing 0.5 wt% MWCNTs significantly increased the modulus, confirming efficient load transfer between polymer chains and dispersed nanotubes. At 1.0 wt%, the modulus plateaued, suggesting a percolation threshold and possible nanotube agglomeration. A minor improvement at 2.0 wt% indicated mechanical saturation. The loss modulus curves (Fig.1 b) displayed distinct glass transition peaks, with higher

Materials Research Proceedings 69 (2026) 1266-1271 https://doi.org/10.21741/9781644904251-219

MWCNT content enhancing energy dissipation. This increase reflects stronger polymer – nanotube interfacial interactions and reduced free water within the gel network.

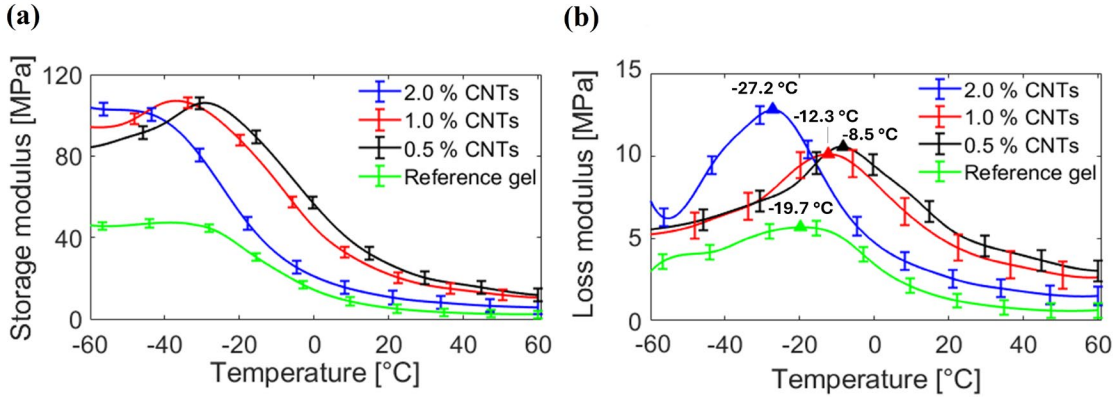

Fig. 1: DMA results of gels: (a) Storage and (b) Loss modulus with varying CNTs content.

SHM behavior through tensile-electrical tests

Tensile tests (ASTM D412-C) on PVA/BA gels with increasing MWCNT content (0–2 wt%) showed significant improvements in mechanical performance (Fig. 2a). The stress–strain curves shifted upward with higher filler content, indicating increased strength, elasticity, and energy absorption. The Young's modulus rose from 6.93 MPa for the reference gel to 18.41 MPa at 2 wt% MWCNTs, representing a threefold increase in stiffness. Additionally, the maximum strain at failure nearly doubled, demonstrating that MWCNT incorporation enhances both rigidity and toughness, allowing the gels to sustain larger deformations before failure.

Surface electrical conductivity measurements during tensile deformation (Fig. 2b) showed a clear increase in conductivity with higher MWCNT content, confirming the formation of interconnected conductive networks within the gels. Conductivity remained stable under strain, indicating good structural integrity of the network. As summarized in Table 11.5, conductivity rose by nearly three orders of magnitude—from 3.3×10^{-8} S/m for the reference gel to 2.4×10^{-5} S/m at 2 wt% MWCNTs.

Electrical conductivity describes how efficiently charge carriers move through a material, while conductance depends on geometry and deformation state. To evaluate the gels' sensing capability, conductance was derived from the real part of the admittance measured at 1 V and 1 kHz. As shown in Fig. 2c, the reference sample (0 wt% MWCNTs) and 0.5 wt% MWCNTs gels exhibited negligible conductance, indicating no percolating network. At higher filler contents, conductance increased markedly, reaching ~3×10^{-3} S for the 2 wt% MWCNT sample. This behavior confirms the formation of conductive pathways once the percolation threshold is achieved. From a Structural Health Monitoring (SHM) perspective, these conductance variations correlate with strain and integrity, providing a sensitive, non-destructive means to detect structural changes.

Numerical simulations

The radioprotective performance of gels was assessed through simulations using NASA's OLTARIS tool, developed at Langley Research Center [10]. In this study, the shielding effectiveness of PVA/BA gels was compared with standard liquid water investigated during PERSEO project. Simulations were carried out for a deep-space environment located at 1 astronomical unit (AU) from Earth, considering exposure to Galactic Cosmic Radiation (GCR) and Solar Particle Events (SPEs). The geometry consisted of a spherical shell with an inner void (radius 150 cm) and an external shielding layer of variable areal depth (0 – 5 g/cm²). This setup enabled a direct comparison between unshielded conditions (0 g/cm²) and progressively thicker protective layers. The Badhwar–O'Neill 2020 (BON2020) model was employed to represent the GCR spectrum, while the NUCFRG3 model was used for heavy-ion fragmentation processes. Historical SPE event of October 1989 was also simulated to evaluate solar proton exposure scenario. Materials of external layers were defined on the "Web Interface" using their density and elemental mass percentages reported in Table 1. Results were computed for the Male Adult voXel (MAX) human phantom modelt o assess radiation effects on human body.

Table 1: Input data for defining materials on OLTARIS tool.

Materials	Density [g/cm^3]	Elemental mass percentages []
PVA/BA (Ref. gel)	1.21	0.3436 C, 0.0931 H, 0.0029 ^{10}B, 0.0118 ^{11}B, 0.5486 O
PVA/BA-0.5 wt% CNTs	1.14	0.3730 C, 0.0909 H, 0.0031 ^{10}B, 0.0124 ^{11}B, 0.5206 O
PVA/BA-1.0 wt% CNTs	1.14	0.3577 C, 0.0912 H, 0.0029 ^{10}B, 0.0115 ^{11}B, 0.5367 O
PVA/BA-2.0 wt% CNTs	1.22	0.3550 C, 0.0903 H, 0.0027 ^{10}B, 0.0108 ^{11}B, 0.5412 O
H_2O (Liquid water)	1.00	0.1111 H, 0.8889 O

Fig. 3 illustrates the behavior of total effective doses equivalent as a function of areal depth for GCR and SPE environments. Results compare liquid water with PVA/BA gels incorporating different concentrations of carbon nanotubes (CNTs). In all cases, the effective dose equivalent decreases as depth increases, and the CNT-reinforced gels demonstrate shielding capabilities comparable to pure PVA/BA and water. These findings suggest that CNT reinforcement can be used to improve electrical and mechanical properties without compromising the radiation protection capability of PVA-based gels.

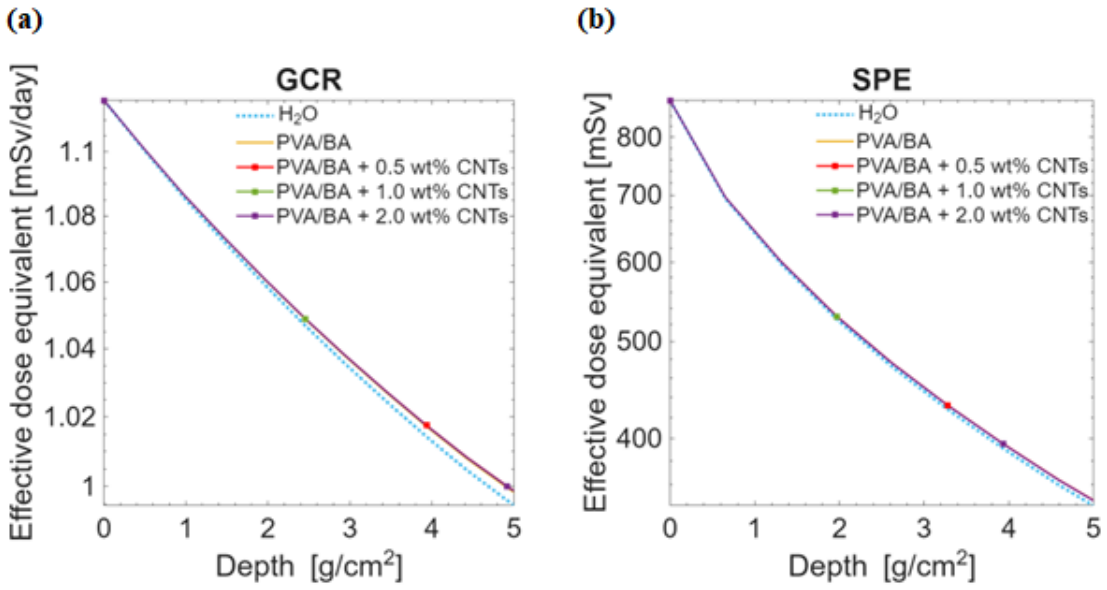

Fig. 3: Total effective dose equivalent as a function of depth for (a) GCR and (b) SPE scenarios.

Conclusions

PVA/BA–MWCNT gels were produced through an optimized nanotube dispersion process in water, ensuring uniform filler distribution within the polymer matrix. The resulting materials exhibited significant improvements in mechanical and electrical properties. DMA results showed that the storage modulus increased notably at 0.5 wt% MWCNTs, marking a mechanical percolation threshold between 0.5 and 1.0 wt%. The glass transition temperature displayed a non-monotonic trend, reflecting the balance between water plasticization and MWCNTs confinement. Electrical analysis revealed frequency-dependent conductivity enhancement, with a sharp rise between 0.5 and 1.0 wt% indicating conductive network formation. Tensile tests confirmed a threefold increase in stiffness (from 6.93 to 18.41 MPa) and nearly doubled strain at failure, while conductivity rose by three orders of magnitude. Overall, these gels combine mechanical strength and high conductivity, demonstrating strong potential for multifunctional sensing and structural health monitoring applications. Finally, numerical simulations confirmed that the incorporation of MWCNTs has a negligible impact on the radiation shielding capability of PVA-based gels, ensuring that the improvements in mechanical and electrical properties are achieved without compromising the protective behavior of pristine PVA/BA gels.

Abstract. Protecting astronauts from radiation during space missions is a critical challenge. In the current context, where space agencies are working to establish permanent bases on the lunar surface, radiation shielding becomes an even more crucial issue. Indeed, as missions venture farther from Earth, crews lose the natural shielding provided by the Earth's magnetic field and atmosphere, resulting in high exposure to ionizing radiation**.** This study explores the integration of poly(vinyl alcohol) (PVA) gels as flexible intermediate layers in lunar spacesuits to enhance radiation shielding on lunar surface. Experimental tests demonstrated that PVA gels possess similar density and thermal conductivity to nylon but greater flexibility, denoted by their high strain at failure during tensile tests. Numerical simulations highlights that the gels' inclusion in spacesuits highly reduces total effective doses equivalent due to Solar Particle Events.

Introduction

Spacesuits have been designed primarily to ensure protection against extreme temperatures, micrometeoroids, and orbital debris [1, 2]. They consist of multiple specialized layers, each engineered for a specific function. The outermost layer, made of orthofabric composites, acts as a shield against micrometeoroids and space debris. Beneath this layer, an insulation system composed of aluminized mylar and dacron fabric provides thermal regulation. Finally, the innermost layers consist of the Pressure Bladder Garment (PBG), made of urethane-coated nylon, and the Liquid Cooling and Ventilation Garment (LCVG), made of nylon with embedded water tubes, designed to maintain a stable internal temperature.

Currently, polymer-based materials have been selected as promising solutions between innovative shielding techniques, due to their lightweight and excellent mechanical, thermal, and electrical properties. Their shielding performance has been further improved by incorporating specific fillers, including boron nitride, polyurethane, graphene, and carbon nanotubes [3 - 8]. However, their inherent rigidity and limited flexibility make them unsuitable for wearable systems such as spacesuits employed during Extravehicular Activities (EVAs). This limitation can be addressed by integrating ductile, hydrogen-rich, and flexible materials with high radiation stopping power directly into the suit's structure. As demonstrated by the PErsonalized Robotics as SErvice Oriented applications (PERSEO) project, hydrogen-rich materials, such as liquid water, are particularly effective in attenuating Galactic Cosmic Radiation (GCR) and Solar Particle Events (SPEs) [9]. However, the use of liquids in microgravity environments determines significant challenges, including increased system volume and complex fluid management. To overcome

Materials Research Proceedings 69 (2026) 1272-1277 https://doi.org/10.21741/9781644904251-220

these constraints, gels have been proposed as innovative solution to enhance radiation protection inside spacesuits for missions beyond LEO [10].

This study examines the feasibility of enhancing radiation shielding for next-generation spacesuits during EVAs on the Moon without compromising their ergonomics by proposing the integration of poly(vinyl alcohol) (PVA) gels as an intermediate layer between the PBG and the LCVG of the spacesuit. Experimental tests were conducted to compare the physical properties of PVA-based gels with those of nylon, which is the primary material used in both the PBG and LCVG systems. The results show comparable density and thermal conductivity between the two materials. Moreover, the gels demonstrated higher flexibility, as evidenced by their local strain under tensile stress. Numerical simulations using the On-Line Tool for the Assessment of Radiation in Space (OLTARIS) confirmed the shielding potential of the gels. Indeed, integrating gel layers within the spacesuit resulted in reductions in both total effective dose equivalent and average organ dose equivalent.

Fabrication of PVA/BA gels

The following materials were purchased from Sigma Aldrich and used as received: PVA (Mw = 30,000 Da, ρ = 1.3 g/cm³, product no. 8438680100), BA (product no. B0394), and ethanol (ρ = 0.790 g/cm³ at 20 °C, product no. 02860-1L). Ultrapure water (resistivity 18.2 MΩ·cm) was produced using a Direct-Q3 UV purification system (Millipore, Molsheim, France).

PVA/BA gels were prepared via chemical crosslinking following a previously reported protocol [10]. Briefly, a 30 wt% aqueous PVA solution was prepared by magnetic stirring at 80 °C for 1 h. Separately, a 10 wt/vol% BA stock solution was prepared in ethanol under identical conditions. Crosslinking was initiated by adding the BA solution to the PVA solution to achieve a final BA concentration of 4 wt/vol%. The resulting mixture was poured into glass molds and conditioned in a climate chamber at 30 °C and 50% relative humidity for 72 h.

Comparison of Nylon and gel properties

The experimental results shown in Table 1 suggests that the PVA/BA gels possess a density (1.25 g/cm³) and thermal conductivity (0.27 W/m·K) comparable to those of Nylon 6 used in aerospace applications. However, the gels exhibit higher ductility compared to 9–25% for nylon, failing at about 65 % strain during tensile tests. Although the Young's modulus (12.75 MPa) is much lower than that of nylon, the gels demonstrate excellent flexibility due to their high water content (≈ 55 %), which also suggests potential benefits for radiation attenuation.

Table1: Comparison of physical and mechanical properties of PVA/BA gels and nylon.

Samples	PVA/BA gels	Nylon	Ref.
Density [g/cm³]	1.25*	1.14	[11]
Thermal conductivity [W/(mK)]	0.27*	0.10 ÷ 0.30	[12]
Strain at maximum elongation [%]	64.71*	9 ÷ 25	[13]
Young modulus [MPa]	12.75 ± 0.86	2450 ÷ 3100	[13]

* Standard deviation < 0.01.

Numerical simulations

Radiation exposure during lunar extravehicular activities (EVAs) was analyzed using NASA's OLTARIS platform [3], which employs the deterministic HZETRN transport code to solve one- or three-dimensional Boltzmann equations. Two primary lunar radiation environments were considered: Galactic Cosmic Radiation (GCR), including both free-space and albedo-reflected

Materials Research Proceedings 69 (2026) 1272-1277 https://doi.org/10.21741/9781644904251-220

components, and Solar Particle Events (SPEs), in which the external environment is negligible. For this study, GCRs were modeled during solar minimum, corresponding to maximum ionization, using a solar modulation parameter of 475 MV and the Badhwar–O'Neill (BON) 2020 model. SPEs were represented using the Tylka Bands Fitting for the October 1989 event. Material cross-sections were calculated with OLTARIS based on the chemical compositions and densities reported in Table 2.

Table 2: Input data used for defining materials on the OLTARIS tool.

Materials	Density [g/cm^3]	Elemental mass percentages []
Aluminized Mylar	1.40	0.624 C, 0.042 H, 0.332 O, 0.002 Al
Dacron	1.38	0.625 C, 0.042 H, 0.333 O
Neoprene coated Nylon	1.05	0.589 C, 0.077 H, 0.205 Cl, 0.060 N, 0.069 O
Nylon	1.14	0.637 C, 0.098 H, 0.124 H, 0.141 O
Orthofabric	1.80	0.470 C, 0.021 H, 0.380 F, 0.058 N, 0.071 O
Polycarbonate	1.20	0.706 C, 0.059 H, 0.235 O
S-glass composite	1.29	0.478 C, 0.046 H, 0.304 O, 0.022 N, 0.150 Si
Urethane coated Nylon	1.13	0.523 C, 0.077 H, 0.246 O, 0.154 N
PVA/BA gel	1.25	0.2147 C, 0.0999 H, 0.0018 ^{10}B, 0.0073 ^{11}B, 0.6763 O

Geometrical model

Simulations investigated the potential integration of gels within spacesuit structures modeled using NASA's Z2 CAD design [14] to assess possible enhancements in radiation protection during extravehicular activities (EVAs). The spacesuit model was oriented normal to the lunar surface and coupled with the MAX and FAX phantoms to assess human exposure. A MATLAB-based ray-tracing algorithm generated 512 rays from a central target and divided the CAD geometry into five anatomical regions aligned with the phantoms. For each region, material composition and thickness followed the Z2 configuration, with optional PVA/BA gel layers (0.5 – 3 cm) added between nylon and urethane-coated nylon. The resulting material profiles were compiled into an XML file compatible with OLTARIS for radiation transport simulations.

Results and discussion

Fig. 1 illustrates simulations in which a PVA/BA gel layer of varying thickness (0 – 3 cm) was incorporated into conventional spacesuit configurations. Under GCR conditions (Fig. 1a), initial Total Effective Dose Equivalents (TEDEs) were nearly identical for both sexes (288.1 mSv for the male and 286.1 mSv for the female phantom). At a 3 cm gel thickness, TEDEs decreased to approximately 260 mSv, corresponding to modest reductions of 9.7 % and 9.5 %, respectively. This limited improvement underscores the weak shielding capability of gels against highly penetrating GCR particles. In contrast, the SPE scenario (Fig. 1b) demonstrates a pronounced shielding effect. Without gel, TEDEs reach hazardous levels of 1313 mSv (male) and 1211 mSv (female). Introducing a 1 cm gel layer reduces these values by nearly 50 % (49.6 % and 47.1 %), while a 3 cm layer achieves dose reductions exceeding 60 % in both phantoms. The narrowing difference between male and female exposures with increasing gel thickness further indicates that effective shielding minimizes sex-based dose disparities. Overall, these results confirm that PVA/BA gels offer limited protection against GCR but are highly effective in mitigating SPE radiation, providing substantial reductions in TEDEs.

Materials Research Proceedings 69 (2026) 1272-1277 https://doi.org/10.21741/9781644904251-220

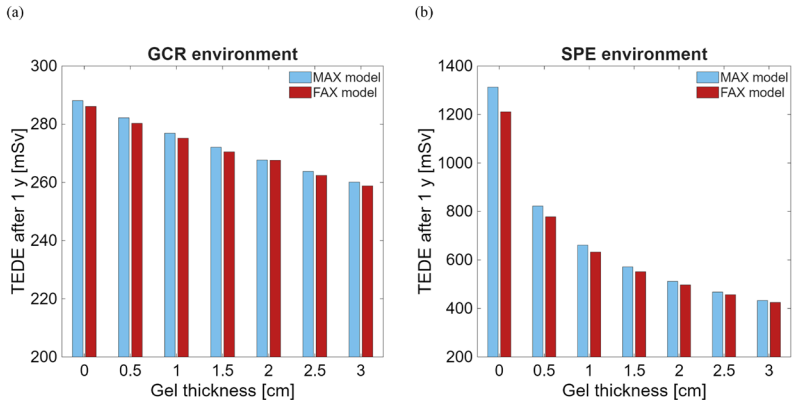

Fig.1: Total Effective Doses Equivalent (TEDEs) after 1 y for MAX (male) and FAX (female) models as a function of gel layer thickness (0 – 3 cm) under (a) Galactic Cosmic radiation (GCR) and (b) Solar Particle Event (SPE) environments.

Fig. 2 and 3 illustrate a comparative analysis of the average organ doses equivalent in male and female phantoms during a 1-year mission. Under GCR conditions (Fig. 2), the skin receives the highest doses (~ 500 mSv in FAX and ~ 450 mSv in MAX), followed by the lens and salivary glands. Increasing the protective gel layer thickness yields only minor reductions, highlighting the limited effectiveness against GCR particles. In contrast, during SPE (Fig. 3), the high skin doses (> 10^5 mSv) decrease sharply with increasing gel thickness, confirming the attenuation capability of gels against solar protons.

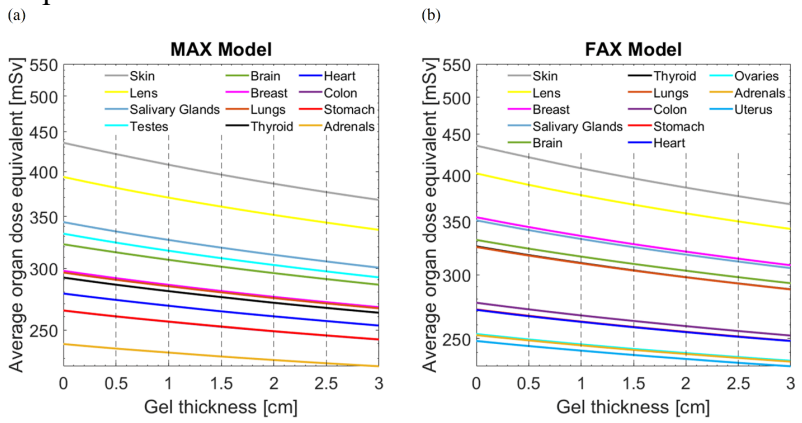

Fig. 2: Average organ dose equivalent as a function of gel thickness integrated into the spacesuit under Galactic Cosmic Radiation (GCR) exposure, for MAX (a) and FAX (b) phantoms.

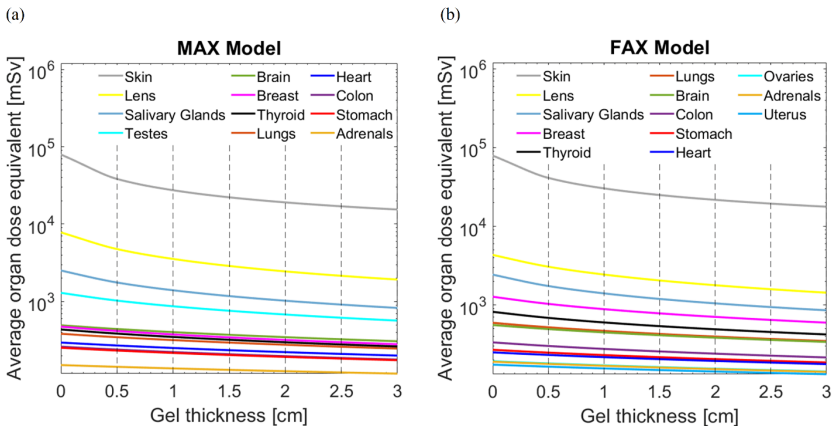

Fig. 3: Average organ dose equivalent as a function of gel thickness integrated into the spacesuit under Solar Particle Events (SPE) exposure, for MAX (a) and FAX (b) phantoms.

Conclusions

This study demonstrates that PVA/BA gels are promising materials for improving personal radiation protection in astronaut spacesuits. Experimental characterization showed that the gels have physical properties comparable to nylon, including similar density and thermal conductivity, but with much higher flexibility (Young's modulus = 12.75 MPa; strain ≈ 65 %). Numerical simulations using OLTARIS tool confirmed the gels' radiation-shielding potential when positioned between the PBG and LCVG. A 1 cm gel layer was identified as the optimal configuration, balancing protection and added mass (~ 21 %). Under GCR exposure, dose reductions were modest (≈ 4 %), while under SPE conditions, reductions reached nearly 50 % for both male and female phantoms.

Abstract. Inflatable and deployable structures are increasingly recognized as a promising solution for long-duration missions on the Moon and beyond. This study addresses the conceptual design and preliminary assessment of a pressurized habitat intended for lunar surface deployment. Three geometric configurations have been evaluated in terms of mass efficiency, stress distribution, and habitability. The fabric restraint shell, made of aluminized Kapton Kevlar (AKK) and sized with a safety factor of four, was combined with a carbon-fiber-reinforced floor designed to support astronaut loads and internal equipment. The cylindrical configuration proved the most suitable option due to its reduced structural mass, modularity, and ease of deployment. A finite element model was developed to investigate static pressurization and thermal loads, confirming structural adequacy with acceptable stress and displacement levels. A digital habitability analysis using anthropometric mannequins further validated the spatial configuration. Finally, a dynamic inflation analysis with LS-DYNA has been done to capture the stress-strain evolution.

Introduction

In recent years, the colonization of celestial bodies has evolved from a distant goal to a tangible objective. The Moon, as a stepping stone toward Mars, serves as a testbed for life-support technologies and infrastructure. Inflatable and deployable habitats have already proven feasible and reliable in orbit: NASA's TransHab concept, Genesis I and II, and the Bigelow Expandable Activity Module (BEAM) on the ISS [1].

Unlike orbital environments, surface habitats must withstand extreme thermal cycles (from –233°C up to +127°C on the moon), leading to thermally induced stresses. Additional challenges include radiation from galactic cosmic rays and solar flares, and the abrasive, contaminant nature of lunar regolith. The low-density atmosphere requires full pressurization, while lunar gravity (17% of Earth's) influences both structure and human physiology. This study presents the conceptual design and structural assessment of a pressurized, inflatable, and deployable lunar habitat. The design emphasizes the membrane maintaining internal pressure of the restraint layer, sized with a safety factor of four, in compliance with NASA habitability standards NASA-STD: 3000 [2] and 3001 [3].

Geometric Conceptual Design

Three continuous-curvature geometries were selected to ensure uniform stress distribution under internal pressurization, reducing local stress concentrations that may cause fatigue or collapse [4]. The analyzed configurations are: (i) hollow torus, (ii) hollow hemisphere, and (iii) hollow cylinder [1]. For the toroidal and cylindrical cases, a reference internal radius of 1.6 meters was adopted, consistent with existing designs such as HALO (Habitation and Logistics Outpost) [5] and CYGNUS [6].

Materials Research Proceedings 69 (2026) 1278-1282 https://doi.org/10.21741/9781644904251-221

A MATLAB code was developed to dynamically link the internal habitable volume (V_{int}) with the geometric parameters of each configuration. The user specifies the habitable volume and the fabric thickness (t); the algorithm then computes the corresponding structural dimensions, ensuring that the required internal volume is maintained.

An analysis was conducted to optimize the floor placement for circular-section habitats such as the cylinder and the torus. The optimization cost parameter (η), shown in Eq. 1, represents a trade-off between the habitable volume and the storage capacity beneath the floor.

$$\eta = \frac{V_{stow}}{V_{int}} \times 100\ (\%). \tag{1}$$

Based on a reference internal diameter of 3.2 meters, the floor position in circular-cross-section habitat varied to maximize habitability, minimize structural clutter, and consequently reduce mass. The optimal floor height was found at approximately 21% of the internal diameter, providing a balanced configuration in terms of usable space and stowage efficiency. Defining the habitable volume as the space above the floor, the cylindrical habitat was chosen for detailed analysis among the three configurations due to its lower mass, modular design, and ease of deployment.

Stiffened Cylinder Sizing

The structural complexity of pressurized extraterrestrial inflatable habitats required resilience against a broad range of loads, primarily including pressurization, thermal, radiation loads, and micrometeoroid impact [1]. The restraint layer sizing focuses on pressurization and thermal loads. In adherence to NASA-STD-3001 [3], a pressurized lunar habitat must maintain an internal condition of 101325 Pa and 20°C and therefore be capable of sustaining a pressure differential (Δp) of 101325 Pa and a thermal differential (ΔT) of approximately 200°C with the external lunar environment. A safety factor (c) of four is applied.

The flexible shell material selected is aluminized Kapton-Kevlar (AKK), which has a yield stress (σ_y) of 3000 MPa and a Poisson's ratio (ν) of 0.36. The combined stress condition for a thin-walled shell under pressure (σ_p) and thermal (σ_T) loading is expressed as follows:

$$\frac{\Delta p \cdot r}{t} + \frac{E \cdot \alpha \cdot \Delta T}{1-\nu} \leq \frac{\sigma_y}{c} \tag{2}$$

From Eq. 2, a wall thickness of 0.8 mm is selected. The reinforced cylindrical shell has two open ends: one interfaces with a docking system connected to a main structure (rover, base, or launcher), while the opposite end can connect modularly to other habitats or terminate with an endcap. According to Niu [7], three endcap types are possible: flat, hemispherical ($\varphi = 90^{\circ}$), and semi-spherical ($\varphi < 90^{\circ}$).

The flat configuration causes stress concentrations, whereas curved geometries ensure smoother load transfer. Owing to deployability, the hemispherical endcap with tangential continuity to the cylindrical body offers the most efficient stress distribution and compact stowage. The total external restraint layer mass of the cylinder connected to the endcap is 107 kg. The floor placement analysis identified an optimal position at 21% of the habitat diameter, providing a 2.5 m width, an efficiency factor (η) of 17%, and a maximum habitable height of 2.56 m. For a two-astronaut pressurized habitat, an internal volume (V_{int}) of 50 m^3 was imposed, yielding to 7 m in length.
The floor was sized for two occupants from the 95th percentile of the ANSUR database: a 101 kg male and a 79 kg female; with an additional 1400 kg representing equipment and furnishings. The load was modeled as uniformly distributed over a 2.5 m × 7 m area. A carbon fiber/epoxy prepreg (T700/epoxy) was selected for its foldability under both equal or opposite-sense methodologies [8].

Materials Research Proceedings 69 (2026) 1278-1282 https://doi.org/10.21741/9781644904251-221

The sizing resulted in a 3.6 mm laminate of 12 plies (0.3 mm each) with stacking sequence $[0/90/0/90/0/90]_s$ and a total mass of 103 kg. Eight circular supports for membrane deployment and eight supports for the floor yielded a preliminary total habitat mass of 219 kg.

Habitability Analysis

The CAD model of the pressurized, inflatable, and deployable habitat in its fully deployed configuration was created in CATIA and subsequently imported into Siemens NX to perform a preliminary habitability assessment.

Two digital human mannequins were positioned within the habitat, both representing the 95th percentile of the ANSUR anthropometric database: a male subject weighing 101 kg and standing 187 cm tall, and a female subject weighing 79 kg and standing 174 cm tall.

The mannequins were placed in a virtual environment populated with volumetric placeholders simulating operational equipment and material usage.

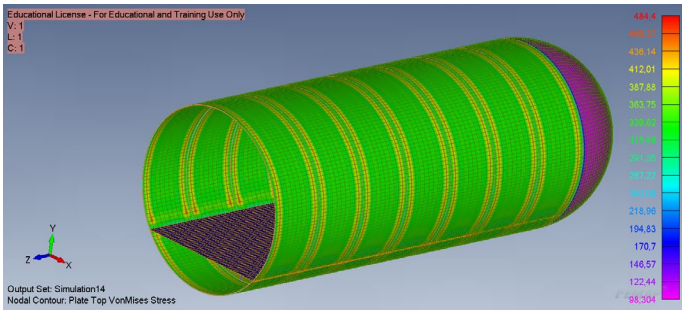

Figure 1: Isometric rendering of the fully deployed pressurized inflatable habitat, showing two digital mannequins and operational equipment placeholders.

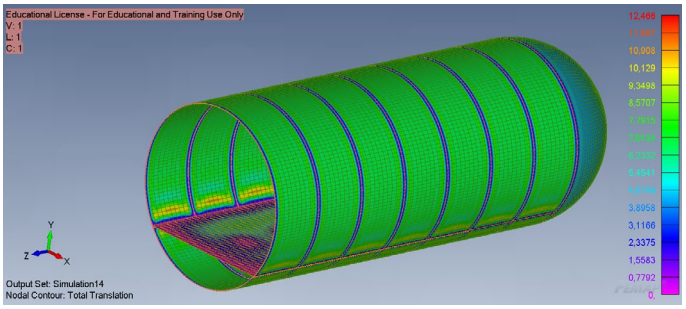

As shown in Fig. 1, the analysis indicates that the dimensions of the habitat are found to be suitable for the designated purpose, thereby confirming that the internal spatial configuration is adequate to meet the requisite habitability criteria.

Static Analysis

Based on the geometric information obtained from the conceptual design and sizing phases, a finite element model (FEM) of the habitat was developed in FEMAP. The model includes plate elements for the cylindrical membrane and the hemispherical endcap, beam elements of various sizes and shapes for the telescopic linear guides and supports, and laminated plate elements for the floor. Thermal loads of 200 °C and a pressure load of 0.101325 MPa were applied to the membrane, while a pressure load of 0.0013 MPa was applied to the floor.

(a) Plate Von Mises stress

(b) Total displacement

Figure 2: Results of the preliminary static analysis for the fully deployed pressurized inflatable habitat: (a) Von Mises stress distribution on plate elements and (b) total displacement field.

The resulting stress analysis indicates a pressure accumulation at the cylinder-endcap interface corresponding to 22.62% of the AKK yield strength (σ_y) when evaluated using elemental contour data.

For the nodal contour representation, shown in Fig. 2a, the corresponding value is 16.14%. Stress concentrations are primarily observed near the circular and linear stiffeners, while the membrane region exhibits a nearly uniform distribution with lower values on the hemispherical endcap, confirming the effectiveness of its geometry.

The maximum displacement is 12.466 mm on the flexible cylindrical membrane mainly occurring between the circular frames and near the linear stiffener and 9.345 mm on the stiffened floor. The observed stress and displacement increments are not sufficient to warrant additional stiffening, and in real configurations they are expected to be further reduced due to the non-perfectly rigid interaction between the structural frames and the membrane.

Conclusion

This study presented the conceptual design and preliminary structural and habitability assessment of a pressurized, inflatable, and deployable lunar habitat. Among the configurations analyzed, the cylindrical geometry proved most efficient in terms of mass, modularity, and stress distribution. Finite element simulations confirmed the structural adequacy of the membrane and floor under combined pressurization and thermal loads. The habitability evaluation validated the internal configuration for a two-astronaut crew. Future work will focus on dynamic simulations using LS-DYNA, experimental tensile testing of fabric materials to derive stress-strain curves to insert in numerical solvers, and experimental validation on scaled prototypes.

Keywords: Titan, Hypersonic Flows, Thermochemical Non-Equilibrium, Multi-Temperature, State-to-State

Abstract. This work shows the development and verification of a model for the simulation of an atmospheric entry on Titan in non-equilibrium conditions. Park's and Nelson's multi-temperature approaches are tested on a literature test case for a neutral mixture and Park's model is also verified for a charged mixture to evaluate the effects of ionization. Finally, a state-to-state model is used for further verification on the neutral mixture.

Introduction

Titan, Saturn's largest moon, has a dense atmosphere characterized by the presence of organic compounds, making it a key target for exploration. Atmospheric entry, however, remains a fundamental problem since the hypersonic entry speed, together with the extreme pressure and heat generated, may exceed material limits. To predict heating and behavior of the vehicle, the developed hypersonic non-equilibrium flow must be characterized.

An accurate model should account not only for gas dynamics but also for processes like dissociation, vibrational and electronic excitation, ionization and radiation [1] and for imbalances in translational, rotational, vibrational and electronic temperatures. For this reason, a thermochemical model is introduced, such as the multi-temperature (mT) or the state-to-state (StS) models: the first characterized by high efficiency, the second by accuracy [2]. In particular, the State-to-State model provides an accurate description of vibrational and electronic excitation by treating each internal state of the most relevant particles as a pseudo-species and formulating a continuity equation for each of them, while the multi-temperature model considers each molecule globally and represents the internal energy distribution using different characteristic temperatures, adding a vibro-electronic energy transport equation for each particle in the mixture [3, 4].

As regards the solver, the multi-GPU code developed by Politecnico di Bari in collaboration with the Istituto per la Scienza e Tecnologia dei Plasmi (ISTP) of CNR in Bari was employed [5]. The finite volume solver applies a second order Runge Kutta scheme to the system of equations, while space discretization is performed by a Steger and Warming flux vector splitting, together with a second order MUSCL reconstruction.

To verify the model and its applicability to atmospheric entry applications, simulations carried out by NASA [6] were used as test case.

Test Case

Simulations were performed on a two-dimensional geometry reproducing half of an axisymmetric, 3.75 m wide, capsule profile entering the atmosphere at an altitude of 269 km.

Materials Research Proceedings 69 (2026) 1283-1286 https://doi.org/10.21741/9781644904251-222

In the case of a neutral mixture, 12 species have been considered (N, N_2, C, C_2, H, H_2, CN, NH, CH, CH_2, CH_3, CH_4), whereas 18 species (N_2^+, CN^+, C^+ N^+, H^+, e^- in addition to the neutral mixture) have been included for the ionized mixture. In both cases the freestream flow is composed of molecular nitrogen at 95% and methane at 5%. Capsule velocity and atmosphere characteristics are shown in Table 1 together with the estimated Mach number.

Table 1 Test case flow characteristics

Velocity [m/s]	Pressure [Pa]	Temperature [K]	Density [kg/m^3]	Mach
5761	6.91	152.7	1.491 x 10^{-4}	22.7

A super catalytic wall condition was imposed to replicate the configuration of the NASA test case where the gas composition on the wall is set exactly equal to the freestream mixture composition. This was done by imposing recombination of N_2 and CH_4 at wall and solving mass balance to evaluate catalysis source terms.

Results

Code verification was carried out by considering the neutral mixture for both Park's and Nelson's multi-temperature models, with the resulting profiles compared against literature data. The main difference between the two models for the neutral mixture lies in the dissociation-recombination reactions of Nitrogen: where Nelson's model considers collisions with any species in the mixture, Park's reactions only consider collisions with N_2 and N. Regarded as the most consistent with the underlying physics [6], only Park's model was used to simulate the ionized mixture. Finally, to verify the model against the state-to-state model, given the high concentration of nitrogen in the mixture, the test was carried out on a pure nitrogen mixture N_2-N to ease calculations.

Fig. 1 shows a temperature contour plot, providing a good overall agreement with the reference solution [6], especially in terms of shock standoff distance.

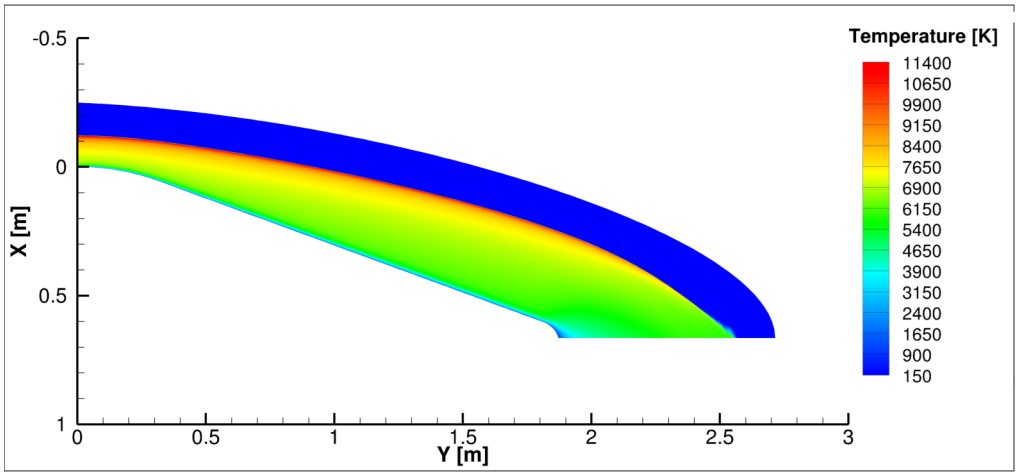

Figure 1 Temperature contour obtained using Park's model with the neutral mixture

This is confirmed by the temperature profiles on the stagnation line of Fig. 2 (left). The higher mesh resolution used in this work at the location of the shock wave allows for a better capture of the discontinuity and thus justifies the difference in heat flux between the simulated models and the reference, in Fig. 2 (right). Furthermore, the temperature relaxation zone downstream the shock is in good agreement with the reference data showing an overall goodness of the model.

Materials Research Proceedings 69 (2026) 1283-1286 https://doi.org/10.21741/9781644904251-222

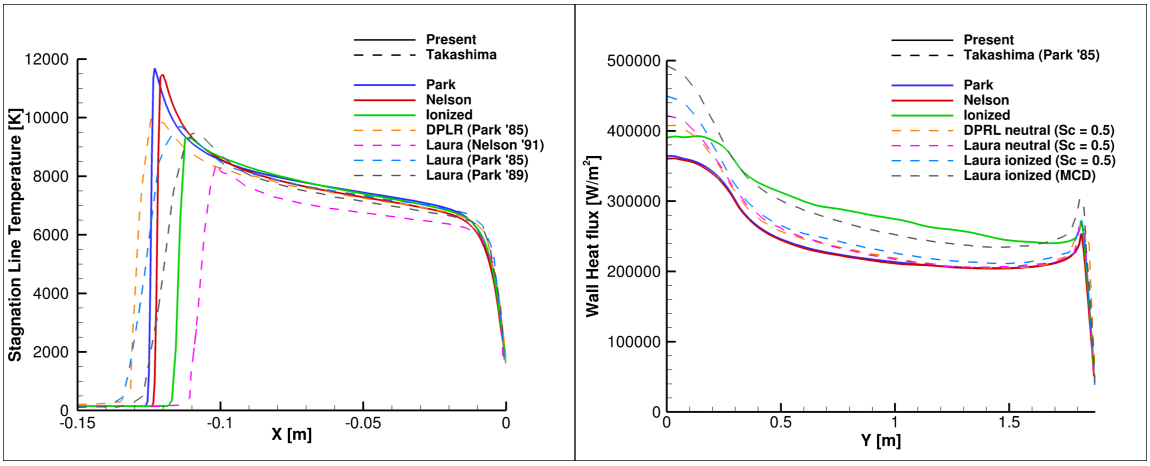

Figure 2 Comparison in terms of stagnation line temperature profile (left) and wall heat flux (right) with the reference [6]

The neutral mixture shows a higher peak temperature and a lower heat flux with respect to the ionized mixture, due to the major absorption of energy in the ionization reactions and the energy release on the wall during recombination.

Results demonstrate an overall agreement between Nelson's and Park's model, with a slight reduction in shock standoff distance, while the reference profiles show a much more significant difference. However, given the high concentration of nitrogen in the mixture, the agreement between the two models is considered consistent, since nitrogen collisions with other species have a lower statistical impact.

Fig.3 shows the comparison between results obtained with Park's model by considering both the twelve species mixture and the binary N_2-N mixture. This was mainly intended to analyze the influence of the species other than molecular and atomic nitrogen on the flow development, and to verify the feasibility of the subsequent test using the state-to-state model with the binary mixture.

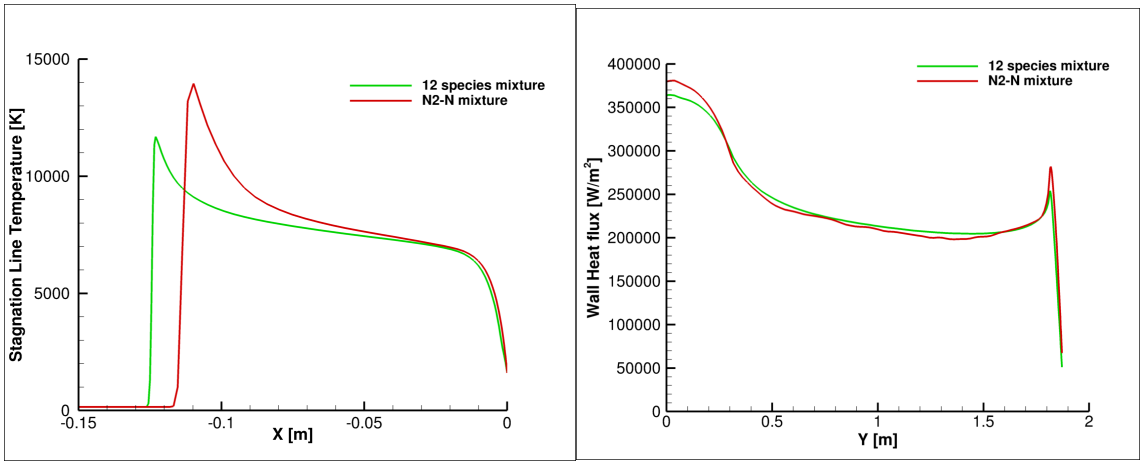

Figure 3 Comparison between the twelve species mixture and the N_2-N mixture

Fig. 4 shows the same quantities, for the binary mixture, comparing the multi-temperature and the state-to-state models, both in case of no wall catalysis. A good overall agreement is shown, although the different approach of the StS to non-equilibrium results in a small difference in terms of shock standoff distance (3%) and wall heat flux (7.5%) since the latter is strongly influenced by shock position and reactions involved.

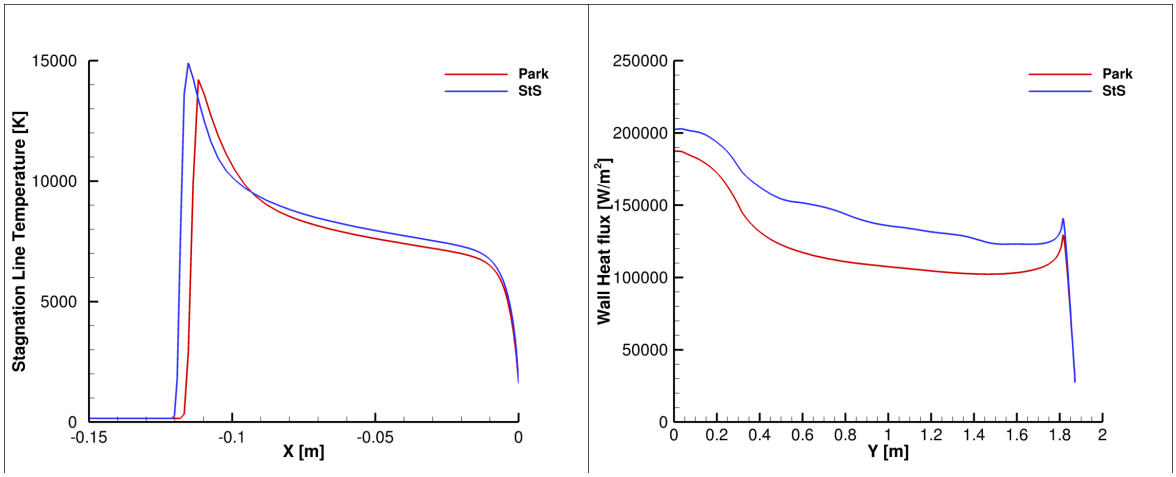

Figure 4 Comparison between Park's and the StS models using the N_2-N mixture

Conclusions

In this work, the implemented multi-temperature model was verified by simulating the atmospheric entry of a capsule into Titan's atmosphere, demonstrating its capabilities to handle realistic two-dimensional cases under complex scenarios, in hypersonic and thermochemically non-equilibrium conditions.

Ionization effects were also considered, and the implemented Park's model was further compared against the reaction rates proposed by Nelson. Finally, additional verification was performed using the results from the state-to-state model.

Keywords: Vibration-Based Monitoring, Modal Damping, Delamination, Structural Health Monitoring, Nonlinear Dynamics

Abstract. This study presents a nonlinear vibration-based framework for early damage identification in viscoelastic sandwich structures with interfacial delamination. Unlike conventional frequency-based indicators, the proposed approach exploits changes in modal damping, which exhibit higher sensitivity to small and localized defects. Both global damping effects arising from the viscoelastic core and local dissipation due to frictional contact at delaminated interfaces are modeled within a combined time–frequency domain analysis. Nonlinear phenomena, including superharmonic responses, are explicitly captured to improve agreement with experimentally observed behavior. The results demonstrate that pseudo-modal damping parameters provide a robust and reliable indicator for detecting early-stage interfacial damage.

Introduction

In vibration-based structural health monitoring (VHM), traditional global dynamic features such as shifts in natural frequencies are commonly used as damage indicators [1,2]. Frequency shifts usually result from localized reductions in stiffness caused by damage mechanisms such as delamination or cracking. However, these indicators exhibit limited sensitivity to small damage sizes. This reduced sensitivity depends not only on the severity of the defect but also on its location relative to the mode shape. In particular, sensitivity is significantly diminished in regions of low strain energy or near nodal points [3]. As a consequence, damage may remain undetected until it progresses to a more advanced stage, thereby reducing the reliability of frequency-based indicators. These limitations are even more pronounced in sandwich structures, where interfacial damage often induces negligible changes in natural frequencies during the early stages of degradation.

Sandwich structures typically consist of viscoelastic (VE) cores bonded between stiff composite or metallic face sheets and are widely used in aerospace engineering due to their high stiffness-to-weight ratios, excellent damping characteristics, and high flexural rigidity [4,5]. The combination of a soft, energy-dissipating core and high-modulus outer layers provides optimized performance under both dynamic and static loading conditions, making these structures particularly suitable for lightweight panels, control surfaces, and vibration-sensitive components [6]. Nevertheless, their structural performance can be severely affected by interfacial delamination, which is one of the most common damage mechanisms in such systems. Delamination alters both local and global dynamic characteristics, while nonlinear behavior arising from frictional contact within the delaminated regions further complicates the prediction and assessment of the dynamic response.

Materials Research Proceedings 69 (2026) 1287-1291 https://doi.org/10.21741/9781644904251-223

In comparison with frequency shifts, modal damping has recently attracted increasing attention as a more damage-sensitive feature, particularly for the detection of early-stage defects [7, 8]. Even small delaminations or localized interfacial damage can lead to significant changes in damping behavior by modifying the mechanisms through which energy is dissipated. This makes damping a promising parameter for vibration-based condition assessment. However, the reliable estimation of modal damping remains challenging, especially in the presence of nonlinear effects. In delaminated sandwich structures, localized mechanisms such as interfacial friction introduce nonlinear phenomena that often manifest as superharmonics or amplitude-dependent responses [9]. These effects complicate the interpretation of vibration data and frequently prevent standard numerical models from accurately reproducing experimentally observed damping trends. Most conventional simulations rely on linear assumptions and therefore fail to capture the complexity of dissipation mechanisms in damaged layered systems.

This paper presents a numerical framework for modeling both global damping effects associated with the viscoelastic behavior of the core and local damping effects induced by frictional contact at delaminated interfaces. To this end, a combined time–frequency domain workflow is developed that accounts for the nonlinear behavior resulting from contact and friction. The proposed approach enables damage identification through modal parameters such as damped natural frequency and pseudo-modal damping, evaluated for the fundamental mode and its first two superharmonics.

Finite Element Model and Numerical Validation

To demonstrate the proposed approach, the sandwich structure shown in Fig. 1 was selected as the case study. The specimen consists of two elastic face sheets bonded to a viscoelastic core, forming a typical sandwich beam configuration with clamped–free boundary conditions. The geometric dimensions and mechanical properties of the beam are summarized in Table 1 [10].

Table 1: Beam Dimensions and Material Properties.

Property	Unit	Elastic Faces (Metal)	VE Core (3M ISD112)
Young's Modulus (E)	GPa	69	0.1523
Density (ρ)	kg/m³	2766	1600
Poisson's Ratio (ν)	–	0.30	0.49
Length (L)	mm	177.8	177.8
Width (b)	mm	12.7	12.7
Thickness (h)	mm	1.524	0.127

Figure 1 illustrates the schematic representation of the sandwich beam subjected to an applied sweep force, along with a detailed cross-sectional view of its layered construction. The face sheets are assumed to behave elastically, while the core exhibits viscoelastic behavior. The viscoelastic properties of the core were incorporated into the model through Prony series coefficients associated with the frequency-dependent shear modulus. A finite element model of the pristine beam was developed and validated by computing its damped natural frequencies using the numerical workflow proposed in [10]. The obtained results were then compared with available analytical solutions and previously reported numerical and experimental studies, showing good agreement and confirming the accuracy of the modeling approach.

Materials Research Proceedings 69 (2026) 1287-1291 https://doi.org/10.21741/9781644904251-223

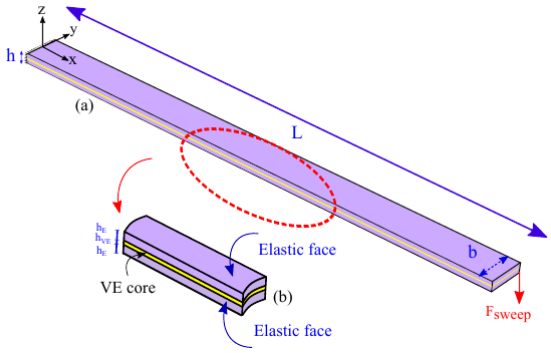

Fig. 1: (a) Schematic of the sandwich beam under the applied sweep force with clamped-free boundary conditions (BCs). (b) The cross-sectional view detailing the layered construction consists of elastic face sheets and a V E core [10]

Numerical Results

Debonding was modeled by decoupling the FE nodes in the delaminated region while maintaining their coincident spatial positions. This allows relative motion be tween the separated substructures, effectively simulating frictional contact. As shown in Fig. 2, 20% of the core-face interface is debonded (highlighted in color). By varying the lamination thickness and the damage offset from the neutral axis, the effects on the frequency response function (FRF) peaks and hysteresis loop area were investigated. A time-varying sinusoidal force covering the first five natural frequencies was applied to the structure. By varying the lamination thickness and the offset of the damaged region from the neutral axis, the effects on the frequency response function (FRF) peaks and the hysteresis loop area were systematically investigated.

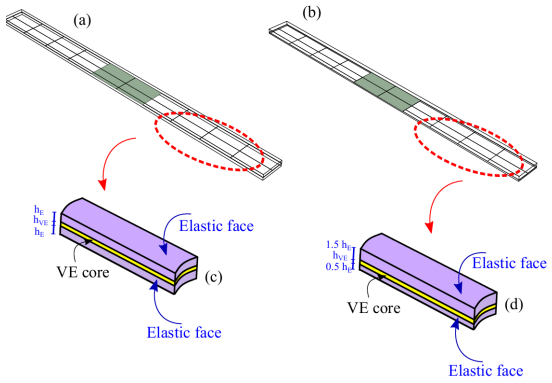

Fig. 2: Beam layup and delamination pattern for the (a,c) symmetric and (b,d) asymmetric configurations

Figure 3 presents the point FRFs of the pristine and delaminated configurations. The results indicate that symmetric delamination mainly affects the third and fourth resonant peaks, which is consistent with its location near the turning points of the corresponding mode shapes. In contrast, the asymmetric delamination, due to its off-center position, exhibits a broader influence across the resonant peaks. This observation highlights the critical role of delamination location in assessing structural integrity and dynamic behavior.

Figure 4 illustrates the force–displacement hysteresis loops for the first three superharmonics and the corresponding percentage change in loop area when the delamination is shifted away from the mid-axis. At lower frequencies, an increase in the hysteresis loop area indicates the dominance of frictional damping mechanisms. Conversely, at higher superharmonics, namely the second and third for the symmetric configuration and the third for the asymmetric configuration, the observed

Materials Research Proceedings 69 (2026) 1287-1291 https://doi.org/10.21741/9781644904251-223

reduction in loop area suggests that motion constraints induced by delamination limit the overall damping, despite the presence of frictional effects. Furthermore, off-center (asymmetric) delamination tends to sustain contact-induced damping at higher frequencies due to increased interfacial slip and more complex modal interactions. In contrast, symmetric delamination exhibits stronger motion constraints in these frequency ranges.

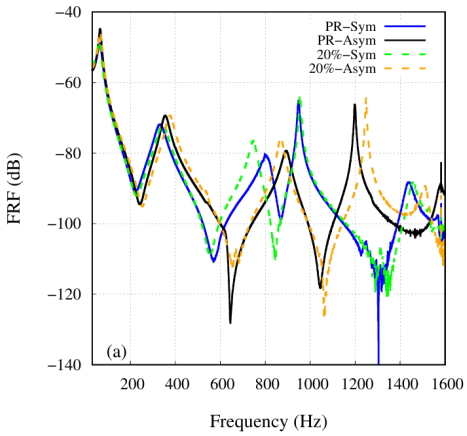

Fig. 3: Point-FRF of the structure symmetric and asymmetric layup, relative to the neutral axis for 20% delamination along the width in the interface (shown in highlighted in Fig. 2)

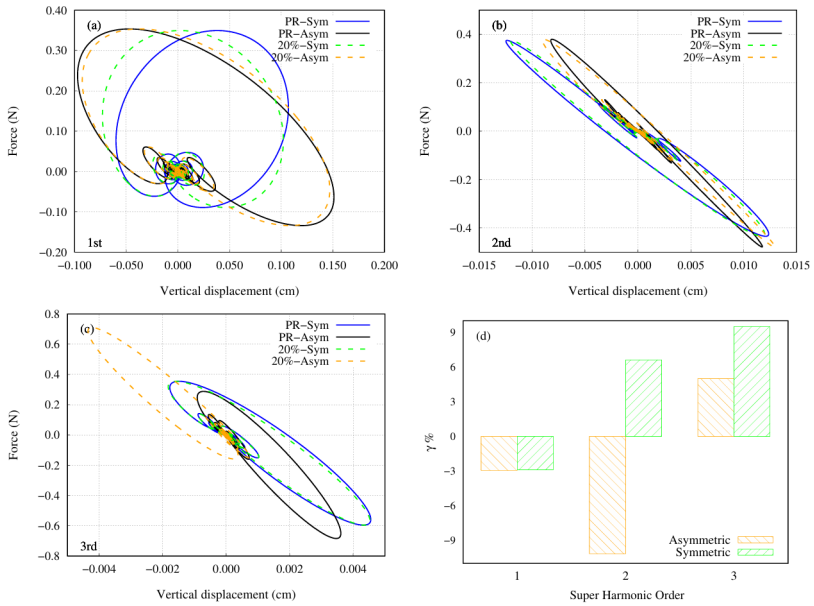

Fig. 4: Force-displacement loops at the excitation point for the first three superhar monics (a-c), comparing pristine, asymmetric, and symmetric layups. The percent age change in the hysteresis loop area (γ) for the reference case with the pristine state is shown in (d).

Overall, the offset of the delamination from the mid-axis plays a crucial role in determining the balance between frictional damping and motion-restricting mechanisms within the structure.

Conclusion

This study introduced a numerical framework for modeling modal damping induced by nonlinear mechanisms such as contact and friction, thereby overcoming the limitations of conventional linear-based approaches. The results demonstrate that these nonlinear interactions generate

distinctive dynamic features, including superharmonics, and produce clearer dissipation-related signatures in the fundamental frequency range. The findings further confirm that modal damping is significantly more sensitive to damage than traditional modal parameters, such as natural frequency. In summary, the proposed framework highlights the strong potential of modal damping as a reliable indicator for the detection of early-stage damage in delaminated structures.

Abstract. Interfacial debonding in layered composite structures introduces localized nonlinearities that can significantly alter their dynamic response. This study investigates the vibrational behavior of debonded structures under sine-sweep and random excitations, with particular emphasis on contact and friction effects between separated layers. Statistical indicators such as root mean square, along with energy-based measures, are employed to characterize response variability and dissipation mechanisms. The results highlight the influence of excitation type on revealing nonlinear damage signatures and provide insights for improved modeling and structural health monitoring of bonded composite systems.

Introduction

Composite panels and adhesively bonded joints are widely used in aerospace engineering due to their high stiffness-to-weight and strength-to-weight ratios. A key challenge in such structures is interfacial debonding, which occurs when bonded layers separate because of manufacturing defects, cyclic fatigue, or impact [1]. Even small debonded regions can alter the mechanical and dynamic behavior of the structure, introducing nonlinear effects primarily through local contact and friction between the separated layers [2–4]. These effects can change stiffness, damping, and energy dissipation, and may significantly influence the overall vibratory response, complicating both analysis and damage detection.

Understanding these nonlinearities requires studying structural responses under both deterministic and stochastic excitations. Deterministic inputs, such as sine sweeps, are commonly used in modal testing to track resonance frequencies and mode shapes [5], while stochastic excitations better represent real operational environments dominated by turbulence, engine noise, and aerodynamic fluctuations [6].

In this study, we compare the dynamic response of layered structures with interfacial debonding under sine-sweep and random excitations. The analysis focuses on the role of contact and friction between separated layers, using statistical measures such as crest factor (CF) and root mean square (RMS) to characterize amplitude variations and response quality [7]. Energy parameters, including strain energy and frictional dissipation, are also examined to assess how excitation type influences energy flow and system stability.

The goal is to clarify how different excitations reveal local nonlinear effects in debonded regions and to quantify the differences in response. These insights can guide the development of predictive models and monitoring strategies for high-performance layered structures.

Excitation Methods and Signal Characterization

Two types of excitations were applied to the delaminated structure: a logarithmic sine sweep and a broadband random force. Both were applied as time-dependent point loads at the tip for 2 s, sampled at 5000 Hz, ensuring 8000 discrete steps. The spectral content and RMS level of the random signal were matched to the sine sweep (0–2500 Hz), allowing a fair comparison of their effects on the nonlinear dynamic response. Sine Sweep Excitation. A logarithmic sine sweep was used to systematically excite the structure across a wide frequency range. This deterministic excitation effectively activates fundamental and harmonic modes, revealing nonlinear responses such as amplitude-dependent stiffness and damping [8]. Random Excitation. Aband-limited Gaussian random signal was generated to match the spectral and RMS properties of the sine sweep. By providing equivalent energy input, differences in structural response can be attributed to the deterministic versus stochastic nature of the excitations rather than to power or frequency content [9, 10]. Figure 1 compares the power spectral densities and integrated energy of the two excitations, showing equivalent bandwidth and energy levels, which ensure a consistent basis for evaluating nonlinear effects.

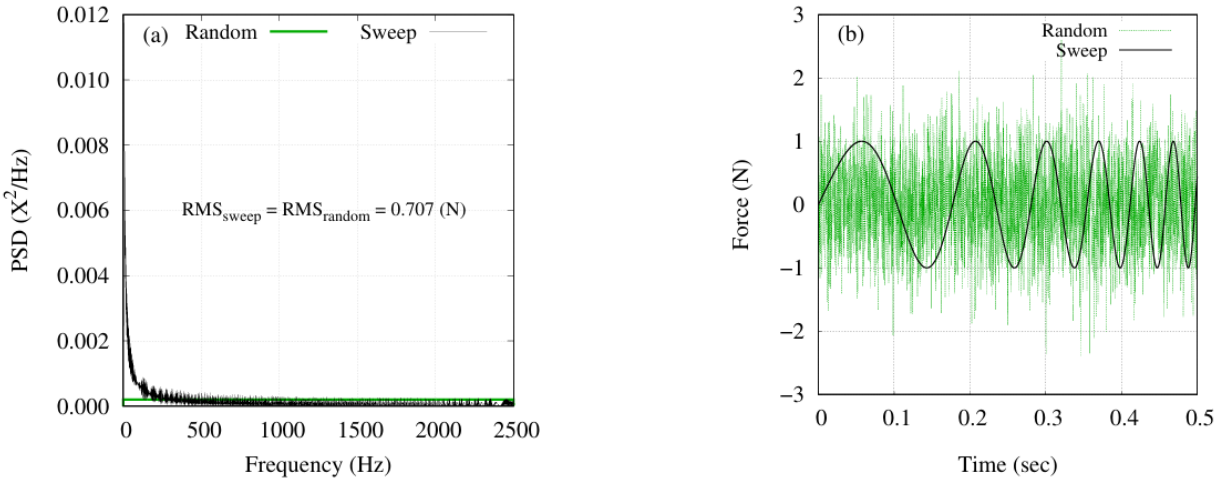

Fig. 1: (a) PSD comparison of sine-sweep and random excitations with equal RMS level. and integrated energy (b) of the sine sweep and RMS-matched random excitation signals. (b) Zoomed-in view of the two signals over 0.5 seconds

Finite Element Model and Numerical Validation

Finite Element Model and Numerical Validation In this work, a simple two-layer finite element (FE) model with clamped-free boundary conditions was developed to study the behavior of laminated beams undergoing debonding. To capture the detailed structural response, the beam was modeled as a three-dimensional solid and discretized using linear hexahedral (C3D8) elements, with small deformation assumed, as illustrated in Fig. 2.

Materials Research Proceedings 69 (2026) 1292-1297 https://doi.org/10.21741/9781644904251-224

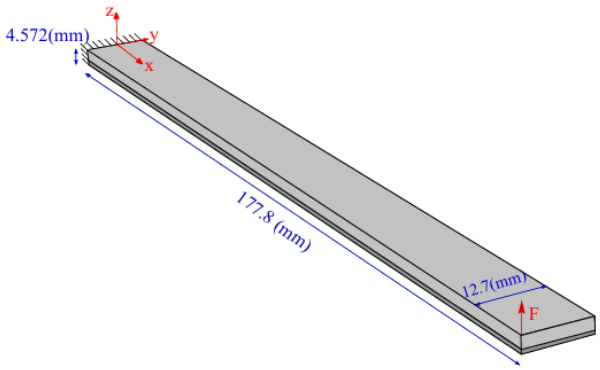

Fig. 2: Two-layered beam, boundary conditions (BCs) and excitation point [11].

The material and geometric parameters follow those used in [4], from which the time–frequency algorithm and overall computational workflow were also adapted. Interfacial debonding was simulated by separating coincident nodes in the debonded area, allowing for relative motion and frictional interaction between the layers. Having established the modeling approach, we now present results for the pristine structure. Figure 3 compares FRF1 and FRF2 for the pristine structure under sweep and random excitations. The FRF peaks in Fig. 3 coincide with the natural frequencies obtained from the FE modal analysis. This coincidence confirms the validity of both the numerical model and the solution workflow described in the authors' prior research [4].

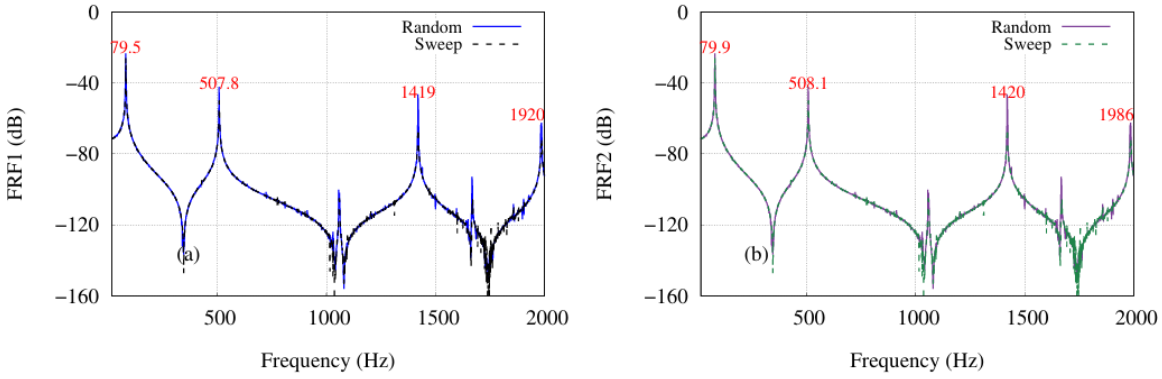

Fig. 3: Point FRF1 and FRF2 of the pristine structure under random and sine-sweep excitations [11].

Figure 4 shows the amplitude spectrum of the vertical displacement (a) and the relative frictional slip (b) of a node located at the center of the damaged region. To assess the frictional nonlinearity [12] at the delaminated interface, one-period friction–slip loops were extracted at the instant of maximum friction for the fundamental frequency and its superharmonics. These loops were consistently extracted at the same instant of maximum friction, enabling a direct comparison between random and sweep excitations. The resulting loops are shown in Fig. 5.

Materials Research Proceedings 69 (2026) 1292-1297 https://doi.org/10.21741/9781644904251-224

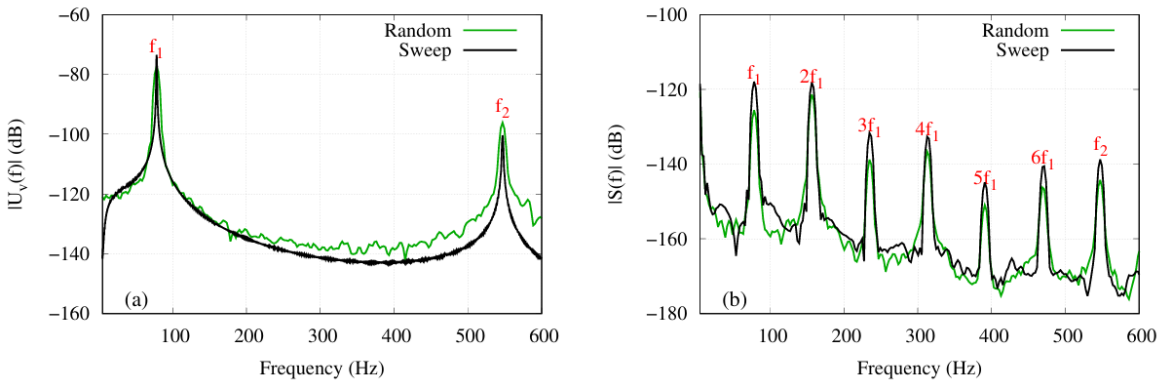

Fig. 4: amplitude spectrum of the vertical displacement (a) and the relative frictional slip (b) of a node located at the center of the damaged region. To assess the frictional nonlinearity at the delaminated interface.

At the fundamental frequency, the loops obtained under both excitation types are almost identical. This indicates that the system behaves nearly linearly and that only a small amount of microslip occurs at the interface. When moving to the first superharmonic ($2f_1$), the slip amplitude becomes noticeably larger; however, the loops corresponding to random and sweep excitations still overlap closely. This suggests that the interface has already entered a saturation-like state in which friction is fully engaged, rendering the response insensitive to how the input energy is distributed across frequencies, even though both excitations have the same RMS level.

Conclusion

This study aims to compare the ability of stochastic and deterministic excitation signals to reveal local nonlinearity effects due to damage. The results demonstrate that even when random and deterministic excitations have the same RMS energy, their responses begin to differ once higher harmonics are examined. At these harmonics, the broadband nature of the random input makes it more effective at exposing localized frictional and slip-related nonlinearities than a sweep signal. When the slip becomes large, however, the difference between the two excitations diminishes, meaning the response is governed mainly by the interface properties themselves. Overall, the way the two excitation types diverge and converge across harmonics provides a clear indicator of damage-related nonlinearities and highlights why excitation choice matters for detecting and characterizing delaminated interfaces.

Keywords: Fatigue Life, Composite Structures, CUF, Gust

Abstract. This work presents a framework for predicting the fatigue life of a composite aircraft wing under von Kármán gust spectrum loads. The approach integrates the Carrera Unified Formulation (CUF) for high-fidelity structural modeling with Dirlik's frequency-domain method for fatigue estimation. The influence of turbulence intensity and scale on fatigue life is examined, demonstrating that the proposed CUF-based method offers an accurate and computationally efficient tool for early-stage design of composite aerospace structures.

Introduction

Fatigue failure remains a major concern in aerospace structures due to the complex and stochastic nature of in-flight loading [1]. Aircraft wings are continuously subjected to random aerodynamic excitations from turbulence and gusts, leading to variable stress histories and cumulative damage. With the increasing use of lightweight composite materials, accurate and efficient fatigue life prediction methods are becoming essential.

Atmospheric turbulence, influenced by climate variability, can alter its intensity and spatial characteristics [2], affecting the fatigue load spectra experienced during flight. Hence, fatigue models must account for a broad range of stochastic gust environments.

Traditional time-domain fatigue analyses, though accurate, are computationally demanding for broadband random loads [3]. Frequency-domain methods, such as Dirlik's approach [4], offer a more efficient alternative by relating fatigue damage directly to the power spectral density (PSD) of the load.

In this study, a CUF-based framework [5] is proposed to predict the fatigue life of a composite aircraft wing subjected to von Kármán gust spectrum loads. The methodology includes: (i) definition of the case study and loading condition, (ii) structural modeling via CUF, (iii) evaluation of the PSD of the most stressed region following [6], and (iv) application of Dirlik's method for fatigue life estimation.

Structural theories: Carrera Unified Formulation

The one-dimensional (1D) model employed in this study is formulated within the Carrera Unified Formulation (CUF) framework. The three-dimensional displacement field of a solid plate can be represented as a general expansion of the generalized displacements, expressed as the product of a one-dimensional shape function, $N_i(y)$, and a two-dimensional expansion function, $F_\tau(x,z)$.

$$\mathbf{u}(x,y,z) = F_\tau(x,z) N_i(y) \mathbf{u_{\tau i}} \qquad \tau = 1,\ldots,M \qquad i=1,\ldots, p \qquad (1)$$

where $F_\tau(x,z)$ is the expansion function modelling the displacement field over the cross section, and its order depends on the parameter M. The vector $\mathbf{u_{\tau i}}$ is the nodal displacement unknown vector, and p is the number of nodes of each element. The results of this work are obtained using

both Lagrange (LE) and Taylor (TE) expansion allowing different levels of kinematic refinement to be achieved according to the desired balance between model accuracy and computational efficiency.

Methodology

The proposed methodology for fatigue life estimation is organized in two main stages: (i) load assessment, where the aerodynamic load spectrum induced by turbulent wind is determined, and (ii) fatigue estimation, where the structural stress response and the resulting fatigue life are evaluated. The full workflow is shown in Fig. 1.

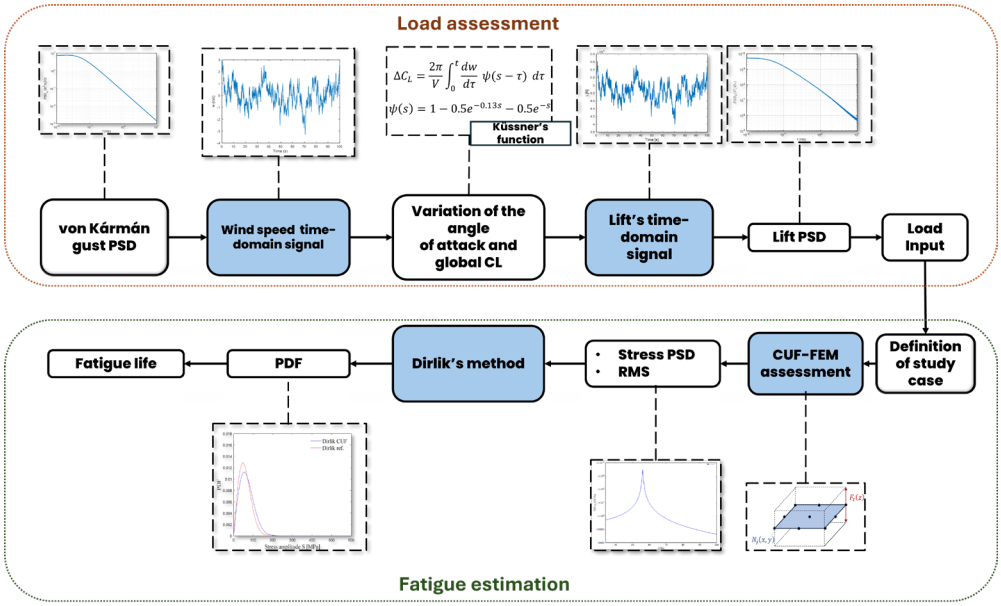

Figure 1. Methodological framework for load assessment and fatigue life estimation.

The gust PSD is defined according to the von Kármán turbulence model, which depends on two key parameters: σ, the root mean square of the gust velocity representing the intensity and L, the turbulence scale length, representing the characteristic size of the gust. The von Kármán spectrum is expressed as:

$$PSD_{vk}(f)=\frac{\sigma^2 L}{\pi V}\frac{1+\frac{8}{3}\left(1.339\frac{2\pi L}{V}f\right)^2}{\left[1+\left(1.339\frac{2\pi L}{V}f\right)^2\right]^{\frac{11}{6}}} \tag{2}$$

Once the gust PSD is defined, a time-domain gust velocity signal can be obtained by applying the inverse Fourier transform. To evaluate the unsteady aerodynamic response of the wing to this gust, Küssner's model is employed [7]. Specifically, it describes the time-dependent lift response of a two-dimensional airfoil to a vertical gust of arbitrary shape. The corresponding expression for the variation of the lift coefficient is given by:

$$\Delta c_L=\frac{2\pi}{V}\int_0^s \frac{dv_g}{d\tau}\psi(s-\tau)\ d \tag{3}$$

Materials Research Proceedings 69 (2026) 1298-1303 https://doi.org/10.21741/9781644904251-225

where V is the undisturbed free-stream velocity, v_g is the vertical component of the gust velocity, $\psi(s-\tau)$is the Küssner function, representing the aerodynamic lag response. s is the reduced time, defined as $s = \frac{Vt}{c}$ with t being the physical time and c the airfoil chord length. The derivative $\frac{dv_g}{d\tau}$ represents the rate of change of the gust velocity, which drives the unsteady lift response, while $\psi(s-\tau)$ acts as a weighting function describing how past gust inputs influence the instantaneous lift through aerodynamic memory effects. The Küssner function is typically approximated using the expression:

$$\psi(s)=-0.5e^{-0.13s}-0.5e^{-s} \quad (4)$$

By applying this formulation, it is possible to compute the time history of the lift coefficient variation induced by the gust and, consequently, to derive the corresponding lift PSD. It is worth noting that Eq. 3 is valid for the single airfoil, so to derive the lift coefficient variation of the entire wing, the geometrical (e.g. aspect ratio) and aerodynamic parameter (e.g. Oswald factor) of the wing has to be known in advance. In this case, we considered that same variation of the lift coefficient for both airfoil and wing, aware that a reduction factor should be considered.

The structural response of the component to the aerodynamic loading is evaluated using a CUF–FEM model. The lift load obtained in the first step is applied to the structural model to compute the dynamic stress response. The power spectral density (PSD) function of the stress $\boldsymbol{G}_{\sigma_j}(f)$ is computed by using lift input PSD function $\boldsymbol{G}_{\boldsymbol{F}}(f)$ and the system transfer function $\boldsymbol{H}(f)$:

$$\mathbf{G}_{\boldsymbol{\sigma_j}}(f)=\overline{\mathbf{H}_{\boldsymbol{\sigma_j}}}(f)\mathbf{G}_{\mathbf{F}}(f)\mathbf{H}^{\mathbf{T}}_{\boldsymbol{\sigma_j}}(f) \quad j=1,\ldots,6 \quad (5)$$

where$\overline{\boldsymbol{H}_{\sigma_j}}(f)$ and $\boldsymbol{H}^{\boldsymbol{T}}_{\sigma_j}(f)$ are the complex conjugate and the transpose of this function. By using the Tsai-Hill criterion is used to provide a satisfactory description of the relationship between multiaxial stresses and to compute $G_{\sigma_{eq}}(\omega)$, as described in [8].

The next step involves the use of Dirlik's method, which provides an analytical estimate of the probability density function (PDF) p(S) of stress range amplitudes directly from the stress PSD:

$$p(S)=\frac{1}{\sqrt{m_0}}\left[\frac{B_1}{Q}e^{-Z}+\frac{B_2 Z}{T^2}e^{-\frac{Z^2}{2T^2}}+B_3 Z e^{-Z^2}\right] \quad (6)$$

where $m_i=\int_0^\infty f^i G_\sigma(f)\,df$ are the spectral moments, as described in [9]. Finally, the stress range PDF is combined with the material S–N (Wöhler) curve to evaluate the fatigue life T:

$$T=\frac{1}{\nu\int_G^\infty \frac{p(S)}{N(S)}\,dS} \quad (7)$$

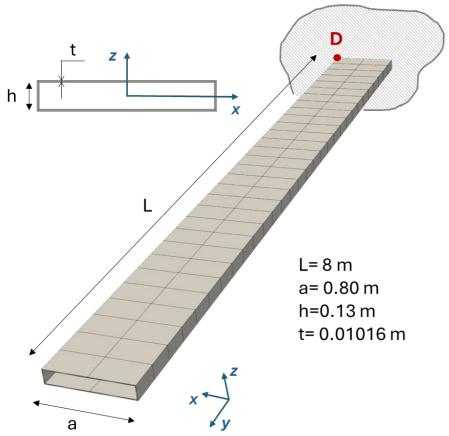
where $\nu=\frac{1}{2\pi}\sqrt{\frac{m_2}{m_0}}$ is the number of the stress cycles in a unit of time and N(S) is the S-N curve of material.

Results

Fatigue life analysis is performed on a clamped-free composite box beam structure that approximates a wing model of the Pilatus PC-12 aircraft (8 × 0.80 × 0.13 m, thickness of 0.01016

Materials Research Proceedings 69 (2026) 1298-1303 https://doi.org/10.21741/9781644904251-225

m), as illustrated in Fig. 2. The material properties are derived from [6], in which a unidirectional (0°) composite is under consideration.



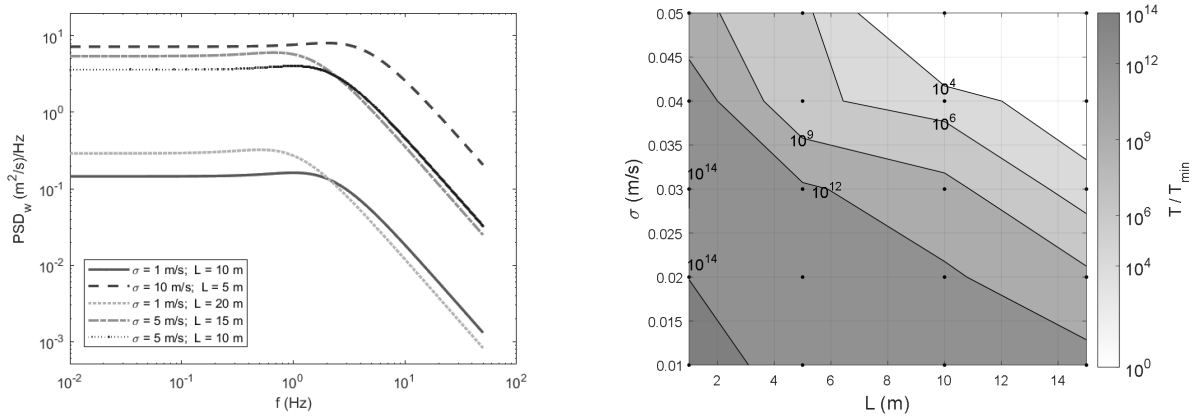


Figure 2. Geometry and mesh of box beam.

Firstly, a modal analysis identified the TE7 expansion as the most suitable CUF model, ensuring good agreement with FEMAP/NX results, as in Table 1. Along the longitudinal direction, 30 four-node beam elements are employed. Across the cross-section, the displacement field is expanded using TE1, TE3, TE6, TE7, TE8, and 12-LE9 functions. In Fig. 3a, the von Kármán gust PSDs are shown as function of turbulence intensity σ and the integral scale length L. These represent the load inputs employed to obtained the fatigue response depicted in Fig. 3b, where the iso-curves of the normalized fatigue life T/T_{min} as function of the von Kármán turbulence parameters σ and L are plotted: lighter shades denote longer life, darker shades shorter life. The contour map shows that the normalized fatigue life T/T_{min} is primarily governed by the turbulence intensity σ, with higher leading to a drastic reduction in life over several orders of magnitude. The influence of the integral scale length L is weaker and non-monotonic: for low turbulence levels, the longest lives are obtained for small scales ($L < 4$ m), while increasing L beyond this range results in a progressive decrease of T/T_{min}.

Table 1. First five natural frequencies for the composite box beam with different expansion functions for CUF and comparison with 2D FEMAP/NX model

Model	f_1 (Hz)	f_2 (Hz)	f_3 (Hz)	f_4 (Hz)	f_5 (Hz)
CUF 12-LE9	5.6	16.4	22.3	24.7	31.4
CUF TE1	6.2	22.9	36.7	41.9	91.4
CUF TE3	5.9	22.3	22.1	28.4	63.2
CUF TE6	5.6	20.2	22.3	24.9	52.1
CUF TE7	5.5	18.6	22.3	23.8	41.6
CUF TE8	5.5	18.6	22.3	23.2	40.7
FEMAP/NX	5.4	19.1	22.3	22.5	47.7

(a) Gust PSD varying parameters (b) Fatigue life varying gust parameters

Figure 3. Effect of the von Kármán gust parameters on a) gust PSD and b)the iso-curves in logarithmic scale of the normalized fatigue life T/T_{min}.

Conclusions

The CUF-based framework accurately predicts the fatigue life of composite wings under von Kármán gust loads. Results show that turbulence intensity strongly affects fatigue life, while the scale length has a secondary, non-monotonic influence. As future developments, the proposed approach will be refined and extended to improve its applicability and robustness for early-stage fatigue assessment of composite aerospace components.

Abstract. In this paper, a detailed locking analysis of novel curvilinear finite element models for the analysis of shells is proposed. In the introduced methodology, novel higher-order shell models are proposed in a non-orthogonal reference frame, recovering the classical Cartesian description via a consistent transformation law. The shell models are defined within the well-established Carrera Unified Formulation (CUF) framework, by which Lagrange-based theory of structures are merged with classical finite element interpolation of the reference mid-surface, obtaining novel shell elements with enhanced three-dimensional geometrical modeling capabilities. By exploiting the computational efficiency of 2D models, these novel 2|3D elements are now being adopted in locking investigations to assess the accuracy and capabilities of the proposed approach when complex structural problems are addressed. The methodology is validated by analyzing classical numerical benchmarks and patch tests proposed in the literature.

Introduction

Modern aeronautical structures, increasingly complex due to performance, weight, and material innovations, demand advanced numerical modeling techniques [1] since numerical simulations have become essential in aerospace structural analysis [2]. Generally, conventional finite element formulations are used to model thick, curved, and variable-thickness components typical of aircraft structures [3]. To overcome the limitations of classical approaches, such as the limited superimposed theory of structures or hexahedral models' aspect-ratio constraints, novel shell models incorporating geometric variation and complex boundary conditions are being developed to improve accuracy and efficiency in modeling components [4]. This work presents a novel class of 2|3D fully curvilinear shell finite elements derived within the framework of Carrera Unified Formulation (CUF) [5], under the Node-Dependent Kinematics (NDK) approach [6]. The proposed framework integrates the three-dimensional shell description into the element formulation within a rigorous differential-geometry framework, thereby generalizing the accurate modeling of variable geometrical features while mitigating numerical locking through higher-order kinematic descriptions [7]. Under this approach, each reference mid-surface node can adopt its own through-the-thickness kinematics description, accounting for local higher-order refinements, in a resulting pure displacement-based numerical approach. The use of the Fundamental Nuclei (FN), the key feature of the CUF formalism, allows for the definition of the governing equations in curvilinear coordinates, exploiting basic elementary units, invariants of the reference mid-surface finite element modeling, and the theory of structural approximation adopted [8]. The curvilinear 2|3D elements, under an isoparametric approach, can represent arbitrary 3D geometries without any superimposed assumption of the geometry. The capabilities of the present modeling strategy have recently been assessed in [8] and are now being extended to comprehensive

convergence and patch test analyses to assess the robustness of the present methodology and the effective mitigation of locking phenomena. This work proposes validation by analyzing classical benchmark problems in locking investigations for shell models [9]. Overall, the proposed formulation significantly advances FE modeling for aerospace applications, offering a powerful and efficient tool for the design and optimization of high-performance structural components.

Curvilinear 2|3 shell models

To address these challenges, novel non-conventional finite elements have recently been developed based on purely displacement-driven formulations [10], which can effectively handle complex geometries while preserving the accuracy and computational efficiency typical of classical 2D models [11]. This advancement allows complex shell configurations to be represented accurately within a unified three-dimensional higher-order framework. Moreover, the proposed modeling strategy also accounts for the use of different polynomial orders of approximation along different directions, thereby enhancing accuracy without sacrificing computational efficiency. Within this methodology, the node-dependent kinematic approach is exploited by means of a rigorous coupling between the finite element interpolation and theory of structure approximation, specifically between the specific FE node of the mid surface and is specific through-the-thickness kinematics under a coupled recursive index formalism:

$$\boldsymbol{u}(\alpha^1,\alpha^2,\alpha^3) = F_\tau^i(\alpha^3)N_i(\alpha^1,\alpha^2)\boldsymbol{u}_{\tau i} = L_{\tau i}(\alpha^1,\alpha^2,\alpha^3)\boldsymbol{u}_{\tau i} \quad \tau = 1,..,\mathrm{M}^i, \quad \mathrm{i} = 1,..,\mathrm{N_n} \quad (1)$$

where $\boldsymbol{M^i}$ is the related to the order of the node-wise structural theory considered, $\boldsymbol{F_\tau^i(z)}$ is the set of the through-the-thickness expansion functions, representing the theory of structure approximation, $\boldsymbol{N_i(x,y)}$ is the set of 2D shape functions of the discrete $\mathrm{N_n}$ finite nodes along the reference mid-surface, and finally $\boldsymbol{u_{\tau i}}$ is the vector of generalized displacements. In the present work, the set of 1D Lagrange's polynomials will be adopted in the z-direction [5]. Starting from these three-dimensional extensions of a classical 2D model, geometric quantities and finite element matrices are evaluated in a general 3D sense in the covariant reference frame, enabling the straightforward inclusion of geometrical feature variations within the element itself [11]. One of the key features of the proposed methodology is that no additional unknowns are added into the global system of equations, as it employs the same set of variables used in classical CUF shell models under an isoparametric approach, where the geometry is also discretized and interpolated by the same formal definition:

$$\boldsymbol{X}(\alpha^1,\alpha^2,\alpha^3) = L_{\tau i}(\alpha^1,\alpha^2,\alpha^3)\boldsymbol{X}_{\tau i} \quad \tau = 1,..,\mathrm{M}^i, \quad \mathrm{i} = 1,..,\mathrm{N_n} \quad (2)$$

Under this formalism, all geometrical quantities required for the computation of finite element matrices are straightforwardly computed from the discretized expression of the geometrical description of the shell, such as co- and contra-variant basis and metric tensor, as well as the transformation law between covariant and Cartesian reference frames [8]. The robustness of the present modeling strategy is ensured by adopting higher-order methods, which naturally mitigate numerical limitations. Figure 1 depicts the proposed curvilinear shell model in a non-orthogonal reference frame, focusing on the possibility to arbitrary model the through-the-thickness kinematics for each finite node.

Materials Research Proceedings 69 (2026) 1304-1309 https://doi.org/10.21741/9781644904251-226

Governing equations

The equilibrium equations for the linear static analysis are derived from the Principle of Virtual Displacements (PVD):

$$\delta\mathcal{L}_{int} = \delta\mathcal{L}_{ext} \tag{3}$$

where $\boldsymbol{\mathcal{L}_{int}}$ and $\boldsymbol{\mathcal{L}_{ext}}$ are the internal strain energy and external work, respectively, and $\boldsymbol{\delta}$ denotes the virtual variation. Adopting the index notation introduced in Eq. (1)-(2) for the displacement field and geometrical interpolation, one can derive the expression of strain and stress tensor in curvilinear coordinates [8] and expressing it in terms of Cartesian components by means of a transformation law. In this way, starting from the definition of involved energetic contributions, the FN (Fundamental Nuclei) of the linear stiffness matrix and external force vector can be derived:, obtaining the matrix form of the governing equation.

$$\delta\mathcal{L}_{int} = \delta\hat{\boldsymbol{u}}_{sj}^{T}\left[\int_{\Omega} \boldsymbol{B}_{curv}^{sj\,T}\boldsymbol{J}_{c2c}\boldsymbol{C}\boldsymbol{J}_{c2c}\boldsymbol{B}_{curv}^{\tau i}\,|\boldsymbol{J}|dV\right]\hat{\boldsymbol{u}}_{\tau i} = \delta\hat{\boldsymbol{u}}_{sj}^{T}\boldsymbol{K}^{\tau sij}\hat{\boldsymbol{u}}_{\tau i} \tag{4}$$

$$\delta\mathcal{L}_{ext} = \delta\hat{\boldsymbol{u}}_{sj}^{T}\left[\int_{\Sigma} L_{sj}(\alpha^1,\alpha^2,\alpha^3)\,\boldsymbol{f}\,|\boldsymbol{J}_{\Sigma}|dV\right] = \delta\hat{\boldsymbol{u}}_{sj}^{T}\boldsymbol{P}^{sj} \tag{5}$$

where $\boldsymbol{B}_{curv}^{\tau i}$ and $\boldsymbol{B}_{curv}^{sj}$ are the algebraic matrices of derivative operators applied to shape functions in curvilinear coordinates, $\boldsymbol{J}_{c2c}$ is the transformation matrix from covariant and Cartesian reference frame, $|\boldsymbol{J}|$ and $|\boldsymbol{J}_{\boldsymbol{\Sigma}}|$ are respectively the Jacobian from curvilinear and natural reference frames for integral evaluation computed in the Gauss-Point of the Ω closed 3D domain or Σ 2D surface for load boundary applications, $\delta\hat{\boldsymbol{u}}_{sj}$ are the Cartesian components of the virtual displacements and finally $\hat{\boldsymbol{u}}_{\tau i}$ are the Cartesian components of the final, unknown, displacement field. The quantities $\boldsymbol{K}^{\tau sij}$ and $\boldsymbol{P}^{sj}$ are the FN of the stiffness matrix and external force vector, independent of the chosen FE implementation models, allowing for a flexible implementation of any arbitrary shell model. More details about the derivation can be found in [8].

Numerical results

The proposed approach is applied to the analysis of a pinched shell supported by rigid diaphragms at both free ends. This case study has been extensively analyzed in the literature to investigate locking phenomena in the shell finite element formulation, as analyzed by Bathe *et al.* [12] and

Materials Research Proceedings 69 (2026) 1304-1309 https://doi.org/10.21741/9781644904251-226

later by Cinefra *et al.* [9]. The addressed case study involves the analysis of a thin shell with a total length L = 600 in, a constant radius of curvature R = 300 in, and a thickness t = 3 in. The shell is loaded with two equal forces acting at two diametral points of value P = 1 lb, as shown in Fig. 1. Thanks to the symmetry of the structure, only one eighth of the shell is discretized by applying symmetry boundary conditions. The material properties considered for the isotropic materials are $E = 3 \times 10^6$ psi and $\nu = 0.3$. The structure is discretized using curvilinear 2|3 models, as introduced, to investigate locking phenomena in this novel finite element approach. The results proposed are compared against available literature references, where the transversal displacement of the point "A" reported in Fig. 2 is computed with classical thin shell theories. Table 1 presents a comparison between higher-order curvilinear 2|3 models and the available literature. Both parabolic and cubic models are consistently adopted in the present case to analyze how higher-order models can mitigate locking phenomena, both along the reference mid-surface and in through-the-thickness kinematics, and to examine the influence of the theory of structures on the solution as well as the polynomial order in the reference mid-surface interpolation. The relative percentage difference between the available reference and the results obtained via the present higher-order curvilinear models is also reported. According to [], the transversal displacement obtained adopting higher-order models is expected to be higher than the reference value, since it is computed with classical shell theories for thin structures, whereas higher-order models take into account shear effects, leading to higher values. This is also demonstrated by the results obtained adopting 15×15 or 20×20 cubic finite elements along the reference mid-surface. Figure 3 presents the results of the convergence analysis, which investigates the convergence ratio of the solution. Regarding the adoption of parabolic models along the mid-surface, larger relative errors and inconsistencies are found, and refined discretization is necessary to obtain consistent solutions. Instead, adopting cubic models yields results in excellent agreement with the reference solution, even for coarser discretizations.

Conclusions

This manuscript discusses the implementation of curvilinear higher-order shell models for the linear static analysis of complex geometries. The capabilities of the present approach are demonstrated by a severe patch test available in the literature for the locking investigation of shell finite element approaches. The model is formulated fully in curvilinear coordinates, including straightforwardly the geometrical features variation within the element definition, under a rigorous differential geometry framework The governing equations for the linear static analysis are defined via numerical procedures based on higher-order CUF-based finite element, an efficient tool for the generation of any arbitrary shell model, here extended to the definition of variable thickness and variable curvature shell structures. The proposed results suggest the robustness and consistency of the proposed approach, where the adoption of higher-order models mitigates numerical effects such as locking in thin shell formulations.

Abstract. Reducing aerodynamic drag via laminar flow on wings offers significant energy savings compared to common, mostly turbulent wings. At TU Braunschweig, an extended Hybrid Laminar Flow Control (xHLFC) concept has been developed, combining a laminar front-wing design with active suction panels in the rear upper shell of the wing [1]. To avoid heavy metal suction skins and panel structures and a complicated assembly, this concept implements a fully integrated, polymer 3D-printed panel employing a sandwich-like structure: a micro-perforated skin with printed perforations on a Triply Periodic Minimal Surface (TPMS) based core. Next to being lightweight, the TPMS core mechanically supports the suction skin and enables internal transport and pressure control of the suction air flow. This study focuses on Gyroid structures with their channel-like inner structure and adaptability through functional grading. To validate the approach, a complete suction panel with a specifically graded Gyroid core was integrated into a swept wing and tested in a laminar low-speed wind tunnel, showing up to 25 % longer laminar boundary layers at 60 m/s.

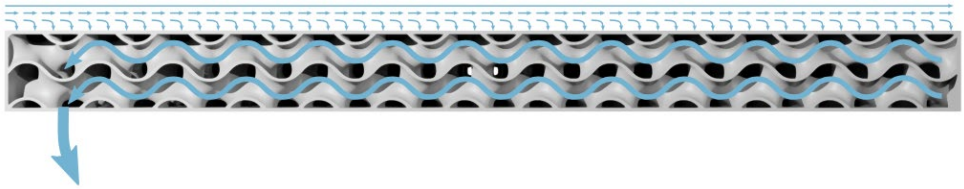

Figure 1: Concept of the core structure for the suction panel. Left: Schematic of the suction panel concept. The air is drawn in from perforations on top of the panel and then transported through the Gyroid structure

Introduction

As aviation moves towards more sustainability, significant gains in aerodynamic efficiency are required to reduce both fuel consumption and emissions. A key lever is the reduction of aircraft drag. Especially the viscous drag as one component is significantly higher for turbulent wings in comparison to wings with a laminar boundary layer. Studies show that laminarization of the wings can reduce the total drag by up to 18 % [2]. Therefore, much research has been conducted in the area, resulting in applications for wind tunnel tests on wings and fins and the implementation in different structural concepts [3]. The implemented concepts mostly focus on the front section of the wing around the leading edge and separately develop the suction skin and core structure which are joined afterwards. This results in structural complexity and high weight, as mostly metals are used.

Materials Research Proceedings 69 (2026) 1310-1313 https://doi.org/10.21741/9781644904251-227

To address these issues, this study presents a fully integrated, additively manufactured suction panel concept. As the suction panels are located at the upper rear section, additive manufacturing (AM) with polymers is used, enabling much lower weight than using metals. The panels employ a sandwich construction featuring a micro-perforated, printed skin [4] and a core based on triply periodic minimal surfaces (TPMS). TPMS structures offer nearly isotropic mechanical properties and multidirectional channels. The concept is shown in Fig. 1 with a Gyroid as the chosen core structure. As the air is sucked in, it runs through the Gyroid structure with its multiple channels and curvatures that lead to a pressure drop. By specifically adjusting the main cell parameters, which are the wall thickness and the unit cell size, this pressure drop can be determined for different flow rates.

The presented approach is designed and tested for a new laminarization approach called *extended* Hybrid Laminar Flow Control (xHLFC). Therefore, an airfoil was designed at TU Braunschweig for natural laminar flow on the front region of the upper wing to allow for the suction panel to be beneficial in the rear area. Wind tunnel tests on this airfoil with the printed suction panel successfully show a downstream shift of laminar-turbulent transition.

Materials and Methods

A major design objective of using TPMS structures as the panel core is fitting a tailored pressure distribution within the core, as wing profiles have a pressure distribution that is not constant. To achieve the right pressure difference from this outer distribution to the panel core structure and thereby the right suction rate, this must be matched with the core design.

To investigate the correlation between pressure drop characteristics and geometry, multiple flat specimens (comparable to Fig. 1) have been manufactured. The specimens vary systematically in unit-cell size and wall thickness, including fully graded Gyroid cores, and represent sections of the sandwich-like suction panels. All specimens were tested with a flow meter recording the volumetric flow rate, while pressure taps along the core measure the internal pressure distribution. For cases with low flow rates, the structures are densified locally by a strong increase in wall thickness, while still keeping the channel structure and flow inside of the Gyroid core. This can increase the pressure drop strongly and is also investigated in this study. Methods for this have been implemented at the Institute of Mechanics and Adaptronics [5].

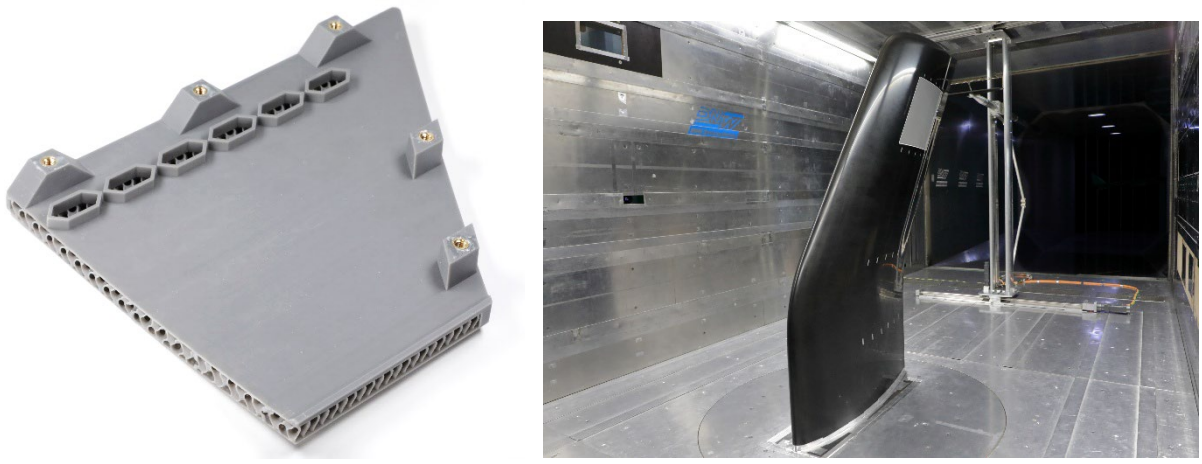

Figure 2: Wind tunnel test of the integral suction panel employing a Gyroid core. Left: Panel section with the core structure, threaded inserts for assembly and suction air outlets. Right: The sickle wing in the DNW-NWB wind tunnel with the integrated suction panel

Materials Research Proceedings 69 (2026) 1310-1313 https://doi.org/10.21741/9781644904251-227

At the Institute of Fluid Mechanics of TU Braunschweig, a special sickle-shaped wing has been designed and manufactured that allows to investigate multiple influences on the transition from laminar to turbulent boundary layers. The model has a cut area where the suction panel can be integrated (grey area in Fig. 2). Based on the pressure-drop results, a suction panel with a graded Gyroid core is integrated and tested in the swept wing area. This is shown in Fig. 2. The Gyroid panel core has a unit cell length of 12 mm and a core wall thickness of 1 mm. The perforation size is 250 µm with square holes with a design porosity of 1 %. There are six densifications in 50 mm distance over the LE-normal length of the panel to increase the pressure drop in the core to the required level. The panel consists of six segments printed in a stereolithography process. Each one combines hull, brackets for threaded inserts, core and perforations in one integral part, as can be seen in Fig. 2. After cleaning in IPA and post-curing, the panel sections are joined together and then built into the wing. The panel dimensions are 450 mm in spanwise direction, going from 35 to 80 % chord length. Surface finishing by sanding is applied as the suction panel is placed in the cut. With this, a high surface quality, matching curvature and a smooth interface between wing and panel can be ensured.

The wing with the panel was then installed in the wind tunnel and tested at different conditions. With applied suction at different suction rates, the wind tunnel speed was varied between 30 and 75 m/s under different angles of attack. With infrared cameras, the transition from laminar to turbulent was observed for different flow conditions and suction rates. Pressure taps in the wing and the panel core allow for measurement of the pressure distributions. The tests were conducted in the Low-Speed Wind Tunnel Braunschweig of the German-Dutch Wind Tunnels (DNW).

Results

The test in the wind tunnel has shown a significant influence of the built-in suction panel on the transition behavior. Because of the polymer base material of the panels, the transition can be detected by IR cameras directly on the suction panel. This is another advantage of the material choice, especially for research applications. Without applied suction, the panel causes a forward shift of the transition compared to the natural transition line. This can be explained by the induced roughness from the holes and blow-out from the front region of the suction panel due to the pressure gradient.

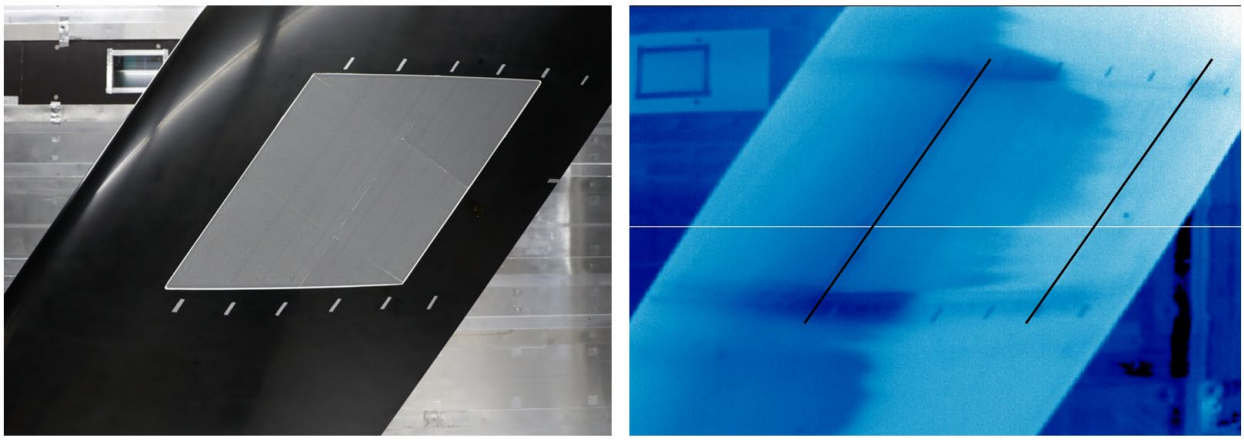

Figure 3: Infrared measurements results. Left: Image of the suction panel in the swept area of the wing. Right: Infrared image at 60 m/s wind tunnel speed and applied suction with the darker laminar area extended by the panel

With applied suction, the transition can be shifted downstream significantly. This was successfully demonstrated at wind tunnel speeds of 45 to 60 m/s, with an extension of the laminar

region by 20 to 25 % compared to the natural flow with a smooth surface, visible in Fig. 3. At 45 m/s, the flow could be kept laminar over almost the whole suction panel area, which can be considered the optimum. Suction rates were varied from zero to up to 40 m^3/s. After the optimum, oversuction leads to a decrease in the length of the laminar boundary layer. The joint between the panel sections and also between the panel and the surrounding wing skin exhibited no visible influence on the transition.

Pressure measurements in the core structure of the suction panel reveal an actual pressure gradient due to the design of the core structure, going in the direction of the aimed pressure distribution. This exhibits the potential of using TPMS structures as a core structure. The trend also matches the results from the flow meter measurements, showing the strong increase in pressure drop due to the densifications in the structure. A uniform TPMS structure yields a near-linear pressure drop, functional grading enables spatially tailored gradients or strong increases.

Summary

The study showed the applicability of additive manufacturing for the implementation of suction panels for xHLFC application. A micro-perforated skin was printed together in one integral part with a Gyroid core structure that supports the suction skin as well as controls the inner pressure distribution for a designed suction rate. The use of polymers makes the concept lightweight and enables transition measurement through IR thermography directly on the suction panels. For future applications, challenges are expected in the manufacturing of bigger panel structures, as the current process involves many joints that have to be precisely shaped to not cause laminar-turbulent transition. With the current progress in printing quality and size, this appears feasible. Together with additional research on mechanical properties and modelling currently conducted, the whole process chain from panel design and dimensioning to implementation can be realized.

Keywords: Embedded Finite Elements, High-Order Models, Unified Formulation, Textile Composites

Abstract. This work presents a framework for simulating fiber–matrix assemblies using an Embedded Finite Element (EFE) approach, where the matrix and fibers are modeled as host and embedded bodies, respectively. One-dimensional beam finite elements represent both constituents, with distinct kinematic models defined through the Carrera Unified Formulation (CUF). Displacement compatibility is enforced via the Lagrange multiplier method, augmented with a perturbation term to prevent stiffness matrix singularity. Furthermore, the variational principle includes a corrective term accounting for the volume redundancy of the embedded elements. The proposed methodology demonstrated high accuracy and computational efficiency, showing strong potential for the analysis of fiber–matrix assemblies and the modeling of complex textile composite geometries.

Introduction

Micro- and mesoscale simulation of composite materials is a challenging task that often requires computationally intensive methods to accurately represent the three-dimensional (3D) stress state. Among these models are tetrahedral and hexahedral solid finite elements (FEs), which adapt to the geometry of the matrix and fibers. However, this approach leads to the generation of highly refined and cumbersome meshes to accurately capture the fiber geometry [1]. An alternative method to reduce the pre-processing effort required for mesh generation is the voxel-based FE approach, where the geometry is subdivided into parallelepiped partitions. Nevertheless, voxel-based meshes cannot accurately capture the mechanical behavior near the fiber–matrix interface [2].

In recent years, Embedded Finite Element (EFE) methods have been proposed to reduce mesh generation times and avoid voxel-based meshes. However, these approaches still rely on 3D solid models [3] to resolve stress distributions with sufficient accuracy, which introduces additional challenges related to element aspect ratios and skewness. As a result, achieving acceptable accuracy often requires a large number of elements. Furthermore, commercial EFE strategies allow for embedding truss, beam, or plate elements into 3D solids, but they suffer from two main limitations: (i) they couple only translational degrees of freedom, leaving rotational ones unconstrained, and (ii) they do not account for volume redundancy [4]. The first limitation has been addressed in geotechnical engineering through the modeling of pile–soil interaction, where piles are modeled as Timoshenko beams with circular cross-sections and the soil as a 3D solid, and the coupling was achieved through Lagrange multipliers and penalty methods [5,6]. Nevertheless, this approach lacks generality for arbitrary cross-sections and higher-order beam models.

The present manuscript aims to overcome these limitations. The proposed EFE framework introduces a novel coupling strategy that accounts for both higher-order kinematic fields and volume redundancy. The former is achieved by employing the Carrera Unified Formulation (CUF) [7,8] to generate low- to high-order beam theories, integrated into a perturbed Lagrangian formulation to enforce kinematic compatibility [9]. The latter is addressed by introducing a corrective term to the internal virtual work in the variational principle. A previous version of CUF-based EFE was proposed by the authors in [10]. The main difference with the present approach is that the previous one only permitted the coupling between 1D FE employing Lagrange expansion for the host and embedded element, while the present one permits the use of arbitrary expansions for both constituents.

The results presented herein demonstrate strong agreement with benchmark solutions from the literature, while achieving a significant reduction in computational cost. This approach paves the way for cost-effective virtual testing of composite parts through accurate mesoscale modeling, among other potential applications.

Unified formulation of embedded one-dimensional finite elements

When combining the Carrera Unified Formulation (CUF) with FEM, the 3D displacement field of a beam-like structure in a Cartesian reference frame can be written as:

$$\boldsymbol{u}(x,y,z) = F_\tau(x,z)N_i(y)\boldsymbol{u}_{\tau i} \qquad \tau = 1,\dots,M \quad i = 1,\dots,N \tag{1}$$

where F_τ are the expansion functions dependent on the beam's cross-sectional coordinates, N_i are the shape functions along the beam axis, and $\boldsymbol{u}_{\tau i}$ are the nodal generalized displacements. The parameter M denotes the number of expansion terms defining the beam's kinematic field, while N is the number of nodes per finite element. The choice of F_τ determines the order and type of the kinematic approximation; in CUF literature, Taylor (TE) and Lagrange (LE) expansions are the most commonly employed [7]. This combined CUF–FEM framework enables the analysis of structures with arbitrary material properties, loading conditions, and boundary configurations.

In the CUF–FEM framework, the system of equations for a static problem, $\boldsymbol{Ku} = \boldsymbol{F}$, is derived from the Principle of Virtual Displacements (PVD), and the assembly of the stiffness matrix is performed through the τ, s, i, and j indices of the so-called Fundamental Nucleus. For brevity, this process is not detailed in this manuscript; further information regarding the assembly procedure can be found in [7].

Kinematic coupling between host and embedded bodies

The kinematic coupling between the host and embedded bodies is achieved by introducing additional terms into the PVD statement, namely the volume redundancy term and the traction $\boldsymbol{\lambda}$ on the physical interface between the host and embedded bodies. In the following, the superscripts h and e denote quantities associated with the host and embedded domains, respectively. The modified PVD statement reads as:

$$\delta\boldsymbol{u}_{sj}^{h^T}\int_{V^h}\boldsymbol{D}^T\left(N_j^hF_s^h\right)\boldsymbol{C}^h\boldsymbol{D}\left(N_i^hF_\tau^h\right)dV^h\boldsymbol{u}_{\tau i}^h + \delta\boldsymbol{u}_{sj}^{e^T}\int_{V^h}\boldsymbol{D}^T\left(N_j^eF_s^e\right)\boldsymbol{C}^e\boldsymbol{D}(N_i^eF_\tau^e)dV^e\boldsymbol{u}_{\tau i}^e$$

$$-\delta\boldsymbol{u}_{sj}^{e^T}\int_{V^h}\boldsymbol{D}^T\left(N_j^eF_s^e\right)\boldsymbol{C}^e\boldsymbol{D}(N_i^eF_\tau^e)dV^e\boldsymbol{u}_{\tau i}^e + \int_{S_c}\delta\boldsymbol{u}_{sj}^{h^T}N_j^hF_s^h\boldsymbol{\lambda}dS_c - \int_{S_c}\delta\boldsymbol{u}_{sj}^{e^T}N_j^eF_s^e\boldsymbol{\lambda}dS_c =$$

$$\delta\boldsymbol{u}_{sj}^{h^T}\int_{V^h}N_j^hF_s^h\boldsymbol{b}dV^h + \delta\boldsymbol{u}_{sj}^{h^T}\int_S N_j^hF_s^h\boldsymbol{t}dS \tag{2}$$

Materials Research Proceedings 69 (2026) 1314-1318 https://doi.org/10.21741/9781644904251-228

where the first term on the second line corresponds to the redundant volume of the embedded body. This term must be subtracted to avoid introducing additional stiffness into the overall system, as discussed in [3]. In the above equation, $\boldsymbol{D}$ is the differential operator relating strains and displacements, $\boldsymbol{C}$ is the matrix version of the fourth-order material stiffness tensor, and $\boldsymbol{b}$ and $\boldsymbol{t}$ are the body and traction forces acting on the host domain, respectively.

The previous equation is complemented by the weak form of the displacement continuity condition on the interface between the two domains, S_c, expressed as:

$$\int_{S_c} \delta\boldsymbol{\lambda}^T(\boldsymbol{u}^h - \boldsymbol{u}^e)dS_c - \frac{1}{\alpha}\int_{S_c} \delta\boldsymbol{\lambda}^T\boldsymbol{\lambda}dS_c = 0 \tag{3}$$

where the second term is introduced to prevent zero diagonal entries in the system matrix, leading to a perturbed Lagrangian formulation of the displacement continuity condition. Here, α is a large penalty parameter.

By discretizing the interface traction as $\boldsymbol{\lambda} = N_i^{\lambda}F_{\tau}^{\lambda}\boldsymbol{\lambda}_{\tau i}$, substituting into the above equations, and expanding over the τ, s expansion, and i, j FE indices, the following system of equations is obtained:

$$\begin{bmatrix} \boldsymbol{K}^h & \boldsymbol{0} & \boldsymbol{B}^{\lambda,h} \\ \boldsymbol{0} & \boldsymbol{K}^e & \boldsymbol{B}^{\lambda,e} \\ \boldsymbol{B}^{\lambda,h^T} & \boldsymbol{B}^{\lambda,e^T} & \boldsymbol{B}^{\lambda,\lambda} \end{bmatrix} \begin{Bmatrix} \bar{\boldsymbol{u}}^h \\ \bar{\boldsymbol{u}}^e \\ \bar{\boldsymbol{\lambda}} \end{Bmatrix} = \begin{Bmatrix} \boldsymbol{F} \\ \boldsymbol{0} \\ \boldsymbol{0} \end{Bmatrix} \tag{4}$$

where $\boldsymbol{K}^h$ and $\boldsymbol{K}^e$ are the assembled stiffness matrices of the host and embedded bodies; $\boldsymbol{B}^{\lambda,h}$ and $\boldsymbol{B}^{\lambda,e}$ are the kinematic coupling matrices; and $\boldsymbol{B}^{\lambda,\lambda}$ is the assembled perturbed Lagrangian matrix. The vector $\boldsymbol{F}$ contains the external loads, which, in this work, are assumed to act only on the host body, while $\bar{\boldsymbol{u}}^h$, $\bar{\boldsymbol{u}}^e$, and $\bar{\boldsymbol{\lambda}}$ denote the vectors of host and embedded displacements and the Lagrange multipliers, respectively. For brevity, the procedure used to compute the coupling matrices is not reported here and can be found in Granitzer et al. [6].

Numerical results

The square-pack unit cell subjected to a uniform transverse displacement, as presented by Tabatabaei et al. [3], was used to verify the proposed methodology. The material properties, unit cell dimensions, and boundary conditions are detailed in the referenced work. The host matrix body employs an LE expansion consisting of 49 bi-quadratic subdomains, while the embedded fiber adopts a first-order TE (TE1) model, a Timoshenko-like beam formulation, to represent the beam cross-section. Both constituents utilize one-dimensional cubic shape functions for the FE discretization. In total, the simulation of the unit cell comprises 2772 degrees of freedom.

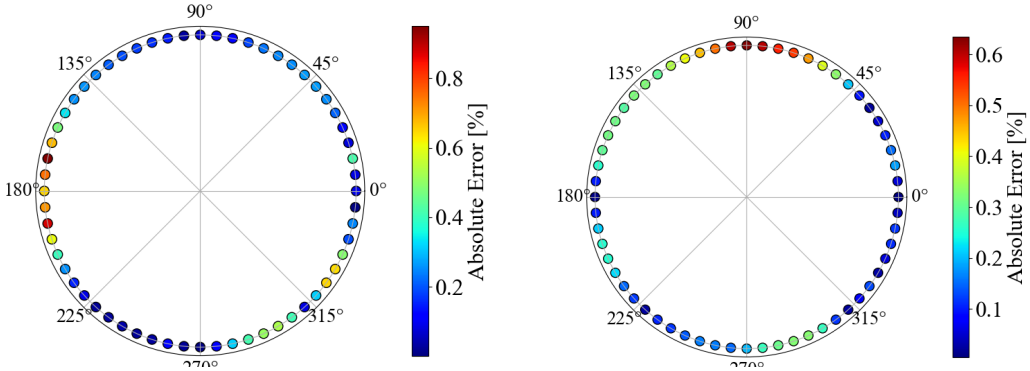

Figure 1. Absolute error in radial and hoop displacements at the fiber-matrix interface.

Materials Research Proceedings 69 (2026) 1314-1318 https://doi.org/10.21741/9781644904251-228

Figure 1 demonstrates the displacement continuity at the fiber–matrix interface. The figure shows the absolute difference between the predicted displacements in the radial and hoop directions. The results indicate excellent continuity across the interface, with weighted mean errors of 0.36% and 0.28% for the radial, u_r, and hoop, u_θ, displacement components, respectively. Similarly, Fig. 2 presents the σ_{yy} and σ_{xx} stress contours for the matrix and fiber domains. These results are consistent with those reported by Tabatabaei et al. [3], where the peak values of σ_{yy} in the matrix and σ_{xx} in the fiber were 0.33 and 0.70, respectively. Note that these quantities are dimensionless. Minor discrepancies can still be observed at the interface, where stress gradients between the fiber and matrix are not fully captured due to the use of a regular host cross-sectional discretization. Although a structured mesh would improve accuracy, it would also increase pre-processing complexity, thereby compromising the simplicity and generality of the proposed methodology for analyzing square-pack unit cell geometries.

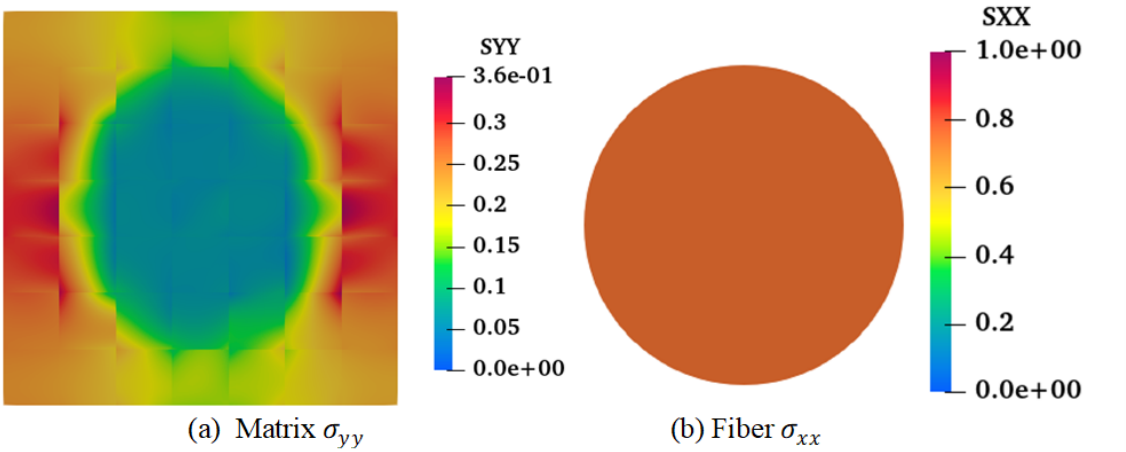

Figure 2. Stress contours for the matrix and fiber. A total of 322 points were used to discretize the fiber-matrix intergace, where the coupling matrices were computed. A 49L9 host cross-section and a TE1 embedded structural model were employed.

Conclusions

This study presented a Carrera Unified Formulation–Embedded Finite Element (CUF–EFE) framework for simulating fiber–matrix assemblies. The matrix and fiber of a square-pack unit cell were modeled as host and embedded bodies using one-dimensional beam elements with distinct CUF-based kinematic models. Displacement compatibility was enforced through Lagrange multipliers, with perturbation and corrective terms addressing stiffness singularity and volume redundancy. The results confirmed the accuracy and efficiency of the proposed approach, demonstrating its strong potential for more intricate fiber-matrix assemblies like those found in textile, 3D printed discontinuous composites, and tow-matrix interactions in variable stiffness composites [11].

Keywords: Structural Health Monitoring, Lamb waves, Aerospace Structures, Stiffened Composite, Damage Detection

Abstract. The assessment of hidden flaws in composite structures is crucial for aircraft safety and requires accurate detection and localization. Conventional damage tolerance relies on design margins and scheduled inspections, resulting in costly maintenance. Structural Health Monitoring (SHM) provides a cost-effective alternative, enabling continuous assessment through guided-wave–based damage imaging. When ultrasonic waves interact with defects, signal variations can be quantified through scalar features related to damage severity and position. This work presents a probabilistic multi-parameter imaging approach to evaluate localization accuracy under varying input parameters and post-processing conditions. Using the open-access *Open Guided Waves* dataset, results show high sensitivity to damage location when energy- and correlation-based indicators are employed. In addition, the findings show that excitation frequency is a key parameter to improve localization accuracy.

Introduction

The widespread use of fiber-reinforced composites in aerospace structures demands advanced Structural Health Monitoring (SHM) methods for detecting internal flaws such as delaminations, matrix cracks, or debonding. Ultrasonic guided waves are particularly effective, as their interaction with defects produces measurable waveform variations from which damage-sensitive features can be extracted [1].

Among imaging techniques, the *Reconstruction Algorithm for Probabilistic Inspection of Damage* (RAPID [2] estimates a spatial probability map of damage occurrence from signal deviations and sensor geometry, providing an efficient and robust localization approach. However, despite its extensive use, a systematic characterization of the method under varying input parameters—such as excitation frequency, feature type, and post-processing strategy—is still lacking. Understanding how these factors influence localization accuracy is essential to ensure reproducibility and reliability of the results.

In this work, RAPID is applied to the open-access *Open Guided Waves* dataset [3], including ultrasonic measurements on composite panels with various artificial damages. The study examines the influence of input parameters and feature selection on localization accuracy, contributing to the development of reliable probabilistic imaging methods for SHM.

Materials and Methods

The tested structure is a quasi-isotropic CFRP plate (550 × 550 mm^2, 2 mm thick) with layup $[45/0/-45/90/-45/0/45/90]_s$. An omega-shaped stringer bonded on the upper surface introduces geometric discontinuities that promote guided-wave scattering and mode conversion.

Artificial damages were simulated by bonding elliptical steel masses at three locations (D1–D3, Fig. 1), each with thirteen size levels obtained by progressively increasing the bonded area. Baseline signals were first recorded on the pristine plate.

Materials Research Proceedings 69 (2026) 1319-1324 https://doi.org/10.21741/9781644904251-229

Twelve surface-mounted PZTs were used for actuation and sensing along multiple paths. Excitation consisted of 5-cycle Hanning-windowed tone bursts with central frequencies between 40 kHz and 260 kHz. For each frequency, all damage and baseline states were measured, with five repetitions for repeatability. Further details are provided in [3].

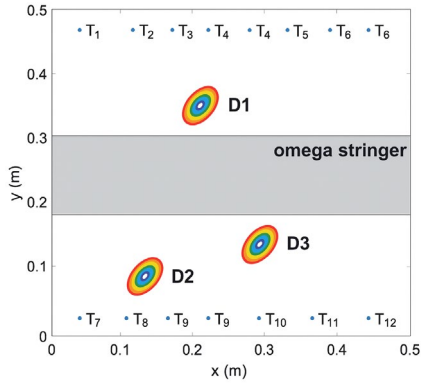

Figure 1: CFRP plate geometry and damage locations, adapted from [3].

RAPID Algorithm

The *Reconstruction Algorithm for Probabilistic Inspection of Defects* (RAPID) [2] was used to estimate the most probable damage location from the actuator–sensor network. The method is applied independently to each configuration, using path-wise damage indicators as input features.

A defect primarily perturbs guided-wave propagation along the direct transmitter–receiver path, with its influence decaying away from the path centerline. For each pair, an elliptical spatial weighting function is defined with the transducers at the foci, representing the probability that a signal deviation originates from any point (x, y) within the inspected area.

The overall probability map is computed as:

$$P(x,y)=\sum_{i=1}^{N_x}\sum_{j=1}^{N_y} A_{ij}\left[\frac{\beta-R_{ij}(x,y)}{\beta-1}\right], \qquad (1)$$

where A_{ij} is the damage indicator of the $i-j$ path, and $R_{ij}(x, y)$ the normalized distance ratio within the ellipse of influence. The factor decreases linearly from the path centerline ($R_{ij} = 1$) to zero at the boundary ($R_{ij} = \beta$), where ($\beta > 1$) (typically 1.05–1.2) defines the ellipse size. The ratio is expressed as:

$$R_{ij}=\frac{\sqrt{(x-x_i)^2+(y-y_i)^2}+\sqrt{(x-x_j)^2+(y-y_j)^2}}{\sqrt{(x_j-x_i)^2+(y_j-y_i)^2}} \qquad (2)$$

In this formulation, A_{ij} quantifies the deviation of each signal from its baseline along path i - j. The full set of metrics is reported in [4]; here, focus is given to the *Energy Difference* and *Pearson Correlation*, which yielded the most consistent performance.

After superimposing all path contributions, the resulting map P(x, y) exhibits a dominant peak near the actual defect. Post-processing (normalization, smoothing, clustering) improves localization robustness and mitigates spurious responses. Fig. 2 illustrates the elliptical influence region of each actuator–sensor path.

Materials Research Proceedings 69 (2026) 1319-1324 https://doi.org/10.21741/9781644904251-229

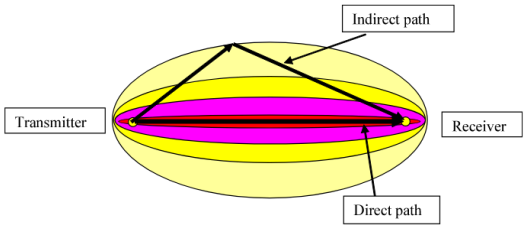

Figure 2: Elliptical spatial weighting function in the RAPID algorithm, showing direct and indirect wave paths [2].

Signal Processing and Feature Extraction

All guided-wave signals were imported and, for each excitation frequency, the five repetitions were averaged to obtain a representative waveform, then filtered and cross-talk removed to enhance signal quality. The damage indices (*DI*) defined in [4] were subsequently extracted, generating a database of interchangeable features for RAPID processing. Each DI's performance was assessed through the Euclidean distance between the real damage position and the estimated *damage centroid* from RAPID imaging.

Fig. 3 presents the tomographic reconstruction for damage location 2, size 13, using *Energy Difference* at 40 kHz, illustrating the offset between the RAPID peak and the actual damage position.

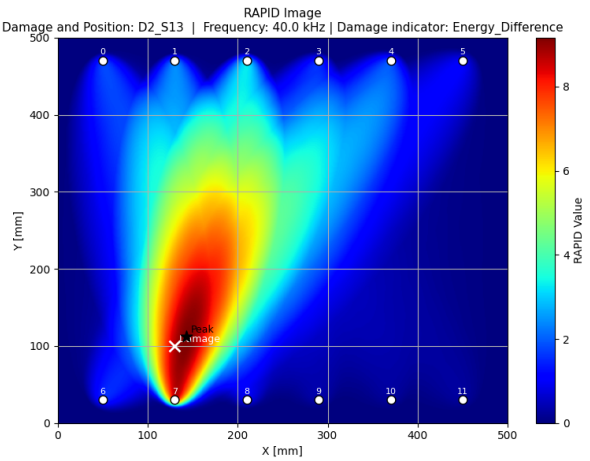

Figure 3: RAPID reconstruction for damage location 2, size 13 at 40 kHz using Energy Difference as damage index.

Effect of Damage Size and Burst Frequency on Localization Error

The Euclidean distance between the RAPID peak and the actual defect position was analyzed as a function of defect size and excitation frequency. As shown in Fig. 4, for damage location D1 the localization error decreases with increasing defect size, indicating that larger damages produce stronger and more distinct signal deviations. In contrast, the frequency trend shows an initial rise up to about 220 kHz, followed by a decrease at higher frequencies. This behavior agrees with guided-wave studies [5, 6], which highlight the trade-off between wavelength, scattering sensitivity, and spatial resolution.

These results confirm that the largest damage size (size 13) and the lowest burst frequency (40 kHz) provide the most reliable conditions for feature-based classification.

Materials Research Proceedings 69 (2026) 1319-1324 https://doi.org/10.21741/9781644904251-229

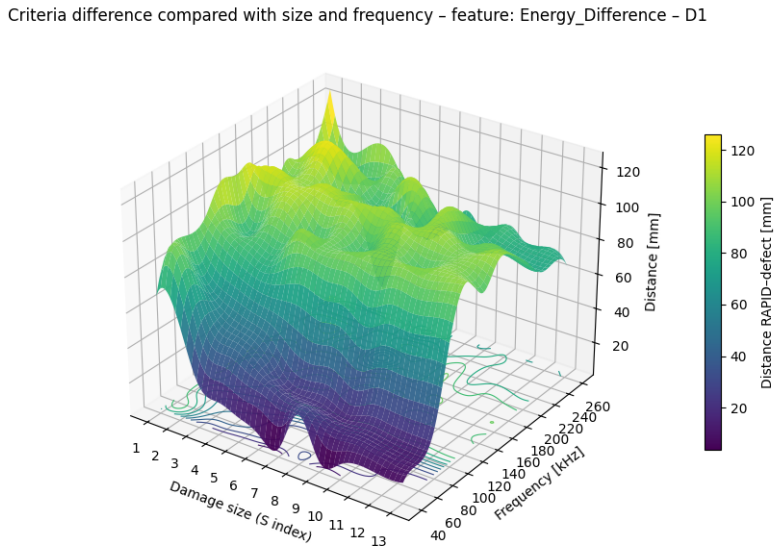

Figure 4: Variation of the Euclidean distance between the RAPID peak and the actual defect position for damage location D1 as a function of damage size and excitation frequency.

Feature Ranking

Table 1 reports the Euclidean distance between the RAPID peak and the actual defect position for the three damage locations (D1–D3) at 40 kHz and damage size 13. Among all features, *Energy Difference* and *Pearson Correlation* yielded the lowest localization errors, confirming their robustness in capturing waveform variations induced by damage. In contrast, amplitude-based features such as *Peak* and *Peak-to-Peak* showed higher sensitivity to noise and scattering, resulting in less accurate localization. These findings highlight the relevance of energy- and correlation-based indicators for reliable RAPID imaging in composite structures.

The best localization result was obtained for damage location D3 using *Pearson Correlation*, with an error of only 0.52 mm. Fig. 5 shows the corresponding RAPID reconstruction, confirming the close match between the estimated and actual defect positions.

Table 1: Euclidean distance between the RAPID peak and the actual defect position (mm) for the best-performing features at 40 kHz and damage size 13..

Feature	D1	D2	D3
Energy Difference	12.58	18.05	18.55
Pearson Correlation	19.33	19.47	0.52
Peak	38.32	59.10	45.53
Peak-to-Peak	38.32	59.10	45.53
RMS	60.36	60.35	48.42

Materials Research Proceedings 69 (2026) 1319-1324 https://doi.org/10.21741/9781644904251-229

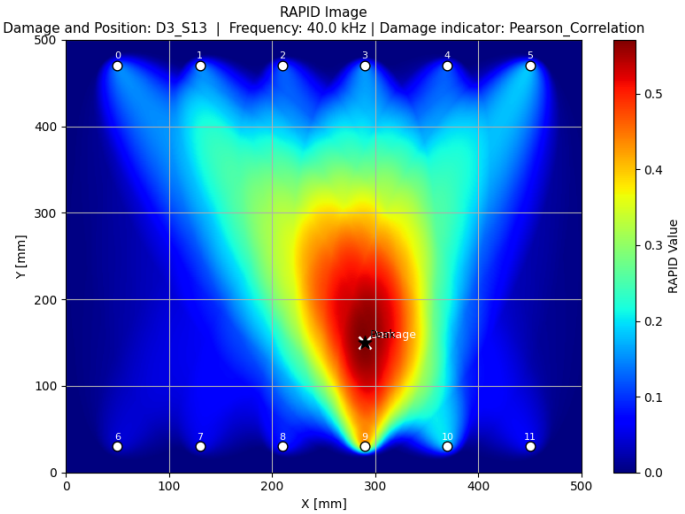

Figure 5: RAPID reconstruction for damage location 3, size 13 at 40 kHz using Pearson Correlation as damage index.

Influence of Environmental Conditions

An additional analysis was performed across all burst frequencies, best-performing features, and damage locations to assess the effect of environmental conditions on RAPID localization accuracy. As an example, Fig. 6 shows results for damage location D1 at 40 kHz using *Energy Difference* as indicator. A localized anomaly occurs for damage size 8 during the first repetition, producing a temporary increase in Euclidean distance and a deviation from the expected decreasing trend (see Fig. 4). This irregularity is attributed to external factors affecting acquisition, confirming the sensitivity of guided-wave measurements to ambient variations.

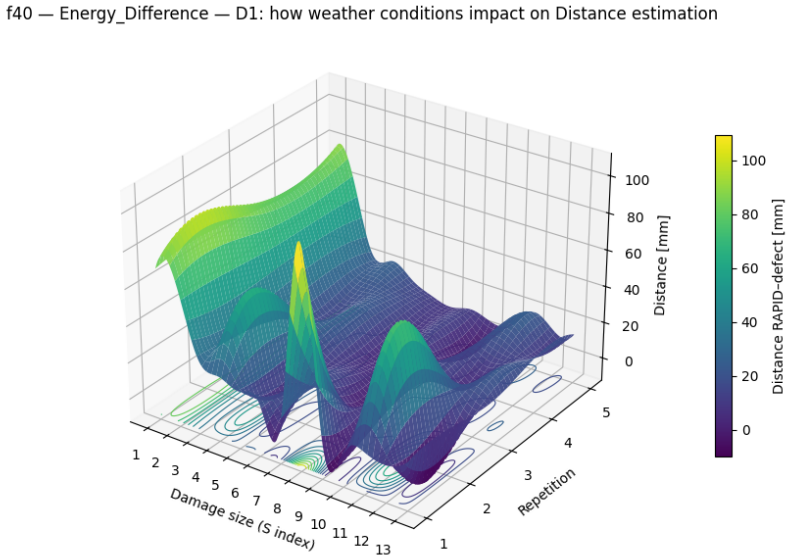

Figure 6: Effect of environmental conditions on the Euclidean distance for damage location D1 at 40 kHz using Energy Difference as damage indicator.

Conclusions

This work assessed the performance of the RAPID algorithm for damage localization in composite structures using guided-wave features. Results demonstrated that energy and correlation-based indicators provide the highest accuracy, with localization errors below 1 mm in optimal conditions. The analysis across frequencies, defect sizes, and repetitions highlighted the influence of both excitation parameters and environmental variability, confirming the robustness and limitations of RAPID imaging for reliable SHM applications. In addition, considering different damage locations did not affect the results significantly.

Abstract. The design and assessment of fragmentation warheads are key to the effectiveness of modern defense systems, particularly in counter-drone applications where unmanned aerial vehicles are increasingly employed. This work presents a preliminary study combining empirical formulations and finite element modeling (FEM) to support early-stage warhead design and lethality evaluation. Gurney and THOR formulations are first used to estimate fragment acceleration and penetration, providing the theoretical baseline for subsequent simulations. Two complementary numerical strategies are then developed: a simplified fragment-to-plate configuration for rapid analytical validation, and a full detonation model resolving the explosive–fragment interaction and impact on a target plate. The simplified model enables a quick assessment of penetration capability, while the full-scale simulation reproduces the acceleration and dispersion of a 225-fragment array. Results show good agreement with theoretical expectations, with ejection velocities around 1500~m/s and residual velocities consistent with the analytical framework. The integrated approach combines fast preliminary evaluation with high-fidelity physical insight, supporting early optimization of warhead design parameters and demonstrating the value of FEM in modeling fragmentation dynamics.

Introduction

The rapid proliferation of unmanned aerial vehicles (UAVs) has profoundly transformed modern warfare, enabling new capabilities in surveillance, intelligence, and precision strikes. Recent conflicts have highlighted the increasing dominance of small, low-cost, and agile drones, which allow rapid deployment, swarm tactics, and persistent reconnaissance at minimal expense. However, their affordability and widespread availability pose growing security challenges, as hostile UAVs can be employed for espionage or explosive delivery with limited financial risk.

This shift towards inexpensive UAVs requires an evolution in counter-drone systems. Traditional high-cost defense solutions are often unsuitable for neutralizing large numbers of small threats [1,2]. Affordable anti-drone missile systems have therefore become essential to modern defense strategies [3]. Countering UAVs remains complex due to their variable size, speed, and flight profiles, demanding advanced detection, tracking, and interception technologies.

Within the *Aerospace Design Project* course at Federico II of Naples, conducted in collaboration with MBDA Roma, the *SAGITTARIUS* missile (Fig. 1) was developed as a ground-to-air system. The project focused on the integration of precision, reliability, and adaptability in modern missile design. This paper concentrates on the preliminary design of the warhead and its lethality assessment, with particular attention to the fragmentation dynamics determining

effectiveness against aerial targets. The analysis examines how the detonation shockwave accelerates fragments toward a representative aluminum plate, providing insight into dispersion and energy transfer mechanisms.

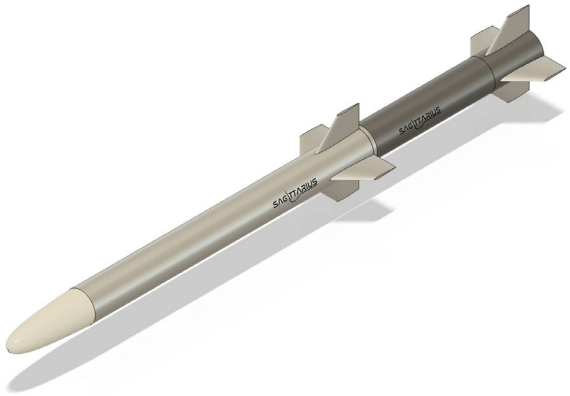

Figure 1: SAGITTARIUS Missile Design.

Preliminary Design and Theoretical Analysis

A cylindrical fragmentation warhead was selected, as this configuration efficiently directs the explosive energy outward, imparting a radial velocity to the fragments and maximizing the impact probability against fast-moving targets.

The radial velocity, a key parameter for lethality, was estimated through the G*urney formula* [4], which relates fragment velocity to the mass and energy distribution of the explosive:

$$V_r=\sqrt{2E}\sqrt{\frac{c/m}{1+0.5(c/m)}} \quad (1)$$

where E is the energy per unit mass of explosive and c/m the charge-to-mass ratio. This radial component, combined with the missile and target velocities (V_a), defines the total after-detonation velocity V_{ae}.

Fragment penetration capability was assessed using the *THOR model* [5], considering an AISI 4340 steel fragment impacting a 7075 aluminum alloy plate of thickness t:

$$V_{res} = V_{imp} - 0.3048\cdot10^{c_{11}}(61023.75\ t\ A)^{c_{12}}(915432.1m_{sf})^{c_{13}}\left(\frac{1}{\cos\alpha}\right)^{c_{14}}(3.28084)^{c_{15}}\ V_{imp} \quad (2)$$

$$M_{res} = m_{sf}-6.48\cdot10^{c_{31}-5}(61023.75\ t\ A)^{c_{32}}\ (915432.1m_{sf})^{c_{33}}\left(\frac{1}{\cos\alpha}\right)^{c_{34}}(3.28084)^{c_{35}}\ V_{imp} \quad (3)$$

where V_{imp} and V_{res} are the impact and residual fragment velocities, M_{res} the residual mass, A the contact area, and c_{ij} the material coefficients for the aluminum target.

TNT was selected as explosive (density 1.6 kg/mm^3, detonation velocity 6780 m/s), with pre-cut spherical steel fragments of radius 5 mm and a charge-to-mass ratio c/m = 0.5. Given the short travel distance, aerodynamic drag was neglected, assuming:

$$V_{ae} = V_{imp} = 1714.6\ m/s \quad (4)$$

Applying the THOR model to a 10 mm aluminum plate yields:

$$V_{res} = 763.9\ m/s, \quad M_{res} = 2.6\ m/s \quad (5)$$

Materials Research Proceedings 69 (2026) 1325-1330 https://doi.org/10.21741/9781644904251-230

Considering missile constraints, the warhead length and diameter were set to L_w = 150 mm and D_w = 77 mm (L/D ≈ 2), which allows for an accurate estimation of the velocity using the Gurney formula [4]. Each ring contains n_{fr} = 15 spherical fragments, giving n_f = 225 in total. The fragment mass is m_f = 0.9189 kg, with m_e = 0.4595 kg of explosive for c/m = 0.5. Assuming fragments and explosive account for 70% of the total mass:

$$m_w=\frac{m_e+m_f}{0.7}=1.97 \text{ kg} \quad (6)$$

Given ρ_e = 1600 kg/m^3, the explosive diameter is:

$$d_e=2\sqrt{\frac{m_e}{L_w\rho_e\pi}}= 0.0486 \text{ m} \quad (7)$$

The final geometry, including fragment distribution and explosive core, is shown in Fig. 2.

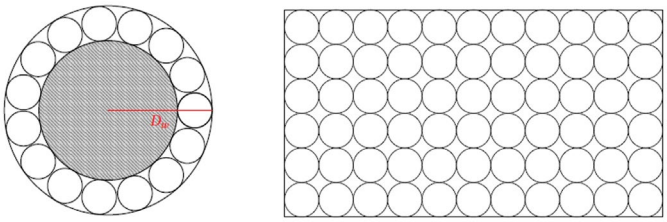

Figure 2: Schematic representation of the warhead geometry.

Simulation Modeling

Two finite element models are developed to reproduce the main physical mechanisms of detonation and fragment impact: a simplified *fragment-to-plate configuration* and a *full explosion-driven warhead model*. Both share the same geometry and materials defined in the preliminary design, differing only in the physical detail represented.

The first model (Fig. 3) isolates the impact phase to analyze the penetration mechanics of a single steel fragment against an aluminum plate. The fragment is assigned an initial velocity equal to the theoretical ejection speed obtained from Eq. 4. This setup allows direct validation of the THOR law by comparing impact and residual velocities, neglecting the influence of the detonation front.

The second model (Fig. 4) reproduces the complete detonation event. The explosive expansion generates a transient pressure field described by the Jones–Wilkins–Lee (JWL) equation of state [6]. This pressure wave transfers momentum to the surrounding fragments, producing their radial acceleration and dispersion. The model captures the coupled behavior between explosive gases, casing confinement, and fragment ejection, offering a physically consistent description of the early fragmentation stage.

Together, these two configurations provide complementary insight: the fragment-to-plate model addresses localized impact response, while the explosion-driven model resolves detonation-induced acceleration and dispersion, enabling a complete representation of the warhead lethality process.

Materials Research Proceedings 69 (2026) 1325-1330 https://doi.org/10.21741/9781644904251-230

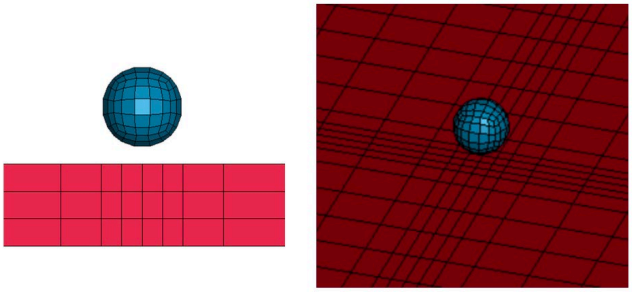

Figure 3: Simplified fragment-to-plate configuration.

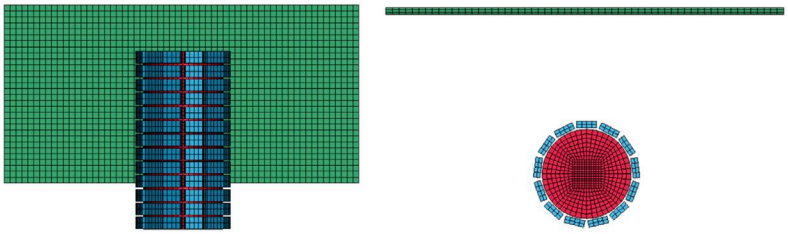

Figure 4: Full explosion-driven model showing the warhead mesh configuration.

Results and Discussion

The analyses carried out for both configurations allow a direct comparison between analytical predictions and finite element (FEM) results in terms of fragment velocity, kinetic energy, and penetration behavior.

For the fragment-to-plate configuration, Fig. 5 shows the time histories of velocity, which exhibits a sharp drop within the first microsecond, corresponding to the impact and energy transfer to the target. The final velocity stabilizes around 760 m/s, in close agreement with the analytical prediction (Eq. 5), with a residual kinetic energy of about 730 J. This confirms the simplified model's accuracy in capturing local deformation and penetration dynamics.

In the full explosion-driven simulation, the TNT detonation generates a transient pressure field through the casing, accelerating 225 fragments outward. The pressure peak reaches about 21 GPa, followed by a rapid expansion phase leading to fragment dispersion. The first impacted fragment achieves an ejection velocity of approximately 1500 m/s and a residual velocity near 760 m/s, in good agreement with the Gurney and THOR formulations. This consistency is notable given that, in the full-scale FEM model, fragments were idealized as rectangular elements to reduce computational cost, introducing only a minor geometric simplification. The corresponding velocity evolution is reported in Fig. 6.

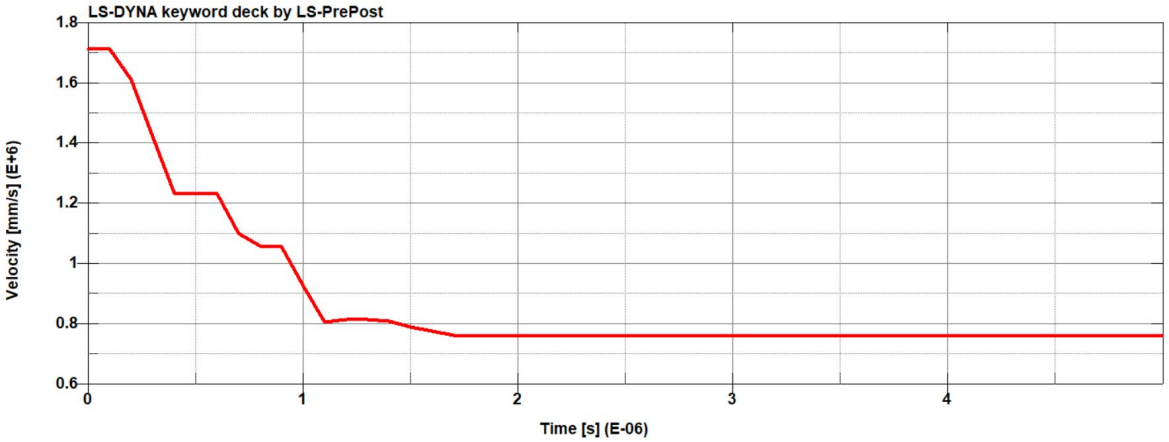

Figure 5: Velocity evolution for the fragment-to-plate configuration.

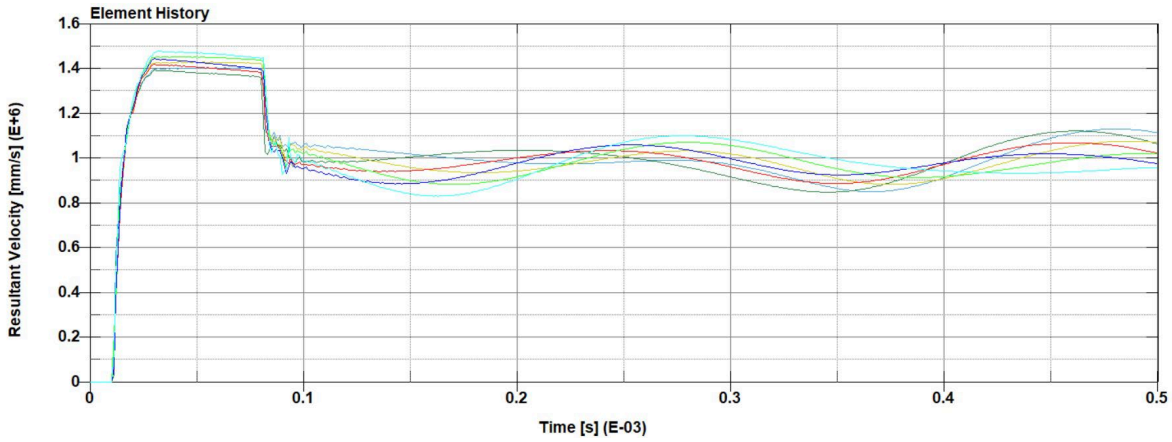

Figure 6: Velocity history of the first impacted fragments in the full explosion-driven model.

The comparison summarized in Table 1 highlights the strong agreement between analytical and FEM results, confirming the reliability of the proposed modeling approach for preliminary design assessment.

Table 1: Comparison between analytical and FEM results.

Parameter	FEM	Empirical (THOR/GURNEY)
Residual kinetic energy	730 J	761 J
Residual velocity	760 m/s	764 m/s
Residual mass	2.6 g	2.6 g
Average ejection velocity	1500 m/s	1715 m/s
Pressure peak	21 GPa	21 GPa

The consistency across all parameters demonstrates that analytical laws offer accurate first-order estimates, while the FEM provides deeper insight into the transient pressure field and fragment dispersion mechanisms.

Conclusions

The combined use of the two FEM simulations — the simplified fragment-to-plate model and the full explosion-driven configuration — enabled an effective validation of the empirical framework provided by the Gurney and THOR formulations. The consistency between analytical predictions

and numerical results confirms the reliability of these models for early-stage warhead design and demonstrates that finite element simulations can accurately capture the physical phenomena governing fragment acceleration and penetration.

Abstract. Adaptive structures are designed to undergo controlled shape changes in response to varying functional requirements, making them highly versatile for advanced engineering applications such as aerospace and space structures. Within this domain, unsymmetrical laminates have gained considerable attention due to bistability arising from residual thermal stresses generated during the curing process. However, the practical applications of the cured shapes of unsymmetrical laminates are often restricted due to the possibility of only two room-temperature equilibrium states. By connecting multiple bistable laminates in series, it becomes possible to realize surfaces with a high degree of multistability. The degree of multistability of such connected laminates is strongly influenced by boundary conditions, which play a critical role in shaping the stability landscape. While most theoretical models in the literature assume simplified center-fixed boundary conditions, such idealized constraints are rarely representative of real-world applications. This study aims to bridge this gap by investigating the influence of boundary constraints on the multistability of series-connected composite laminates. Specifically, a one-end-fixed boundary configuration is analyzed, in which one end of the laminate is clamped. The study shows that the clamped edge imposes significant mechanical constraints that limit bending parallel to the clamped edge. A solution to retain multistability could be the use of a transition region, ensuring that a laminate can recover its original multistable state even when one edge is clamped. Such a transition region helps preserve the multistability of the connected laminate. The results offer new insights into how fixed boundary conditions affect the design space, thereby deepening the understanding of multistable laminates and advancing their application potential in morphing systems.

Introduction

Adaptive structures are designed to alter their shape in response to varying external conditions, making them highly valuable in applications such as aerospace and wind energy systems. Multistable components form a crucial part of these structures due to their ability to maintain multiple stable shapes without the need for continuous energy input to retain those shapes. The potential of unsymmetrical laminates to exhibit multistability, owing to their cured shapes, has attracted considerable attention since the pioneering studies by Hyer [1,2]. When multiple bistable laminates are integrated or interconnected within a structure, they enable continuous and controllable shape transformations. By arranging these bistable laminates in series or parallel, higher-order multistable systems can be achieved. Theoretically, a system composed of n bistable elements in series can exhibit up to 2^n distinct stable states [3]. Transitions between these stable configurations can be realized through appropriate actuation strategies [4].

Materials Research Proceedings 69 (2026) 1331-1335 https://doi.org/10.21741/9781644904251-231

Several studies have explored the behavior of connected multistable laminates [5,6]. Although series-connected laminates have successfully demonstrated the maximum theoretical number of stable configurations [3,7], these investigations predominantly employed a center-fixed boundary condition, which is not representative of most practical scenarios. To move toward more realistic configurations, it is essential to investigate clamped boundary conditions, which can retain the multistability [8,9,10]. Research by Boddapati et al. [11] on clamped bistable laminates demonstrated that clamped boundaries significantly influence the strain energy profile of prestressed laminates and established criteria for the minimum length required to preserve bistability under edge clamping. However, these findings are still limited to bistable laminates, while the behavior of multistable laminates remains unexplored. Understanding how clamped boundaries affect the multistability of series-connected laminates is, therefore, of practical importance.

In the present study, one end of the series-connected unsymmetrical laminates is clamped to reflect a fixed boundary condition. The existence or potential loss of multistability under such clamped configurations is examined by introducing a specially designed transition region. Furthermore, the influence of the stacking sequence on the required transition region length is systematically analyzed.

Methodology and results

In this study, square laminates with dimensions of $L_x = L_y = 135$ mm are considered. The material properties used for the analysis are listed in Table 1. Finite element analysis is performed using the commercial software ABAQUS, employing a four-node, reduced-integration, general-purpose shell element (S4R) for modeling. An initial curing temperature of 180 ºC is applied to the entire assembly, which is subsequently cooled to room temperature (20 ºC), resulting in the first stable configuration. The actuation strategy adopted follows the approach reported in the literature for series-connected laminates with center-fixed boundary conditions [7]. Nonlinear geometric effects are included in the analysis by enabling the NLGEOM option, which is essential for accurately capturing large deformations and snap-through behavior.

Theoretically, up to four stable states are possible for series-connected laminates when their centers are fixed, as illustrated in Fig. 1 (a). However, when one end of the laminate is directly clamped, the curvature in the clamping direction (i.e., the $\boldsymbol{y}$-direction) is restricted. As a result, all configurations involving curvature in the $\boldsymbol{y}$-direction are suppressed, and only the state exhibiting curvature solely in the $\boldsymbol{x}$-direction remains stable. Consequently, the laminate becomes monostable, as shown in Fig. 1 (b).

Table 1: Properties of laminate selected in the present study

Component	E_{11} (GPa)	E_{22} (GPa)	G_{12} (GPa)	$\boldsymbol{\nu}_{12}$	$\boldsymbol{\alpha}_{11}$ (10^{-6}/ ºC)	$\boldsymbol{\alpha}_{22}$ (10^{-6}/ ºC)	$\boldsymbol{t}$ (mm)
Lamina	164	6.8	3.4	0.28	-0.02	33	0.140

Materials Research Proceedings 69 (2026) 1331-1335 https://doi.org/10.21741/9781644904251-231

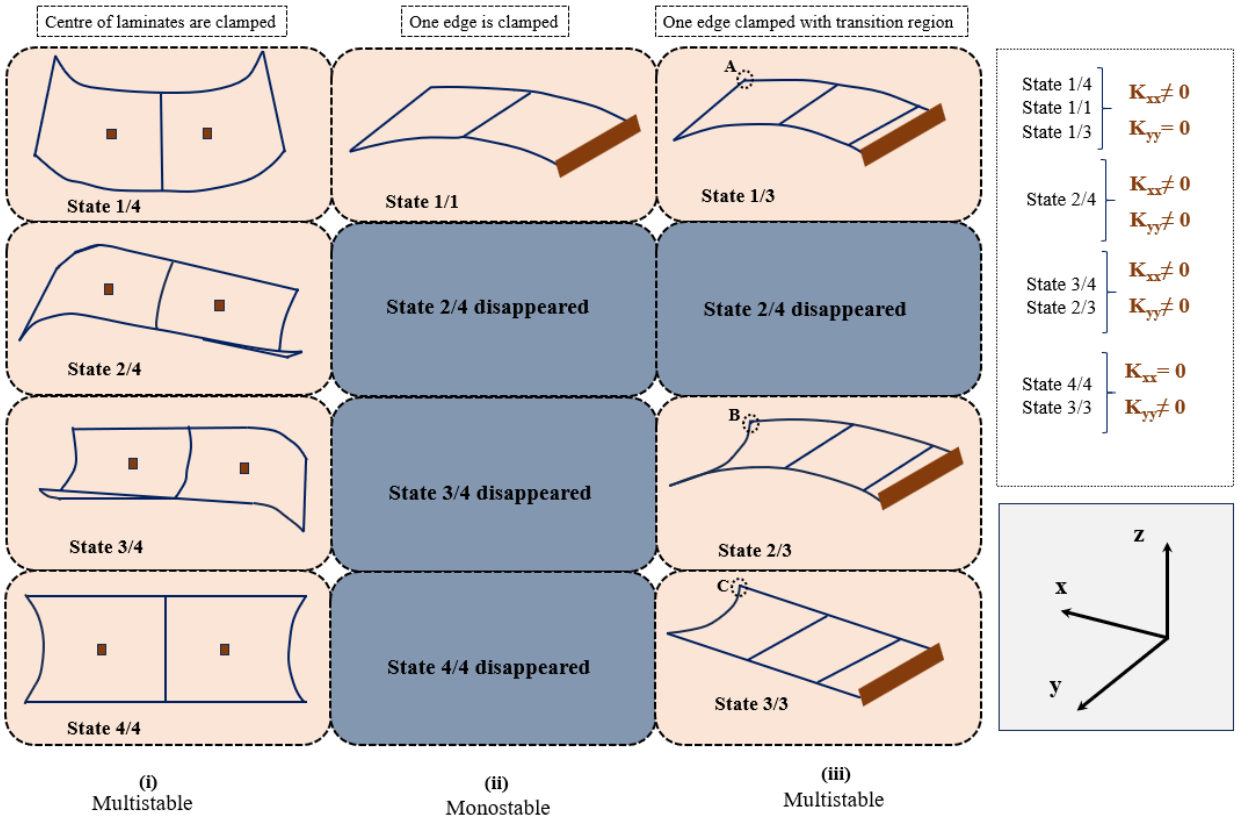

Figure 1. Schematic representation of (i) mathematically possible configurations of series connected laminates when the center of the laminates are fixed, (ii and iii) the effect of clamped boundary on the multistability when the edge is clamped, and the significance of transition plate in regaining the lost states

A transition region is introduced between the laminate and the clamped support. One edge of the transition plate is clamped, and no other boundary conditions are imposed on the assembly. The length of the transition plate is denoted by T_x, and the width of the transition plate is taken to be equal to L_y, since it must be attached to the laminate edge. The transition ratio ($\boldsymbol{TR} = \frac{T_x}{L_x}$) is defined as the ratio of the length of the transition plate to the length of one laminate plate (both laminate plates have the same dimensions). Different stacking sequences are used for the transition region, with the transition ratio varied from 0.05 to 0.5 in increments of 0.05. The transition ratio at which the $\boldsymbol{y}$-direction curvature is maintained, or bistability/multistability exists, is then identified.

The addition of a transition region facilitates the regaining of multistability. A maximum of three stable states is regained by introducing the transition region, as shown in Fig. 1(c). However, the extent of this recovery depends on the stacking sequence of the transition region, as shown in Fig. 2. For a stacking sequence of [0/90], bistability or multistability reappears at a $\boldsymbol{TR}$ of 0.2, whereas for the [0/0] and [90/90] configurations, it occurs at $\boldsymbol{TR}$ = 0.25. In the case of [90/0], bistability is regained only at $\boldsymbol{TR}$ = 0.5. Conversely, the [-45/45] stacking sequence exhibits monostable behavior across all transition ratios considered. Specific examples of the multistable configurations identified in Fig. 2 are summarized in Table 2. The corresponding out-of-plane displacements measured at the laminate corner for state 1, state 2, and state 3 are also provided in Table 2.

Materials Research Proceedings 69 (2026) 1331-1335 https://doi.org/10.21741/9781644904251-231

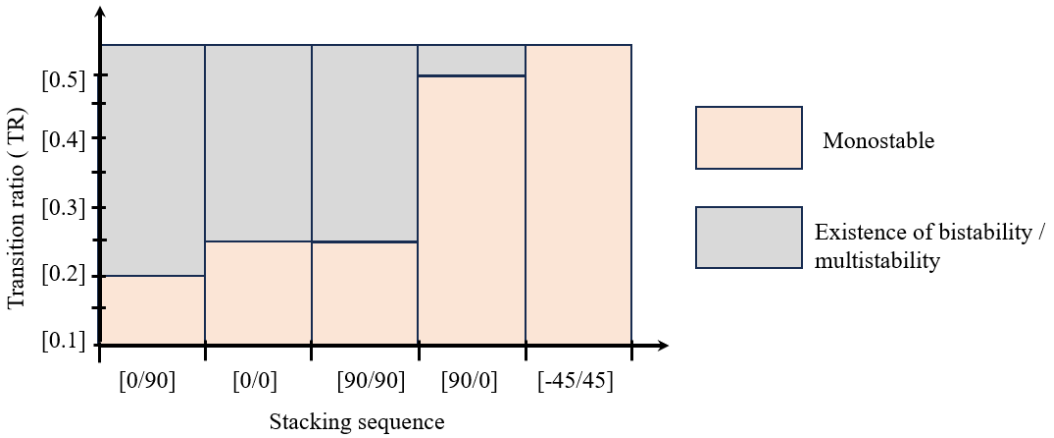

Figure 2. Representation of regaining of bistability/multistability for change in transition ratio for different stacking sequences

Table 2: Out-of-plane displacement values (A, B and C) at the corner for different states for the successful multistable cases depicted in the Fig. 1(c)

Transition ratio	Stacking sequence	Out-of-plane displacement (mm)		
		State 1 (A)	State 2 (B)	State 3 (C)
0.25	[90/90]	174.03	292.84	159.97
0.25	[0/90]	216.34	286.37	173.58
0.30	[90/90]	173.44	299.33	279.96
0.35	[0/90]	182.44	199.77	123.64
0.50	[0/90]	151.83	274.64	210.22

Summary and conclusions

The multistable behavior of series-connected laminates under clamped boundary conditions is investigated in this study. It is observed that clamping leads to a loss of multistability, resulting in a monostable configuration. However, introducing a transition region between the clamped support and one edge of the laminate restores the lost stable configurations, enabling the existence of three stable shapes. The restriction imposed by the clamped edge suppresses curvature in the y-direction, which is the primary cause of the loss of multistability. The addition of the transition region alleviates this restriction, allowing the laminates away from the clamped edge to regain curvature in the y-direction, thereby recovering multiple stable states. The influence of different stacking sequences on the multistability of laminates with a transition region is also examined. However, laminates directly connected to the clamped edge through the transition region are unable to exhibit significant curvature in the y-direction. This investigation holds considerable practical relevance, as it represents a step toward boundary conditions commonly encountered in real-world applications.

Keywords: Surrogate-Based Optimisation, Finite Element Model Updating, Constrained Optimisation, Kriging, Modal Analysis

Abstract. Finite element model updating represents a pivotal process in civil aircraft development, enabling the reconciliation of numerical models with experimental data obtained from static or ground vibration testing. Traditional surrogate-based optimisation methods, particularly Efficient Global Optimization through Kriging modelling, often lack robust constraint handling mechanisms, which are essential for real-world aerospace applications. This study presents the development and validation of a Constrained refined Efficient Global Optimisation (CrEGO) framework that addresses this limitation by integrating a Probability of Feasibility-penalised Expected Improvement acquisition function into the refined EGO methodology. The CrEGO algorithm constructs Kriging surrogate models for both objective and constraint functions, enabling rapid feasibility assessment without costly evaluations. Validation on the eXperimental BearDS 2 high-aspect-ratio wing spar demonstrates remarkable performance improvements, reducing the Modified Total Modal Assurance Criterion from 0.214 to 0.006 (97% improvement) whilst maintaining strict mass constraints, using only 829 expensive finite element evaluations.

Introduction

The evolution of modern aeronautical design has been characterised by the increasing reliance on high-fidelity numerical simulations, including Computational Fluid Dynamics and Finite Element Methods (FEM), which provide essential insights for structural analysis and certification processes. However, discrepancies between numerical predictions and experimental observations necessitate systematic model updating procedures to ensure accurate representation of real-world behaviour.

Finite element model updating (FEMU) has evolved from its foundations in the 1980s to become an indispensable tool in the study of structural dynamics, with a strong influence on aircraft development [1], allowing for the numerical models to reconcile with the experimental data obtained, either by static or ground vibration testing. The discipline encompasses both direct methods, including matrix updates, optimal matrix and error matrix, and eigenstructure assignment; and indirect methods that use experimental data through modal parameters or frequency domain information. Modal parameters, particularly natural frequencies (ω_n) and mode shapes ($\boldsymbol{\phi_n}$) [2], have emerged as preferred choices due to their stability compared to damping ratios.

Though many optimisation strategies have been proposed, most are predominantly classified as evolutionary, gradient- or local search-based, and surrogate-assisted approaches, a category now also including artificial intelligence-driven methods. Nevertheless, the primary objective of any optimisation technique is to address the specific problem with maximum efficiency [3]; therefore, in most practical applications, it is rarely necessary to employ exceedingly intricate or data-intensive models.

Content from this work may be used under the terms of the Creative Commons Attribution 3.0 license. Any further distribution of this work must maintain attribution to the author(s) and the title of the work, journal citation and DOI. Published under license by Materials Research Forum LLC.

Materials Research Proceedings 69 (2026) 1336-1340 https://doi.org/10.21741/9781644904251-232

Traditional optimisation approaches face significant challenges when applied to the FEMU procedure. Gradient-based methods struggle with non-linear, noisy objective landscapes where direct numerical derivatives lose accuracy and optimisers become prone to local minima stagnation, unless very good initial parameter estimates are available. Conversely, evolutionary algorithms, whilst providing a more global search and being more robust to derivative noise, require prohibitively high evaluation budgets incompatible with expensive numerical simulations inherent in FEMU applications.

Surrogate-based optimisation techniques have emerged as powerful solutions by constructing efficient approximation models from limited, expensive function evaluations. The Efficient Global Optimisation (EGO) framework [4], with Kriging modelling and Expected Improvement criteria, has demonstrated remarkable success in balancing exploration and exploitation. Enhanced variants such as refined Efficient Global Optimisation (rEGO) [5] have further improved performance through hybrid global-local search strategies and adaptive domain reduction. Despite these advances, a critical limitation persists for rEGO: the absence of robust constraint handling mechanisms essential for real-world aerospace applications. Practical FEMU problems invariably involve constraints related to performance requirements, manufacturing restrictions, and regulatory guidelines. This study addresses this gap by developing the Constrained refined Efficient Global Optimisation (CrEGO) framework.

Methodology

CrEGO extends the rEGO algorithm by integrating non-linear constraint handling capabilities whilst preserving its improved characteristics. The framework constructs Kriging surrogate models for both objective and constraint functions, represented as Gaussian processes, approximating the functions with the model:

$$\mathrm{Y}(\mathrm{x}) = \mu + \epsilon(\mathrm{x}) \tag{1}$$

where μ represents the average of the stochastic process and $\epsilon(\mathrm{x})$ is the error term distributed with zero mean and variance $\sigma(\mathrm{x})$. The constraint handling mechanism is based on variations of the Expected Improvement (EI) acquisition function, representative of the Kriging modelling [6]. The full expression becomes:

$$\mathrm{EI}(\mathrm{x}) = \left(\mathrm{f_{min}} - \mu(\mathrm{x})\right) \cdot \Phi\left(\frac{\mathrm{f_{min}} - \mu(\mathrm{x})}{\sigma(\mathrm{x})}\right) + \sigma(\mathrm{x}) \cdot \phi\left(\frac{f_{min} - \mu(x)}{\sigma(x)}\right) \tag{2}$$

where $\Phi(\cdot)$ and $\phi(\cdot)$ represent the cumulative distribution function and probability density function of the standard normal distribution, respectively, and $\mathrm{f_{min}}$ is the current minimum solution found. The EI is modified to penalise the acquisition function through the product of the Probability of Feasibility (PoF) for each constraint [7]:

$$\mathrm{EI}_{mod}(x) = \mathrm{EI}(x) \prod_{i=1}^{m} min(2 \cdot \mathrm{PoF}(g_i(x) \leq 0), 1) \tag{3}$$

being m the total number of constraints and having the PoF for the i-th constraint calculated using the Kriging model parameters:

$$\mathrm{PoF}(g_i(x) \leq 0) = \Phi\left(-\frac{\mu(x)}{\sigma_i(x)}\right) \tag{4}$$

Algorithm Enhancement.

CrEGO refines rEGO for constraint management: Latin hypercube sampling is used to verigy feasibility within $(\mathrm{d} \times 50)$ samples; constraints use individual Kriging models at the objective sample sites to evaluate PoF at low cost; if $(\mathrm{EI_{mod}})$ returns unfeasible points, the genetic algorithm enforces feasibility during EI maximisation; stopping combines an EI threshold with a minimum

Materials Research Proceedings 69 (2026) 1336-1340 https://doi.org/10.21741/9781644904251-232

Euclidean distance between successive feasible candidates. CrEGO is implemented in MATLAB R2024b and it is based on the DACE toolbox[1] for Kriging and data declustering.

High Aspect Ratio Wing Case Study

The CrEGO framework is applied to the eXperimental BeaRDS 2 (XB-2) high-aspect-ratio wing spar [8] for validation. The spar, shown in Fig. 1, geometry consists of a St. George's cross-shaped cross section, which changes proportions along the span, and a rectangular cross section in the root section, where the spar can be clamped. It is constructed from aluminium alloy 6082-T6 with a density $\rho = 2700$ kgm^{-3}, Young's modulus $E = 70$ GPa and a total mass $M_{\text{spar}} = 1.225$ kg.

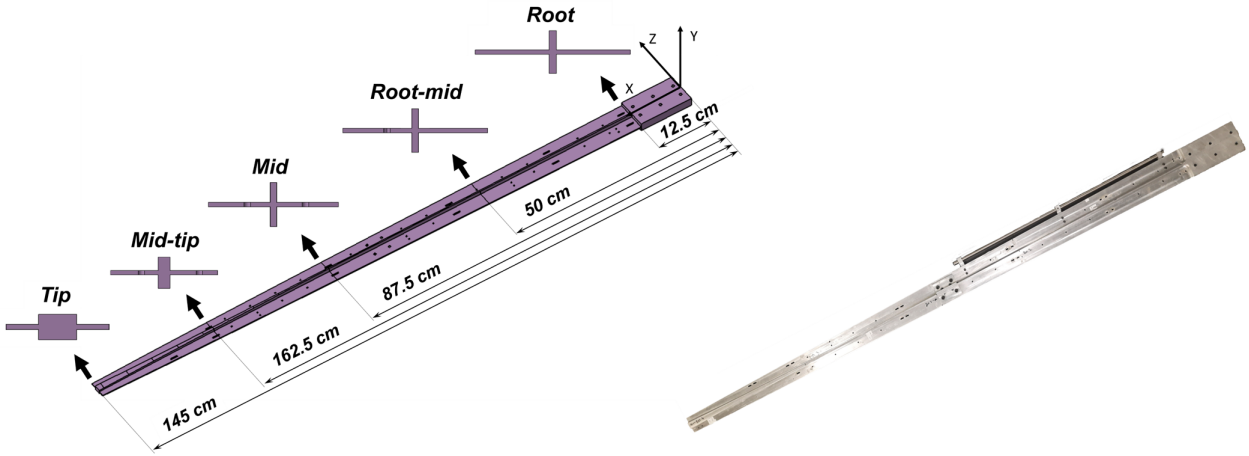

Figure 1 Spar CAD model (on the left), with the interested sections divisions and position, next to the real spar image (on the right), retrieved from [9].

The optimisation scenario involved tuning sectional density and Young's modulus parameters across the four taper segments of the spar described in Fig. 1, considering a fixed root section corresponding with the area where the spar is clamped. Limit bounds to the parameter variations are set to [0.7, 1.3] relative to baseline values of 1, constituting eight design variables total. The complement of the Modified Total Modal Assurance Criterion (MTMAC) [10] served as the objective function.

As per the main constraint, a critical mass restriction was imposed to maintain structural resemblance to the original configuration:

$$g(x) = \left(\mathrm{M}_{\mathrm{FEM}}(x) - \mathrm{M}_{\mathrm{spar}}\right)^2 - \left(\gamma \cdot \mathrm{M}_{\mathrm{spar}}\right)^2 \leq 0 \tag{5}$$

where $\mathrm{M}_{\mathrm{FEM}}$ represents the Finite Element Model (FEM) mass as a function of design variables, $\mathrm{M}_{\mathrm{spar}}$ denotes the baseline spar mass and γ stands for the maximum variation allowed between the previous masses. This formulation ensures the optimised configuration remains within $\pm$5% of the original mass, $\gamma = 0.05$.

Ground vibration testing (GVT) data [9] for the first three vertical bending modes provided experimental reference values for model updating. Modal measurements were extracted at strategically positioned nodes corresponding to accelerometer locations used in experimental testing, ensuring consistent comparison between numerical and experimental modal data. The optimisation used ANSYS Mechanical APDL for finite element analysis, with automated model parameter extraction integrated within the MATLAB CrEGO workflow.

Results are presented as a comparison between the experimental data [9], the Baseline FEM model analysis and the CrEGO FEMU procedure. Starting from a Baseline MTMAC value of 0.214, the CrEGO algorithm achieved a final value of 0.006, representing a 97% improvement in

[1] The DACE toolbox is available at https://orbit.dtu.dk/en/publications/dace-a-matlab-kriging-toolbox/

Materials Research Proceedings 69 (2026) 1336-1340 https://doi.org/10.21741/9781644904251-232

modal correlation. This enhancement was accomplished using 829 finite element evaluations whilst strictly maintaining the imposed mass constraint. The final optimised spar mass of 1.164 kg remained within the allowable ±5% deviation from the baseline 1.225 kg, consistently identifying the constraint boundary as optimal.

The parameter optimisation revealed consistent density reductions across spar elements, particularly concentrated in the third element, where the scaling factor reached the lower bound. Conversely, Young's modulus parameters generally approached upper bounds. Notably, during the GVT in [9], plastic deformation near the spar root was spotted, leading to enhanced resistance to further deformation in the area. The optimisation procedure captured this material stiffening through high E values in the first (closest to the root) spar element.

In terms of modal behaviour, the results presented in Tab. 1 and Fig. 2 show a clear enhancement with respect to the Baseline analysis. MAC values increased significantly, where the biggest effect was found in the 3rd bending mode, changing from 0.988 to 0.995.

Table 1 Modal natural frequency values for the Experimental, Baseline, and CrEGO updated model with percentage difference w.r.t. experimental values.

Natural Frequency [Hz] – (Difference in %)			
Mode	**Experimental**	**Baseline**	**CrEGO**
1st Bending	4.855	5.563 (14.58)	4.855 (0.00)
2nd Bending	26.966	31.193 (15.68)	26.965 (0.00)
3rd Bending	76.851	92.012 (19.73)	76.861 (0.01)

Conclusions

This study successfully developed and validated the Constrained refined Efficient Global Optimisation (CrEGO) framework, addressing a critical gap in surrogate-based optimisation for aerospace applications. By integrating Probability of Feasibility-penalised Expected Improvement into the refined EGO methodology, CrEGO enables effective constraint satisfaction whilst efficiently exploring the design space, making it practical for real-world FEMU problems. The framework's robust constraint handling mechanisms, incorporating Kriging surrogate models for both objective and constraint functions, enable efficient feasibility assessment without expensive constraint evaluations. This represents a significant advancement over traditional penalty methods. The adaptive stopping criteria combining Expected Improvement thresholds with explicit feasibility checks ensured reliable convergence whilst preserving computational efficiency throughout the optimisation process. Validation on the eXperimental BearDS 2 high-aspect-ratio wing spar demonstrated exceptional performance. The algorithm achieved a 97% improvement in modal correlation, reducing the MTMAC from 0.214 to 0.006 whilst maintaining strict mass constraints using only 829 expensive finite element evaluations. The final optimised spar mass of

1.164 kg remained well within the allowable ±5% deviation from the baseline. Modal correlation analysis revealed substantial improvements across all considered modes. Maximum modal frequency deviation decreased from 19.73% to 0.01%, whilst MAC values increased significantly, approaching 1.

These findings establish CrEGO as a powerful tool for aerospace FEMU problems where computational efficiency and constraint satisfaction are paramount. The framework contributes to more efficient, accurate, and reliable structural analysis methodologies essential for future aviation developments.

Keywords: Structural Health Monitoring, Smart Composite, Passive Sensors, Copper Wires, Strain Sensing

Abstract. This study presents a multifunctional Carbon Fiber Reinforced Polymer (CFRP) composite integrating embedded copper wires for Structural Health Monitoring (SHM) through strain-induced resistance variation. The monitoring principle relies on the linear relationship between mechanical strain and the change in electrical resistance of the copper wires. A preliminary feasibility test was carried out through a three-point bending experiment up to failure, with real-time resistance acquisition managed by an Arduino Giga R1 WiFi controller. A complementary Finite Element Method (FEM) analysis in Ansys was employed to predict wire deformation and corresponding resistance change. The first correlation between the experimental and numerical results confirms the effectiveness of the proposed sensing approach as a continuous, non-invasive, and cost-efficient strain monitoring technique for advanced composite structures.

1. Introduction

Carbon Fiber Reinforced Polymers (CFRPs) are widely used in aerospace, automotive, civil, and marine engineering due to their superior mechanical performance, lightweight, and design flexibility. The growing demand for reliability and structural safety has driven the development of multifunctional composites that can integrate self-sensing and damage monitoring capabilities, known as Structural Health Monitoring (SHM) systems [1,2].

Conventional inspection methods typically rely on periodic or post-damage evaluation, limiting their applicability for real-time monitoring. Embedding passive sensors directly within the composite matrix offers a practical solution for continuous structural assessment at low cost and with minimal additional weight.

In this work, copper wires are integrated within CFRP laminates to serve as in-situ strain sensors. The sensing mechanism is based on monitoring the electrical resistance variations resulting from mechanical elongation during loading. The resistance increases proportionally with the strain-induced length change of the wire [3−5]. While wire rupture provides a discrete damage indicator (loss of electrical continuity), this study aims to achieve continuous strain monitoring throughout the entire deformation process. Copper was selected for its high electrical conductivity and ductility, ensuring good compatibility with the composite matrix. The embedded longitudinal and transverse copper wires allow for localized deformation monitoring, and the first correlation between numerical and experimental results supports the feasibility of the proposed sensing approach.

2. Materials and Methods

Rectangular CFRP specimens (100 mm × 20 mm) were fabricated via the Vacuum Assisted Resin Transfer Molding (VARTM) process, ensuring uniform resin infiltration and void-free consolidation. The composite consisted of ten woven carbon-fiber plies, each approximately 0.2 mm thick. Copper wires (diameter 0.2 mm) were embedded as passive strain sensors between specific layers.

Two distinct wire arrangements were implemented: Transverse sensors (20 short wires placed between the 3rd and 4th plies) and Longitudinal sensors (4 long wires positioned between the 7th and 8th plies). The wires were embedded 2.5 mm from the specimen edges, with 5 mm spacing between adjacent wires (Figure 1).

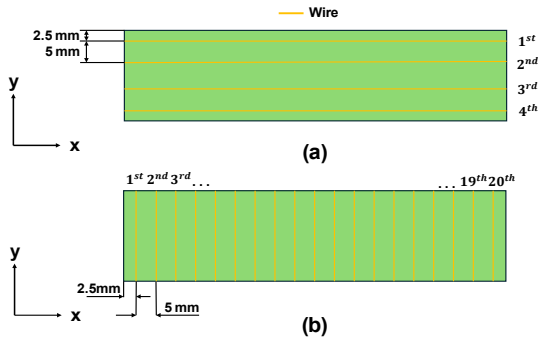

Figure 1. Schematic in plane representation of the embedded copper wire network in the CFRP: a) Longitudinal and b) Trasversal wires

Table 1 summarizes the mechanical and physical properties of the composite constituents.

Table 1. Mechanical and Physical Properties of Constituent Materials

	CFRP laminate	Copper
Young's Modulus E [GPa] (in Plane)	60	110
Young's Modulus E [GPa] (out of Plane)	3	
Poisson's ratio v (in Plane)	0.04	0.34
Poisson's ratio v (out of Plane)	0.3	
Shear Modulus G [GPa] (in Plane)	1	-
Shear Modulus G [GPa] (out of Plane)	2	-
Electrical resistivity ρ [Ω × m]	-	1.68×10^{-8}

3. Finite Element Modeling

A linear static Finite Element Analysis (FEA) was performed in Ansys to predict the mechanical strain and elongation of the embedded copper wires. The model reproduced the geometry, material properties, and boundary conditions of the tested specimens.

A high-resolution mesh with 20-node solid elements (SOLID 186) and element size of approximately 0.25 mm was used. Local mesh refinement was applied at the copper–matrix interface to capture high strain gradients (Figure 2). To enforce perfect bonding between the CFRP layers and the embedded copper wire, a node merge technique was implemented at the interfaces.

Materials Research Proceedings 69 (2026) 1341-1346 https://doi.org/10.21741/9781644904251-233

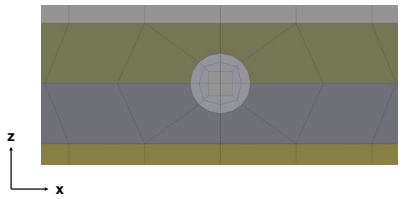

Figure 2. Finite Element Mesh detail of the copper wire cross-section

The resistance variation was estimated from the classical resistence formula:

$$\Delta R = \rho \frac{\Delta L}{S_0}. \tag{1}$$

where ρ is the electrical resistivity of copper, S_0 is the initial cross-sectional area of the copper wire and ΔL is elongation computed from the deformed nodal coordinates.

To obtain ΔL,the deformed length L_{def} of the wire's centerline axis is computed by summing the lengths of all elemental segments in the final, loaded configuration.

If the wire's centerline is defined by a sequence of nodal coordinates $\boldsymbol{X}_i^{def} = (x_i^{def}, y_i^{def}, z_i^{def})$ for node i, the length of the segment between node i and node $i+1$ in the deformed state is found using the Euclidean distance:

$$L_{def} = \sum_{i=1}^{N-1} \sqrt{\left(x_{i+1}^{def} - x_i^{def}\right)^2 + \left(y_{i+1}^{def} - y_i^{def}\right)^2 + \left(z_{i+1}^{def} - z_i^{def}\right)^2}. \tag{2}$$

$$\Delta L = L_{def} - L_0. \tag{3}$$

where N is the total number of nodes along the wire axis. The initial undeformed length L_0 is calculated similarly using the initial nodal coordinates $\boldsymbol{X}_i^0$.

Numerical results were obtained for Longitudinal Wires 1 and 2, with symmetry assumed for Wires 3 and 4. The predicted ΔR–displacement curves for both wires showed nearly identical nonlinear trends, confirming a uniform strain field near the specimen mid-plane (Figure 3**)**

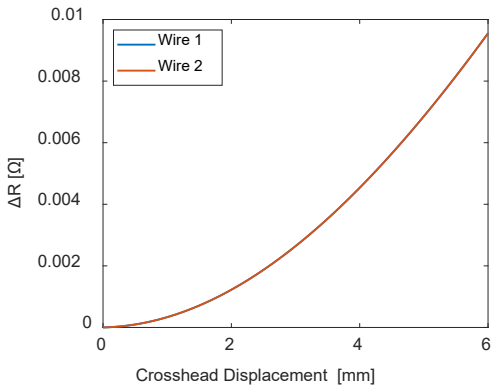

Figure 3. Numerical prediction of $\Delta \boldsymbol{R}$ *for Longitudinal Wires 1 and 2*

4. Experimental Setup for Resistance Measurement

The resistance measurement system was built around an Arduino Giga R1 WiFi microcontroller connected to a set of parallel voltage divider circuits. Each channel consisted of a fixed resistor ($R = 100\ [\Omega]$) in series with the variable resistance of the copper wire (R_i).

The output voltage V_{out} of each divider is given by:

Materials Research Proceedings 69 (2026) 1341-1346 https://doi.org/10.21741/9781644904251-233

$$V_{out} = \frac{R}{R+R_i} V_{in}. \quad (4)$$

and the resistance of each wire is calculated as:

$$R_i = \left[\left(\frac{V_{in}}{V_{out}}\right) - 1\right] \times R, i = 1,2, \dots N. \quad (5)$$

where V_{in} is the input voltage of the circuit, typically 5 [V] for the Arduino system. This relationship was implemented in the Arduino code to compute real-time resistance changes (ΔR) for all sensing channels (Figure 4).

It is important to note that the electrical resistivity (ρ) of copper increases with temperature according to its positive temperature coefficient. During the tests, a slight thermal rise was observed in the wires connected to the Arduino board due to Joule heating and continuous current flow. This thermal effect contributes to a baseline drift in the measured resistance, which was subsequently compensated during signal post-processing.

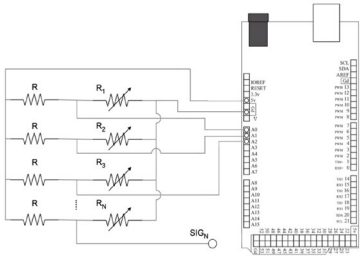

Figure 4. Arduino Giga R1 Wifi connected to the designed system with N denoting the number of channels on the structure [1]

4.1. Experimental Procedure

The sensor-reinforced composite specimens were subjected to three-point bending tests until failure. The experimental setup involved a central load application, with the supports placed between the 4th and 5th transversal wires and between the 16th and 17th transversal wires. This setup (Figure 5) allowed for the analysis of the resistance change under a controlled and localized stress state.

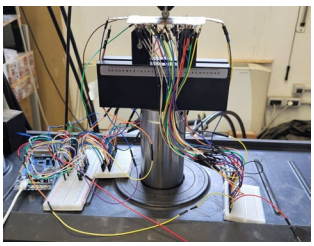

Figure 5. Experimental setup for the three-point bending test and real-time resistance measurement

Transverse wires exhibited negligible resistance changes due to their orientation and proximity to the neutral axis, making them unsuitable for quantitative correlation. Therefore, the analysis focused exclusively on the four longitudinal wires, which provided, strain-dependent resistance variations.

The specimen failed at a maximum load of 640 N and a crosshead displacement of 6 mm, defining its ultimate flexural capacity.

The raw electrical signals were filtered using a two-step procedure: a moving median filter to remove high-frequency spikes and a zero-phase Butterworth low-pass filter to extract the underlying trend. Additionally, to compensate for the thermal drift caused by resistivity increase

at higher temperature, each filtered curve was corrected by subtracting a reference baseline obtained from a separate "no-load" experiment, in which the system was powered and allowed to reach its steady-state thermal condition without mechanical loading.

Figure 6 illustrates the recorded ΔR profiles for longitudinal Wire 1 and Wire 2.

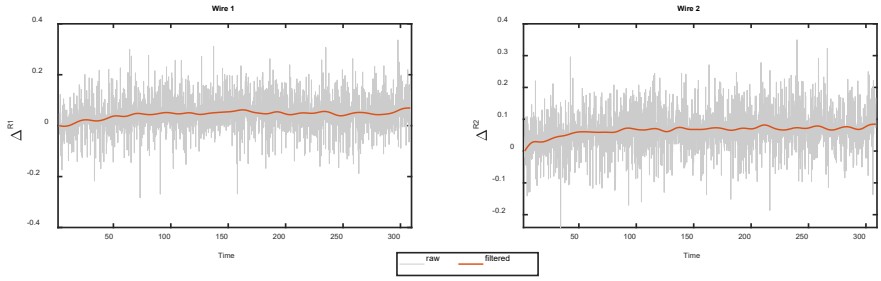

*Figure 6. Experimental resistance variation (Δ**R**) over time for the four longitudinal copper wires (Wire 1 to Wire 4) during the three-point bending test*

The filtered curves exhibit a smooth, nonlinear increase in ΔR consistent with progressive structural deformation.

5. Results and Discussion

During the bending test, longitudinal wires exhibited clear strain-dependent resistance increases, while transverse wires showed minimal variations masked by electrical noise. The ultimate load and displacement at failure were 640 N and 6 mm, respectively, consistent with the expected flexural strength for the tested laminate.

Figure 7 illustrates the feasibility of the proposed sensing approach through a comparison between the numerically predicted and experimentally measured ΔR curves for the longitudinal wires. Both trends exhibit a gradual increase in resistance variation with increasing displacement, as expected from strain-induced effects. The overall variations remain very small – on the order of 0.02 at most – making them difficult to discern experimentally. Despite this, the model successfully captures the general evolution of ΔR and provides a reasonable estimate of the magnitude, strongly supporting the feasibility and reliability of the proposed method.

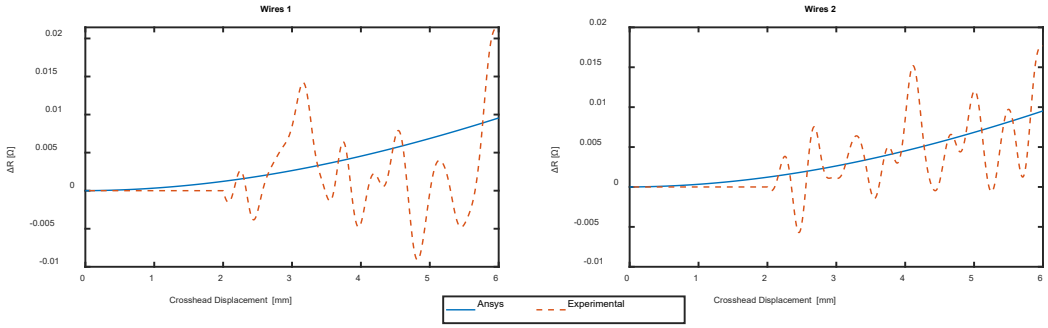

*Figure 7. Comparison of predicted vs. experimental Δ**R** for the longitudinal copper wires*

6. Conclusion

This work demonstrated the feasibility of embedding copper wires as passive strain sensors within CFRP composites for real-time SHM applications.

- Sensing Mechanism Validation: The Arduino-based monitoring system successfully acquired resistance changes during deformation, revealing strong correlation with mechanical strain.

- Numerical–Experimental Correlation: FEM simulations accurately reproduced experimental resistance variations by computing the strain-induced wire elongation.

The correlation between experimental and numerical data confirms the reliability of the proposed approach as a low-cost, integrated, and non-invasive strain monitoring solution. Future developments will focus on extending this methodology to multi-sensor networks for distributed SHM and dynamic loading conditions.

Keywords: Carrera Unified Formulation, Non-linear Analysis, Buckling, Tapered Beam

Abstract. Variable cross-section beams are highly susceptible to instability phenomena, and traditional 3D Finite Element (FE) methods are often computationally demanding for slender members. This work proposes a refined, fully nonlinear one-dimensional (1D) beam model for tapered and twist geometries, developed within the Carrera Unified Formulation (CUF) framework. The element directly accounts for cross-sectional variation by performing a three-dimensional integration of of approximating function in the Jacobian matrix. The nonlinear governing equations, derived via the Principle of Virtual Work, are solved using a Newton-Raphson linearization scheme coupled with an arc-length path-following method. The formulation's effectiveness is validated through numerical applications, including the buckling of a tapered steel C-section beam.

1. Introduction

The structural analysis of tapered beams, members with continuously varying cross-sections, is crucial for high-performance structures in engineering [1]. Although analytical solutions exist for prismatic beams, tapered geometries typically require computationally expensive 3D Finite Element (FE) models., particularly for thin-walled slender structures where fine meshes are needed to capture nonlinearities.

To address this, we present a novel, fully nonlinear 1D beam element for tapered geometries, developed within the Carrera Unified Formulation (CUF) framework [2]. This formulation systematically derives hierarchical models with 3D capabilities, thus overcoming the inherent limitations of conventional 1D beam theories..

The proposed element directly incorporates cross-section variation through a three-dimensional integration of the approximation functions and the Jacobian [3,4]. This approach enables a consistent representation of non-uniform geometries while preserving accuracy. The nonlinear governing equations, derived via the Principle of Virtual Work, are solved using a Newton-Raphson linearization scheme combined with an arc-length constraint path-following method [5-7].

The effectiveness is validated through numerical applications, including the buckling of a tapered steel C-section benchmark [8]. Comparisons with experimental data available in the literature and conventional 3D FE simulations confirm the model's high fidelity and significant improvement in computational efficiency in predicting the nonlinear buckling response of variable cross-section beams.

2. Theoretical Framework and Numerical Methodology

The finite elements employed here are an extension of the Carrera Unified Formulation (CUF) [9]. CUF allows for the consistent derivation of one-dimensional (1D) beam theories with arbitrary kinematic hypotheses by approximating the three-dimensional displacement field $\boldsymbol{u}(x,y,z) = (u_x(x,y,z), u_y(x,y,z), u_z(x,y,z))$ as a generalized expansion. This field is approximated by combining the CUF expansion functions (F_τ) along the cross-section/thickness with the standard Finite Element (FE) shape functions (N_i) along the beam axis, leading to the combined displacement formulation:

$$\boldsymbol{u} = F_\tau(x,z)N_i(y)Q_{\tau i} = L_{\tau i}(\xi,\eta,\nu)Q_{\tau i}. \tag{1}$$

where $q_{\tau i}$ represents the generalized nodal degrees of freedom, and (ξ,η,ν) are the natural coordinates corresponding to (x,y,z). In this expression, $L_{\tau i}(\xi,\eta,\nu)$ represents a new 3D shape function in which the order of expansion can be different along one of the spatial directions. Considering this formalism, the volume integrals involved in the governing equations will be not split in 1D and 2D integrals as usual, but the functions $(N_i F_\tau)$ will be handled as regular 3D shape functions; consequently, the Jacobian matrix relative to the transformation from natural coordinates (ξ,η,ν) to global coordinates (x,y,z) will be computed in 3D form. However, a formal separation of the coordinates as in Eq. (1) is still possible and the choice CUF FE approximations follows the same principles as in conventional beam and plate elements based on CUF, that is functions with higher polynomial order are employed along the larger directions.

The resulting elements, including the novel formulations [3,4], are specifically designed to consistently model non-orthogonal geometries. This is achieved by explicitly treating the element as a full 3D domain for the integration of stiffness and mass matrices, ensuring geometric consistency and improved accuracy compared to classical 1D formulations.

Figure 1 illustrates the modeling approach, which depicts the combination of 2D cross-section discretization (four node plate element Q4, nine node plate element Q9, sixteen node plate element Q16) and 1D beam elements (two nodes beam element B2, three node beam element B3, four node beam element B4) in a tapered geometry.

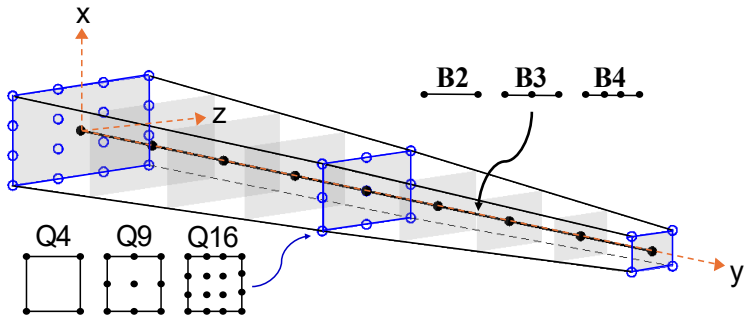

Figure 1. Conceptual representation of the Tapered CUF element showing the coupling of 2D cross-section discretization and 1D through-the-thickness expansion in a tapered geometry.

2.1 Geometrically Nonlinear Solution Strategy

The structural analysis is conducted in the geometrically nonlinear regime adopting a finite element procedure based on the Total Lagrangian formulation. The large displacement behavior is described adopting the Full Green-Lagrange strain tensor, defined as:

$$\boldsymbol{E}_{ij} = \frac{1}{2}\left(\boldsymbol{u}_{i,j} + \boldsymbol{u}_{j,i} + \boldsymbol{u}_{k,i}\boldsymbol{u}_{k,j}\right). \tag{2}$$

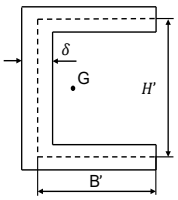
Materials Research Proceedings 69 (2026) 1347-1352- https://doi.org/10.21741/9781644904251-234

where $\boldsymbol{u}_{i,j}$ represents the displacement gradient $\partial \boldsymbol{u}_i / \partial x_j$. The last term, $\boldsymbol{u}_{k,i}\boldsymbol{u}_{k,j}$ is essential for capturing large displacements, rotations, and buckling phenomena.

The nonlinear equilibrium equations, derived from the Principle of Virtual Work ($\delta L_{int} = \delta L_{ext}$), are solved using an incremental-iterative procedure based on the Newton-Raphson scheme. Linearization around the non-trivial equilibrium state leads to the definition of the Tangent Stiffness Matrix $\mathbf{K_T}$:

$$\delta L_{int} = \delta Q^T(\mathbf{K_0} + \mathbf{K_{T1}} + \mathbf{K}_\sigma)\Delta Q = \delta Q^T \mathbf{K_T} \Delta Q. \quad (3)$$

Here, ΔQ is the vector of incremental degrees of freedom, $\mathbf{K_0}$ is the linear stiffness matrix, $\mathbf{K_{T1}}$ is the nonlinear contribution to the tangent stiffness matrix coming from the linearization of the constitutive law, and $\mathbf{K}_\sigma$ is the geometric stiffness matrix (or initial stress matrix), which accounts for the influence of pre-stressed effects for predicting the critical buckling load.



To trace the equilibrium path, especially beyond limit points (instability regions), a path-following method (such as the Arc-Length method [5]) is implemented, allowing for the stable and accurate calculation of the post-buckling response.

3. Case Study I: Lateral Buckling of a Variable C-Beam

This initial case study validates the proposed formulation by reproducing the post-buckling behavior of a variable cross-section steel C-beam, benchmark against the experimental results of Mascolo et al. [8].

The C-beam is tapered along the -axis; dimensions for the initial and final cross-sections are documented in Table 1. A compressive load, F, is applied along the line connecting the cross-section centroids (G). The beam has a length $L = 0.9\ m$ and is modeled with simply supported boundary conditions (Section A: u_x and u_z constrained; Section B: u_x, u_y, u_z constrained)(Figure 2.a). The equilibrium path is traced using the displacement measured at mid-length (Figure 2.b).

Table 1 - End cross-sections (A and B) details.

	$Section\ A$: $B' = 28.5\ mm;\ H' = 87.0\ mm;$ $\delta = 3\ mm;\ A = 642\ mm^2$
	$Section\ B$: $B' = 18.5\ mm;\ H' = 177.0\ mm;$ $\delta = 3\ mm;\ A = 432\ mm^2$

The material properties correspond to S420 steel grade, utilizing a Young's Modulus of 210 GPa and Shear Modulus of 80.77 GPa. The setup includes two elastic transverse plates (diaphragms) located at $z = 0.3\ m$ and $z = 0.6\ m$, with a thickness of $3\ mm$, modeled using B3 elements and 32 Q9 elements in the cross-section (Figure 2. c). The remainder of the beam employs B4 elements along the axis and 14 Q9 elements in the cross-section, ensuring a robust discretization suitable for thin-walled structures.

3.1 Results and Validation

The numerical analysis using the tapered CUF elements and the arc-length path-following technique yielded a critical load of 51.6 kN. This result demonstrates excellent agreement with the experimental critical buckling load of 53.6 kN reported in the reference paper.

Materials Research Proceedings 69 (2026) 1347-1352- https://doi.org/10.21741/9781644904251-234

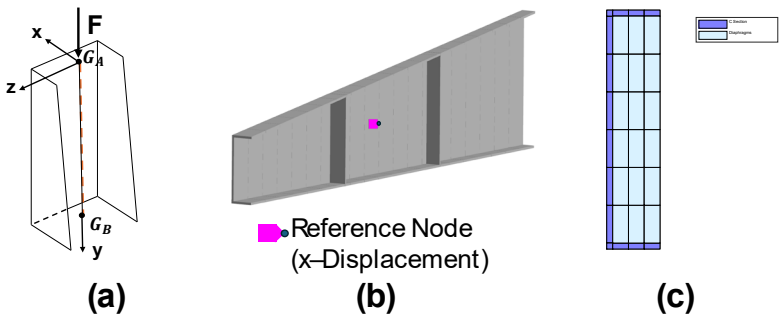


***Figure 2**. a) Schematic of the analyzed beam and basic notation, b) Reference node (used to build the equilibrium curve), c) Diaphragms section, CUF expansion detail*

Furthermore, the equilibrium path (F vs. u_y) obtained from the CUF analysis showed a consistent trend when compared against a full geometrically nonlinear structural analysis performed with the commercial FE software Ansys. This consistency confirms the reliability of the CUF formulation in capturing the complex instability mode (Figure 3.a) and resulting deformed shape (Figure 3.b) for thin-walled tapered structures.

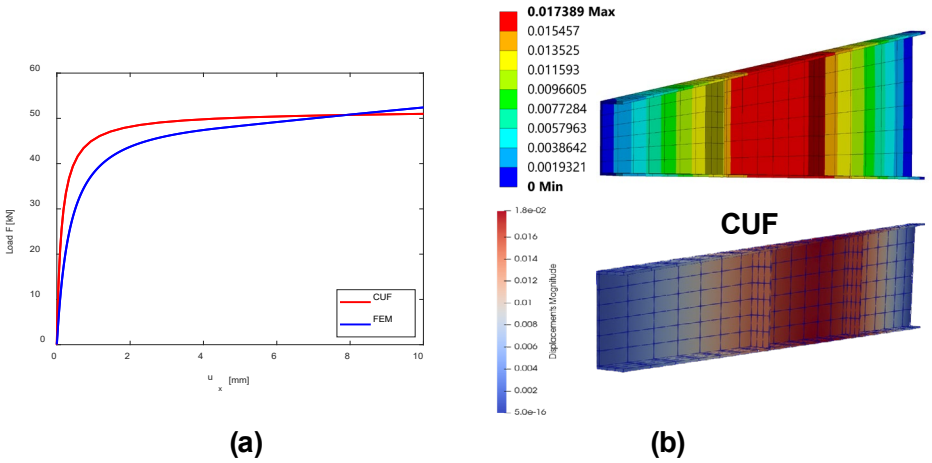

Figure 3. a) Equilibrium curve F vs u for the variable C-beam. Comparison between CUF and Ansys results. b) Deformed shape of the variable C-beam at critical load

4. Case Study II: Post-Buckling of a Tapered and Twisted Beam

This second case study provides a purely numerical comparison designed to test the model's performance under geometric non-uniformity. It analyzes a simply-supported beam of length $L = 1\ m$, subjected to an axial compressive load, F, and made of S420 steel. The geometry presents a double geometric complexity:

1. Tapering: The dimensions (height and width) of the final section B are two times those of the initial section A. The initial section dimensions are 5 mm (height) and 25 mm (width).
2. Twist: the final cross-section is subjected to an anticlockwise twist of one full turn (2π) relative to the initial section along the beam axis.

A visual representation of the geometry and loading conditions is provided in Figure 4. The mesh discretization consists of 30 B4 elements along the axis and a cross-section discretized with a 2×8 array of Q16 elements (height × width).

This combination of tapering and twist aims to test the element's performance under geometric variation and its capability to capture instability in highly non-conventional structures.

Materials Research Proceedings 69 (2026) 1347-1352- https://doi.org/10.21741/9781644904251-234

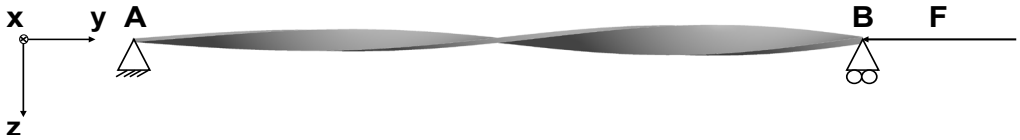

Figure 4. Schematic of the analyzed beam and basic notation

4.2. Results and Discussion

The critical load and post-buckling response were obtained using the nonlinear CUF model and compared against a full 3D structural nonlinear simulation in Ansys. The CUF formulation demonstrated remarkable computational efficiency, achieving results comparable to the 3D model with a significant reduction in computing time, while accurately capturing the entire post-buckling trend (Figure 5.a). This confirms the model's robustness and efficiency even under severe geometric variation and axial twist (Figure 5.b).

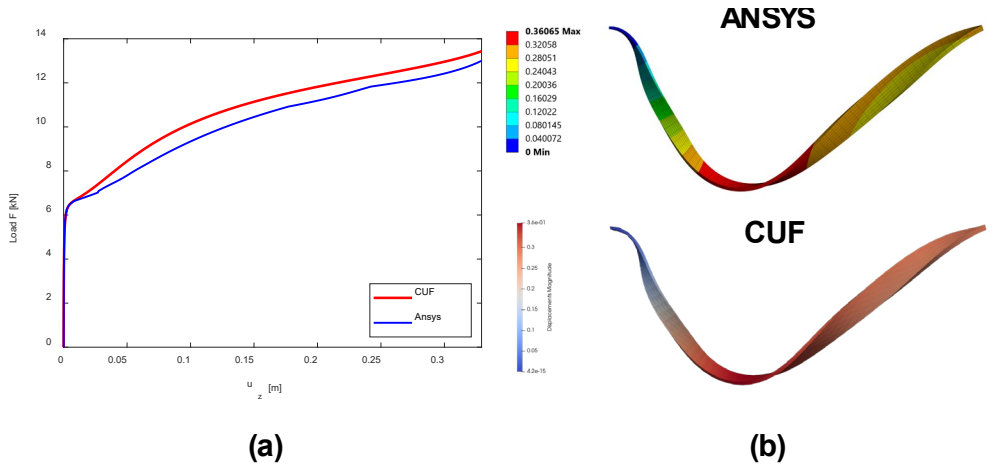

Figure 5. a) Equilibrium curve F vs $\boldsymbol{u_x}$ for the variable rectangular beam. B) Deformed shape (axial buckling mode)

5. Conclusions

This paper successfully introduced and validated a novel class of Tapered Finite Elements developed within the Carrera Unified Formulation (CUF) framework for the geometrically nonlinear buckling analysis of variable cross-section beams. The key contribution of the formulation lies in the consistent incorporation of cross-sectional variation directly into the element matrices through three-dimensional integration, coupled with a path-following method for tracing highly nonlinear equilibrium paths.

The method's reliability was demonstrated through two rigorous benchmarks. A comparison against experimental data for the lateral-torsional buckling of a clamped C-beam showed a good correlation with the critical load reported in the literature. Furthermore, a numerical benchmark involving an extremely complex, twisted geometry successfully captured the entire nonlinear post-buckling trend when compared against full 3D simulations. In summary, the proposed CUF tapered elements are an accurate, robust, and computationally effective alternative to conventional 3D Finite Element models, offering a powerful tool for the high-fidelity analysis and design of complex non-prismatic components.

Abstract. Previous studies have demonstrated that coupling three-dimensional Peridynamics (PD) with one-dimensional high-order refined elements via the Lagrange multipliers method ensures physical consistency at the PD–FE interface [1]. This coupling strategy has also been applied to quasi-static crack propagation analyses of brittle materials [2]. Building upon this framework, the present work extends the approach by incorporating a peridynamic fatigue model, providing an efficient framework for fatigue crack analysis, especially in three dimensional cases [3]. The accuracy of the proposed model has been verified by reproducing the S–N and Paris curves of the 7075–T651 aluminum alloy. It demonstrates a promising method for fatigue crack analysis in aeronautical structures.

Introduction

Peridynamics (PD) is a nonlocal theory of continuum mechanics that uses integral equations to model material behavior, making it particularly well suited for simulating the initiation and propagation of fracture and damage [4]. Beyond the original formulation by Silling, PD has been effectively used for discontinuous structural problems and fracture modeling in aerospace contexts [5]. This PD theory has been extended to simulate fatigue by incorporating damage accumulation laws into the nonlocal formulation, allowing the explicit prediction of crack initiation and propagation under cyclic loading [3]. However, peridynamic fatigue analysis faces a significant challenge in its high computational cost, which often becomes prohibitive due to the nonlocal interactions and the large number of loading cycles required. To mitigate this computational burden, many researchers have proposed hybrid modeling strategies that couple peridynamics with more efficient methods, such as the Finite Element Method (FEM), restricting the computationally intensive peridynamic domain to critical regions where damage is expected to occur [6]. The present work follows this approach. In particular, the one-dimensional high-order refined elements employed here are based on the well-known Carrera Unified Formulation (CUF), a hierarchical framework that enables refined structural modeling with reduced computational cost. Recent advances in CUF-based analysis have further demonstrated its capability to efficiently handle complex composite and anisotropic structures [7]. Building upon these foundations, the present study extends the existing CUF–PD coupling framework by incorporating a peridynamic fatigue model to achieve unified simulation of fatigue crack initiation and growth under cyclic loading.

Bond-Based Peridynamics (BBPD)

In the linear elastic and static case, the bond-based peridynamic equilibrium of a material point $\mathbf{x}_i$ is expressed as

Materials Research Proceedings 69 (2026) 1353-1357 https://doi.org/10.21741/9781644904251-235

$$\sum_{j=1}^{N_{H_i}} \mathbf{C}(\mathbf{x_j} - \mathbf{x_i})\,(\mathbf{u_j} - \mathbf{u_i})\,V_j = \mathbf{0} \tag{1}$$

Where. $\mathbf{C}(\boldsymbol{\xi}) = c\frac{\boldsymbol{\xi}\boldsymbol{\xi}^{\mathbf{T}}}{|\boldsymbol{\xi}|^3}$ is the micromodulus tensor and V_j is the nodal volume. By assembling the contributions of all interacting pairs, the discrete peridynamic formulation can be written compactly as

$$\mathbf{K}^{\mathrm{PD}}\mathbf{K}^{\mathrm{PD}} = \mathbf{F}^{\mathrm{PD}} \tag{2}$$

which is formally analogous to the global stiffness equation in the finite element method.

High-Order 1D Theories Based on Classical Elasticity

In the framework of CUF, the 3D displacement field of a beam with main axis along y is expressed as a generic expansion of the generalized displacements $u_\tau(y)$:

$$u_\alpha(x,y,z) = \sum_{\tau=1}^{M} F_\tau(x,z)\,u_{\alpha\tau}(y), \qquad \alpha = x,y,z \tag{3}$$

Where $F_\tau(x,z)$ are expansion functions over the cross-section and M denotes the number of terms adopted in the expansion. The choice of F_τ defines the class of 1D CUF models: for instance, Taylor Expansion (TE) models employ polynomial terms, whereas Lagrange Expansion (LE) models use Lagrange-type shape functions to capture cross-sectional variations.

Along the beam axis, the generalized displacements are discretized by finite elements as

$$u_{\alpha\tau}(y) = \sum_{i=1}^{p+1} N_i(y)\,u_{\alpha\tau i} \tag{4}$$

Where $N_i(y)$ are the 1D FE shape functions and $u_{\alpha\tau i}$ are the nodal unknowns. Substituting the kinematic expansion (3) and the FE approximation (4) into the virtual work principle leads to the discrete equilibrium equation:

$$\mathbf{K}^{FE}\mathbf{K}^{FE} = \mathbf{F}^{FE} \tag{5}$$

Where $\mathbf{K}^{FE}$ is the global stiffness matrix obtained from the integration of the 3D constitutive relations over the cross-section and beam axis, $\mathbf{U}^{\mathrm{FE}}$ is the vector of nodal unknowns, and $\mathbf{F}^{\mathrm{FE}}$ is the external force vector.

Coupling of PD and CUF via Lagrange Multipliers

The coupled domain is divided into a 3D peridynamic (PD) region and a 1D high-order refined element region based on the Carrera Unified Formulation (CUF). Neglecting interface constraints, the two subdomains can be independently assembled as

$$\mathbf{KU} = \mathbf{F}, \text{ i.e. } \begin{bmatrix} \mathbf{K}^{\mathrm{PD}} & 0 \\ 0 & \mathbf{K}^{\mathrm{FE}} \end{bmatrix} \begin{bmatrix} \mathbf{U}^{\mathrm{PD}} \\ \mathbf{U}^{\mathrm{FE}} \end{bmatrix} = \begin{bmatrix} \mathbf{F}^{\mathrm{PD}} \\ \mathbf{F}^{\mathrm{FE}} \end{bmatrix} \tag{6}$$

To ensure displacement compatibility along the PD–FE interface Γ_I, Lagrange multipliers λ are introduced, see Fig.1. The interface constraint is enforced by requiring $\mathbf{u}_k^{PD} = \mathbf{u}^{FE}(\mathbf{x}_k)$ for each particle k located on Γ_I. This leads to the weak form of the coupled problem:

$$\begin{cases} \mathbf{KU} + \mathbf{B}^{\mathrm{T}}\boldsymbol{\lambda} = \mathbf{F} \\ \mathbf{BU} = \mathbf{0} \end{cases} \tag{7}$$

or equivalently, in matrix form,

$$\begin{bmatrix} \boldsymbol{K} & \boldsymbol{B}^{\mathrm{T}} \\ \boldsymbol{B} & \boldsymbol{0} \end{bmatrix} \begin{bmatrix} \boldsymbol{U} \\ \boldsymbol{\lambda} \end{bmatrix} = \begin{bmatrix} \boldsymbol{F} \\ \boldsymbol{0} \end{bmatrix} \tag{8}$$

where **B** is the coupling matrix assembled from the interface kinematic relations. This formulation guarantees full displacement continuity between the PD and CUF regions while preserving the nonlocal nature of the peridynamic model.

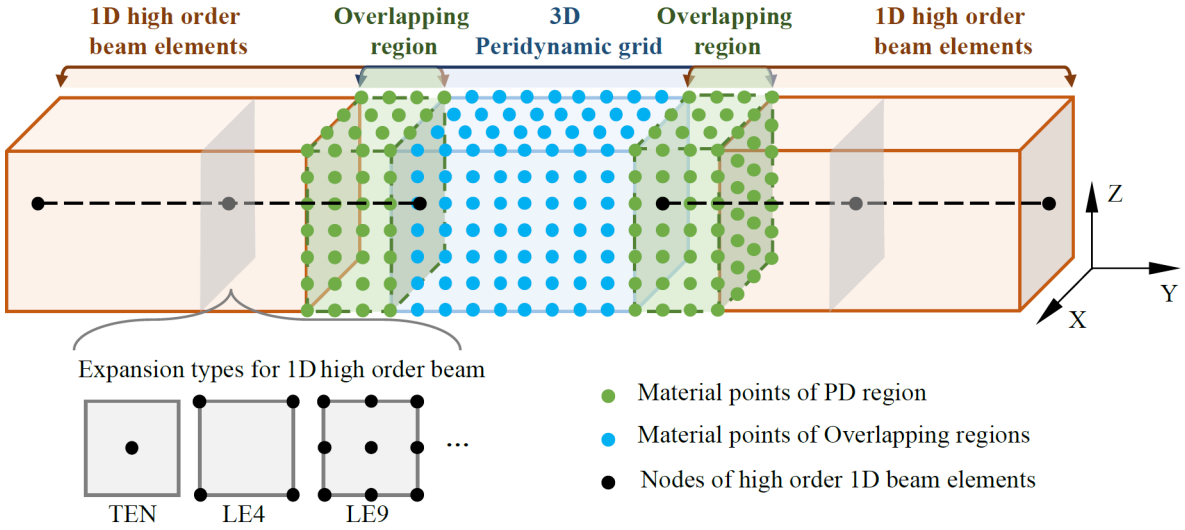

Figure 1: CUF-PD Coupling Scheme

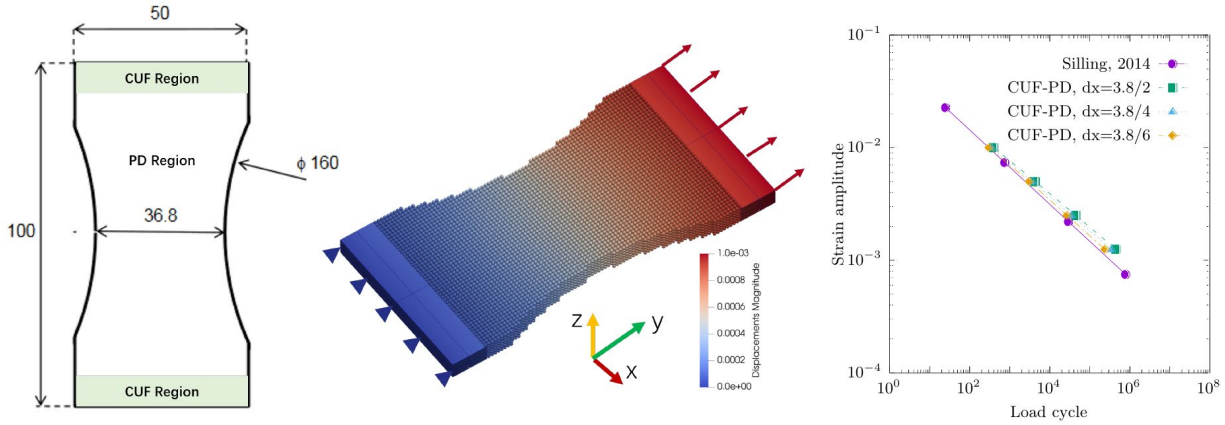
Peridynamic Fatigue Model (Silling, 2014)

The peridynamic fatigue model proposed by Silling introduces a history-dependent damage law in which each bond is assigned a remaining life variable $\lambda = (\mathrm{x}, \boldsymbol{\xi}, \mathrm{N})$ evolving with the number of load cycles N as

$$\frac{d\lambda}{dN} = -A\varepsilon^{m}, \qquad \lambda(0) = 1 \tag{9}$$

where ε is the cyclic bond strain, and A, m are material parameters calibrated from S–N or Paris law data. A bond irreversibly fails when $\lambda \leqslant 0$, enabling spontaneous nucleation and growth of fatigue cracks without introducing additional crack-growth criteria. The model distinguishes between the nucleation phase (parameters A_1, m_1) governed by strain–life relations and the growth phase (parameters A_2, m_2) calibrated to the Paris law, ensuring consistency with experimental $da/dN - \Delta K$ curves. This formulation naturally captures fatigue crack initiation, coalescence, and propagation within the peridynamic framework while preserving its nonlocal and mesh-independent character.

Numerical Results



The proposed CUF–PD coupled framework has been applied to reproduce the fatigue behavior of 7075–T651 aluminum alloy, following the benchmark study of Silling (2014). The peridynamic fatigue law defined in Eq.(9) was integrated within the coupled BBPD–CUF formulation described above, enabling the simultaneous treatment of 3D peridynamic regions and 1D refined finite elements under cyclic loading. The model successfully reproduced both the S–N curve and the Paris law crack growth rate observed experimentally for this alloy. Table 1 summarizes the reduction in the total number of degrees of freedom achieved by the CUF–PD model compared

with the full-PD approach for both specimens, highlighting the significant gain in computational efficiency.

Table 1: Illustrative DOF reduction of CUF–PD(B2+L4) versus full-PD

Specimen	Model	PD-DOFs	FE-DOFs	Total DOFs	Reduction
Hourglass	Full-PD(dx = 3.8/6)	77,462	–	77,462	–
	CUF–PD(dx = 3.8/6)	49,287	1,188	50,475	34.8%
CT	Full-PD(dx = 3.8/8)	145,487	–	145,487	–
	CUF–PD(dx = 3.8/8)	26,532	2,328	28,860	80.2%

As shown in Fig.2 and Fig.3, the numerical predictions demonstrate close agreement with the reference data, capturing the slope of the S–N relation, and the linear trend in the $\log(da/dN) - \log(\Delta K)$ domain. This confirms the capability of the coupled CUF–PD formulation to accurately describe fatigue crack initiation and propagation within a unified nonlocal framework. The demonstrated consistency with experimental fatigue behavior highlights the potential of the CUF–PD approach for reliable fatigue assessment in complex structural components.

Keywords: Phased-Array Antennas, Multiscale Modelling, Thermo-Elastic Deformations, Carrera Unified Formulation

Abstract. Current trends in space observation require lightweight phased-array antennas capable of electronic beam steering from geostationary orbit. In this work multiscale numerical framework is developed, combining thermo-elastic micromechanical and macroscopic analyses, both formulated within the Carrera Unified Formulation (CUF). The Variational Asymptotic Method (VAM) is employed to derive effective properties at the microscale, while the Principle of Virtual Displacement (PVD) is employed for thermo-mechanical predictions at the structural level. Validation against commercial tools confirms the reliability and computational efficiency of the proposed approach, demonstrating its suitability for future space antenna design.

Introduction

Modern spaceborne observation and communication missions increasingly employ phased-array antennas, which enable electronic beam steering with high precision and adaptability [1]. Unlike mechanically steered systems, these arrays consist of dense networks of radiating elements, each individually controlled in phase, delay, and amplitude to achieve real-time beam reconfiguration and enhanced resolution, essential for geostationary radar applications [2]. Typically, these antennas are designed as ultra-light planar composite structures with dielectric patches and embedded electronics, combining high stiffness and low mass. However, their continuous solar exposure in geostationary orbit, interrupted only by brief eclipse phases, generates severe thermal gradients. These gradients induce thermo-elastic deformations caused by mismatched Coefficient of Thermal Expansion (CTE) among composite layers, potentially degrading antenna performance [3]. To accurately capture such behavior, a multiscale and multifield modelling approach is required, since the critical thermo-elastic phenomena are strongly scale dependent [4]. Establishing this micro–macro link efficiently, without the excessive computational cost of conventional commercial multiscale analyses, is a key challenge [5].

The present study introduces a strategy combining micromechanical and macroscopic analyses within the unified framework of the Carrera Unified Formulation (CUF). At the microscale, the analysis is based on the Mechanics of Structure Genome (MSG), which employs the Variational Asymptotic Method (VAM) to extract effective thermo-elastic properties directly from material characteristics and geometry, without explicit load application. The microstructural model is constructed using high-order, geometrically accurate beam finite elements derived within CUF, where Hierarchical Legendre Expansions (HLE) describe the cross-sectional fields, ensuring efficiency and accuracy [6].

Materials Research Proceedings 69 (2026) 1358-1363 https://doi.org/10.21741/9781644904251-236

At the macroscale, the antenna structure is modeled using high-order CUF-based plate finite elements. The in-plane domain is discretized through two-dimensional elements, while the through-the-thickness behavior is represented using high-order expansion functions. These can be formulated following either the Equivalent Single Layer (ESL) approach, typically employing Taylor expansions (TE), or a Layer Wise (LW) approach based on Lagrange expansions (LE) [7].

The comparison between results obtained from the developed CUF-based framework and those from commercial software demonstrates the robustness, reliability, and computational efficiency of the proposed methodology for the analysis of complex space structures.

Carrera Unified formulation for high order theories

CUF is employed to model the structural behavior of the antenna component. Within the CUF framework, the three-dimensional (3D) unknown field for beam (1D) and the plate (2D) models are defined as:

$$\begin{aligned} \boldsymbol{q}_{1D}(x,y,z) &= F_\tau(x,z)N_i(y)\boldsymbol{q}_{\tau_i} \\ \boldsymbol{q}_{2D}(x,y,z) &= F_\tau(z)N_i(x,y)\boldsymbol{q}_{\tau_i} \end{aligned} \qquad \tau = 1,\dots,M \qquad i = 1,\dots,N \tag{1}$$

where F_τ are expansion functions, N_i are shape functions. M is the number of expansions, τ denotes summation and N is the number of beam/plate nodes. Note that $\boldsymbol{q}$ denotes nodal unknowns: in micromechanics it corresponds to the fluctuation field $\boldsymbol{\chi}$, while in macroscopic thermo-elastic analysis it represents the displacement $\boldsymbol{u}$.

At the microscale, the 1D model uses $F_\tau(x,z)$ to discretize the cross-section into multiple expansion subdomains and $N_i(y)$ to represent the beam axis. RUC constituents are modeled by enforcing displacement compatibility at their interfaces so $\boldsymbol{\chi}$ remain continuous. Subdomains are described with HLE, and accuracy improves by adding higher-order polynomials. HLE subdomains match the geometry of microstructural constituents via non-isoparametric mapping. Blending functions parameterize arbitrary geometries for direct inclusion in the numerical model. These CUF capabilities enable a Component Wise (CW) description of the RUC.

At the macroscopic scale, the structure is represented by a 2D model. The in-plane domain is discretized with $N_i(x,y)$, while the through-thickness response is captured by $F_\tau(z)$. Two strategies are compared: in ESL, laminate stiffness is derived by homogenizing layer properties, producing a kinematically uniform model that neglects interlaminar effects. TE functions are usually employed in this approach. In LW, each layer is assigned an independent displacement field with interface continuity enforced, enabling an explicit description of interlaminar stress transfer and delamination; LE are typically employed in this approach.

Microscale modeling

In micromechanical analyses the size of RUC is assumed to be much smaller than the global structure. It is assumed that geometry, loading and boundary conditions at the macroscale do not affect the effective properties obtained at the microscale, and that the local solutions, averaged over the RUC volume, correspond to the global macroscopic solution:

$$\bar{\boldsymbol{u}}(\boldsymbol{x}) = \frac{1}{V}\int_V \boldsymbol{u}(\boldsymbol{x};\boldsymbol{y})\, dV \tag{2}$$

where $\bar{\boldsymbol{u}}$ denotes the global displacement components and V the RUC volume.

According to the VAM, by minimizing the difference between the heterogeneous and homogeneous strain energy, one can compute the solution to the stationary value problem as:

$$\boldsymbol{\Pi} = \frac{1}{2}\left\langle \boldsymbol{\varepsilon}^T\boldsymbol{C}\boldsymbol{\varepsilon} - 2\boldsymbol{\beta}\boldsymbol{\varepsilon}\theta + c_v\frac{\theta^2}{T_0}\right\rangle - \frac{1}{2}\left(\bar{\boldsymbol{\varepsilon}}^{\boldsymbol{T}}\boldsymbol{C}^*\bar{\boldsymbol{\varepsilon}} - 2\boldsymbol{\beta}^*\bar{\boldsymbol{\varepsilon}}\theta + c_v^*\frac{\theta^2}{T_0}\right) \tag{3}$$

where $\langle\cdot\rangle$ denotes the volume average, $\mathbf{C}$ is the elasticity matrix, $\boldsymbol{\beta}$ is the thermal stress tensor defined as $\boldsymbol{\beta} = \mathbf{C}\boldsymbol{\alpha}$, with $\boldsymbol{\alpha}$ being CTE, the superscript * denotes the same quantities in the homogenized material. $\mathbf{T_0}$ is the reference temperature, $\mathbf{c_v}$ is the specific heat, and θ is the variation

Materials Research Proceedings 69 (2026) 1358-1363 https://doi.org/10.21741/9781644904251-236

of temperature with respect of $\mathbf{T_0}$. With $\boldsymbol{\varepsilon} = \bar{\boldsymbol{\varepsilon}} + \boldsymbol{D\chi}$, $\boldsymbol{\chi}$ must satisfy the constraint $\langle \boldsymbol{\chi} \rangle = 0$; under periodic boundary conditions applied in the three directions of the RUC, this is automatically fulfilled. In CUF-FEM framework the functional in Eq. (3) can be expressed in terms of the Fundamental Nuclei (FN) to be assembled over the four indices of the problem. After some mathematical passages the $\boldsymbol{\chi}$ are obtained through a linear system and finally the effective properties are obtained as:

$$\boldsymbol{C}^* = \frac{1}{\Omega}\left(\boldsymbol{\chi}_0^T \boldsymbol{D}_{h\varepsilon} + \boldsymbol{D}_{\varepsilon\varepsilon}\right) \qquad \boldsymbol{\beta}^* = \frac{1}{\Omega}\left[\frac{1}{2}\left(\boldsymbol{\chi}_0^T \boldsymbol{D}_{h\theta} - \boldsymbol{D}_{h\varepsilon}^T \boldsymbol{\chi}_\theta\right) + \boldsymbol{D}_{\varepsilon\theta}\right] \qquad c_v^* = \frac{1}{2\Omega}\left[\frac{D_{\theta\theta}}{T_0} - \boldsymbol{\chi}_\theta^T \boldsymbol{D}_{h\theta}\right] \tag{4}$$

In the case of a 3D macroscopic model, **C*** corresponds to the full 3D elasticity matrix, whereas for a 2D macroscopic model it reduces to the matrices **A**, **B**, and **D**, representing membrane stiffness, coupling stiffness and bending stiffness, respectively.

After the structural analysis, the global strain response $\bar{\boldsymbol{\varepsilon}}$ can be used to recover the local stress field over the RUC volume based on Hooke's law:

$$\boldsymbol{\sigma} = \boldsymbol{C}\bar{\boldsymbol{\varepsilon}} - \boldsymbol{\beta}\theta \tag{6}$$

Thermo-elastic problem

The Principle of Virtual Displacements (PVD) yields the governing equations of the thermo-elastic problem. In the decoupled setting, the temperature field is prescribed. Equilibrium holds when internal and external virtual work are equal, with the virtual internal work given by the sum of mechanical and thermal parts:

$$\delta L_{int} = \int_V \delta \boldsymbol{\varepsilon}_m^T \boldsymbol{\sigma} dV = \int_V \delta \boldsymbol{\varepsilon}_m^T (\boldsymbol{\sigma}_m + \boldsymbol{\sigma}_\theta) dV = \int_V \delta \boldsymbol{\varepsilon}_m^T \widetilde{\boldsymbol{C}} \boldsymbol{\varepsilon}_m dV - \int_V \delta \boldsymbol{\varepsilon}_m^T \theta \widetilde{\boldsymbol{\alpha}} dV \tag{7}$$

where $\widetilde{\boldsymbol{C}}$ the constitutive matrix. When the structure is subjected only to a thermal profile, the virtual external work, which refers to mechanical loads, vanishes. FN of the stiffness matrix can be identified as $\boldsymbol{K}^{\tau s i j}$, while the thermal load vector nucleus is defined as $\boldsymbol{\Theta}^{sj}$:

$$\boldsymbol{K}^{\tau s i j} \boldsymbol{u}_{\tau i} = \boldsymbol{\Theta}^{sj} \tag{8}$$

The complete system matrices are assembled through CUF automatic building process, independent of the selected expansion theory.

Antenna model

The antenna considered here is adapted from [3]. The macroscopic configuration is a finite plate with multiple surface-mounted patches, as shown in the right part of Fig. 1, with a 200 mm base and 100 mm height. The length of the square patch is 8 mm, while the thickness of the plate is 0.1 mm and that of the patch is 0.5 mm. The plate is made of conventional fabric composite with E = 50 GPa, a Poisson's ratio of 0.2, and a CTE of 1.44×10^{-7} K^{-1}. In contrast, the patch, representing a dielectric layer, exhibits a substantially lower E = 0.9 GPa, a Poisson's ratio of 0.3, and a much higher CTE of 4.00×10^{-5} K^{-1}. The macroscopic numerical model imposes a clamped constraint at the center patch along the thickness direction.

In this preliminary multiscale study, the antenna is idealized in the microscopic part as RUC shown on the left of Fig. 1, with the patch embedded in the host plate to reflect its slender geometry. These models are illustrative only, and no rigorous scale separation is enforced at this stage; the work should therefore be read as a preliminary step toward a fully validated workflow.

Materials Research Proceedings 69 (2026) 1358-1363 https://doi.org/10.21741/9781644904251-236

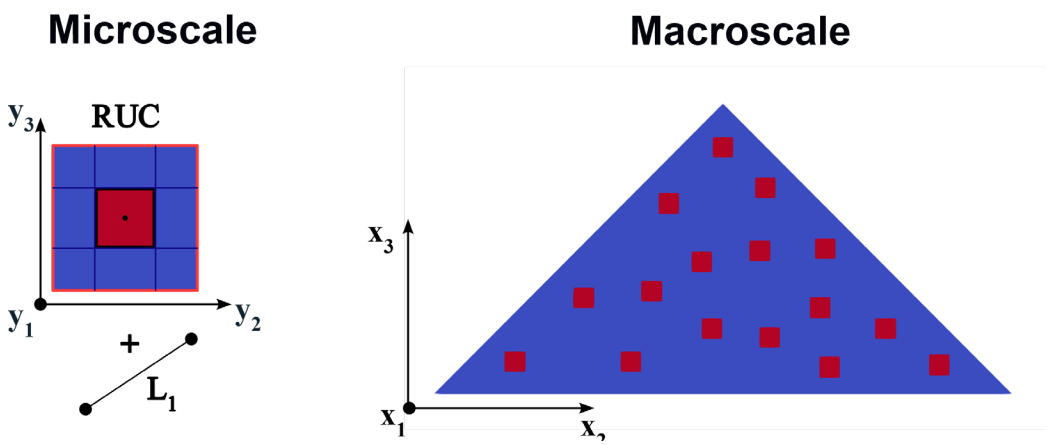

Figure 1. Micro- and Macroscale model of antenna.

Numerical results

Micromechanics. The first step of the multiscale analysis is the homogenization of the thermo-elastic properties. The RUC is modeled with two sections in the y_2–y_3 plane, connected through 2 two-nodes beam elements (B2), placed along the y_1 direction. Linear Lagrange shape functions are employed along the beam direction, whereas the cross-section is discretized using HLE functions of varying order. Table 1 reports the results of the 3D homogenization obtained with HLE of order 4, 6, and 8. It is observed that increasing the HLE order leads to the convergence of the results.

Table 1. Effective 3D thermo-elastic properties.

HLE order	E_1 (Pa)	E_2=E_3 (Pa)	G_{12}=G_{13} (Pa)	G_{23} (Pa)	ν_{12}=ν_{13}	ν_{23}	α_1 (1/K)	α_2=α_3 (1/K)
4	4.418 E10	3.999 E10	1.687 E10	1.666 E10	0.192	0.184	2.784E-07	3.206E-07
6	4.414 E10	3.952 E10	1.654 E10	1.641 E10	0.191	0.185	2.795E-07	3.253E-07
8	4.412 E10	3.9421 E10	1.642 E10	1.633 E10	0.191	0.185	2.799E-07	3.265E-07

Now, the localization of stresses due to a uniform temperature variation of 100 K applied over the structure, is performed on the RUC. Figure 2 shows the in-plane stress distribution at the interface between the two components. Due to the mismatch between the constituents' CTEs, thermal stresses develop. The in-plane stress components σ_{22} and σ_{33} exhibit a compressive character. Whereas, for the out-of-plane shear stresses σ_{13}, opposite regions of the patch are subjected to tension and compression along the y_3-direction. Finally, for the in-plane transverse shear component, σ_{23}, a doubly antisymmetric distribution is observed.

Materials Research Proceedings 69 (2026) 1358-1363 https://doi.org/10.21741/9781644904251-236

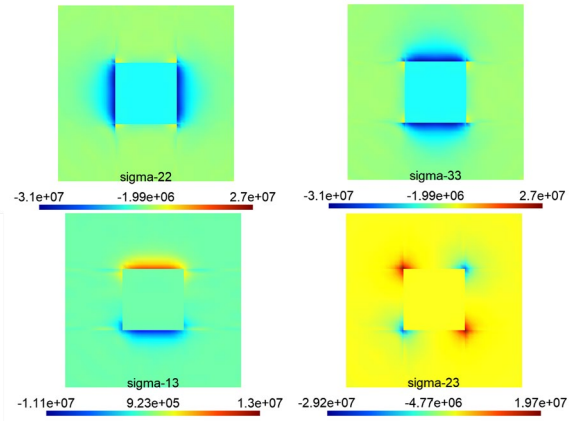

Figure 2. Stress state [Pa] due to the application of $\theta = 100$ K.

Evaluation of macroscopic thermal deformation. Lastly, the thermo-elastic analysis of the complete model is performed to assess the macroscopic thermal deformation. The comparison involves both the ESL and LW approaches, considering TE and LE models of different orders. The obtained CUF results demonstrate a good correlation with the Abaqus reference solution, accurately reproducing the global deformation trend under thermal loading. CUF-based models achieve this accuracy with a substantially lower number of DOF, thus ensuring a remarkable reduction in computational cost.

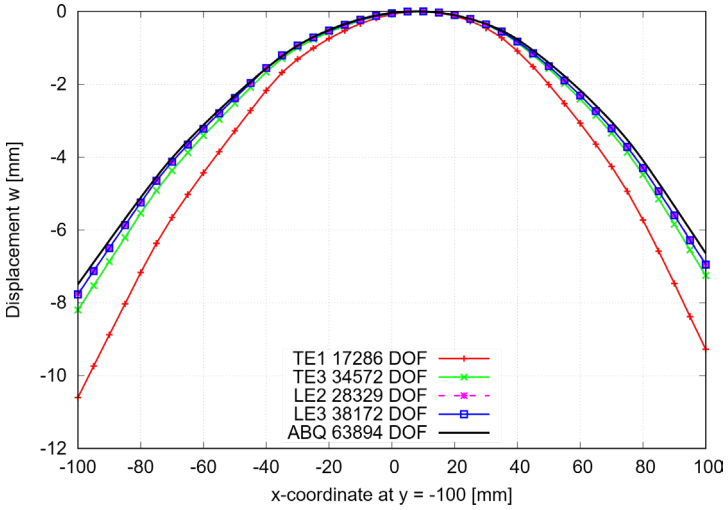

Figure 3. Out-of-plane displacement under a thermal load of 100 K: comparison between TE, LE, and Abaqus results with respective DOF.

Conclusions

This work presented a multiscale thermo-elastic analysis of a patch-mounted antenna within the Carrera Unified Formulation (CUF). At the microscale, the MSG/VAM approach using high-order CUF beam elements with HLE, provided accurate effective properties and local stress distributions. At the macroscopic CUF-based analysis, both ESL and LW models successfully reproduced the global thermal deformation. The CUF results showed excellent agreement with Abaqus while requiring far fewer DOF, confirming the efficiency and accuracy of the proposed method. Overall, the framework proves suitable for a future reliable and computationally efficient multiscale framework of lightweight space structures such as phased-array antennas.

Abstract. Piezoelectric composite materials are increasingly used in sensors, actuators, ultrasonic imaging probes, and radar systems as they efficiently convert electrical energy into mechanical deformation. However, the variety of configurations complicates the evaluation of effective properties and the prediction of performance, requiring robust and high-fidelity design tools. This study introduces a micromechanics model based on the Variational Asymptotic Method (VAM) to determine the effective piezoelectric properties of composites. The structural formulation follows the Carrera Unified Formulation (CUF) with high-order beam elements representing the Repeatable Unit Cell (RUC) and Hierarchical Legendre Expansions (HLE) describing cross-sectional kinematics. Numerical studies on PZT-epoxy composites verify the model, showing accurate homogenized elastic, piezoelectric, and dielectric properties compared with reference data. The proposed CUF micromechanics framework is established to be inherently multifield and suitable for hierarchical multiscale analyses, enabling rigorous design, optimization, and reliability assessment of advanced piezoelectric composites.

Introduction

Piezoelectric composite materials have gained growing attention for their wide range of applications in sensors, actuators, ultrasonic imaging devices, and radar systems, owing to their ability to efficiently convert electrical energy into mechanical deformation. Embedding the piezoelectric active phase within a lightweight matrix mitigates the weight and shape limitations of bulk ceramics and enables the design of tailored composite architectures [1]. Driven by the increasing demand for intelligent systems and Industry 4.0 applications, smart components based on materials such as lead zirconate titanate (PZT) can produce an electric response under mechanical loading, providing direct feedback on structural stress and strain for adaptive and self-aware systems [2].

However, the wide variety of possible microstructural configurations poses significant challenges in accurately predicting the effective electromechanical properties and overall performance of these composites. To facilitate their design and optimization, reliable and efficient modelling tools are essential. Traditional analytical approaches are limited to simplified geometries and cannot capture the complex interactions occurring within heterogeneous architecture. Numerical micromechanical homogenization methods provide greater accuracy but often at a high computational cost.

In this work, a novel micromechanics model based on the Variational Asymptotic Method (VAM) is proposed for the homogenization of the Repeating Unit Cell (RUC) of piezoelectric composites [3]. The formulation combines VAM with the Carrera Unified Formulation (CUF) to derive a computationally efficient high-fidelity description of composite behavior [4]. The micromechanical problem is discretized using the Finite Element Method (FEM), enabling the treatment of complex boundary conditions and heterogeneous materials. The CUF framework

Materials Research Proceedings 69 (2026) 1364-1368 https://doi.org/10.21741/9781644904251-237

employs high-order, geometrically exact beam elements and Hierarchical Legendre Expansions (HLE), ensuring full three-dimensional (3D) accuracy with reduced computational effort [5].

The proposed method is verified through numerical case studies involving unidirectional PZT-epoxy composites with varying fiber volume fractions V_f. The homogenized elastic, piezoelectric, and dielectric properties are benchmarked against the literature and commercial finite element homogenization tools, demonstrating excellent accuracy and efficiency.

Micromechanics for the piezoelectric problem within CUF framework

The fundamental idea of micromechanical analysis is that the size of RUC is much smaller than the global structure. Assuming **y** and **x** as local and global reference systems of the RUC, respectively, the relation **y** = **x**/δ defines the link between the two scales, where δ is a small scaling parameter, as shown in Fig. 1.

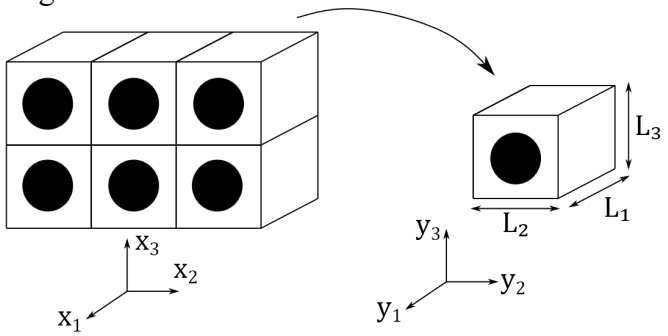

Figure 1. Coordinate reference systems of a periodic heterogeneous material and its RUC.

It is assumed that geometry, loading and boundary conditions at the macroscale do not affect the effective properties obtained at the microscale, and that the local solutions, averaged over the RUC volume, correspond to the global macroscopic solution:

$$\bar{\boldsymbol{u}}(\boldsymbol{x}) = \frac{1}{V}\int_V \boldsymbol{u}(\boldsymbol{x};\boldsymbol{y})\, dV$$
$$\bar{\boldsymbol{\psi}}(\boldsymbol{x}) = \frac{1}{V}\int_V \boldsymbol{\psi}(\boldsymbol{x};\boldsymbol{y})\, dV \tag{1}$$

where $\bar{\boldsymbol{u}}$ denotes the global displacement components, $\bar{\boldsymbol{\psi}}$ is the global electric potential and V the RUC volume.

In piezoelectric materials, the elastic and dielectric responses are coupled: the mechanical variables of stress and strain are related not only to each other but also to the electric field and the electric displacement. This electromechanical interaction is governed by the piezoelectric coefficients, and the linear coupled constitutive equations can be written in indicial notation as:

$$\sigma_{ij} = C_{ijkl}\varepsilon_{kl} - e_{ijk}E_k$$
$$T_i = e_{ikl}\varepsilon_{kl} + k_{ij}E_j \tag{2}$$

where σ_{ij} is the stress tensor, ε_{kl} the strain tensor, E_i the electric field vector, T_i the electric displacement vector, C_{ijkl} the fourth-order elasticity tensor (at constant electric field), k_{ij} is the second-order dielectric permittivity tensor (at constant strain), and e_{ijk} is the third-order piezoelectric coupling tensor.

According to the VAM, by minimizing the difference between the strain energy between the heterogeneous and the homogenized material, one can compute the solution to the stationary value problem as:

$$\Pi = \frac{1}{2}\langle \boldsymbol{\epsilon}^T\, \boldsymbol{G}\, \boldsymbol{\epsilon}\rangle - \frac{1}{2}(\bar{\boldsymbol{\epsilon}}^T \boldsymbol{G}^* \bar{\boldsymbol{\epsilon}}) \tag{3}$$

Materials Research Proceedings 69 (2026) 1364-1368 https://doi.org/10.21741/9781644904251-237

where $\boldsymbol{G}$ is the 9 × 9 constitutive matrix, including the elastic coefficients **C**, the piezoelectric coefficients **e**, and the dielectric coefficients **k**, and $\boldsymbol{\epsilon} = \bar{\boldsymbol{\epsilon}} + \boldsymbol{D}\boldsymbol{\chi}$ contains both strain field $\boldsymbol{\varepsilon}$ and the electric field **E**. **D** is the 9 × 4 differential operator matrix and $\boldsymbol{\chi}$ is the fluctuation vector containing both the elastic and the fluctuations associated with the electric potential. The * refers to the correspondent homogenized quantity. These fluctuation functions must satisfy the constraint $\langle \boldsymbol{\chi} \rangle = 0$, which, in the case of periodic boundary conditions applied over the three directions of the RUC, is automatically satisfied.

According to CUF, the 3D RUC can be reduced to a high-order beam model, where the beam axis is aligned with the fiber direction y_1, and the y_2–y_3 plane defines the beam cross-section Ω. The fluctuation unknowns, $\boldsymbol{\chi}$, can be expanded over the cross-section by means of arbitrary functions F_τ depending on the local coordinates y_2 and y_3, along the y_1, the problem is discretized using FEM with Lagrange shape functions N_i:

$$\boldsymbol{\chi}(\boldsymbol{x};\boldsymbol{y}) = F_\tau(y_2, y_3)\, N_i(y_1)\, \boldsymbol{\chi}_{\tau i}(x) \qquad \tau = 1, \dots, M \quad i = 1, \dots, N \tag{4}$$

where M is the number of expansions, τ denotes summation and N is the number of the beam nodes. To represent generic microstructural cross-section geometries, the domain can be discretized into multiple expansion subdomains. HLE functions are used to describe the subdomains, exploiting their hierarchical features. The accuracy of the unknowns is improved by adding higher-order polynomials.

By rewriting the fluctuation functions in the CUF-FEM framework and substituting into the functional of Eq. (3), the functional can be expressed in terms of the Fundamental Nuclei (FN) to be assembled over the four indices of the problem. Therefore, the strain functional becomes:

$$\Pi^* = \frac{1}{2}(\boldsymbol{\chi}_{sj}^T \boldsymbol{H}^{\tau sij} \boldsymbol{\chi}_{\tau i} + 2\boldsymbol{\chi}_{sj}^T \boldsymbol{D}_{h\epsilon}^{sj} \bar{\boldsymbol{\epsilon}} + \bar{\boldsymbol{\epsilon}}^T \boldsymbol{D}_{\epsilon\epsilon} \bar{\boldsymbol{\epsilon}}) \tag{5}$$

By minimizing the functional in Eq. (5), the following linear system is obtained:

$$\boldsymbol{H}\boldsymbol{\chi} = -\boldsymbol{D}_{h\epsilon}\bar{\boldsymbol{\epsilon}} \quad \text{with} \quad \boldsymbol{\chi} = \boldsymbol{\chi}_0 \bar{\boldsymbol{\epsilon}} \tag{6}$$

where $\boldsymbol{\chi}_0$ is the fluctuation solution vector. Finally, the effective constitutive matrix $\boldsymbol{G}^*$ of the homogenized piezoelectric medium is obtained as:

$$\boldsymbol{G}^* = \frac{1}{V}(\boldsymbol{\chi}_0^T \boldsymbol{D}_{h\epsilon} + \boldsymbol{D}_{\epsilon\epsilon}) \tag{7}$$

Numerical results

The present procedure provides a unified framework for general 3D RUC problems using high-order beam models. First, the proposed homogenization methodology is benchmarked against results from the literature; then, a novel microstructure comprising SiC fibers and PZT-7A inserts in a Epoxy matrix is investigated.

The piezoelectric composite analyzed here consists of circular PZT fibers embedded in an epoxy matrix. The epoxy matrix is considered isotropic, whereas the fiber properties are orthotropic and taken from [3]. The RUC is modeled as a square-pack arrangement (Fig. 1). V_f is varied from 10% to 70%, using fifth-order HLE. The results in Fig. 2 compare the present outputs with VAMUCH and an ANSYS FEM model reported in [3].

Materials Research Proceedings 69 (2026) 1364-1368 https://doi.org/10.21741/9781644904251-237

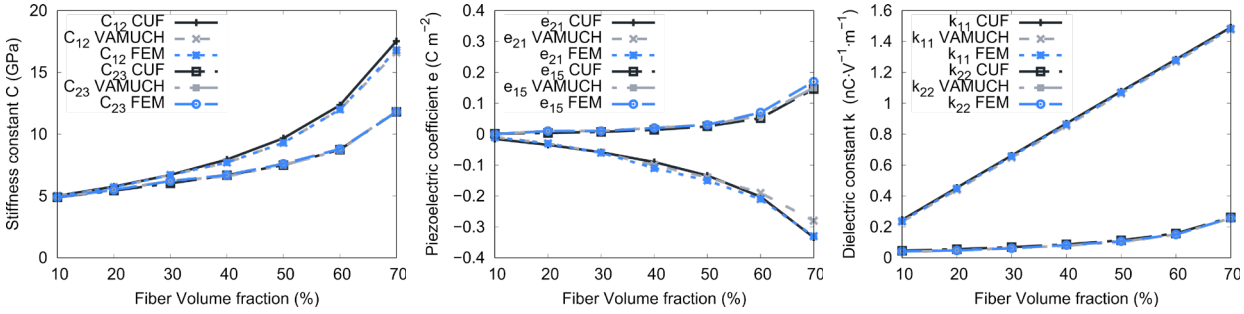

Figure 2. Effective coefficients for the square-pack model as a function of V_f: elastic (a), piezoelectric (b), and dielectric (c), compared with VAMUCH and ANSYS FEM [3].

It can be observed that CUF predictions show excellent agreement with both reference approaches. In the case of component e_{21}, the results are particularly close to the FEM outcomes.

The second case study considers a modified hexa-pack structure, shown in Fig. 3(a), comprising Epoxy matrix, SiC fibers and PZT-7A inserts. V_f is computed by parameterizing the fiber radius and the half-length of the piezoelectric insert. Figures 3(b–d) report the effective elastic, piezoelectric, and dielectric coefficients, respectively, as V_f varies. The results confirm that, for all effective properties, longitudinal and transverse quantities tend to coincide at lower V_f.

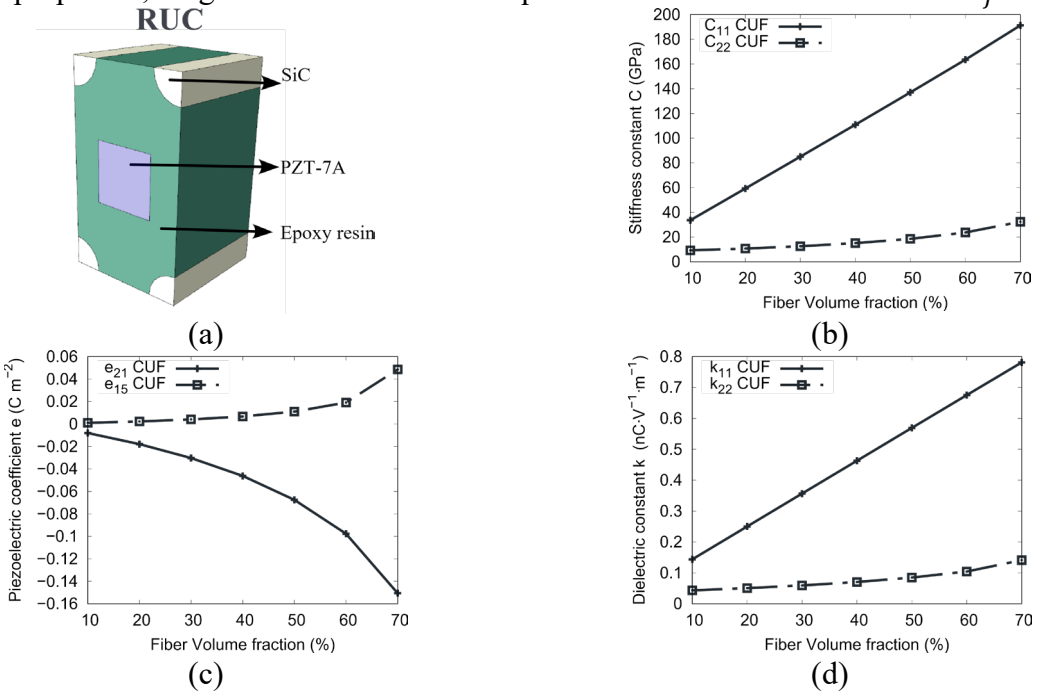

Figure 3. Novel microstructure with multiple materials (a), effective coefficients of the novel model as a function of V_f: elastic (b), piezoelectric (c), and dielectric (d).

Conclusions

This work presented a micromechanical framework that integrates the Variational Asymptotic Method (VAM) with the structural analysis capabilities of the Carrera Unified Formulation (CUF) to compute homogenized piezoelectric properties in an accurate and efficient scheme. The formulation was verified against VAMUCH and an ANSYS finite-element model, showing close agreement for elastic, piezoelectric, and dielectric tensors. These results build confidence in applying the method to more complex, multiphase RUC while reliably predicting effective

properties. The CUF–VAM approach is naturally suited to hierarchical multiscale analyses and supports design, optimization, and reliability assessment of advanced piezoelectric composites.

Abstract. This paper presents a method for a thermo-mechanical analysis of ultra-thin multilayered structures for space applications. A geostationary radar microstrip patch antenna circuit is designed using a simulated annealing algorithm. Material properties are determined from literature, and preliminary thermal analyses are performed with ESATAN-TMS. The application of the Carrera Unified Formulation (CUF) in the Finite Element Method (FEM) framework enables decoupled thermo-elastic analyses to identify deformations, stresses, and critical areas. Results demonstrate that the method reduces computational cost via high order theories, while accurately identifying specific regions most affected by thermal stress.

Introduction

The concept of microstrip patch antennas gains attention at the beginning of the 1970s. Its basic geometry consists of a flat conducting patch mounted on a dielectric substrate which is then backed by a plate. Compared with conventional microwave antennas, microstrip patch antennas provide a more compact profile, lower weight, ease of integration into circuits and higher power efficiency [1]. In addition to the benefits mentioned, the ability of the design to be arranged in large, ultra-lightweight phased array antennas accounts for its effectiveness in geostationary radar applications [2]. During orbital operations, extreme conditions in space may irreversibly alter the proper functioning of a large, ultra-thin planar antenna. Excessive thermal loads can compromise the maintenance of the antenna's proper temperature range and cause excessive thermal stress and deformation. The underlying issue is not only the risk of structural integrity being compromised, but also the loss of flatness requirements, which leads eventually to severe degradation of the radiation pattern and overall electromagnetic performance. Thermo-mechanical analyses have a fundamental role in predicting the overall response in space, particularly when composite materials are employed. With regard to multilayer structures, the CUF [3] proves to be suited for performing these analyses as it allows the description of all the kinematic models, from classical to high order theories. Moreover, it reduces the computational cost associated with 3D models.

In the present work, a square patch circuit is studied. The circuit serves as the fundamental unit of the ultra-lightweight phased array radar antenna. Following the explanation of the theoretical aspects involved, the second section presents the geometry of the circuit and its characteristics in terms of materials. Subsequently, on-orbit thermal analysis is displayed, while, in the last section, the CUF is used both with Equivalent Single Layer (ESL) models and Layer Wise (LW) models. This study assumes homogeneous thermal loads, as its primary objective is to validate the effectiveness of the proposed methodology. Future analyses will address the implementation of spatially varying thermal loads.

Thermo-mechanical Problem and Theoretical Framework of the approach

CUF is a well-established theory that enables the hierarchical development of structural theory through the use of an extensive index notation and generalized expansions of the primary mechanical variables from lower to higher orders.

By using CUF, the 3D displacement field $\mathbf{u}(x, y, z)$, which can be seen in Eq. 1, is expressed through a condensed notation. In the 2D case, the formulation combines expansion functions $F_\tau(z)$, that describe the through-thickness displacement component, and the general 2D displacement vector $\mathbf{u}_\tau(x, y)$ (Eq. 2)[3,4].

$$\mathbf{u}^T(x, y, z) = (u_x \; u_y \; u_z) \tag{1}$$

$$\mathbf{u}(x, y, z) = F_\tau(z)\mathbf{u}_\tau(x, y) \qquad \tau = 1,2,\dots N \tag{2}$$

Where N represents the order of expansion function. It is worthwhile to mention that within this theory, the formulation remains invariant when the order of expansion is changed.

In the present study, Lagrange Expansion (LE) [5] with Layer Wise theory (LW) [3,6] and Taylor Expansion (TE) [7], with Equivalent Single Layer theory (ESL) [3,6], are used as expansion functions.

The CUF can be applied to the FEM framework, which if included in Eq. 2 allows us to obtain:

$$\mathbf{u}(x, y, z) = F_\tau(z)N_i(x, y)\mathbf{q}_{\tau i} \tag{3}$$

where $\mathbf{q}_{\tau i}$ and N_i are the nodal displacement and the shape function, respectively.

The governing equations can be obtained by applying the Principle of Virtual Displacements (PVD), which, in the absence of mechanical loads, can be expressed as:

$$\delta L_{int} = \int_V \delta\boldsymbol{\varepsilon}^T\boldsymbol{\sigma}dV = \int_V(\delta\boldsymbol{\varepsilon}_m + \delta\boldsymbol{\varepsilon}_\theta)^T\boldsymbol{\sigma}dV = \int_V \delta\boldsymbol{\varepsilon}_m^T\boldsymbol{\sigma}dV \tag{4}$$

The term $\delta\boldsymbol{\varepsilon}_\theta$ is zero when decoupled analyses are considered, as it is done in this work. Introducing CUF and FEM formulations, Eq. 4 becomes:

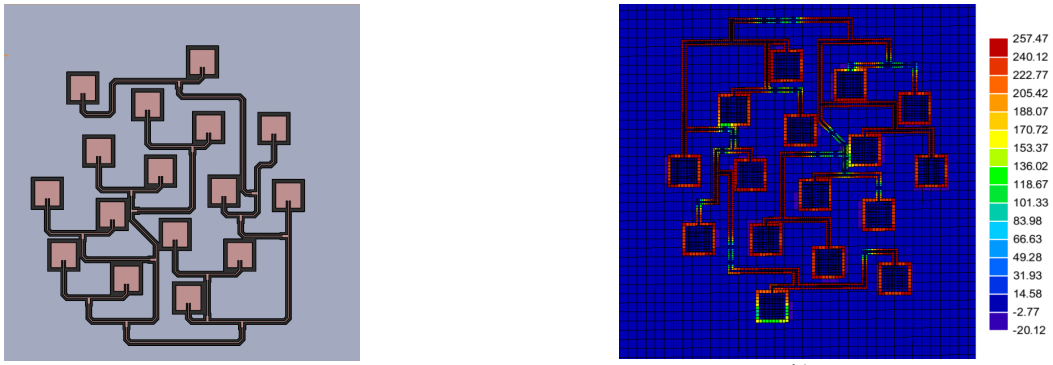
$$\delta L_{int} = \delta\mathbf{q}_{sj}^T\mathbf{K}^{\tau sij}\mathbf{q}_{\tau i} = \boldsymbol{\Theta}^{sj} \tag{5}$$

By means of the indices i, j, τ, s the stiffness matrix can be decomposed and represented through 3×3 matrices known as Fundamental Nuclei (FN). Moreover, $\boldsymbol{\Theta}$ is a 3×1 matrix, which represents the fundamental nucleus of the thermal load matrix. Details and additional information on the aforementioned matrices and their derivation procedure can be found in [3].

Microstrip Patch Antenna Circuit

The studied circuit is composed of 16 patches. The position of their center of mass is determined by a simulated annealing algorithm [7], which is written with connection length between patches as the only parameter to be minimized and optimized. No additional initial considerations on the circuit are made since the aim of the work is to validate the suitability of the adopted methodology. In Fig. 1(a) the final structure can be seen. The proposed structure consists of four layers, arranged from bottom to top as follows: a CFRP support plate (10 cm × 10 cm) fabricated using IM600/133 composite, a copper foil layer serving as the ground plane, where a reduction in area occurs relative to the support plate, an RT/duroid® 5880 laminate acting as the dielectric substrate, and a second copper foil layer for the implementation of the patches and feed lines. Comparing the patches layer with the duroid laminate, a further reduction in area is present.

On-orbit Thermal Analysis



To conduct on-orbit thermal analysis, the software ESATAN-TMS is used. Material properties are determined after conducting a meticulous literature review. The geostationary orbit is discretized

Materials Research Proceedings 69 (2026) 1369-1373 https://doi.org/10.21741/9781644904251-238

into 11 timesteps, at each of which the temperatures of the 44,841 thermal nodes in the model are computed. A set of three nodes per layer is used in the thickness direction of the model. Nodes are positioned at the top, bottom, and mid-plane of each layer.

In Fig. 1(b) the most critical timestep, which corresponds to the timestep 25920 s in the 86400 s orbit, is depicted. It should be noted that the temperature range exceeds the survival range of spacecraft components.

As has previously been stated, the purpose of this work is to validate the analysis methodology. Consequently, the analyzed structure does not correspond to a real application. The obtained results serve as the basis for justifying the load assumptions adopted in the subsequent thermoelastic evaluation.

a) b)

Fig. 1: a) Microstrip patch antenna circuit, b) critical timestep (degree Celsius).

CUF-based Thermo-mechanical Analysis

The mechanical model is implemented in Abaqus and is composed of 3078 elements. More specifically, Q9 elements are used and a constant thermal load of 100 °C is imposed over the whole structure. This step serves to verify the results before proceeding to variable thermal loads in space. The following boundary condition is selected for the following analyses: constraint along the thickness of four points in the vicinity of the central point. The rationale for the choice lies in the possibility of evaluating a more complex displacement field. Regarding the LW theory, the following analyses are conducted for each layer of the structure: 1 LE1, 2 LE1, 3 LE1, 4 LE1, 1 LE2, 2 LE2, 1 LE3, and 2 LE3, whereas for the ESL approach, TE from order 1 up to order 6 are implemented.

Fig. 2 shows the comparison with Abaqus in terms of out-of-plane displacement. In particular, 21 points were selected along a line passing through the center of the structure and parallel to the x-axis, and an additional 21 points were taken along another line, also passing through the center and parallel to the y-axis. Fig. 3(a) and Fig. 3(b) show the overall out-of-plane displacement field obtained from Abaqus and from the 1 LE3 analysis, respectively.

To assess which of the two High Order Theories is more appropriate for the study of the structure, convergence analyses via normal and shear stresses through thickness are performed. Stress distribution is evaluated at the central point of the northernmost patch. Data shows that the same stress distribution is consistently obtained with 2 LE2, 1 LE3 and 2 LE3 analyses, while convergence is not equivocally attained from TE analyses. Furthermore, the LE stress field through thickness is consistent with the literature.

Conclusions

The study employed the CUF within FEM framework to investigate the decoupled thermo-mechanical response of ultrathin multilayer structures. Results demonstrate the validity of the

Materials Research Proceedings 69 (2026) 1369-1373 https://doi.org/10.21741/9781644904251-238

model with respect to commercial software and a complete stress characterization is obtained. High Order Theories allow to reduce the computational cost, still providing overall accuracy in predicting the mechanical response to the applied load.

Among these, LW approach with Lagrange expansion function proved to be most suitable to the case under study as it allows to describe the discontinuity of mechanical properties along the thickness with high accuracy. Future analysis will address the implementation of spatially varying thermal loads.

Keywords: Moon, Microcapsule Self-Healing, Dust Mitigation Technology, Innovative High-Performance Polymers, Space Exploration

Abstract. Lunar regolith dust poses a critical challenge for sustained surface operations, as its highly abrasive, sharp-edged, and electrostatically charged particles readily adhere to surfaces, degrading optical, thermal, and mechanical systems and posing health hazards to astronauts. To address this issue, the SELENE project, led by CIRA with contributions from Sapienza Università di Roma under ASI financial support, aims to develop lightweight, high-performance fluorinated co-polyimide composites engineered for passive dust mitigation and durability. The material integrates dual self-healing mechanisms: (i) an extrinsic system based on microcapsules containing UV-curable healing agents released upon mechanical damage, and (ii) an intrinsic supramolecular component capable of reversible non-covalent bonding to autonomously repair microcracks. An innovative feature of SELENE project is the magnetic manipulation of microcapsules containing Fe_3O_4 nanoparticles, enabling targeted positioning before thermal imidization to enhance crack interception and surface damage protection. This multifunctional approach aims to significantly enhance longevity, survivability, wear resistance and reliability of lightweight, high-performance materials for building lunar infrastructures and allows human long-term settlement.

Introduction

The growing international interest in space exploration and colonization has long underscored the need to develop and raise to an adequate Technology Readiness Level (TRL), technologies capable of supporting both robotic and crewed missions through systems that are increasingly compact, efficient, and cost-effective. Numerous lunar and Martian exploration missions are planned for the coming years, including, but not limited to, Artemis, ExoMars, Mars Sample Return, and Terrae Novae.

Future lunar and Martian missions must overcome a range of technological challenges to ensure human survival in such hostile environments [1]. Indeed, the surfaces of both the Moon and Mars are characterized by extreme thermal fluctuations, minimal or absent atmospheric pressure, micrometeorite bombardment, and intense exposure to electromagnetic radiations, all of which can cause severe and irreversible damage to both biological tissues and electronic systems. In addition, the presence of micrometric regolith dust particles, sharp-edged, abrasive, irregularly shaped, chemically reactive, electrostatically charged, highly adhesive, and in some cases magnetic, poses a further major threat.

Materials Research Proceedings 69 (2026) 1374-1378 https://doi.org/10.21741/9781644904251-239

These fine dust particles, highly toxic if inhaled, can interfere deleteriously with numerous mechanical, optical, photovoltaic, and electronic components, e.g., by reducing solar panel efficiency through surface darkening and accumulation, disrupting sensors and measuring instruments, and degrading the thermal performance of radiators and heat exchangers. Moreover, lunar and Martian dust can adhere strongly to astronauts' suits and visors, causing a wide range of critical operational and safety issues during both exploration and long-term habitation missions (see Figure 1) [2-3].

Figure 1. Examples of lunar dust issues.

In this context, SELENE project aims to design and synthesize an innovative multifunctional polymeric material exhibiting low surface adhesion to lunar regolith microparticles, high thermo-mechanical performance, and self-healing capability to autonomously repair microcracks and abrasions induced by the sharp and abrasive dust particles typical of the lunar environment [4].
At the core of the SELENE project lies the development of a dual-mode self-healing strategy embedded within a fluorinated co-polyimide matrix, specifically engineered to exhibit low surface energy and superior dust-repellent properties belonging to the category of passive dust mitigation technologies in agreement with an international accepted [3].

Methodology

One of the core functionalities of the SELENE project's Proof of Concept (PoC) is the ability to autonomously repair microcracks generated by the abrasive action of sharp and angular lunar regolith particles. Structural integrity recovery is achieved through an extrinsic, autonomous self-healing mechanism enabled by the homogeneous dispersion of polymeric microcapsules with diameters ranging from a few to several hundred micrometres within the polymeric matrix and containing a UV-curable monomer and crosslinking photo-initiators, as schematically illustrated in Figure 2.

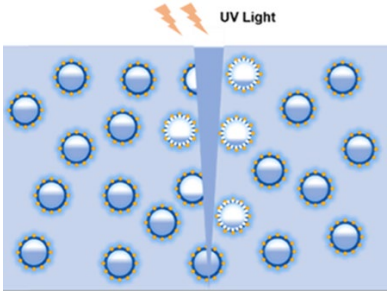

Figure 2. Conceptual representation of UV triggered microcapsule self-healing

Microencapsulation is a process in which solid particles, liquid droplets, or gas bubbles are enclosed within an inert spherical or ellipsoidal shell that isolates and protects the internal phase from the surrounding environment. In its simplest configuration i.e., mononuclear, a microcapsule consists of a single-core structure enclosed by a uniform shell, where the core contains the active monomers i.e., healing agents, and the shell generally acts only as the protective barrier. Instead, in the SELENE project to the external layer of the microcapsule is provided also the fundamental function to improve the dust mitigation capacity of the final material. This has been achieved by the advantageous use of innovative and specifically selected poly dimethyl siloxanes (PDMS).

Materials Research Proceedings 69 (2026) 1374-1378 https://doi.org/10.21741/9781644904251-239

In self-healing polymers, microcapsules are primarily used as microscopic reservoirs of reactive monomers or oligomers, which are released when the capsule ruptures due to crack propagation. The released healing agents diffuse toward the crack tip through capillary forces and react with the catalysts, initiating polymerization or crosslinking reactions that seal the crack and restore the original mechanical integrity.

This extrinsic self-healing approach offers significant advantages e.g., simpler fabrication, faster healing kinetics, and no need for chemical modification of the host matrix, although it cannot be used multiple times due to its inherent configuration. The process involves three main stages as depicted in Figure 3 [8]:

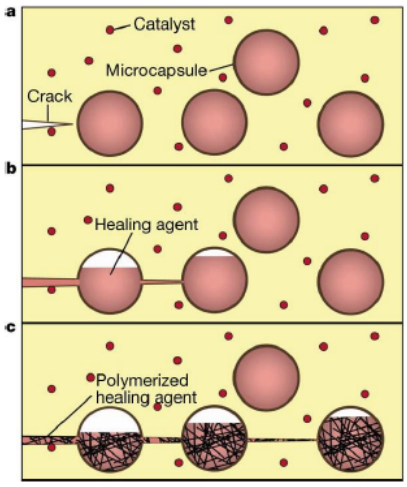

Figure 3. Schematic illustration of the three fundamental steps of the crack induced microcapsule self-healing mechanism [8].

a. Activation: initiation of capsule rupture upon damage occurrence;
b. Transport: diffusion of the healing agent toward the damage site;
c. Repair: polymerization or crosslinking reaction, whose kinetics depend on temperature and catalyst concentration.

The overall healing efficiency depends on the balance between the crack propagation rate and the healing kinetics of the released agents. Although this mechanism enables effective and rapid crack closure, it remains limited to a single healing event per site, since the local supply of healing agents cannot be replenished. Moreover, due to the heterogeneous nature of the microcapsule-based approach, it may be incompatible with optically transparent components where high transmittance is required.

One of the most critical challenges hindering the efficient implementation of the microcapsule-based self-healing mechanism lies in achieving a homogeneous dispersion of the healing agent reservoirs within the co-polyimide matrix during the intermediate stage of polymerization. This difficulty arises from the intrinsically high viscosity of the polyamic acid precursor, which exhibits substantial drag resistance to particle diffusion and dispersion. Conventional mechanical stirring techniques cannot be employed, as they would inevitably induce the formation of gaseous bubbles and other forms of contamination within the sensitive and highly reactive co-polyamic solution.

Results and Discussion

Instead, a distinctive innovation of SELENE project consists of the magnetically controlled positioning of microcapsules [9-10]. Each capsule contains superparamagnetic Fe_3O_4 nanoparticles, allowing their directed migration within the polyamic acid precursor under an

external magnetic field. By precisely controlling their spatial arrangement before curing, this approach ensures targeted reinforcement, enhanced crack interception, and a homogeneous distribution of the healing system across the matrix as shown in Figure 4.

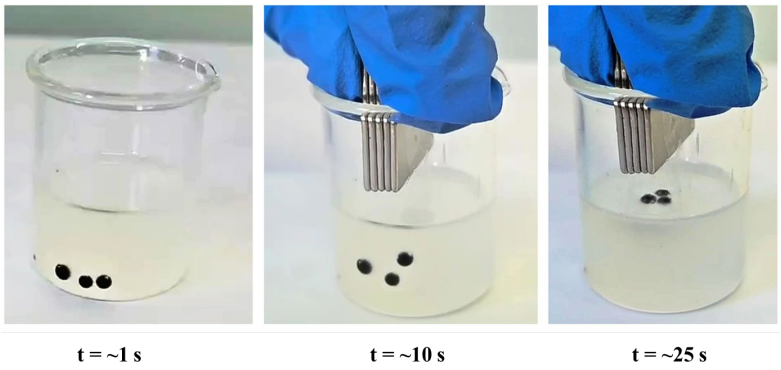

Figure 4. Sequence of successive frames illustrating the magnetically induced migration of microcapsules containing magnetic nanoparticles

The core–shell microcapsules feature a PDMS-based shell compatible with the polyimide host, and a liquid core comprising a photo-activated healing agent premixed with a UV initiator, taking advantage of the intense solar UV radiation on the lunar surface. Upon crack formation and subsequent UV exposure, the released agent polymerizes in situ, restoring the composite's mechanical continuity and integrity.

Beyond its smart healing functionality, the SELENE material is tailored to endure lunar environmental extremes, providing abrasion resistance, thermal endurance, and low dust adhesion, which mitigate the degradation of critical systems. The magnetically guided healing network further increases protection in high-stress regions, extending operational life.

This multifunctional composite is envisioned for space-critical components, including rovers, landers, habitats, solar panels, optical systems, radiators, and astronaut gear, where micrometric, abrasive lunar regolith represents a persistent threat. Its high *abhesivity*, resilience, and autonomous repair capability make it a promising solution for durable, reliable, and sustainable materials in future lunar surface operations.

Summary

In essence, SELENE introduces an adaptive polymer platform that combines passive dust mitigation with active self-repair, paving the way for a new generation of smart materials for long-duration extra-terrestrial missions.

Novel Modeling Technique of Metamaterials Using One-Dimensional Finite Elements

Riccardo Augello[1,a *], and Erasmo Carrera[1,b]

[1]MUL2 Lab, Department of Mechanical and Aerospace Engineering, Politecnico di Torino, Corso Duca degli Abruzzi 24, 10129 Torino, Italy

Abstract. Geometry-driven metamaterials offer negative Poisson's ratios, vanishing shear stiffness, and programmable multi-stability, but their slender struts and large rotations overwhelm conventional finite-element meshes. A streamlined framework that couples classical finite elements with the Carrera Unified Formulation (CUF) resolves cross-sectional deformation through higher-order beam expansions, reproducing three-dimensional behaviour while retaining a one-dimensional model. Contrary to the conventional beam definition, in this study the structural beam axis is aligned with the thickness of the sandwich panel, while the cross-section extends across its width. This particular application is useful to highlight the flexibility of CUF in modelling any structural configuration as an advanced 1D element. Representative static linear analyses are presented of the hexagonal metamaterial design.

Introduction

In the past decade, lattice-based metamaterials have risen to prominence as engineered architectures whose macroscopic behaviour is dictated far more by geometry than by chemistry. Built from periodically replicated unit cells (UCs), these structures are meticulously tuned to deliver unprecedented mechanical responses. For instance, by judiciously sculpting the UC, targeted properties can be achieved—from auxetic systems with a negative Poisson's ratio [1, 2] to pentamodes that suppress shear almost entirely [3], or non-linear responses can be elicited through large bending deformations and elastic instabilities. Because the global behaviour of a lattice hinges on its microscopic architecture, many studies have sought closed-form links between UC geometry and effective properties. Pioneering work based on Bernoulli–Euler and Timoshenko theories yielded analytical expressions for the elastic moduli and Poisson's ratio of cuboid microlattices [4].

Transitioning to three dimensions unlocks richer behaviours: 3D NPR lattices have been conceived through both additive manufacturing [5] and mechanical assembly. Li's 3-D re-entrant lattice, experimentally validated in compression [6], and its augmented counterpart with extra struts, capable of wide-range tunability [7], are prime examples. The interlocking-assembly route further reduces fabrication overheads compared to layer-wise printing [8]. Accurately simulating the rich mechanics of such structures requires numerical tools capable of resolving rigid-body rotations, large strains, and steep stress gradients without prohibitive cost. Conventional FEM, though ubiquitous, struggles: reproducing the fine architectural details typically forces excessively dense meshes and long runtimes. A general solution is presented by integrating classical FEM with the Carrera Unified Formulation (CUF) [9]. CUF enriches one-dimensional finite elements through tailored expansion functions that faithfully recover cross-sectional deformation modes. When Lagrange expansions are employed, the method accommodates arbitrarily intricate cross-sections—making it especially suited to the convoluted geometries of metamaterials [10].

Metamaterial structure

A metamaterial structure is used as a benchmark to demonstrate the CUF-based modelling capabilities. The geometry of a generica metamaterial is reported in Fig. 1. In this study,

Materials Research Proceedings 69 (2026) 1379-1383 https://doi.org/10.21741/9781644904251-240

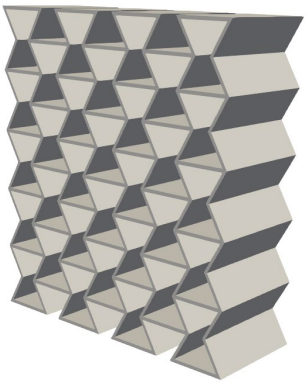

Figure 1: Re-entrant metamaterial structure.

exploiting CUF capabilities, the whole structure is modelled as 1D beam elements. The beam axis is aligned with its width, leaving the conventional beam definition, as reported in Fig. 2. The cross-sections of the metamaterial is discretized using high-order Lagrange polynomials;

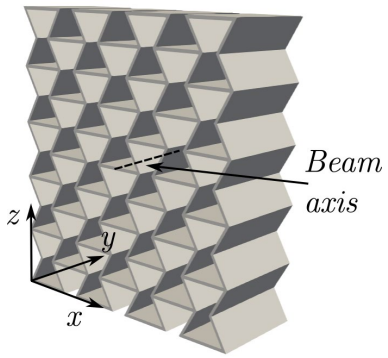

Figure 2: CUF model of the re-entrant metamaterial structure.

this discretization ensures detailed representation of geometry and its mechanical behaviour. To maintain displacement continuity between the domains, shared Lagrange points are defined at their interfaces, as reported in Fig. 3. The precise alignment of shared Lagrange points eliminates any potential discontinuities at the interfaces, enabling an accurate representation of the coupling the elements. The use of high-order Lagrange polynomials enables

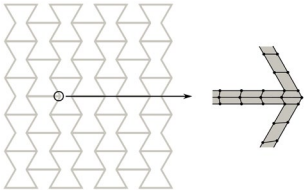

Figure 3: Lagrange elements for the discretization of the re-entrant metamaterial structure.

enhanced cross-sectional resolution, capturing thoroughly the displacement field. This is achieved by significantly reducing DOFs without compromising accuracy with respect to the high fidelity 3D FEM simulations, as widely discussed in the following. To perform comparisons, the same metamaterial structure has been analysed by means of commercial FEM

software, i.e. Abaqus. In CUF, the displacement field u(x, y, z) for a 1D beam is represented as:

$$\boldsymbol{u}(x,y,z) = F_\tau(x,z)N_i(y)\boldsymbol{u}_{\tau i} \qquad \tau = 1,2,\dots,M \quad i = 1,2,\dots,N_n$$

Materials Research Proceedings 69 (2026) 1379-1383 https://doi.org/10.21741/9781644904251-240

where $F_\tau(x,z)$ denotes the expansion functions in the cross-sectional plane, $N_i(y)$ the shape functions along the beam axis, and $\boldsymbol{u}_{\tau i}$ the nodal unknowns. As earlier mentioned, Lagrange polynomials are used as $F_\tau(x,z)$.

Numerical results

The numerical study focuses on a metamaterial with hexagonal topology (Fig. 4). Three modeling strategies are considered: (i) a 2D Abaqus model discretized on the surface (inplane section), (ii) a 2D Abaqus model discretized across the width (transverse section), and (iii) a 3D model based on the Carrera Unified Formulation (CUF), which explicitly represents the metamaterial's three-dimensional geometry. The structure is subjected to a uniform transverse pressure and is clamped along one boundary, with all remaining edges free. For each model, a mesh-refinement study was performed. Table 1 reports the total number of degrees of freedom (DOFs) together with the lateral displacement values evaluated at a selected control point. The entries that achieved mesh convergence are highlighted in blue in the table. Compared with the 2D Abaqus reference discretizations, the CUF model reaches the converged response with roughly 20% of the DOFs, indicating a substantial reduction in problem size for a comparable accuracy. This reduction in DOF count translates into lower memory requirements and shorter solution times, while preserving the fidelity needed to capture the characteristic deformation mechanisms of the hexagonal architecture. Finally, Fig. 5 illustrates the deformed configurations (plotted with an exaggerated scale for clarity). The three modeling approaches yield consistent global deformation patterns and confirm the expected stiffness trends under transverse loading, further validating the efficiency and accuracy of the CUF-based 3D representation for this class of metamaterials.

Conclusions

This work presented a numerical study of a hexagonal metamaterial structure using the Carrera Unified Formulation (CUF) to achieve accurate and efficient modeling. The key findings and contributions of this research are summarized as follows.

- The use of CUF enabled the development of enhanced one-dimensional finite elements with three-dimensional capabilities. This allowed for precise detection and prediction of deformations across the structure's cross-section, providing a robust framework for analyzing future complex mechanical behaviors.
- The proposed model accurately captured the static behavior of the hexagonal metamaterial, comparing the results with Abaqus results. The gain in terms of number of DOFs is high.
- Metamaterial structures, featuring any cross-sectional geometry across their width, can be modeled easily using CUF. This capability opens up possibilities for adapting the model to further investigate three-dimensional metamaterials.

The findings of this study provide a robust foundation for future research into the design and optimization of metamaterial structures.

Keywords: Sandwich, CUF, Component-Wise, Layer-Wise, Stress, Failure

Abstract. This paper presents a Component-Wise (CW) 1D beam formulation within the Carrera Unified Formulation (CUF) [1] to model and simulate the mechanical behaviour of sandwich panels. The approach treats skins and cellular cores as distinct sub-domains in a single one-dimensional element. By representing the true cross-sectional geometry with high-order Lagrange polynomials, the model achieves high three-dimensional accuracy [2], including the capture of localized deformations and through-thickness stresses, while significantly reducing the degrees of freedom (DoFs) with respect to 3D FEM simulations. This paper provides evidence that this single refined 1D beam is easy to model, numerically efficient and mechanically accurate for any sandwich/metamaterial cores, from classic honeycomb to novel butterfly lattices, thereby enabling parametric studies and precise failure-onset assessment.

Sandwich and lattice-core metamaterials represent advanced and efficient lightweight structures for aerospace sector thanks to their high stiffness-to-mass ratio and multifunctionality [3]. Their architectural complexity, however, challenges traditional modelling processes. Homogenised Layer-Wise (LW) models are not able to detect the actual mechanical behaviour of the complex core geometry, whereas detailed 3D solids elements explode the number of DoFs and therefore the design-space exploration time. A modelling and simulation framework that is simultaneously efficient, accurate, and local-effect resolving is thus essential.

CUF allows to model complex sandwich structures with a single 1D beam element. The beam reference axis does not follow the panel length, as in the canonical beam descriptions, but aligns to the thickness direction, see Figure 1; the full cross-section is represented by arbitrary-order Lagrange polynomials describing independently skins and core. This CW discretisation preserves representation of actual structure geometry, including local variations, allowing to overcome core homogenisation while reaching 3D FEM accuracy. The polynomial order of Lagrange expansion is user-tunable, allowing trade-offs between level of resolution and number of degrees of freedom. Continuity across skin-core interfaces is guaranteed through shared Lagrangian nodes, producing reliable displacement and stress fields in critical interface regions.

This approach is extremely flexible, as it allows the modelling of any core geometry for sandwich panels. To provide quantitative results, six different core topologies were simulated under several static load cases: butterfly, large and small unit cell hexagonal honeycomb, large and small unit cell square, and triangular lattice, see Figure 2.

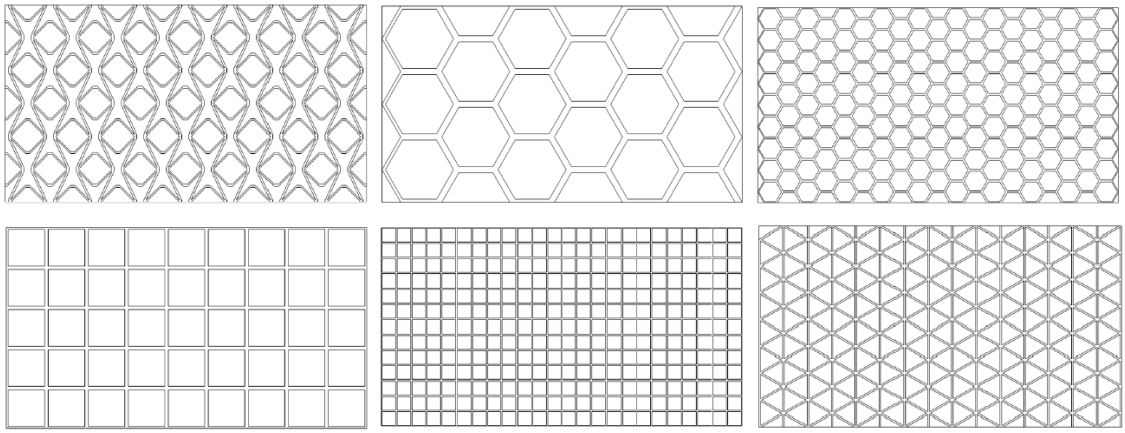

Figure 2. Cross sections of the different core geometries considered

Focusing on the large-cell honeycomb, several static load scenarios representative of service loads were applied: concentrated load on specific cells, uniform pressure, torsion, concentrated forces on skins edge, core inflection, and single-cell crushing. Each case was modelled and simulated with both CW and LW model whose core is homogenised [4].

Considering a case of sandwich panel clamped on both edges and with groups of concentrated forces on some selected cells, the potential of CW representation and the limitations of the LW model appear evident. Results in terms of deformed shape and Von Mises stress contour map comparisons are provided in Figure 3 and Figure 4, respectively. The CW model resolves the three distinct indentations in the upper skin, each corresponding to a loaded honeycomb cell. In contrast, the LW counterpart exhibits a smooth global inflection produced by bending; no local indentations appear because the core is represented as an equivalent continuum. This clearly anticipates major differences in the quantitative fields. Indeed, considering Von Mises stress distributions, in the CW model the stress field forms pronounced circular bands around each indented cell, with steep gradients that quickly decay into the surrounding webs, representing localised load transfer at skin-core interfaces. The LW displays an almost uniform distribution with only mild variations in the acting areas of the concentrated forces; the distinct zones evident in the CW analysis are entirely smoothed out. This proves that homogenised formulations prevents the identification of critical stress areas that the CW approach allows to detect, underscoring its superiority to capture failure-relevant local effects.

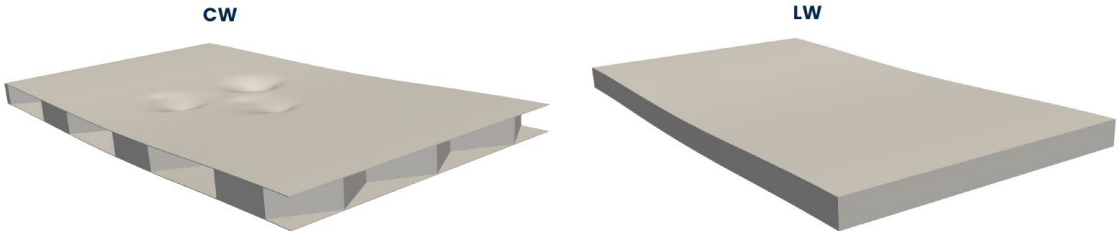

Figure 3. CW vs LW sandwich panel deformed shapes

Materials Research Proceedings 69 (2026) 1384-1386 https://doi.org/10.21741/9781644904251-241

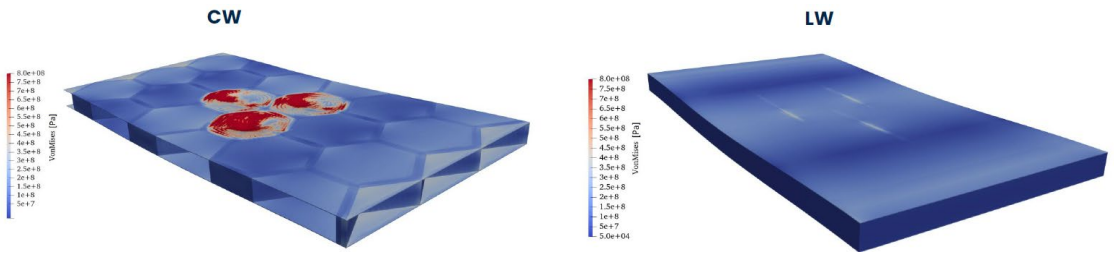

Figure 4. CW vs LW Von Mises stress distributions

The resolution of CW reveals how bending of individual hexagonal cell drives skin indentation; the homogenised LW model, lacking geometric detail, ignores these local kinematics and cannot identify the onset points for face-sheet wrinkling or local core stress peaks. These results highlight the indispensable role of CW kinematics when failure-critical local fields are required. Results provided in ref. [5] proved the accuracy of the approach, comparable to that of 3D FEM models, and its efficiency, as CW model reduces the number of DoFs up to six times compared to the 3D FEM counterpart.

The component-wise CUF beam element forms a unified and flexible tool for high-fidelity yet computationally efficient analysis of sandwich and metamaterial panels. By integrating exact geometrical and mechanical descriptions with high-order kinematics, it bridges the gap between oversimplified LW homogenized model and prohibitively heavy 3D solids FEM models. The framework not only provides an excellent framework for parametric design or structural optimization, but also provides a reliable tool for the local stress assessment indispensable for accurate failure-onset assessment, paving the way for accurate design of next-generation lightweight structures.

Keywords: Deployable Structure, Carrera Unified Formulation, Foldable Flat Array

Abstract. The shift toward smaller satellites has sparked growing interest in deployable booms that can stow compactly and extend to full length once on-orbit [1]. These booms are typically rolled into a coil and, when released, unroll into slender rods made of thin-walled composite shells, releasing stored strain energy in the process; such mechanisms are common in spaceborne telescopes and other large-aperture payloads [2,3]. Tape springs, thin elastic strips, remain the most prevalent deployable boom. The introduction of carbon-fibre-reinforced-plastic (CFRP) tape springs has further improved stiffness-to-mass ratios [4]. A related concept, the Triangular Rollable and Collapsible (TRAC) boom, links two tape-spring "flanges" along a common "web," forming a triangular cross-section that offers markedly higher bending stiffness. First developed at the Air Force Research Laboratory by Murphey and Banik [5], metallic TRAC booms flew on NASA's NanoSail-D solar sail [6]; more recent work has shifted to composite TRAC designs to mitigate temperature-gradient problems seen in metal versions. One high-profile application is Caltech's Space Solar Power Project (SSPP), which envisions a modular lattice of TRAC longerons and rectangular CFRP battens that supports arrays of multifunctional tiles. These tiles harvest solar energy, convert it to RF power, and beam it to Earth [7]. The SSPP structure consists of bending-stiff trapezoidal strips, arranged in four identical quadrants. The two edges of each strip are formed by composite TRAC longerons, connected by carbon fiber rectangular battens. Accurate simulation is vital for sensitivity studies and for minimizing costly hardware tests. Conventional finite-element analysis often relies on 2-D shell elements to model slender booms, a choice that struggles to capture out-of-plane responses and local effects, especially critical in composite laminates [8]. To overcome these shortcomings, this work employs a Carrera Unified Formulation (CUF)–based finite-element model [9]. CUF enriches one-dimensional beam elements with high-order cross-sectional expansions, allowing three-dimensional and localized behaviours to appear within a low-degree-of-freedom framework. The method has already proven effective for buckling and post-buckling studies of deployable booms [10]; here, it is extended to simulate the full folding and deployment sequence of the SSPP flat-array module.

Refined one-dimensional finite element

For the numerical model, a Cartesian reference system is used, so that the y direction is placed in the length direction, and the x,z identify the cross-sectional domain as shown in Fig. 1.

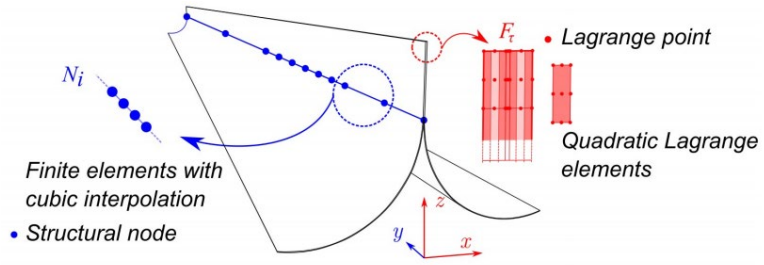

Figure 1 - Model of the TRAC longeron based on the Carrera unified formulation.

Materials Research Proceedings 69 (2026) 1387-1390 https://doi.org/10.21741/9781644904251-242

According to the Carrera Unified Formulation (CUF), the three-dimensional displacement field can be written in the following unified manner:

$$\boldsymbol{u}(x,y,z) = F_\tau(x,z)\boldsymbol{u}_\tau(y) \qquad \tau = 1,2,\dots,M \tag{1}$$

where $\boldsymbol{u}(x,y,z)$ is the displacement vector, whose components are expressed in the general reference system (x,y,z), $F_\tau(x,z)$ represent the cross-sectional functions depending on the x,z coordinate, τ is the sum index and M is the number of terms of the expansion in the cross-section plane assumed for the displacements. The proposed work adopts quadratic Lagrange polynomials (L9) as $F_\tau(x,z)$ to approximate the kinematics of the theory.
To approximate the displacement field over the beam axis, the Finite Element Method (FEM) is adopted. The generalized displacement vector $\boldsymbol{u}_\tau(y)$ is expressed as follows:

$$\boldsymbol{u}_\tau(y) = N_i(y)\boldsymbol{u}_{\tau i} \qquad \tau = 1,2,\dots,N_n \tag{2}$$

where N_i stands for the i-th one-dimensional shape function, i indicates summation and N_n is the number of the FEs nodes per element. Finally, $\boldsymbol{u}_{\tau i}$ is the following vector of the FE nodal parameters:

$$\boldsymbol{u}_{\tau i} = \{\boldsymbol{u}_{x_{\tau i}}, \boldsymbol{u}_{y_{\tau i}}, \boldsymbol{u}_{z_{\tau i}}\}^T \tag{3}$$

Here, 1D finite Lagrangian elements are used along the y-axis.

Methodology

The deployable structure analyzed in this study is a complex structure made of longerons, transverse battens, and hinges. A simple version is shown in Fig. 2(a), and it is referred to as a double-strip due to its composition of two sub-structures connected by two hinges.

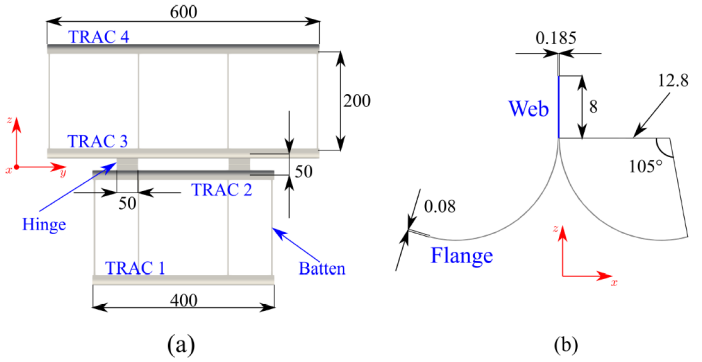

Fig. 2 (a) double-strip structure (b) one TRAC longeron cross-section. The dimensions are given in mm.

Each strip consists of two TRAC longerons and four battens. The cross-section of the longerons is shown in Fig. 2(b), with all dimensions provided in millimeters. As far as the material properties are concerned, the composite layup in the flanges of the longeron is [± 45 GFPW/ 0 CF/ ± 45 GFPW]°, and the layup of the web region is [± 45 GFPW/ 0 CF/ ± 45 GFPW/ 0 CF/ ± 45 GFPW]°, where CF represents a thin ply with unidirectional carbon fibers and GFPW stands for plain weave scrim glass. Both plies are impregnated with resin. In this case, six different cross-sections are utilized, as illustrated in Fig. 3(b).

Materials Research Proceedings 69 (2026) 1387-1390 https://doi.org/10.21741/9781644904251-242

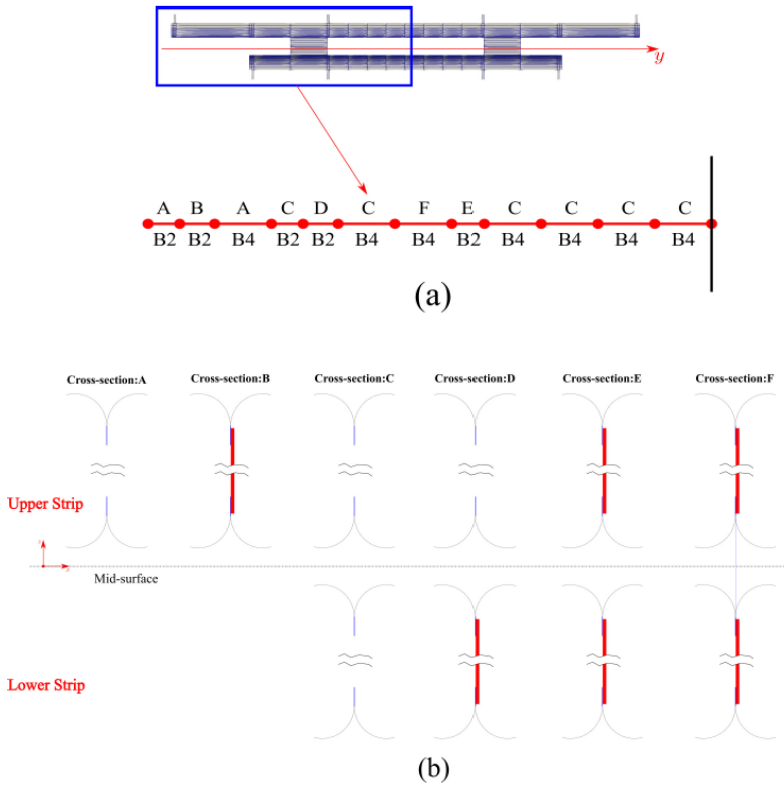

Fig. 3 Mesh discretization for the double-strip structure. (a) Beam finite element used along y-axis. (b) Representation of the six cross-sections.

Finally, Fig. 4 shows a four-strip structure that the will be also analysed in the full paper. It involves four strips joined together with hinges and both transverse and diagonal battens. The structure is modeled using a single axis refined beam, using the same approach described above.

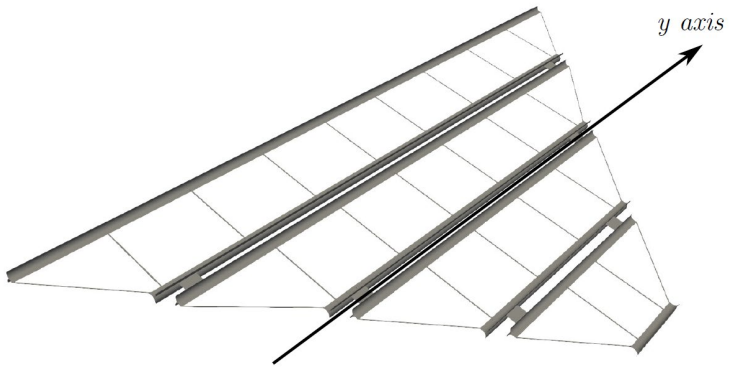

Fig. 4 Model of the elastically foldable flat array.

The full paper will deal with the folding of the elastically foldable flat array.

Keywords: Hard Anodization, PLD, Space Applications, Aluminum, TVAC, SEM, Brillouin Spectroscopy, Elastic Properties

Abstract. Aluminium alloys used in space structural applications are exposed to extreme environmental conditions. To preserve the integrity of structural materials in such environments, various surface treatments have been developed with the goal of forming thin films of hard oxides. Traditionally, the standard surface treatment for space applications has been hard anodization, which produces aluminium oxide layers through an electrochemical reaction between the substrate and an electrolyte. As an alternative to this well-established technique, thin film deposition via Pulsed Laser Deposition (PLD) has been explored. This study compares the traditional hard anodization method with PLD to evaluate their respective strengths and weaknesses and assess the potential of PLD as a viable alternative to coat AA7075-T6, a widely used alloy in the space industry. This work examines the effects of Low Earth Orbit (LEO) conditions on the morphology and on the interface between the aluminum substrate and the deposited alumina. The LEO environment experienced by the "6S CubeSat" of the PoliSpace project [1] is simulated through thermal cycling in a Thermal Vacuum Chamber (TVAC), in accordance with the "ECSS-E-ST-10-03C" standard. The samples underwent a tailored thermal cycle, in which the maximum and minimum temperatures represent limiting conditions selected to prevent damage to sensitive components, such as the structural batteries. A high vacuum level was ensured during each test to fully simulate the space environment. The physical and elastic properties of both coatings were evaluated employing Brillouin spectroscopy, offering insights into how the fabrication method influences the final characteristics of the deposited films. Visual tests confirmed the different nature of the two interfaces and the expected higher compactness of the PLD-deposited alumina with respect to the anodic one.

Introduction

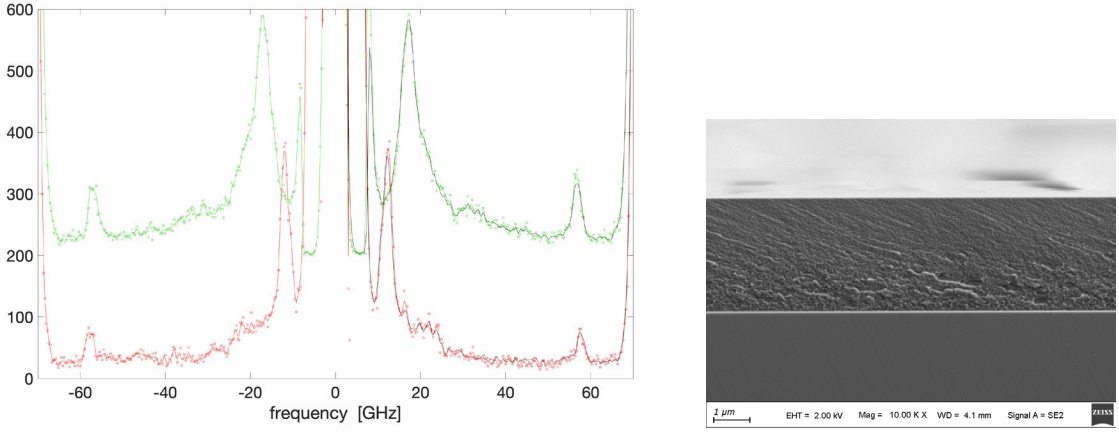
Structures working in space environments are exposed to a complex environment, which can affect their integrity in different ways. To avoid their failure under these conditions, a common solution for aluminium components is to coat them by hard anodization, which generates a thick, columnar and porous outer layer of aluminium oxide (Al_2O_3) [2].

However, alternative coating techniques have been proposed to replace the previous method. A particularly innovative and promising approach is pulsed laser deposition (PLD), in which a laser ablates a target to deposit a layer of Al_2O_3 onto the substrate. This process offers several advantages, including thinner alumina layers that reduce component volume [3], lower average power consumption, minimal impurity incorporation due to the high vacuum environment, and the ability to tailor the deposition pattern as needed [4].

In this study, both hard anodize and PLD coatings are produced on AA7075-T6 substrate and then characterized with scanning electron microscopy. After being subjected to cycles inside a thermal vacuum chamber (TVAC) to simulate space conditions, the effect of this treatment on the elastic properties of the coatings is evaluated via Brillouin spectroscopy, estimating the variation in their Young's moduli and Poisson's ratios.

Materials and Methods

Thermal Vacuum Chamber (TVAC). This study is based on the "6S CubeSat" project of the PoliSpace association of Politecnico di Milano, a cubic satellite designed to operate in a Low Earth Orbit environment [1]. To reproduce the effects of this environment, a TVAC test session was designed for both coatings, consisting of one non-operative cycle followed by three operative cycles. The threshold temperatures were determined from a thermal study on the CubeSat and the tests were conducted in accordance with the "ECSS-E-ST-10-03C" standard. In a medium-high vacuum and starting from +25 °C, the samples first underwent a non-operative thermal cycle with temperatures ranging from -20 °C to +40 °C. Then three operative cycles followed, ranging from +50 °C to -40 °C. For all these cycles, each threshold temperature was held for 15 minutes.



Brillouin Spectroscopy. Brillouin scattering techniques rely on spontaneous thermal fluctuations in the acoustic modes, namely phonons, and on their detection by local inelastic scattering of light. The probing light is therefore not responsible for the thermal vibrations, but it is the medium through which the measurement is performed, and since the beam is in the visible, the probed frequencies are on the order of tens of GHz. However, given the weak fluctuations investigated, the measurements are typically time-consuming. A laser beam in the visible range is focused onto the sample at an incidence angle θ from the surface normal. Scattered light is collected and its spectrum is analysed by a tandem multi-pass Fabry-Perot interferometer. The scattering geometry and the laser wavelength select the probed acoustic wavevector.

Spectral peaks (Fig. 1a) show the frequencies of the acoustic modes which propagate at the selected wavevector. In the bulk the probed wavevector scales as the refractive index n, and the acousto-optical interaction is mediated by the acoustically induced modulation of n. Bulk waves can be longitudinal or transversal, respectively at higher and lower frequencies, and characterized by a medium-to-low intensity. At the surface, scattering involves only the wavevector component parallel to the surface, which scales as $\sin(\theta)$ but does not depend on n, and the acousto-optical interaction is mediated by the acoustically induced corrugation of the surface. These surface wavevectors, or Rayleigh waves, give intense lower frequency peaks. In both cases, from frequencies and wavevectors the velocities of the acoustic modes are obtained, from which derived constants can be obtained if mass density is known. [5]

Materials Research Proceedings 69 (2026) 1391-1396 https://doi.org/10.21741/9781644904251-243

Results

Spectra analysis and mathematical model for PLD samples. Fig.1a shows measured spectra on PLD untreated and treated samples.

(a) *(b)*

Figure 1: (a) PLD spectra for untreated sample at an incident angle equal to 40° (red curve) and treated sample at an incident angle equal to 70° (green curve); (b) Cross-section of PLD-coated samples.

Three different peaks can be distinguished at around 15, 20 and 55 GHz respectively. For the first peak, associated with the Rayleigh wave, its velocity and frequency can be related as follows:

$$f = \frac{2v_R}{\lambda} \cdot sin(\theta) \tag{1}$$

where f is the frequency, v_R is the velocity of the Rayleigh wave, θ is the angle between the incident light and the sample surface and λ is the wavelength of the incident light, in this study 532 nm. This dependence justifies the relevant shift of the first peak for the two curves, which are obtained at two different incident angles. The peak at 55 GHz is associated with the bulk longitudinal wave, for which, by means of solid-state physical considerations, the relation between frequency and velocity can be expressed as:

$$v_L = \frac{f\lambda}{2n} \tag{2}$$

where v_L is the velocity of the longitudinal wave and n is the refractive index of the coating, which, in this study, was considered equal to 1.65 [6].

The last peak at 20 GHz normally represents the bulk transversal acoustic mode, but in this case it does not depend on n: in addition, the peak also appears at lower frequency than expected, suggesting the possibility of an indirect scattered bulk mode, i.e. the propagating wave inside the bulk is scattered by a phonon with a wavevector parallel to the surface [5]. As previously described for the Rayleigh wave, the velocity is governed by the θ angle as described in Eq. 1. To verify the

Materials Research Proceedings 69 (2026) 1391-1396 https://doi.org/10.21741/9781644904251-243

indirect scattering in the bulk, the following relation between the frequencies and the velocities of the indirect bulk and Rayleigh acoustic modes must be verified:

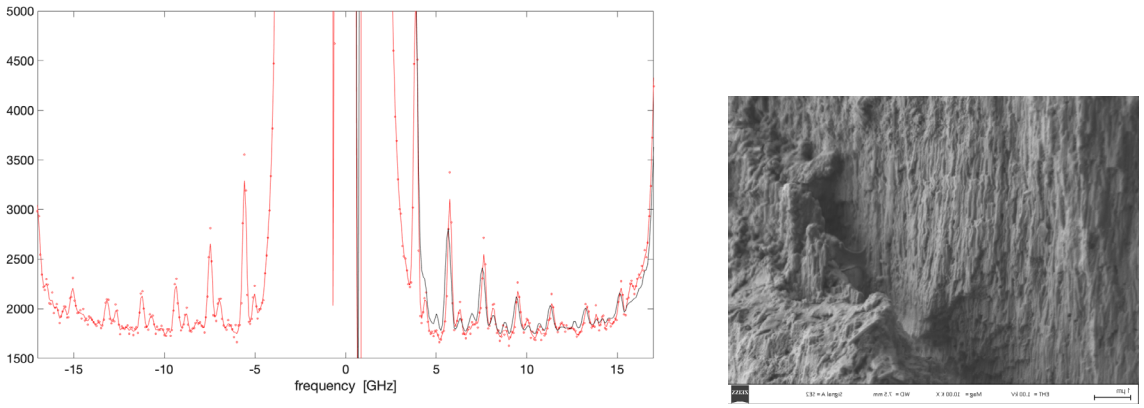
$$\frac{v_b}{v_R} = \frac{f_b}{f_R} \tag{3}$$

Eq. 3 is verified allowing the determination of the refractive index without further tests, showing accordance with the values found in literature. A similar consideration can be made for the middle peak in the spectrum obtained after TVAC (green curve), from which it is possible to extract a similar value for the refractive index. However, to completely confirm the presence of the indirect bulk scattering and that the refractive index is not affected by the treatment, further tests are required to provide a statistical validity.

Fig. 1b shows that the PLD coating appears to be amorphous and homogeneous: hence, an isotropic behaviour can be validly assumed. Moreover, the thickness of the coating (3 μm) is enough for Brillouin spectroscopy to be considered a semi-infinite material, meaning that no influence of the substrate is expected. From these considerations it is possible to relate the frequencies and the velocities extracted from the peaks in the spectra to the elastic properties of the coating through a simplified model. Therefore, the Young's modulus (E) and the Poisson's coefficient (ν) are sufficient to fully characterize the material, since the two parameters are linked to the velocities and the frequencies of the spectral peaks through the C_{11} and C_{44}, ij-th components of the stiffness matrix. The following relations can be used [6]

$$v_l = \sqrt{\frac{C_{11}}{\rho}}, \qquad v_t = \sqrt{\frac{C_{44}}{\rho}}, \qquad v_R \approx v_t \frac{2.87C_{11} - 4C_{44}}{3C_{11} - 4C_{44}} \tag{4}$$

where v_l and v_t are the bulk longitudinal and bulk transversal velocities respectively, v_R is the velocity of the Rayleigh (surface) wave and ρ is the density of the coating which is equal to 3470 Kg/m^3. The expression for v_R is an approximate solution of the cubic equation relating v_R to v_t. From the two components of the stiffness matrix, E and ν can be obtained via the following equations [6]:



$$C_{11} = \frac{E(1-\nu)}{(1+\nu)(1-2\nu)} \qquad C_{44} = \frac{E}{2(1+\nu)} \tag{5}$$

Observing the Brillouin spectra, it is possible to notice an invariance in the significant peaks analysed for the extraction of the elastic properties, which reflects also to the final elastic constants.

However, due to the limited number of analysed samples, further investigation is required to understand whether the two populations are statistically different.

Materials Research Proceedings 69 (2026) 1391-1396 https://doi.org/10.21741/9781644904251-243

Hard Anodized Samples. Fig.2a shows measured spectra on untreated hard anodized sample.

(a) ***(b)***

Figure 2: (a) Untreated Hard Anodized spectrum; (b) Cross-section of hard anodized coated samples.

Fig. 2a shows numerous peaks which, however, are not of the type mentioned before. In fact, for high frequencies no bulk peaks are observed, while a series of small peaks are present for very low frequencies, with a dependence on the refractive index, behaviour typical of bulk waves. This excludes the possibility that the slowest wave is the Rayleigh one. Moreover, the columnar nature of the anodic film (Fig. 2b) invalidates the homogeneous and isotropic hypotheses, thus requiring a dedicated model for anisotropic materials for which Eq. 1 and Eq. 2 are no longer valid. Nevertheless, the porous structure of the coating may create a series of collective/stationary waves that, being non-propagating, will not contribute to the characterization of the elastic properties of the coating, and changes given by the TVAC cycling.

Conclusion and future activities

Overall, the measurements obtained for the PLD samples following the TVAC cycles show no discernible alteration in their properties, indicating that the microstructure of the coating remains amorphous, with no evidence of sporadic crystalline domain formation [6]. Confirmation of this hypothesis will require additional characterization, including XRD and SEM analyses. Conversely, the observed behaviour of the hard anodized samples may be attributable to collective motions inherent to the porous structure of the coating. Both phenomena necessitate more detailed studies and will be the focus of subsequent investigations.

Acknowledgments

The authors would like to thank Dr. C. Martina and Prof. D. Scaccabarozzi from the MetroSpace Lab for providing the TVAC facility, and Prof. M.G. Beghi for his supervision in Brillouin spectroscopy. Acknowledgments are also due to Dr. F. Piccagli and Dr. F. Di Fonzo at X-nano Srl (Milan, Italy) for their assistance with PLD equipment access, coating deposition and preliminary characterization. Furthermore, the authors acknowledge YDF (Carimate, Italy) for the aluminum laser cutting, Al Ti Color (Piazzola sul Brenta, Italy) for the electropolishing of the substrates, and Argos ST (Opera, Italy) for the hard anodization process

Keywords: Hard Anodization, PLD, Space Applications, Aluminium, TVAC, Mechanical Performance, Tribological Tests

Abstract. In the space environment, aluminum alloys used in structural applications are exposed to severe conditions such as debris impacts and extreme temperature fluctuations. These phenomena can significantly compromise surface integrity, leading to increased wear, reduced mechanical performance, and premature failure of components. To address these challenges, various surface treatments have been developed to form protective oxide films on aluminum surfaces. Hard anodization is the traditional and widely adopted method, producing thick, hard and columnar aluminum oxide through an electrochemical reaction. Recently, Pulsed Laser Deposition (PLD) has emerged as a potential alternative, offering the possibility of depositing dense, uniform thin films with strong adhesion to the substrate. The aim of this work is to assess the reliability of both coating techniques when samples are subjected to TVAC cycling. To achieve this objective, AA7075-T6 coated samples underwent both thermal cycling in vacuum and tribo-mechanical tests. To simulate the Low Earth Orbit (LEO) exposure, the environment in which the "6S CubeSat" of the PoliSpace project is subjected, a Thermal Vacuum Chamber (TVAC) was used, following "ECSS-E-ST-10-03C" standard. By maintaining a high vacuum level, the samples underwent a specifically designed thermal cycle, with the maximum and minimum temperatures chosen based on the thermal study of the cited project. These temperatures were the ones at which premature

failure of some components of the CubeSat was observed [1]. Subsequently, the mechanical behaviour of the coatings was characterized both before and after TVAC exposure, focusing on properties critical to in-orbit durability. Vickers and Berkovich tests were conducted to monitor changes in surface hardness for hard anodized and PLD coatings, respectively. Vickers micro-hardness tests followed the procedures outlined in "ISO-4516-2002", while Berkovich nano-hardness tests were selected for the PLD coatings due to their limited thickness. The friction coefficient and coating wear must be considered for the CubeSat rails, as these components are critical for the satellite's release from the rocket's storage chamber. To assess the performance of our coatings in relation to these factors, a pin-on-disk wear test was conducted under dry conditions. Coating adhesion, a crucial factor for the stability of space structures in the presence of sliding space debris, was evaluated through scratch tests following "ASTM-C-1624-05". These tests provided insights into interface stability, coating adhesion under increasing applied load, and the failure mechanism. A quasi-static load ramp was applied to avoid impact-like loading conditions.

Introduction

Structures operating in the space environment are subjected to various phenomena of different natures. This study is based on the "6S CubeSat" project developed by the Politecnico di Milano student association PoliSpace, where the combined effects of thermal and mechanical loads create a highly demanding environment for the materials employed. In this context, hard anodization is the most common and ECSS-recommended coating technique for protecting aluminum structures by producing a thick, columnar, and porous layer of alumina (Al2O3) on the substrate [2]: the oxide layer obtained in this study is 40 μm thick. However, recent advancements in coating technologies have enabled the deposition of thinner and compact oxide layers on various substrates. In this study, the pulsed laser deposition (PLD) technique, a physical vapour deposition (PVD) method that deposits Al2O3 from a target onto the substrate, is investigated as a promising alternative to traditional hard anodization; this deposition technique allowed us to obtain 3 μm thick coatings [2]. The primary objective of this preliminary study is to evaluate the tribo-mechanical properties of both coatings applied on square samples of AA7075-T6 substrate through hardness, wear, and scratch tests, under conditions representative of the Low Earth Orbit (LEO) environment, with the final aim of mitigating issues such as excessive wear during the launch of the CubeSat. To simulate LEO conditions, cycles in a thermal vacuum chamber (TVAC) were performed on both coatings.

Materials, methods and results

TVAC. To replicate the effects of the LEO environment on both coatings, a TVAC cycle, consisting of one non-operative cycle and 3 operative ones, was designed for both coatings, following "ECSS-E-ST-10-03C". Under medium-high vacuum, the samples underwent a thermal cycle with a temperature range from –40 °C to +50 °C for the operative cycles, and from –20 °C to +40 °C for the non-operative one, limits identified by the thermal design on the components of the CubeSat [1]. For all the cycles, the initial temperature was +25 °C and, for all the boundary temperatures, a holding time of 15 minutes was applied, as shown in Fig. 1.

Materials Research Proceedings 69 (2026) 13971401- https://doi.org/10.21741/9781644904251-244

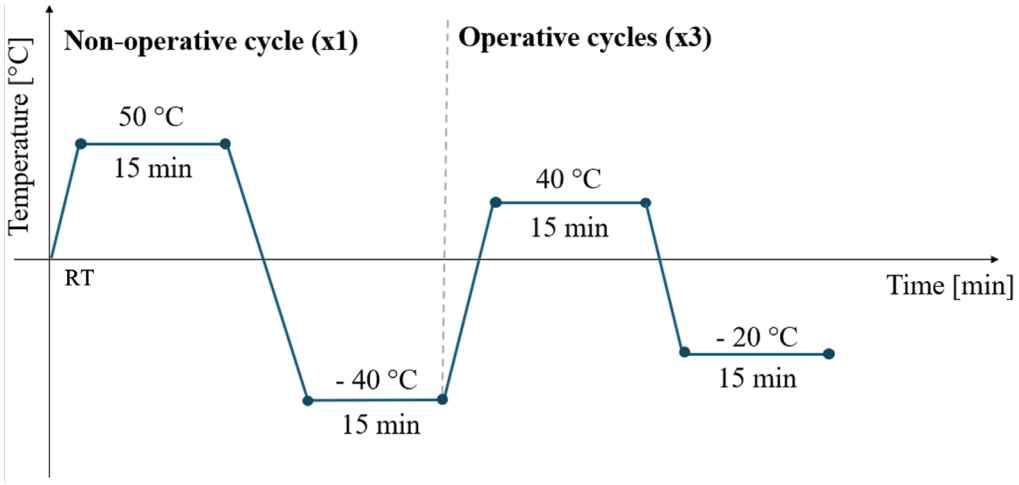

Figure 1: Applied TVAC cycles: the starting temperature (RT) is 25 °C, heating/cooling rate of 0,1 °C/min.

Hardness test. Vickers micro-hardness tests were performed on hard anodized samples at four different loads (3 N, 5 N, 10 N and 20 N) to evaluate the field of influence of the substrate [4]. A preliminary set of micro-hardness tests on the hard anodized samples shows that the actual value of hardness depends on the applied load, highlighting the growing influence of the substrate. However, this phenomenon is also affected by the microstructure: with smaller loads the actual values have a stronger dependence on the position of the indentation since the porosities will have a major effect (Fig. 2a). Moreover, after TVAC cycles, a reduction in hardness is observed. As shown in Fig. 2b the effect of the TVAC treatment is less relevant at higher loads, probably due to the interference of the substrate. Still, this variation in hardness suggests a possible effect of the TVAC cycles on the microstructure of the coating.

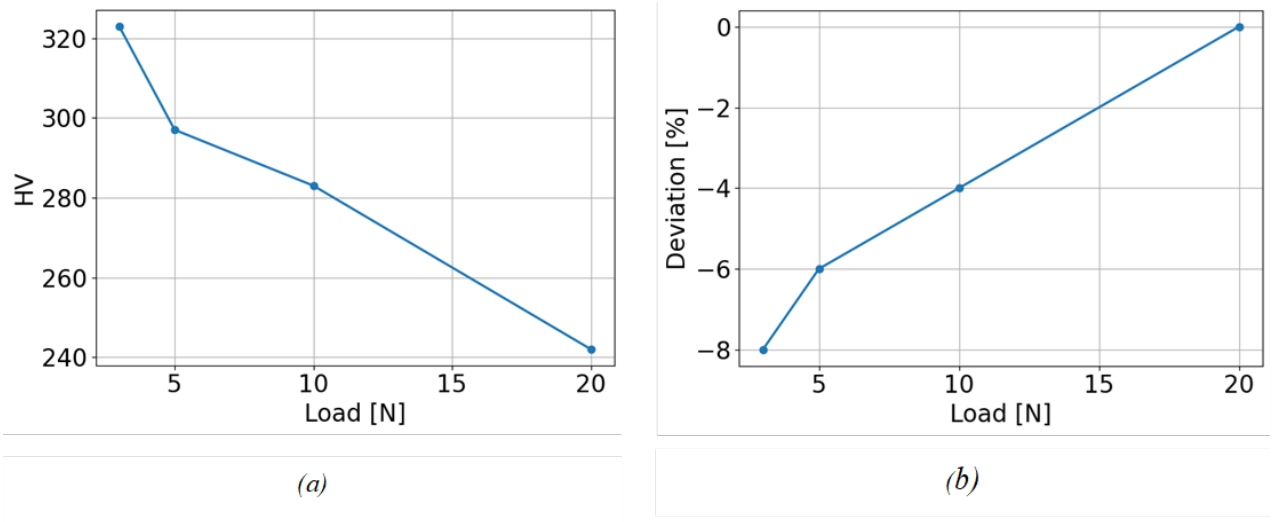

Figure 2: Vickers micro hardness change on hard anodized samples [4] (a) varying the load, (b) after TVAC cycles

On the other hand, PLD samples could not be tested the same way because the thickness of the coating is not at least ten times greater[1]. For this reason, the study of the hardness variation in PLD samples after the TVAC cycles needs to be conducted based on future Berkovich nanoindentation tests.

Materials Research Proceedings 69 (2026) 13971401- https://doi.org/10.21741/9781644904251-244

Scratch test. In both PLD and hard anodized samples, after TVAC, no relevant differences were found in terms of the load needed to start fracture and the friction coefficient. Hard anodized samples break by arc tensile cracking, while PLD samples break by wedging spallation, as shown in Fig. 3.

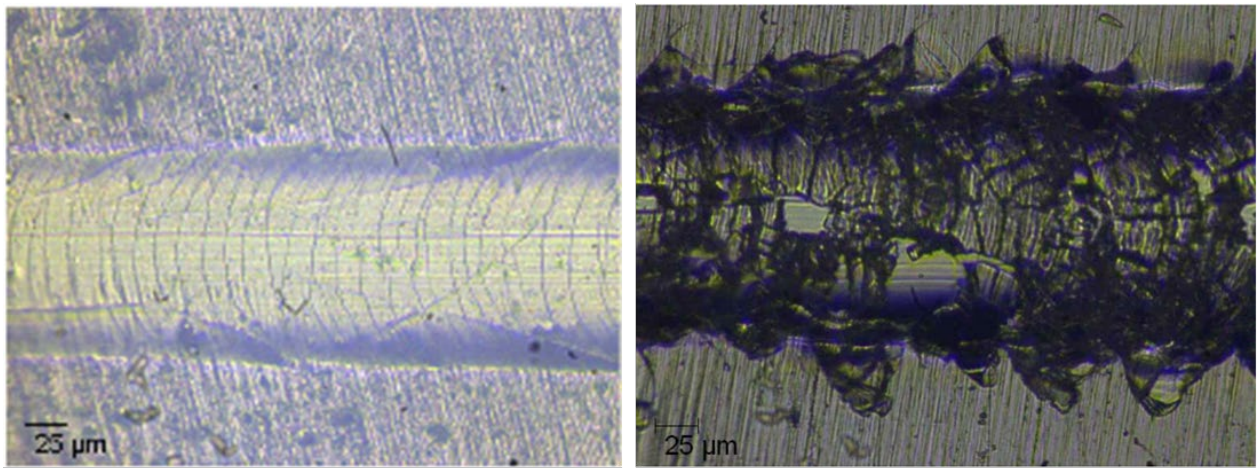

Figure 3: Scratch trace on (a) hard anodized and (b) PLD samples taken at 20 N

A preliminary investigation of Fig. 3[2], highlights a radically different fracture mode between the two coatings: the hard anodized samples present cracks only inside the scratch trace, meaning that the inherent cohesion of the coating is lower with respect to its adhesion to the substrate, possibly because the process transforms the base metal into the coating material. On the other hand, PLD samples present cracks also outside the scratch trace: this may be due to a higher cohesive strength with respect to the adhesive one.

Wear test. From a preliminary analysis, it is possible to observe a difference in the wear behaviour of the two coatings, perhaps due to dissimilar active wear mechanisms, which would be supported by the diverse fracture mechanisms highlighted with the scratch tests. Moreover, after TVAC, both hard anodized [5] and PLD samples show a reduction in the friction coefficient and seem to change in their wear trend (Fig. 4a - Fig. 4b). However, this characteristic is still under investigation and further mechanical testing is essential to assess the reliability of the previous hypothesis.

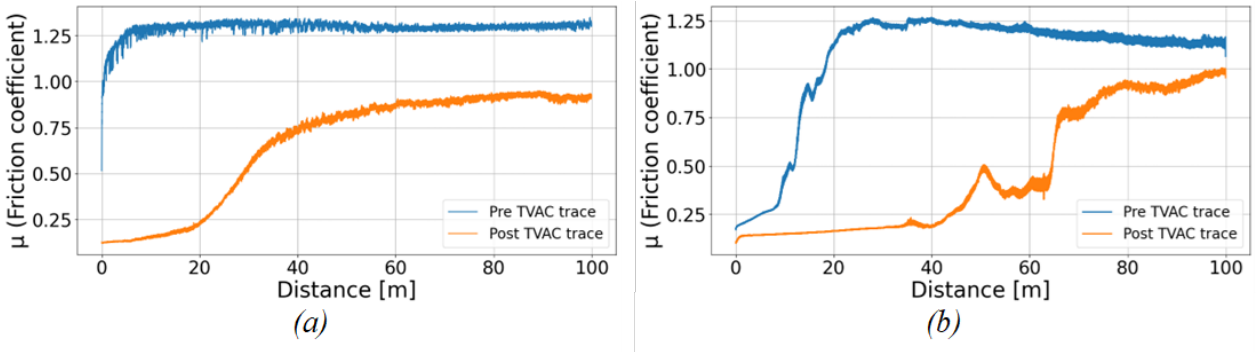

Figure 4: Wear traces for (a) hard anodized components, (b) PLD components before and after TVAC cycling

Future prospects

While the results are still under evaluation, further analysis is required to confer statistical validity to the work and to give a deeper insight of the implications of the detected changes. Firstly, a more comprehensive understanding of the wear mechanisms of both anodic and PLD coatings is necessary: specifically, profilometry measurements and SEM imaging will be conducted to assess wear trace depth and identify peculiar microstructural features that may influence coating behaviour. Moreover, TVAC cycling did not significantly affect the adhesion of either coating, as evidenced by scratch test results. However, hardness values changed by approximately 8% after TVAC cycling, suggesting a potential effect on hard anodized samples; consequently, nanoindentation will be performed to verify if PLD samples are similarly affected. Nevertheless, amorphous alumina produced by PLD appears promising for space applications. Its superior control over film composition, density, and purity compared to hard anodization offers distinct advantages for protective coatings, such as those for solar panels. Furthermore, by eliminating the use of acid electrolytes, PLD enables a safer and more sustainable waste management process.

Acknowledgments

The authors express their gratitude to Dr. C. Martina and Prof. D. Scaccabarozzi of the MetroSpace Lab for their valuable assistance and for providing the TVAC facility for thermal- vacuum testing. We also thank Dr. F. Piccagli and Dr. F. Di Fonzo at X-nano Srl (Milan, Italy) for their assistance with PLD equipment access, coating deposition and preliminary characterization. Appreciation is extended to Prof. N. Lecis for granting access to the laboratory equipment for tribological characterization. Finally, the technical contributions of YDF (Carimate, Italy) for laser cutting, Al Ti Color (Piazzola sul Brenta, Italy) for substrate electropolishing, and Argos ST (Opera, Italy) for the hard anodization process are gratefully acknowledged.

Keywords: Lattice Structures, Manufacturing Defects, Additive Manufacturing

Abstract. The response of additively manufactured lattices is strongly affected by manufacturing induced imperfections. This work presents a numerical framework to model and assess these imperfections effectively. A simplified beam model is developed starting from accurate three-dimensional finite element analyses carried out on struts where the imperfections are modeled explicitly. The results show that the simplified models proposed here are capable of obtaining good matching with 3D simulations in terms of stiffness and strength, while requiring significantly lower computational cost.

Introduction

Lattice structures present attractive features for space applications. They are characterized by high structural efficiency and their cost is limited even for low production volumes [1, 2]. Furthermore, their production via additive manufacturing (AM) allows innovative configurations to be designed. So peculiar requirements of space structures can be met with larger flexibility. However, the AM process inevitably introduces dimensional inaccuracies, surface defects, and porosity [3]. Several studies have investigated these issues, particularly geometric defects in selective laser melting (SLM) of metallic parts [4, 5, 6]. The waviness and radius variation of struts have been analyzed with several models, including variable elliptical cross-sections [7], imperfect beams [8], and FEM incorporating scan-based data [9].

Despite the relatively vast literature on the topic, the modelling of defects is often based on costly analyses, which are unsuitable for preliminary assessments, where multiple configurations need to be analyzed. In particular, typical geometrical defects due to AM can have a drastic impact on both the linear and nonlinear structural response of lattices. Therefore, an effective modelling technique is crucial to simplify and speed-up the preliminary design phase, fully exploiting the potential of these structures.

In this paper, geometrical defects are modelled referring to the strategy proposed in Ref. [10], the KRK model: the struts are represented as the union of multiple spheres, each characterized by random variation in radius, axial offset, and penetration between adjacent spheres. Previous studies proved the impact of these features on the mechanical response of imperfect lattice structures.

Simplified beam models are developed to represent the structural behavior of lattice panels, using the KRK model to extract the constitutive laws for imperfect struts from three-dimensional finite element analyses. These models enable a rapid assessment of the non-linear response of complete lattice structures, making them particularly suitable for exploring different configurations and performing preliminary optimization.

Modelling of imperfections

Due to the relevance of manufacturing-induced defects, their explicit modelling is first addressed using 3D finite elements. With this purpose, a code has been developed to create either single struts or lattice configurations with multiple struts using Abaqus with Python scripting. The geometry is

Materials Research Proceedings 69 (2026) 1402-1406 https://doi.org/10.21741/9781644904251-245

generated automatically by assigning random distributions to the model parameters. Specifically, the parameters of the model are associated with a normal distribution whose average value and deviation can be determined from CT images [5, 10, 11]. Multiple struts are then merged together to form lattice cells. Once the geometry is generated, the component is meshed with tetrahedral C3D4 elements.

In addition to geometric imperfection, porosity caused by unmelted powder is modelled by generating spheres with diameters between 30 − 40 μm, uniformly distributed along the strut axis, radial offset, and angular coordinate. To avoid excessive mesh refinement, the elements located within these porosity spheres are identified, and their Young's modulus is reduced by a factor of one thousand with respect to the nominal material. This approach greatly simplifies the meshing process.

Simplified models

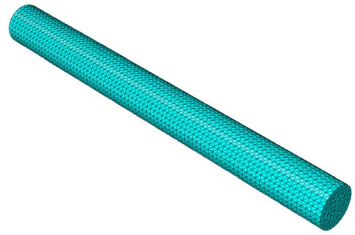
The 3D models just presented provide a refined description of the manufacturing imperfections. However, the large number of degrees of freedom resulting from the generation restricts the applicability of this approach. For this purpose, a simplified modelling strategy based on 1D beam elements is proposed herein. Two different techniques are investigated to capture the initial stiffness of the structure, the critical load, and the post-critical behavior of the structure under compressive loading.

The first class of simplified models relies on a 1-element-per-strut modelling. In this case, both the material and geometric nonlinearities are embedded in the constitutive law, which is defined by the force–displacement response of an imperfect strut under tension or compression. Two different strategies are investigated in this context: one using truss elements and the other using beam elements. To determine the section properties of the beam elements, a reduced section is considered. Specifically, it is obtained as the equivalent circular section of a perfect beam that undergoes the same deflection u of the imperfect strut in a cantilever bending test. The equivalent radius Req is obtained by inverting the formula from the vertical displacement of a linear elastic beam:

$$R_{eq} = \left(\frac{FL^3}{3\pi Eu}\right)^{\frac{1}{4}} \quad (1)$$

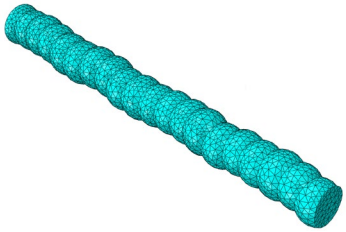
A second class of beam models considers multiple elements per strut. In these models, the constitutive law of the elements is obtained from a traction test. The presence of multiple elements allows a more accurate representation of the compressive deformation. Two of these models are analyzed: one includes regions near the nodes with artificially increased Young's modulus to account for local material accumulation, as in [10], while the other neglects these regions. The section of the beam elements is assigned with the equivalent radius Req of Eq. 1.

Numerical results



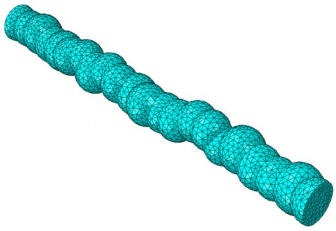
A set of analyses is conducted on both the single strut and the periodic octet cell. This latter is a cell composed by 24 struts merged at their intersection. The aim of the analyses is to evaluate the influence of imperfections and to assess the predictive capabilities of the simplified models. A bilinear constitutive law is adopted for the material, with Young's modulus E = 70000 MPa, yield strain ε = 0.002, Poisson's ratio ν = 0.33 and plastic modulus Ep = E/50.

To illustrate the impact of AM-induced defects, three FE models of a single strut with nominal radius R = 0.1 mm and length 2 mm, are analyzed, consistent with the dimensions of the CT data. In the first case, Fig. 1a, a strut is generated with the ideal geometry. In the second, Fig. 1b, the defects are introduced by considering a typical distribution with radius average R_{avg}= 0.1 mm and deviation R_{dev}= 0.028 R_{avg}, offset from the axis average $A_{d,avg}$ = 0.01 mm and deviation $A_{d,dev}$



Materials Research Proceedings 69 (2026) 1402-1406 https://doi.org/10.21741/9781644904251-245

= 0.012 R_{avg}, penetration average $L_{p,avg}$ = $R_{avg}$and deviation $L_{p,dev}$ = R_{dev}. An even clearer representation of the imperfect strut is provided in Fig. 1c, where the defects are introduced with the offset from the center $A_{d,avg}$ and all deviations doubled, hence leading to an even rougher surface.



A compression analysis is performed for all three struts. The introduction of geometric imperfections significantly reduces the critical load, which shows a reduction of 20% and 29% for the two defective cases shown in Figs. 1b and 1c, respectively.

(a) *Ideal strut.*

(b) *Strut with typical defects.*

(c) *Strut with larger defects.*

Figure 1: Comparison of struts with different imperfections.

The effect of porosity is evaluated by a set of traction tests on single struts from 0% to 10% of volumetric porosity. For each percentage, 10 different struts are generated and the mean force-displacement curve is obtained. As expected, increasing porosity leads to lower yield and plastic loads.

The influence of strut length is also investigated, as imperfections affect both the stress– strain response in tension and the equivalent section properties in bending. A set of 100 3 struts is generated varying the length in the range of L = 0.2 − 10 mm. Each strut is clamped at one end and subjected to a prescribed displacement u = 0.18L on the opposite side. The stress is reconstructed for a circular section of radius R_{avg}. From the results is clear how longer struts are characterized by smaller yield stress. This effect is ascribed to the more extensive role played by imperfections. For the assessment of the equivalent section, each strut is fixed at one end and loaded transversely at the other end with a force F. The equivalent radius is then obtained with Eq. 1. The results of these analyses show that the equivalent radius stays in the range of R_{eq}= 0.5 − 0.65 R_{avg}, noticeably lower than the nominal radius.

Materials Research Proceedings 69 (2026) 1402-1406 https://doi.org/10.21741/9781644904251-245

Finally, a compression analysis of the periodic octet cell is performed to assess the performance of the simplified models. The cell consists of 24 struts with the typical defect distribution. A reference point is associated with the nodes at each exterior intersection to impose the periodic boundary conditions. Each pair of reference points on opposite faces is constrained to have equal in-plane displacements. Along the compression axis, a shortening Δ is applied. Free displacements are allowed along the remaining two axes, with identical values for each face.

The results of the compression analysis are presented in Fig. 2. As shown, for the single element-per-strut models, the initial stiffness and maximum load are captured accurately. However, the post-critical deformation is not represented correctly, as the model is inherently limited by the adoption of a single element per strut. The truss model performs particularly well, as expected for a stretch-dominated cell. Among the multi-element-per-strut models, only the configuration with a stiffer region near each vertex reproduces the initial stiffness accurately. Both multi-element models, however, capture the post-critical deformation with good agreement to the 3D solid-element model. For comparison, results from an ideal beam model with the nominal material and section properties are also reported; this model clearly overestimates the overall structural strength.

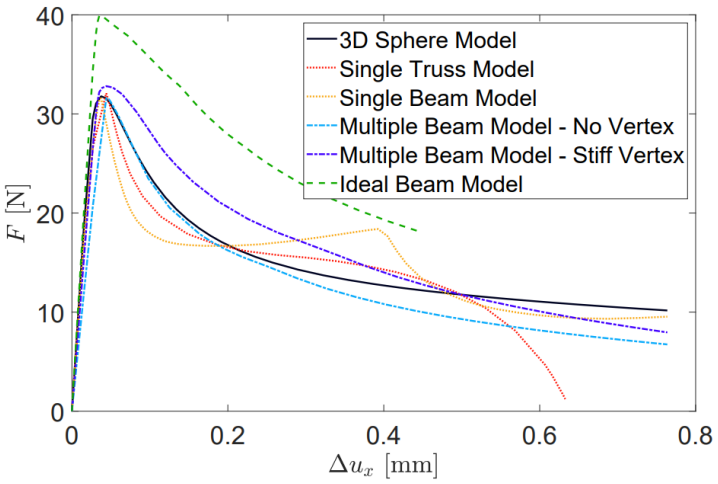


Figure 2: Comparison of struts with different imperfections.

Conclusions

The results demonstrate that geometric imperfections significantly reduce the critical load under compression, while porosity lowers the yield point of the material. The mechanical response is also affected by the strut length: longer members exhibit larger sensitivity to defects and lower yield stresses. The equivalent radius obtained from bending tests was found to be significantly lower than the nominal value.

The simplified 1D models reproduced the overall compression behavior of the octet cell in good agreement with high-fidelity 3D solid models, while requiring drastically lower computational cost. Therefore, the proposed approach is a promising way to account for manufacturing-induced defects, while preserving computational effectiveness.

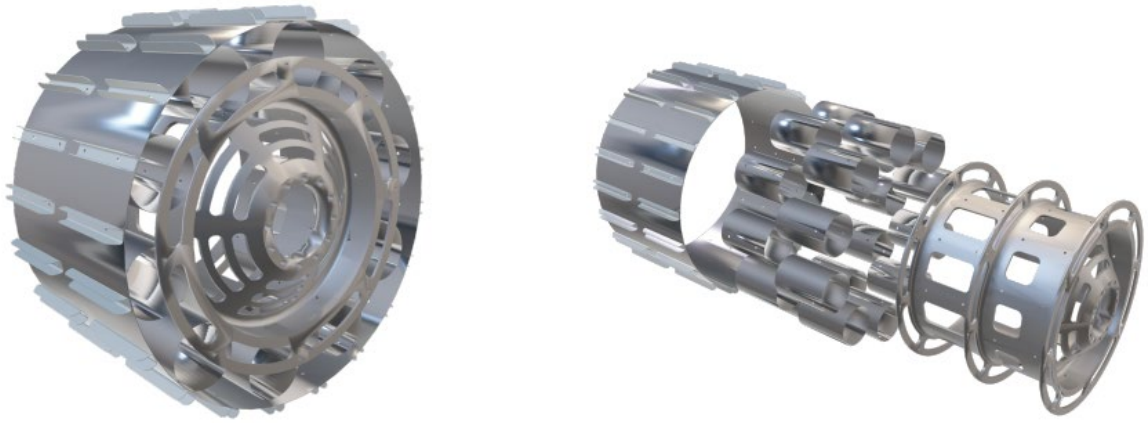
Abstract. This work presents the dynamic characterization of a compliant wheel [1] designed for ARDITO [2] a modular Martian rover. The wheel is composed of two main structures: a rigid Al2024 hub made from a single milled raw aluminum block and the external spring steel structure. The outer structure is made from twenty cylinders, an external skin and forty grousers, all made from C67 spring steel. This material ensures wheels' elastic behavior, essential to navigate and adapt in different conditions, while keeping the design mechanically reliable. This study aims to compare a FEM [3] model of the compliant wheel, used to perform structural analyses, with an Experimental Modal Analyses (EMA) [4] through a vibrational test of both the internal hub and the elastic part. Since the materials are very different the central hub and the outer compliant structure were analyzed and compared separately but the same methodologies were applied to both structures. This combined study is a start to understanding the dynamic behavior of the locomotion system and pave the way to many more analyses in order to better understand the system and how it interacts with other structures. A key objective is to ensure that the wheel's resonance modes do not couple with operational excitations, preventing unwanted dynamic amplification during planetary missions specially for what regards launch operations, where it is imperative to ensure that launch vibrations don't resonate with the structure's natural frequencies in order to prevent damages. This work was developed within the DIANA student team at Politecnico di Torino, which participated in competitions such as the Rover Challenge Series, bringing together student teams worldwide and individuals from various engineering disciplines to design a working space rover prototype.



Introduction

Exploring extraterrestrial environments, like Mars, demands the rovers' mobility systems to handle uneven terrain in extreme conditions such as: irregularities, drastic temperature changes and reduced gravity. This environment place severe constraints on how the rover moves and maintains traction, that is why wheel design is a critical factor for mission success. Traditional rigid wheels, while mechanically simple, struggle to provide the adaptability required in such conditions. This has led to growing interest in compliant wheels architectures, capable of elastically deforming to overcome terrain deformations without relying on active suspension systems. The combination of flexibility and strength help maintain the rover's contact with the ground and distribute its load more evenly, thereby improving stability and durability. The ARDITO rover embraces this approach with a modular and adaptable mobility system. A new compliant wheel has been developed and optimized for small-scale planetary rovers. The design integrates a rigid Al2024 aluminum hub with an external C68 spring steel structure composed of multiple cylinders,

grousers, and an outer skin. This design ensures both mechanical reliability and the elastic response necessary for navigating uneven terrain. This paper focuses on the dynamic characterization of the compliant wheel. In the following section, the experimental setup and the FEM analyses are described in order to understand how its modal shapes can effect the overall structure. This study lays the foundation for future research aimed at gaining a deeper under-standing of the ARDITO rover's behavior. Characterizing the modal shapes of the wheel components is essential to understanding how they influence each other and whether these vibrations can be transmitted to the rover, potentially affecting its precision during operation.

Figure 1: Render of ARDITO's wheel

Test campaign

Two test campaigns were conducted, the first focused on the dynamic characterization of the central part of the hub while the second on the elastic part of the whole wheel, with the objective of identifying the modal frequencies of the structure. Since the number of measured point were conspicuous, we relied on the DEWESoft company and the Mul2 Laboratory. The experimental setup was composed of the following elements:

- DAQ SIRIUSie-8xUNI+
- Instrumented hammer PCB 086C03
- Accelerometer PCB 356BA43
- Foam to simulate an unconstrained environment
- A protoype of the rover's wheel
- Software DEWESoft X with the following plugin:
  - plug-in Modal Testing.
  - plug-in Modal Analysis.

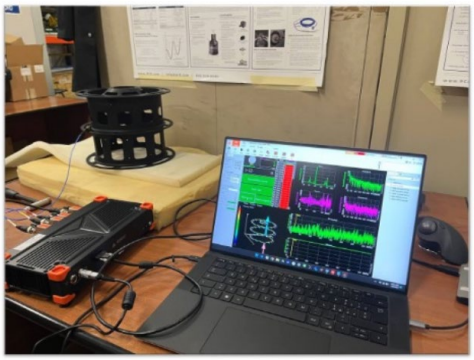

Figure 2: *EMA Setup*

Due to the complexity of the component, measurement points were defined and strategically distributed over the structure. Installing a large number of accelerometers wouldhave required excessive setup time, so the reciprocity principle [8] of modal analysis wasapplied. This approach made it possible to characterize the entire structure using a singleaccelerometer.To further simplify the measurement process, data acquisition was limited to a singleaxis. This choice was based on preliminary FEM analyses.To simulate a free-free boundary condition [9], the component was placed on a polyurethanefoam support. This setup eliminated the need for rigid support while ensuring accurate dynamic measurements.

Materials Research Proceedings 69 (2026) 1407-1411 https://doi.org/10.21741/9781644904251-246

FEM Analysis of the hub

Regarding the hub, two numerical analyses were carried out using finite element models developed in MSC Apex and MSC Patran/Nastran. The first model was discretized with a standard three-dimensional tetrahedral mesh, consisting of approximately 145,000 nodes and about 868,000 degrees of freedom. This configuration allowed for an accurate representation of the structural behavior.

The second model used a two-dimensional mesh with planes placed at mid-thickness to reduce computational effort while maintaining a good approximation of the structural response. This approach made it possible to assess which modeling strategy provided a more accurate discretization of the structure and a closer representation of the real component. To enable a direct comparison with the experimental setup, the nodes that best matched the measurement points were selected. The analyses were performed using the SOL103 solver, with the structure left unconstrained and no external forces applied. This produced 28 mode shapes within the 100–1600 Hz range. The first six rigid-body modes were excluded, as they are not relevant to the dynamic analysis of the component.

The results from both FEM analyses show a difference in modal frequencies ranging from 16 to 100 Hz. This demonstrates how the discretization method affects the outcomes. The variations come from differences in stiffness between the two models. In Figures 3 and 4, CrossMac results are shown.

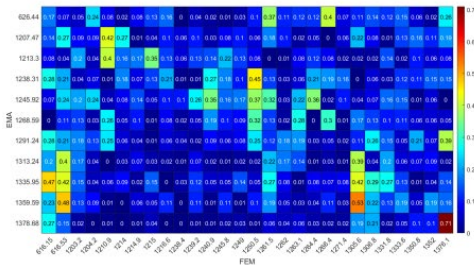

Figure 3: *CrossMAC between the 3D-Mesh Model and the experimental data*

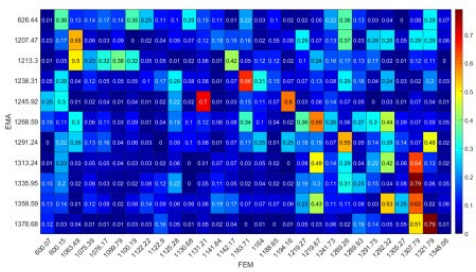

Figure 4: *CrossMAC between the 2D-Mesh Model and the experimental data*

After a visual comparison, the first mode shape at around 620 Hz involves the overall structure and can potentially transmit vibrations to the rover. The second global mode, at around 3000 Hz, concerns the interface between the hub and the rover. This mode showed good correlation between the experimental and numerical results, indicating that the numerical model represents it accurately. The remaining modes are local, mainly located in the three radial flanges of the hub, and are not relevant to the overall behavior of the system.

Elastic part

The second test campaign focused on the elastic outer part of the wheel, the goal was to correlate the experimental measurements of natural frequencies to the ones obtained by a mathematical analyses.

In order to do so, three progressively refined 2D models were developed using Patran to better capture the dynamics of the full assembly and a SOL103 was made to extract natural frequencies and modal shapes. The first and more basic model simulated the outer structure using surface elements. The second model had thicker surfaces to approximate the real wheel's weight as closely as possible. The third and more accurate was composed of surfaces to mimic the cylinders, coupled with all 40 grousers distributed equally along the wheel. Analyses show that the second one can be used with no problem, it's less computationally demanding and the results are comparable to those of the full wheel with grousers. The model used during analyses had a rigid hub, contact between surfaces was added and rivets were simulated trough node equivalence. Regarding testing,

the accelerometer was mounted radially along the skin of the wheel, and 40 nodes were identified for characterization between the grousers to avoid signal noise as much as possible.

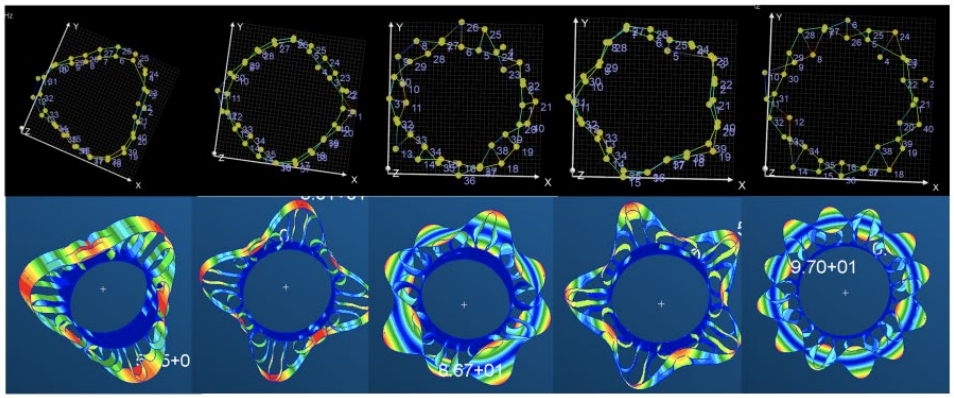

Figure 5: *Comparison between EMA and FEM analyses*

In the picture you can see a visual correlation of some of the modal shapes obtained by the DewesoftX software (on top) and the ones obtained by Patran (on the bottom). As shown on the picture we obtained the same shapes trough both of the methods and the frequencies associated differ by a margin of less than 10%.

Conclusion and future developments

This work represents a fundamental step towards assuring that mathematical models can closely simulate the behavior of mechanical components. Understanding and accurately identifying the natural frequencies of rover components is essential in space-related projects because dynamic loads encountered during launch, landing, and surface operations can excite structural vibrations. If these vibrations coincide with the component's natural frequencies, resonance can occur, leading to amplified stresses, reduced performance, or even structural failure. The correlation between FEM predictions and Experimental Modal Analysis provides confidence in the wheel's dynamic performance and informs future design refinements. Overall, the study of natural frequencies is a crucial step in developing robust, efficient, and safe mobility systems for planetary exploration. Future work on this matter may consist of a deep analysis of the wheel under operational conditions with different structural stresses and scenarios. This, correlated to a series of test campaigns, would allow us to deeply understand the behavior of not only the wheel
sub-system but also the mobility system as a whole.

Abstract. The design of compact heat exchangers (HXs) for hydrogen fuel cell and battery-electric aircraft presents unprecedented challenges in terms of thermal management and structural integration. This study introduces an open-source multiscale–multiphysics framework for predicting the thermo-hydraulic and structural performance of cross-flow HXs based on repeated unit cells. The framework combines detailed microscale conjugate heat transfer simulations with macroscale modelling through two complementary reduced-order strategies: upscaling and homogenisation. The reduced-order models are benchmarked against fullscale, high fidelity simulations. Results demonstrate good agreement of both the upscaled and homogenised models with full-scale CFD simulations, particularly deviations below 4 % for fluid temperatures, with the upscaled model performing consistently better.

Introduction

The design methodologies for HXs have evolved significantly over recent decades, transitioning from traditional empirical correlations to advanced numerical simulation and multiscale modelling techniques. Multiscale approaches are particularly relevant for aircraft-scale systems, where sustainable propulsion architectures such as battery-electric and hydrogen fuel cells generate large quantities of low-grade heat that must be rejected efficiently. As direct high-fidelity analysis of fullscale configurations is computationally prohibitive, performance evaluation and optimisation down to the microscale can deliver significant system-wide gains, particularly in the case of additively manufactured periodic HX cores. While previous studies have applied multiscale methods to compact HXs in automotive applications [1, 2], they have primarily focussed on thermo-fluidic performance. More recently, researchers have adopted high-fidelity CFD to study novel configurations enabled by additive manufacturing [3]. On the structural side, Imediegwu et al. [4] used a multiscale approach for thermo-structural coupling to improve thermal performance in a heat sink. On the thermo-hydraulic side, porous flow modelling and homogenisation techniques have also emerged as promising alternatives means to accurately characterise complex, periodic geometries [3]. Despite these advances, the explicit coupling of multiphysics effects combining thermofluidic and structural responses, which are particularly important in aerospace applications, remains rare.

Methodology

Overview. A novel open-source framework is introduced for multiscale and multiphysics analysis of a compact cross-flow HX with repeating unit cells (RUCs). The framework starts with a parametric model for a microscale unit cell of the HX core, as seen in Figure 1a, generating a multi-region mesh that can then be used for thermofluid and structural analysis. As part of the multiscale strategy, two reduced order models (ROMs) are considered, namely upscaling and homogenisation. The performance of these ROMs is evaluated against high-fidelity macroscale simulations to determine their accuracy and efficiency.

Microscale. A conjugate heat transfer (CHT) model is first solved using the multi-region mesh by means of the continuity, momentum and energy equations. The structural domain is solved using Cauchy's momentum equation for solids using combined mechanical loading and thermal stresses.

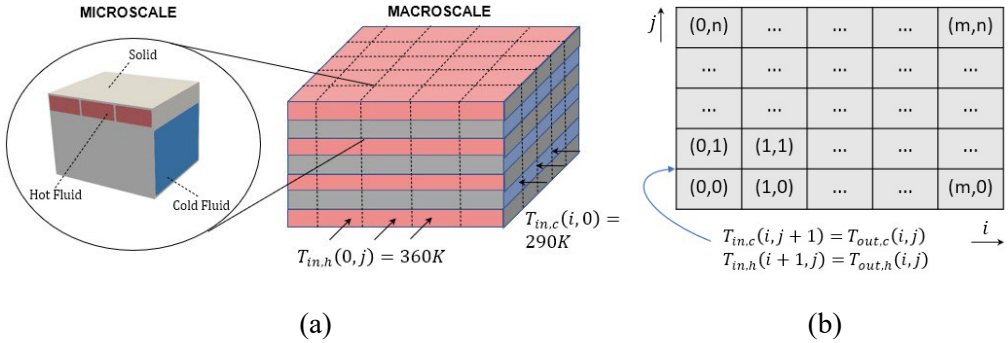

Figure 1: (a) The microscale and macroscale HX multi-region domain (b) boundary conditions transfer using the upscaling algorithm.

Macroscale. For the upscaling procedure, the algorithm originally proposed by Ciuffini et al. [2] is first implemented in a single layer of the HX block consisting of RUCs, and later adapted to a 3-dimensional framework. Each RUC represents a fully resolved microscale CHT simulation. The coupling between neighbouring RUCs is achieved through a sequential mapping procedure, defined by the boundary transfer relationships shown in Figure 1b, with the initial conditions of the hot and cold fluids defined as shown in Figure 1a.

Subsequently, homogenisation is employed as an alternative reduced-order approach to predict the effective thermo-mechanical behaviour of the HX. This method enables two-scale coupling, where heat-transfer and structural properties are first evaluated at the microscale and then averaged to define equivalent parameters at the macroscale. While upscaling relies on cell-to-cell coupling, homogenisation replaces detailed local variations with averaged quantities that preserve the overall physical response.

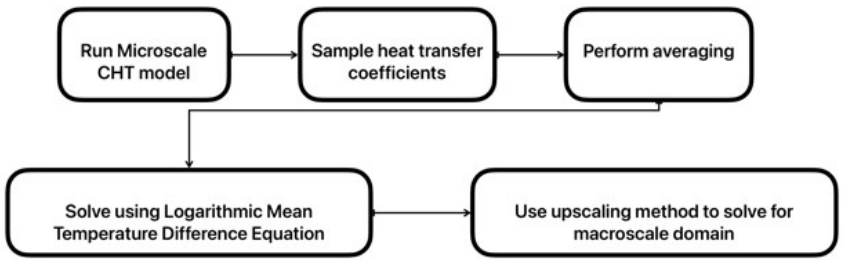

Figure 2: Homogenisation steps to reconstruct the macroscale temperature distribution from microscale simulations using LMTD equation and upscaling

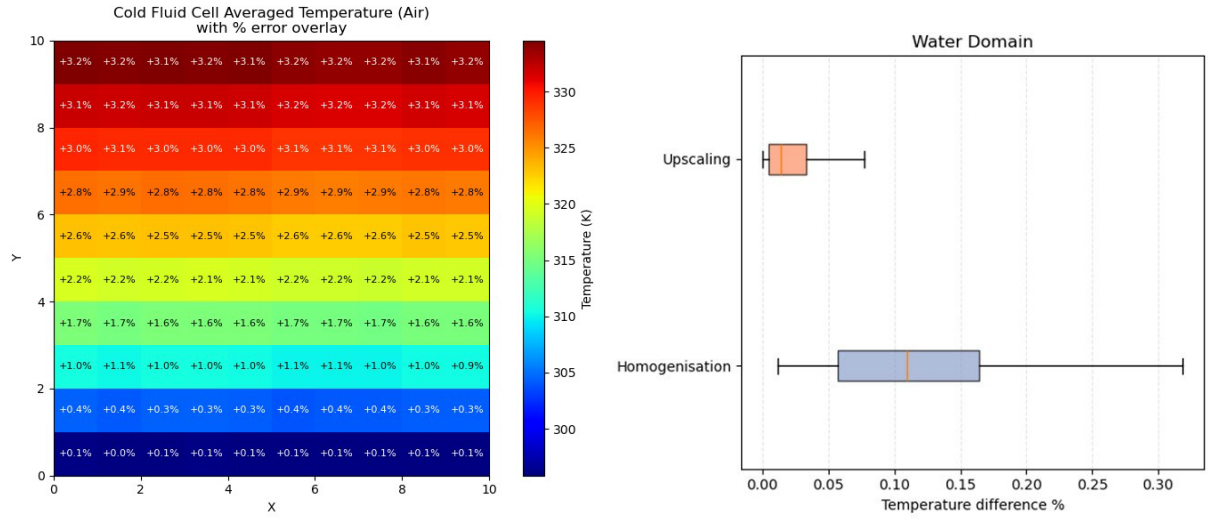
Materials Research Proceedings 69 (2026) 1412-1415 https://doi.org/10.21741/9781644904251-247



The procedure for reconstructing the macroscale temperature distribution using homogenisation is highlighted in Figure 2. For the structural characterisation, the unit cell is evaluated under six independent loading cases to determine the uniaxial and shear components of the effective stiffness matrix. The resulting properties, which are orthotropic because of the geometric configuration of the RUC used, are subsequently used to solve a macroscale model of homogenised material with equivalent overall dimensions.

Results and Discussion

The upscaling algorithm from Ciuffini et al. [2] is implemented on a two-dimensional 10×10 RUC array representing a layer of the compact cross-flow HX and is subsequently benchmarked against full-scale CFD results with the same configuration. A direct error comparison between the upscaling and homogenisation approaches is performed to assess their predictive accuracy. As shown in Figure 3a, the upscaling method achieves excellent agreement with the full-scale solution, with deviations below 4% for the cold-fluid domain. Figure 3b further confirms that the upscaling approach outperforms homogenisation for the hot fluid region. Future work will focus on integrating surrogate models to reduce the number of microscale simulations required for homogenisation, thereby extending the framework's applicability to a wider range of inlet flow and thermal conditions.

Conclusion

This work presented an open-source multiscale–multiphysics framework for predicting the thermo-hydraulic and structural performance of cross-flow HXs. The upscaling and homogenisation approaches were benchmarked against full-scale CFD, with the upscaling method achieving higher accuracy at reduced computational cost. The framework's consistent use of a single multi-region mesh enables efficient extraction of coupled thermal and structural properties, providing a foundation for future optimisation and design of lightweight, multifunctional HXs for sustainable aircraft.

Keywords: Carrera Unified Formulation, Finite Element Analysis, Nonlinear Analysis, Wingbox Structure

Abstract. The integration of postbuckling behavior into aeroelastic optimization frameworks faces a critical barrier in the computational cost of nonlinear finite element analyses with traditional shell-based wingbox models. This study investigates whether variable-section 1D finite elements based on the Carrera Unified Formulation (CUF) can replicate the nonlinear response of wingbox structures with reduced computational cost. Nonlinear analyses of the Simple Transonic Wing benchmark are performed using MSC Nastran shell elements and two CUF models with different mesh refinements. While the CUF models achieve comparable or better computational efficiency, the approaches predict substantially different onset points for geometric nonlinearity: the Nastran model exhibits softening behavior at the linear buckling load of 133 kN, whereas the CUF models maintain nearly linear response until approximately 264–272 kN. Importantly, the close agreement between the two CUF mesh refinements demonstrates that this discrepancy cannot be attributed to insufficient CUF discretization. These findings raise a critical question about the minimum fidelity required to accurately capture global nonlinear postbuckling behavior, whose answer is essential for including nonlinear structural stability analysis in aeroelastic optimization.

Introduction

The aviation industry is facing unprecedented challenges as it strives to achieve net-zero carbon emissions by 2050, as targeted by the Air Transport Action Group (ATAG) [1]. While sustainable aviation fuels (SAF) have been identified as a cornerstone for meeting these climate goals, recent trends indicate that SAF development is progressing at a pace insufficient to deliver the ambitious emissions reduction targets within the required timeframe [2]. In parallel, radical technological solutions such as hydrogen propulsion and unconventional aircraft configurations have encountered significant uncertainties and program suspensions, as highlighted by the recent delays and pauses in major initiatives like Airbus' ZEROe hydrogen-powered aircraft program and Boeing's X-66 truss-braced wing flight demonstrator.

Given these uncertainties, maximizing the structural efficiency of conventional airframes has become increasingly critical. One promising avenue is the exploitation of the load-carrying capacity of aeronautical structures in their elastic postbuckling regime [3], thereby enabling lighter, more efficient wing designs. However, integration of postbuckling behavior into preliminary design and modern aeroelastic optimization processes remains a major challenge. Traditionally, global aeroelastic optimization frameworks have relied on linear buckling constraints, whereas advanced postbuckling analyses, capable of demonstrating safe operation beyond linear buckling limits, have largely been confined to detailed panel-level studies and have remained isolated from the overall wing design process.

Content from this work may be used under the terms of the Creative Commons Attribution 3.0 license. Any further distribution of this work must maintain attribution to the author(s) and the title of the work, journal citation and DOI. Published under license by Materials Research Forum LLC.

Materials Research Proceedings 69 (2026) 1416-1421 https://doi.org/10.21741/9781644904251-248

Recent work has attempted to bridge this gap by proposing a paradigm shift for the assessment of structural stability in aeroelastic optimization [4]. Rather than viewing stability through the binary lens of buckling and postbuckling, this approach continuously monitors the structural stability through path-following continuation and enforces the positivedefiniteness of the tangent stiffness matrix to impose a stable deformation of the structure. This methodology enables wingbox optimization with nonlinear structural stability constraints, potentially unlocking significant weight savings while maintaining structural integrity.

However, a key barrier is the computational intensity of nonlinear Finite Element (FE) analyses with typical shell-based wingbox models, which can be prohibitive in optimization problems with many design variables. To address this challenge, the present study investigates whether variable-section 1D FEs based on the Carrera Unified Formulation (CUF) [5] can replicate the nonlinear response of a wingbox structure with reduced computational cost. Using the benchmark Simple Transonic Wing (STW) [6] as a test case, the nonlinear response from a CUF-based model is compared to a shell-based analysis in MSC Nastran.

CUF Methodology

The CUF provides a systematic framework for developing FE models with enhanced kinematic descriptions. The three-dimensional displacement field $u(x, y, z)$ of the variable-section 1D FEs employed in this work is expressed through a generalized expansion that combines expansion functions (F_τ) over the cross-sectional domain with conventional FE shape functions (N_i) along the beam axis [5]:

$$\boldsymbol{u}(x, y, z) = F_\tau(x, z) N_i(y) \boldsymbol{Q_{\tau i}} = L_{\tau i}(\xi, \eta, \nu) \boldsymbol{Q_{\tau i}} \tag{1}$$

where $\boldsymbol{Q_{\tau i}}$ denotes the generalized nodal degrees of freedom, and ξ, η, ν represent the natural coordinates[1]. The quantity $L_{\tau i}(\xi, \eta, \nu)$ defines a three-dimensional shape function in which the expansion order can vary independently along different spatial directions. The volume integrals appearing in the governing equations are evaluated directly in three dimensions rather than being decomposed into separate 1D and 2D integrals. The Jacobian matrix for the transformation from natural to global coordinates is therefore computed in full 3D form. Nevertheless, the formal coordinate separation shown in Eq. (1) remains valid, and higher-order polynomial functions can still be assigned to directions with larger geometric extent.

This formulation enables finite elements that accurately represent variable-section beamlike structures while potentially maintaining significantly fewer degrees of freedom compared to shell-based discretizations. The modeling approach is illustrated in Fig. 1.

For nonlinear analyses, the structural response is computed using a Total Lagrangian formulation with the Full Green-Lagrange strain tensor. The nonlinear equilibrium equations are solved through an incremental-iterative Newton-Raphson scheme, with the tangent stiffness matrix decomposed into linear, material nonlinear, and geometric components. The arc-length method is employed to trace the equilibrium path.

[1] The natural coordinates are dimensionless coordinates that represent the physical coordinates over the interval $[-1, +1]$, either along the cross-sectional dimensions of the beam or along its length.

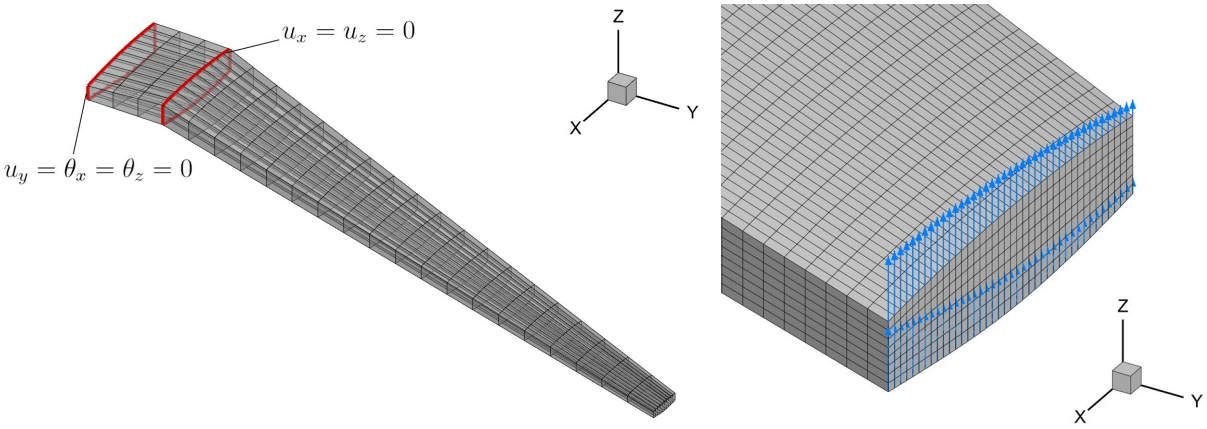

Figure 2: Overview of the STW model showing the wingbox geometry and loading conditions. Left: STW wingbox with boundary conditions. Right: Applied load distribution.

STW Description

The STW is a benchmark model for aeroelastic optimization [6]. Its structural design consists of a 14 m semispan wingbox comprising upper and lower skins, leading and trailing edge spars, and 23 ribs. The version used in this work is a modification of the original model employing an aluminium structure and 9 blade stiffeners for each skin [7]. All stiffeners span root to tip with constant 50 mm height. The baseline wingbox features uniform thickness of 6.5 mm for ribs, skins, and spars, and 6.0 mm for stiffeners.

The Nastran model uses four-node quadrilateral shell elements with six degrees of freedom per node, employing Mindlin-Reissner theory. Two CUF models are constructed: CUF 2-B4 employs two B4 elements between each rib pair, while CUF 3-B4 employs three B4 elements for increased refinement. Both use one B3 element across each rib thickness and 540 Q16 elements for each beam node expansion.

The load case consists of distributed forces in the positive z-direction over tip nodes of both skins, as illustrated in Fig. 2. Each row of nodes experiences linearly varying forces from 4P on the rear spar node to P on the front spar node, simulating the nose-down tip twist typical of backward-swept wings. Boundary conditions include symmetry at the centerline and constraints in chordwise (x) and vertical (z) directions at the side-of-body (SOB) break located at y = 1.5 m.

Results

Three nonlinear analyses of the baseline STW wingbox are executed: one using MSC Nastran's SOL 106 arc-length method, and two using CUF methodology with different mesh refinements. All employ a 10−5 tolerance on the respective load and displacement convergence criteria. Table 1 summarizes the computational characteristics. The coarser CUF 2-B4 model exhibits 8% fewer degrees of freedom than Nastran and achieves comparable wall-clock time, while the refined CUF 3-B4 model has 19% more degrees of freedom but completes 11% faster. It should be noted that analyses were performed on different processors and no mesh tailoring was performed for the CUF models, which could further improve computational efficiency.

Figure 3 compares the load-displacement response for tip displacement, indicating global structural behavior. The horizontal dashed line shows the linear buckling load predicted by Nastran (approximately 133 kN). All models exhibit identical initial stiffness, evidenced by the coincident linear regime at low loads. However, they predict substantially different onset points for geometric nonlinearity. The Nastran model shows characteristic softening near the linear buckling load. In contrast, the CUF models maintain nearly linear response until approximately 272 kN (CUF 2-B4) and 264 kN (CUF 3-B4).

Materials Research Proceedings 69 (2026) 1416-1421 https://doi.org/10.21741/9781644904251-248

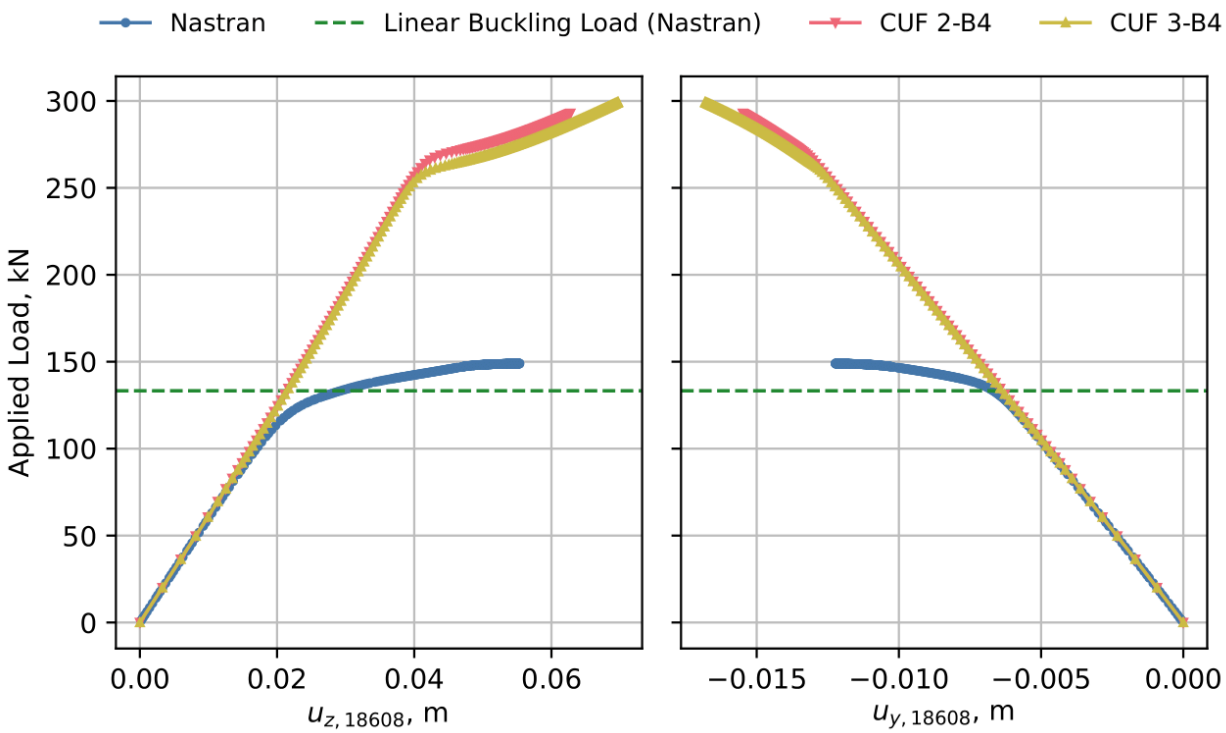

Figure 4: Load-displacement diagrams of node 18608.

The minimal difference between the two CUF mesh refinements demonstrates that the discrepancy with Nastran cannot be attributed to insufficient CUF discretization. Finally, the nonlinear stiffness reduction magnitude in both CUF models is noticeably smaller than in Nastran. To examine local response, Fig. 4 presents load-displacement diagrams for node 18608, which experiences maximum displacement in the first linear buckling mode. This node is located approximately at the center of the second top skin panel outboard of the SOB break. Two displacement components are shown: z-displacement and y-displacement, the latter indicating panel shortening. For the CUF models, equivalent displacements are obtained by interpolating surrounding nodes. The local response exhibits trends consistent with global tip displacement: identical initial stiffness, followed by nonlinear behavior onset at the linear buckling load for Nastran, while in the CUF models nonlinearity appears at higher loads. The magnitude of the stiffness variation is once again more pronounced in the Nastran model.

The discrepancy between Nastran and CUF models is obtained despite the Nastran mesh convergence having been verified in a previous work [7], and the employed 1D CUF elements having been validated for nonlinear postbuckling analyses of variable cross-section beam structures [8]. Two potential sources of this discrepancy have been identified and are currently under investigation. First, the stringer-rib intersections are modeled with independent nodes in Nastran, leaving these junctions essentially free as in a real wingbox with mouseholes, whereas the CUF models enforce shared nodes at these intersections, potentially adding artificial rigidity. Second, the sectional expansion in CUF builds thickness outward from the reference geometry, effectively increasing the cross-sectional area and moment of inertia compared to Nastran's symmetric thickness assignment. Both effects could contribute to the increased stiffness observed in the CUF models. At the same time, establishing a definitive ground truth remains challenging: the STW is a purely numerical benchmark without experimental data, and a reference three-dimensional solid element model has not yet been developed.

Conclusions

These findings raise a critical question: what level of model fidelity is minimally required to accurately capture global nonlinear postbuckling behavior of wingbox structures? Answering this question is a prerequisite for realizing the nonlinear structural stability paradigm shift that seeks to bridge the gap between high-level aeroelastic optimization frameworks and detailed component-level postbuckling analyses. The observed discrepancy between traditional shell-based and CUF-based approaches highlights the importance of carefully accounting for modeling assumptions, particularly regarding structural connectivity at component intersections and thickness reference planes. Future work will address the development of a three-dimensional finite element model of a simplified wingbox structure to provide an independent reference for validating both approaches, as well as more consistent Nastran and CUF models that more accurately replicate modeling assumptions regarding stringer-rib connectivity and thickness assignment.

Keywords: Correspondence Model, Fracture Mechanics, Hyperelastic Constitutive Model, Volumetric Locking, Large Deformations

Abstract. Soft materials are increasingly integrated into modern aerospace systems due to their unique ability to deform, adapt, and absorb energy under extreme conditions. Applications such as morphing wing skins, soft robotic components for extraterrestrial exploration, and impact-absorbing systems in UAVs and space capsules, to cite a few, rely on soft polymers and elastomers subjected to large deformations. A major concern in these applications is the initiation and evolution of cracks, which can arise from cyclic loading, environmental exposure, or sudden impacts, possibly leading to failures like tearing or puncture. Predicting such damage with advanced numerical tools is essential for ensuring structural integrity, reliability, and mission success. Peridynamics, a nonlocal continuum mechanics theory, is particularly well-suited to modeling discontinuities due to fracture phenomena as the integral formulation of the internal forces allows to easily remove interactions between points across the crack surface. Therefore, cracks are not required to propagate along predefined paths, but can evolve along the most energetically favorable paths. Furthermore, peridynamic correspondence models allow to embed into the peridynamic framework hyperelastic constitutive laws used in classical continuum mechanics to describe the behavior of soft materials. Correspondence models require a stabilization technique to avoid zero-energy modes, which can undermine numerical accuracy. However, when modeling nearly-incompressible soft materials, stabilized correspondence models exhibit a numerical issue which leads to unrealistically stiff responses and an incorrect reproduction of the strain energy density for non-homogeneous deformations. Therefore, we propose a robust yet simple method to mitigate this issue and validate it through numerical examples of benchmark problems involving hyperelastic materials.

Introduction

Soft and compliant materials (typically soft polymers, elastomers, and composite hydrogels) are increasingly being used in advanced aerospace and robotic systems due to their unique mechanical capabilities, including large reversible deformations and exceptional energy absorption under extreme mechanical or environmental conditions. Notable applications include morphing aircraft wing skins, which alter aerodynamic profiles in response to flight conditions [1,2], soft robotic actuators designed for extraterrestrial exploration or manipulation in uncertain environments [3,4], impact-absorbing and adaptive landing systems used in unmanned aerial vehicles (UAVs),

planetary landers, and space capsules [5]. In all of these systems, soft materials experience large nonlinear deformations and are often subjected to complex, multiaxial, and cyclic loading regimes.

A critical concern in the long-term performance of such systems is the initiation, propagation, and coalescence of cracks due to repeated cyclic loading, aggressive thermal or ultraviolet environments, or high-velocity impacts. Accurately predicting these failure mechanisms is essential to ensure structural integrity, durability, and mission reliability in demanding aerospace applications. Traditional finite element methods (FEM) based on classical continuum mechanics often face challenges when simulating crack evolution because the formation and progression of discontinuities require either complex remeshing or predefined crack paths.

To address these limitations, a nonlocal reformulation of continuum mechanics, i.e. the peridynamic (PD) theory, has emerged as a powerful computational framework for modeling fracture and damage evolution. Unlike classical differential-based continuum formulations, peridynamics represents internal forces through integrals over a finite horizon, allowing natural handling of discontinuities without the need for additional criteria or remeshing [6]. In this model, interactions (bonds) between material points across newly forming crack surfaces can be simply removed, enabling cracks to evolve spontaneously along energetically favorable directions without prior assumptions on crack path.

Correspondence models [7] allow to embed constitutive models from classical continuum mechanics, such as hyperelastic laws (e.g., Neo-Hookean or Mooney–Rivlin models), into the peridynamic framework. These models require a stabilization technique, such as the bond-associated approach [8], to prevent numerical instabilities due to zero-energy deformation modes. Nonetheless, when simulating nearly-incompressible hyperelastic materials, stabilized correspondence models may exhibit artificial stiffening and distort the representation of strain energy density under non-homogeneous deformation fields, similarly to volumetric locking in FEM models. Therefore, the selective bond-associated approach was proposed in [9] to avoid locking phenomena by stabilizing only the deviatoric part of the strain energy density.

The selective bond-associated correspondence model was validated for nearly-incompressible materials whose deviatoric strain energy density can be described with invariant-based hyperelastic models, such as Neo-Hookean or Mooney-Rivlin laws. However, the Ogden constitutive law offers superior flexibility and accuracy compared to the Mooney–Rivlin formulation because it expresses the strain energy density as a function of the principal stretches raised to non-integer exponents, rather than as low-order polynomials of the invariants of the deformation tensor. This allows the Ogden model to capture both the strain-stiffening behavior observed at large stretches and the asymmetric tension-compression responses typical of many soft materials [10]. In this work, the selective bond-associated correspondence model applied to a nearly-incompressible material described with the hyperelastic Ogden law is validated by means of the benchmark problem of Cook's membrane.

Ogden hyperelastic model for nearly-incompressible materials

Ogden proposed in [10] to express the hyperelastic strain energy density in the form

$$\psi = \sum_{p=1}^{N} \frac{\mu_p}{\alpha_p} \left(\lambda_1^{\alpha_p} + \lambda_2^{\alpha_p} + \lambda_3^{\alpha_p} - 3 \right), \tag{1}$$

where λ_1, λ_2, and λ_3 are the principal stretches, and α_p and μ_p are the constitutive parameters of the material. Principal stretches can be computed as the square roots of the eigenvalues of the left Cauchy-Green strain tensor $\mathbf{C} = \mathbf{F}^{\mathrm{T}}\mathbf{F}$, with $\mathbf{F}$ being the deformation gradient tensor. Note that Neo-Hookean and Mooney-Rivlin constitutive models can be obtained as a particular case of Eq. 1.

Several materials, such as the unfilled elastomers, can be regarded as incompressible since volumetric deformations (even in regions with high strains) are negligible. Perfect incompressibility assumes that $\lambda_1\lambda_2\lambda_3 = 1$, but the constitutive equations are often regularized by

Materials Research Proceedings 69 (2026) 1422-1426 https://doi.org/10.21741/9781644904251-249

modeling incompressible materials as slightly compressible and assigning a large value to the bulk modulus k:

$$\psi = \psi_{\text{dev}} + \psi_{\text{vol}} = \sum_{p=1}^{N} \frac{\mu_p}{\alpha_p} [(\lambda_1^*)^{\alpha_p} + (\lambda_2^*)^{\alpha_p} + (\lambda_3^*)^{\alpha_p} - 3] + \frac{1}{2} k(J-1)^2 \,, \tag{2}$$

where $J = \det(\mathbf{F})$ and λ_1^*, λ_2^*, and λ_3^* are the deviatoric principal stretches computed as the square roots of the eigenvalues of $\mathbf{C}_{\text{dev}} = J^{-2/3}\mathbf{C}$. Note that, as k increases, the function used for ψ_{vol} penalizes the volumetric deformation of the material ($J \to 1$).

Selective bond-associated correspondence model

Peridynamic correspondence models are based on the nonlocal definition of the deformation gradient tensor ($\bar{\mathbf{F}}$ in the original version [7] and $\tilde{\mathbf{F}}$ in the stabilized version [8]), which can be used into classical continuum mechanics constitutive laws. The peridynamic deformation gradient at a point $\mathbf{x}$ is defined as

$$\bar{\mathbf{F}} = \mathbf{I} + \left[\int_{H_\mathbf{x}} (\mathbf{u}' - \mathbf{u}) \otimes \boldsymbol{\xi}\, dV_{\mathbf{x}'}\right] [\bar{\mathbf{K}}(\mathbf{x})]^{-1}, \tag{3}$$

where $\mathbf{I}$ is the identity tensor, $H_\mathbf{x}$ is the neighborhood of $\mathbf{x}$ (sphere in 3D or circle in 2D, centered at $\mathbf{x}$, with radius δ called the horizon size), $\mathbf{u}'$ and $\mathbf{u}$ are the displacement vectors respectively of $\mathbf{x}'$ (material point within the neighborhood $H_\mathbf{x}$) and $\mathbf{x}$, $\boldsymbol{\xi} = \mathbf{x}' - \mathbf{x}$ is the bond vector (the relative position between the interacting points), $dV_{\mathbf{x}'}$ is the volume associated to $\mathbf{x}'$, and $\bar{\mathbf{K}}$ is the shape tensor given as

$$\bar{\mathbf{K}} = \int_{H_\mathbf{x}} \boldsymbol{\xi} \otimes \boldsymbol{\xi}\, dV_{\mathbf{x}'}, \tag{4}$$

To avoid zero-energy modes, the stabilized deformation gradient can be defined for each bond $\boldsymbol{\xi}$ as

$$\tilde{\mathbf{F}} = \mathbf{I} + \left[\int_{H_\mathbf{x} \cap H_{\mathbf{x}'}} (\mathbf{u}' - \mathbf{u}) \otimes \boldsymbol{\xi}\, dV_{\mathbf{x}'}\right] \left[\tilde{\mathbf{K}}(\mathbf{x})\right]^{-1}, \tag{5}$$

where the difference with the original version lies in the integration region, which is the intersection of the neighborhoods of $\mathbf{x}$ and $\mathbf{x}'$ in the bond-associated model. The stabilized shape tensor can be determined accordingly as

$$\tilde{\mathbf{K}} = \int_{H_\mathbf{x} \cap H_{\mathbf{x}'}} \boldsymbol{\xi} \otimes \boldsymbol{\xi}\, dV_{\mathbf{x}'}. \tag{6}$$

The integrands of all these equations can also be multiplied by an arbitrary influence function, which is chosen to be unitary here.

To avoid locking phenomena in the peridynamic correspondence model, the deviatoric and volumetric part of the first Piola-Kirchhoff stress tensor are separately computed using the deformation gradient in Eq. 3 and Eq. 5, respectively:

$$\tilde{\mathbf{P}}_{\text{dev}}(\boldsymbol{\xi}) = \frac{\partial \psi_{\text{dev}}(\tilde{\mathbf{F}})}{\partial \tilde{\mathbf{F}}}, \qquad \bar{\mathbf{P}}_{\text{vol}}(\mathbf{x}) = \frac{\partial \psi_{\text{vol}}(\bar{\mathbf{F}})}{\partial \bar{\mathbf{F}}}, \tag{7}$$

Therefore, in the selective bond-associated correspondence model, the force state (force in the bond per unit volume squared) can be computed as

$$\hat{\mathbf{T}}\langle\boldsymbol{\xi}\rangle = \left(\tilde{\mathbf{P}}_{\text{dev}}(\boldsymbol{\xi}) + \bar{\mathbf{P}}_{\text{vol}}(\mathbf{x})\right)[\bar{\mathbf{K}}(\mathbf{x})]^{-1}\boldsymbol{\xi}. \tag{8}$$

Finally, the peridynamic equation of motion at point $\mathbf{x}$ is given as

$$\rho\ddot{\mathbf{u}} - \int_{H_\mathbf{x}} \left(\hat{\mathbf{T}}\langle\boldsymbol{\xi}\rangle - \hat{\mathbf{T}}\langle-\boldsymbol{\xi}\rangle\right) dV_{\mathbf{x}'} = \mathbf{b}. \tag{9}$$

where ρ is the density of the material, $\ddot{\mathbf{u}}$ is the acceleration of $\mathbf{x}$, and $\mathbf{b}$ is the volume force density at $\mathbf{x}$. The numerical implementation of this model is similar to that illustrated in [9].

Numerical example

To validate the selective bond-associated correspondence model with the use of the hyperelastic Ogden law for nearly-incompressible materials, we numerically solved the problem of Cook's membrane with the presented method and with FEM using high-order elements (so that volumetric locking does not affect the solution). The geometry, boundary conditions, and the numerical results are shown in Fig. 1. The membrane is made of neoprene rubber which is modeled with a one-term Ogden law with $\mu_1 = 2.29$ MPa and $\alpha_1 = 2.23$ [11]. The imposed force, uniformly distributed on the free edge at the left-hand side of the membrane, is equal to $f = 3$ N.

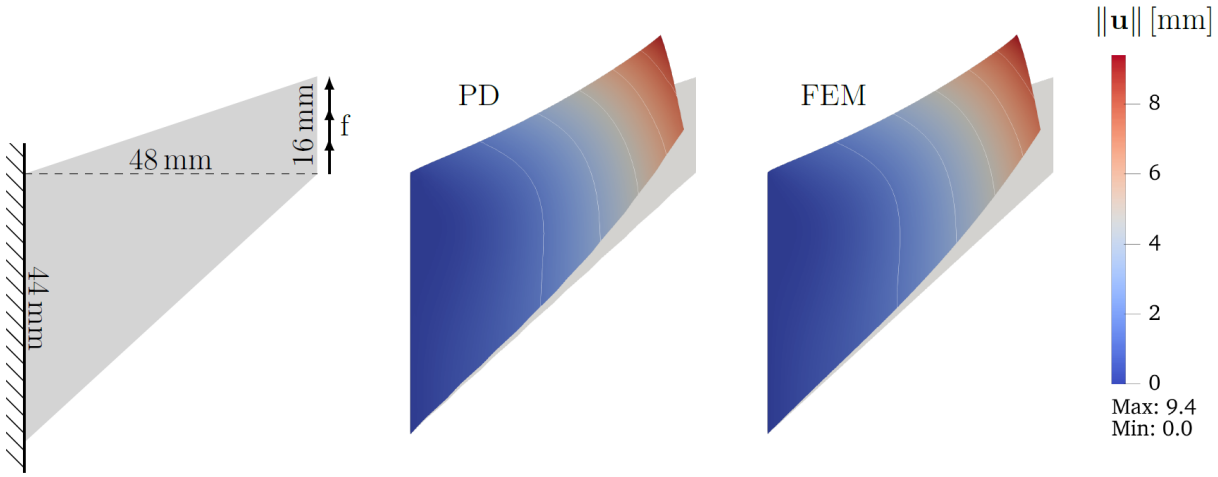

Figure 1. Geometry and boundary conditions for Cook's membrane problem and its numerical solution obtained with peridynamics (PD) and classical continuum mechanics discretized with the finite element method (FEM).

The numerical results show that the magnitudes of PD and FEM displacements are in excellent agreement. Therefore, the selective bond-associated correspondence model is suitable for modeling elastomeric nearly-incompressible materials with Ogden-like constitutive laws based on principal stretches.

Conclusions

In this work, the recently proposed selective bond-associated correspondence model within the peridynamic framework has been validated for the modeling of nearly-incompressible soft materials with the use of the Ogden hyperelastic constitutive law. This development represents an important advancement in modeling the complex mechanical response of soft polymers and elastomers that exhibit strain-stiffening and nonlinear tension-compression asymmetry, features that simpler constitutive models such as Neo-Hookean or Mooney–Rivlin cannot accurately reproduce. The selective bond-associated stabilization effectively avoids the artificial stiffening typical of volumetric locking while preserving numerical stability of the peridynamic correspondence models. The validation through the benchmark problem of Cook's membrane confirms that the model can accurately reproduce the expected deformation field, demonstrating its robustness and suitability for simulating nearly-incompressible soft materials used in advanced aerospace and soft-robotic applications.

Keywords: Crack propagation, Peridynamics, Fast Convolution Based Method

Abstract. The accurate prediction of failure in structural components is a crucial requirement in modern aerospace applications, particularly with the rise of reusable launch systems. Traditional finite element methods, based on Classical Continuum Mechanics, are limited when it comes to modelling discontinuities such as cracks. Peridynamics (PD) theory overcomes these limitations by using integral equations which allow describing a natural and autonomous damage evolution. However, PD suffers from high computational costs, particularly when solved using the commonly adopted mesh-free method with one-point Gaussian quadrature. The Fast Convolution Based Method (FCBM) exploits the convolutional structure of PD equations and the Fast Fourier Transform to critically reduce the computational time. However, it can compromise accuracy in the simulation of crack propagation, due to the damage model adopted. This work presents a novel Hybrid PD method (developed for both the Bond-Based and Ordinary State-Based formulations) that combines the accuracy of PD mesh-free formulation with the efficiency of FCBM, achieving a significant reduction in computational time.

Introduction

The peridynamic (PD) theory, proposed by S.A. Silling [1], is an alternative (nonlocal) framework to the (local) theory of Classical Continuum Mechanics. The mathematical formulation is based on integral equations, rather than spatial derivatives, and it allows modelling long-range interactions between material points within a limited domain with a size defined by a length-scale called *horizon*. Therefore, since discontinuities in the displacement field do not affect the validity of integral operators, Peridynamics is able to *naturally* simulate propagating cracks in an *autonomous* way. Once discretized, peridynamic equations are usually solved through a meshfree method with one point Gaussian quadrature (MM) [2], characterized by a computational complexity $\mathcal{O}(N^2)$ (with N the number of nodes).

Many strategies have been developed to reduce the computational cost of peridynamic simulations [3, 4]. One of the most promising methods is the Fast Convolution Based Method (FCBM) [5, 6], which rewrites PD equations as linear combination of circular convolutions and exploits the FFT algorithm to scale as $\mathcal{O}(N\log_2 N)$.

However, the applicability of this method to crack propagation problems depends on a modified damage model, which is formulated on the basis of a material-point removal approach, as opposed to the standard MM framework, where damage evolution is governed by the progressive breakage of bonds. As a consequence, mass losses are introduced in the regions close to the propagating crack and, sometimes, the crack paths differ from those obtained with MM.

The present work proposes a new hybrid method (Hybrid PD) [7], which combines the FCBM and the MM with the aim of reducing the computational cost while preserving the accuracy of the crack paths predicted by the MM. The method is based on the subdivision of the problem domain into two regions, limiting the application of MM to the points close to the propagating crack (MM

Content from this work may be used under the terms of the Creative Commons Attribution 3.0 license. Any further distribution of this work must maintain attribution to the author(s) and the title of the work, journal citation and DOI. Published under license by Materials Research Forum LLC.

region) and analyzing the remaining part of the domain with the FCBM (FC region). The combination is realized within an overlap region between MM and FC domains, enabling the consistent exchange of peridynamic quantities computed by the two methods. The hybrid method has been developed for the linearized Bond-Based (BB-PD) and Ordinary State-Based (OSB-PD) formulations.

Fast Convolution Based Method

The Fast Convolution Based Method [5], rewrites PD equations as linear combination of circular convolutions to exploit the relation between the Discrete Fourier Transform (DFT) and the circular convolution (for details see [5]). This allows using the optimized FFT algorithm, reducing the computational complexity from $\mathcal{O}(N^2)$ to $\mathcal{O}(N\log_2 N)$.

As an example, consider the i-th component of the internal force density according to the BB-PD formulation [1]:

$$L_i(\mathbf{x},\mathbf{x}',t) = \int_{\mathcal{H}_x} \mu\,(\mathbf{x},\mathbf{x}',t)\mathbf{C}(\boldsymbol{\xi})\boldsymbol{\eta}(\mathbf{x},\mathbf{x}',t)\,dV_{x'}, \quad \mathbf{C}(\boldsymbol{\xi}) = c\;\omega(\|\,\boldsymbol{\xi}\,\|)\frac{\boldsymbol{\xi}\otimes\boldsymbol{\xi}}{\|\,\boldsymbol{\xi}\,\|^2} \tag{1}$$

where μ is the history-dependent integrity function of the bond $\boldsymbol{\xi} = \mathbf{x}' - \mathbf{x}$, $\boldsymbol{\eta} = \mathbf{u}(\mathbf{x}',t) - \mathbf{u}(\mathbf{x},t)$ is the relative displacement, c is a material dependent constant called *micromodulus*, ω is the *influence function* and $\otimes$ denotes the tensorial product.

Following the procedure explained in [5] and exploiting the Einstein's notation, the final convolutional form of Eq. 1 can be written as follows:

$$L_i(\mathbf{x},\mathbf{x}',t) = \chi_B(\mathbf{x},\mathbf{x}')\lambda(\mathbf{x})\{\big[C_{ij}\circledast\big(\chi_B\lambda u_j\big)\big](\mathbf{x},t) - u_j(\mathbf{x},t)\big[C_{ij}\circledast(\chi_B\lambda)\big](\mathbf{x},t)\} \tag{2}$$

where $\circledast$ denotes the circular convolution, χ_B is the characteristic function of the body B defined as follows (see Fig. 1b):

$$\chi_B(\mathbf{x}) = \begin{cases}1 & \mathbf{x}\in B\\ 0 & \mathbf{x}\in\Lambda = \mathbb{T}^d\backslash B\end{cases} \tag{3}$$

and λ is the *integrity index*:

$$\lambda(\mathbf{x},t) = \begin{cases}1 & W(\mathbf{x},t) < W_c\\ 0 & W(\mathbf{x},t)\geq W_c\end{cases}, \quad W_c = \frac{G_0}{2\delta} \tag{4}$$

where W_c is the critical strain energy density and G_0 is the critical energy release rate.

A similar procedure can be employed to obtain the equations of the FCBM according to the OSB-PD formulation [5].

The characteristic function χ_B allows excluding the undesired nonlocal interactions between the material points inside the extension region Λ and the points inside the body domain B (Fig. 1b). The extension region Λ is necessary to build the periodic box $\mathbb{T}^d$ (where d is the spatial dimension of the considered problem) represented in Fig. 1b, which allows exploiting the relation between the circular convolution and DFT, after a proper discretization [5].

The product $\lambda(\mathbf{x})\lambda(\mathbf{x}')$, which is implicitly present in Eq. 2, replaces the standard history-dependent function μ of Eq. 1, which does not have a structure suitable to be expressed as convolution [5]. However, the definition of λ (Eq. 4) implies the removal of fully damaged material points, which inherently results in a reduction of the system mass and may lead to crack paths differing from those predicted by the MM [5].

Hybrid PD

The Hybrid PD method [7] has been developed to restore the "original" damage evolution and crack propagation criterion of the standard damage model and overcome the issues related with the mass loss introduced by the modified damage model of FCBM.

Materials Research Proceedings 69 (2026) 1427-1431 https://doi.org/10.21741/9781644904251-250

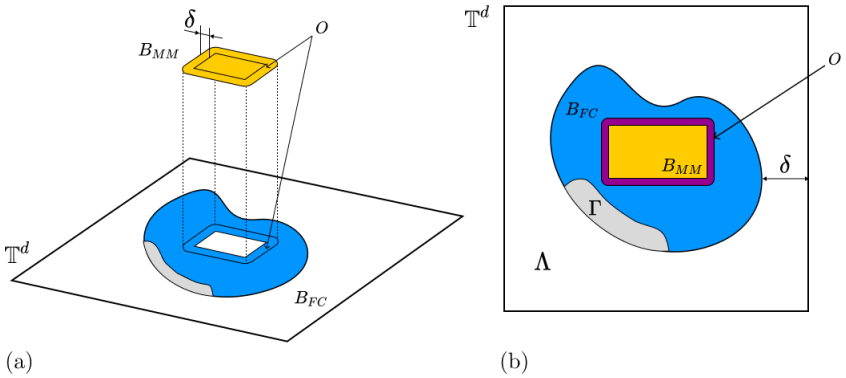

Figure 1: Domains subdivision of periodic box $\mathbb{T}^d$ according to Hybrid PD: the yellow region is analyzed through the MM, while the blue one is analyzed through the FCBM. The purple region is the overlap region.

To apply the hybrid approach, the body domain is split into two regions (see Fig. 1): one analyzed through the MM approach (called *MM region*, B^{MM} and defined by the masking function μ_{MM}) and the other one through the FCBM approach (called *FC region*, B^{FC} and defined by the masking function μ_{FC}). To guarantee the correct application of the method, it must be also ensured that the MM and FC regions share a layer of points of width δ, called *overlap region* and defined by the masking function μ_O, as shown in Fig. 1. Furthermore, the bonds with both ends inside the overlap region must be excluded from the integrals of MM to avoid the introduction of an "overstiffened" zone. This can be achieved with the complementary masking function of the overlap region defined as:

$$\overline{\mu_O}(\mathbf{x}, \mathbf{x}') = 1 - \mu_O(\mathbf{x}, \mathbf{x}') \tag{5}$$

To describe the damage evolution with the standard damage model of the MM, it is necessary to ensure that all points of the FC region are enough away from the propagating crack. This can be achieved by ensuring that the MM region has a minimum width of δ around the crack path in the BB-PD formulation, and a minimum width of 2δ in the OSB-PD formulation.

Based on the BB-PD definition of internal force density, the masking functions introduced above enable a linear combination of the quantities from the MM and FC regions [7]:

$$\begin{aligned} L_i &= L_i^{FC} + L_i^{MM} = \\ &= \chi_{FC}\chi_B\{[C_{ij} \circledast (\chi_{FC}\chi_B u_j)] - u_j[C_{ij} \circledast (\chi_{FC}\chi_B)]\} + \\ &+ \int_{\mathcal{H}_x} \overline{\mu_O}\,\mu_{MM}\mu\; C_{ij}\eta_j\; dV_{x'} \end{aligned} \tag{6}$$

A similar procedure can be applied to derive the hybrid approach equations within the OSB-PD framework, following a careful algebraic reformulation of the peridynamic quantities [7].

Numerical examples

To show the capabilities of the proposed approach, a crack propagation test is carried out on the model depicted in Fig. 2. The model consists of a 0.1×0.04 m^2 rectangular plate of soda-lime glass discretized into a uniform grid 400×160, resulting in a grid spacing $\Delta = 0.25$ mm. A horizon size of 0.75 mm has been adopted, with $\overline{m} = \delta/\Delta = 3$.

Materials Research Proceedings 69 (2026) 1427-1431 https://doi.org/10.21741/9781644904251-250

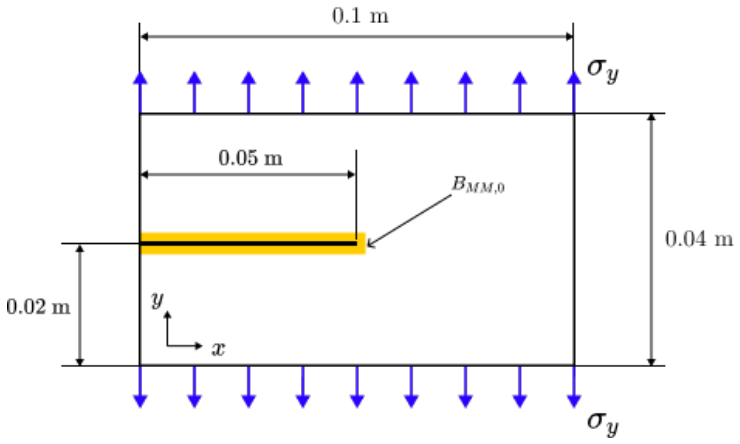

Figure 2: 2D Hybrid BB-PD model for the crack propagation test. $B_{MM,0}$ denotes the initial extension of the MM region.

The material properties of the soda-lime glass are [4]: $E = 72$ GPa (elastic modulus), $\nu = 1/3$ (Poisson's ratio), $\rho = 2440$ kg/m^3 (mass density), $G_0 = 3.8$ J/m^2 (critical energy release rate).

The model has been analyzed through the three methods: MM, FCBM and Hybrid PD. The Hybrid PD simulation has been run with an adaptivity energy threshold of 0.7 W_c. The expected MM region maximum extension is chosen to match the entire domain. A vertical traction load $\sigma_y = 8$ MPa has been used.

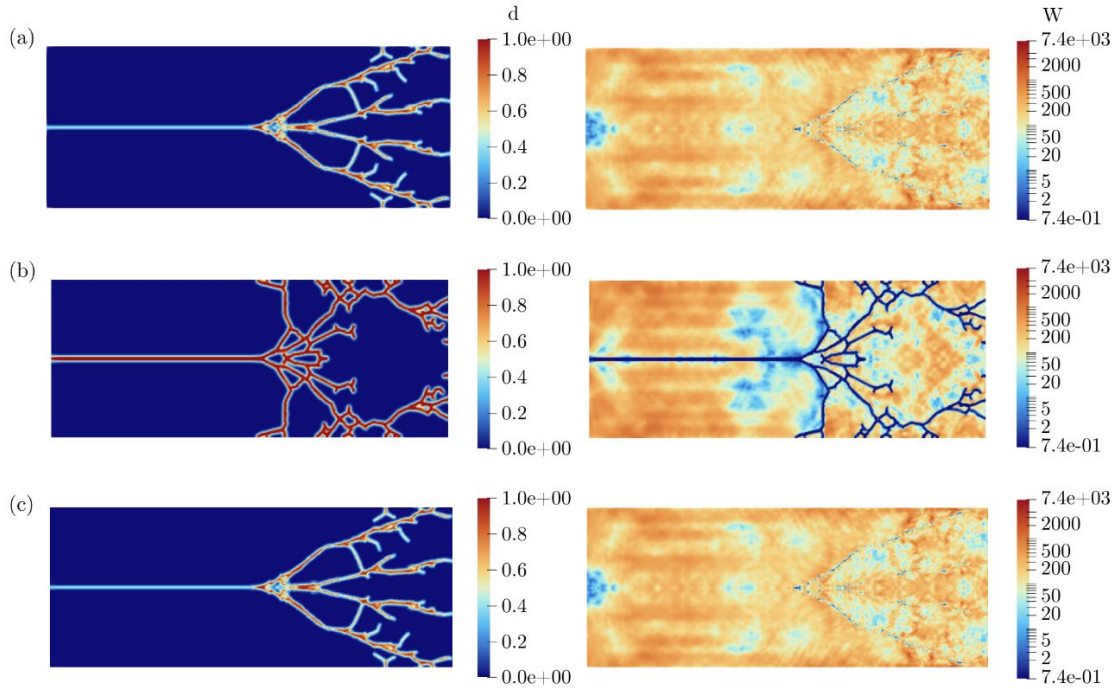

Figure 3: Results of the 2D crack propagation test at $t = 30$ μs, with an externally applied load of 8 MPa. From top to bottom: MM (a), FCBM (b), Hybrid PD with adaptivity (c).

As shown in Fig. 3, the Hybrid PD method reproduces the crack paths and strain energy distribution of the MM, even in the presence of multiple branching features. On the contrary, the FCBM is not able to capture well the branching phenomena. On a laptop computer equipped with 11th Gen Intel Core i3-1115G4 3 GHz dual-core processor and 32 GB of RAM, the MM simulation takes 240 s, while the FCBM and the Hybrid PD method require 40 s and 60 s respectively, with

the Hybrid PD method reducing the computational time by 75% compared to MM for the studied example.

Conclusions

The paper presents a new hybrid approach (Hybrid PD) to combine the FCBM and MM. The method has been developed for the Bond-Based and Ordinary State-Based formulations. The body domain is subdivided into two regions which overlap within a layer of nodes of width equal to δ. The MM application is limited to the MM region located close to the damaged area, while the FCBM is applied to the remaining part of the body.

The Hybrid PD method allows implementing the standard damage model of the MM near the damaged area, restoring the original bond breakage feature of the MM. The size and location of the MM region is adapted throughout the whole simulation through an adaptive strategy. This allows minimizing the extent of the MM application region and analyzing the remaining part of the domain through the FCBM, which significantly reduces computational time thanks to the application of the Fast Fourier Transform algorithm.

Abstract. The transition toward electric aviation demands energy storage technologies that overcome the weight limitations of conventional lithium-ion batteries. Structural batteries, capable of simultaneously carrying load and storing electrical energy, offer a promising route toward lighter and more efficient aircraft systems. This work presents the development and experimental evaluation of a type-III structural battery cell concept tailored for aeronautical integration. A multifunctional cell demonstrator was manufactured and tested to assess its electrochemical behavior and verify its feasibility as an energy-storing composite. Considerations on manufacturing scalability and material reclamation further highlight the potential of this approach for sustainable aerospace applications.

Introduction

This paper deals with the manufacturing of a prototype of a cell-like type III core for a laminated structural battery. A type III [1] SB integrates both load-bearing and electrochemical functions within a single multifunctional composite, where carbon fibers act simultaneously as structural reinforcement and active electrodes, and a solid polymer electrolyte serves as both the ionic conductor and matrix material. A key aspect of this study is to prove the multifunctional performance, highlighting the energy storage capability of the cell-like core structure of the SB. An additional focus of this study is the end-of-life management of the multifunctional composite. Unlike conventional crosslinked polymer matrices, the selected solid polymer electrolyte forms reversible physical bonds that can be disrupted through mild mechanical or ultrasonic agitation. This enables the recovery of carbon fibers, glass fibers, and active electrochemical constituents.

Manufacturing of the Cell-like Core of the SB

The complete structural battery (SB) will ultimately be realized through the stacking of multiple lithium-ion cell layers. Each cell is bonded within a tailored stacking sequence designed to meet the specific mechanical and electrical requirements of the intended application. This paragraph explains the details of the manufacturing process of the SB cell.

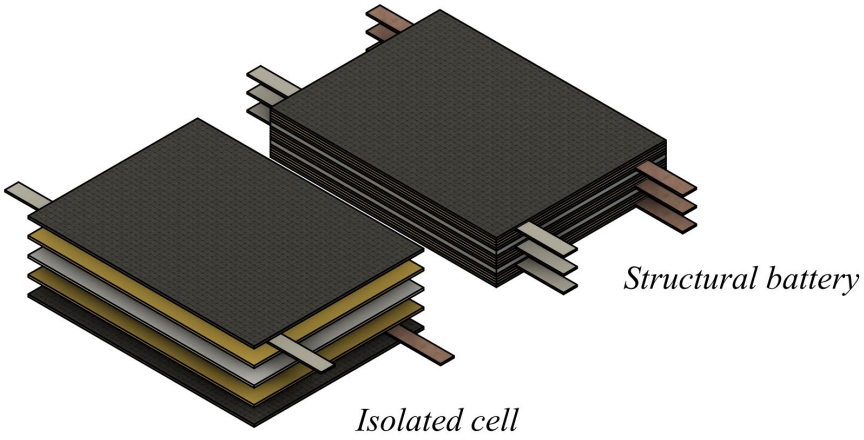

Fig. 1 - structural battery laminate

Cells are manufactured by layering two SPE films (SPE), two carbon fibers twill plies (CF), a glass fiber ply (GF) and the current collectors (cc) though the following stacking sequence (Eq. 1).

$$[CF_{anode}/cc(Cu)/SPE/GF/SPE/cc(Al)/CF_{cathode}] \quad (1)$$

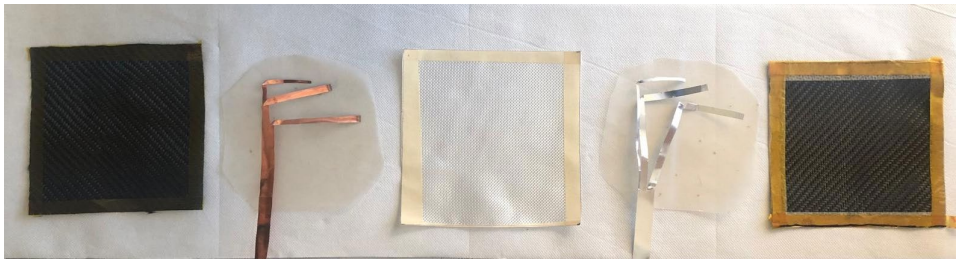

Fig. 2 - cell layup

Material and Methods

The two carbon fiber plies act as cathode and anode. While as anode an untreated ply of carbon fiber can be utilized, the ply acting as cathode is required to be exposed to an active material ($LiFePO_4$) through the process of functionalization [2]. The functionalization is obtained by distributing a solution of $LiFePO_4$**,** nitric acid (65% v/v)**,** hydrochloric acid (35% v/v) and **s**ulfuric acid (pure) onto a plasma treated ply of carbon fiber. The plasma treatment improves the wettability of the carbon fiber surface through cycles of ionized gas injections at high-frequency voltage within a controlled very low-pressure chamber (Diener Pico). The solid polymer electrolyte (SPE) films are manufactured through a one-pot preparation technique. A mixture of polyethylene glycol (PEG), sepiolite (SEP), polyethylene oxide and Lithium triflate (LiTfr), was prepared as follows. In a 400 mL erlenmeyer flask, SEP (1,75 g) was suspended in demi water (250 mL) and 2,63 g of PEG1000 was added. A dispersion/homogenization device (Ultraturrax, IKA T25) was used at 12000 rpm for 15 minutes to obtain a homogenous suspension. The suspension was organo-modified sepiolite (SEPmod) with PEG. The second step was to add in the same flask 87,5 g of polyethylenoxide (PEO) and 8,13 g of lithium triflate (LiTfr) and a dispersion/homogenization device was used at 12000 rpm for 15 minutes more. The resulting suspension was washed 3 times with demineralized water and centrifuged. The precipitate was collected and dried in an oven at 40°C under vacuum overnight (14 hours). The solid polymer electrolyte (SPE), was obtained through their mass solvent mixing (water solvent). To erase stratification effect after solvent evaporation and to uniformize composition, the obtained

Materials Research Proceedings 69 (2026) 1432-1437 https://doi.org/10.21741/9781644904251-251

compound was chopped in very small parts and dried at 40°C for 24 hours, under vacuum, so to remove the moisture. Finally, the SPE films (Fig. 3) were prepared by using a table hydraulic hot-press (Collin Press Model P100) at 130°C and subjected to 0 bar (thermal ramping) for 5 minutes, 20 bar for 3 minutes, 40 bar for three minutes, followed by a rapid quenching phase.

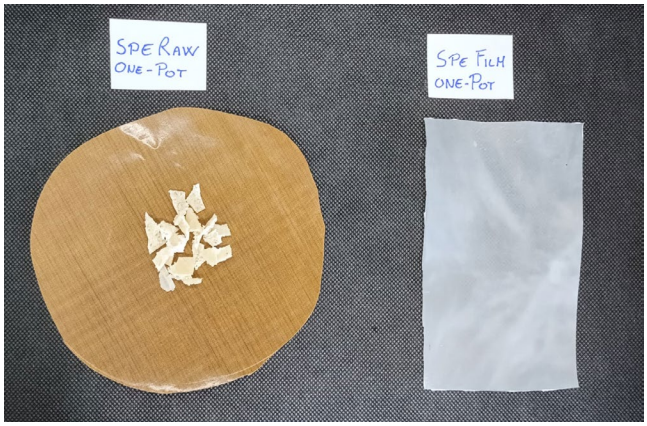

Fig. 3 - raw and film state of SPE

For energy storage characterization, a 300x300 mm cell was manufactured (Fig. 4). The assembly of the laminate was conducted following a tuned thermal-pressure cycle, allowing for the correct flow of the SPE within the carbon fiber bundles, acting as matrix and fixing the structure of the cell. The stacked unbound components (Fig. 2) were inserted in the table hydraulic hot-press (Collin Press Model P100) at 60°C and subjected to the same pressure and quenching profile followed for the SPE manufacturing.

Fig. 4 - assembled structural battery cell

To avoid the carbon fibers layers to be in contact at the cell border, and the consequential short-circuiting, the glass fiber separator was extended beyond the cell edges and polyimide film (Kapton) tape was added to those critical areas. All the processes employed in the fabrication of the SPE and the full cell are meant to be easily scalable for mass production.

Energy Storage Characterization of the Structural Battery Cell

An enabling step for the development of the full laminate SB is the characterization of the isolated cell energy storage performance. A CC/CV bench power supply tailored for lithium-ion batteries was used for charging the cell to its estimated maximum capacity. Due to the experimental nature of the cell, a 0.1C charging current was employed. In order to properly estimate the current to supply, as a first assumption, weight-specific capacity was assumed identical to already proven similar specimen found in literature [3], equal to 8.55 Ah/kg. Due to testing on previous iterations of the cell [4], a 2.7 V maximum voltage was selected for the CC/CV switch activation. The charging cycle was terminated once the absorbed current reached 60 mA, equal to C/20, following industry standard. To avoid the formation of metallic dendrites and consequential internal short-circuiting, a 2.1 V lower cut-off voltage was considered when discharging the cell. From the resulting discharging curve (Fig. 5), it was possible to extrapolate the energy storage capabilities of the cell.

SB Laminate

To enhance the energy storage performance per unit area of the proposed structural battery (SB), multiple cells will be stacked (Fig. 1). A secondary material will be employed to bond the cells, serving as an interface matrix and improving the overall mechanical integrity of the assembly. Future studies will address the selection of this interfacial material and the mechanical characterization of the resulting laminate. The matrix is required to provide electrical insulation between adjacent cells. Potential aeronautical applications of such SB laminate include non–structurally-critical secondary components [5,6] where multifunctionality can provide tangible mass and volume savings without imposing excessive certification burden. Examples include access panels and cabin interior panels. The adoption of SB laminates in these zones would enable progressive validation within a reduced regulatory envelope, serving as a stepping-stone toward

future integration in higher-criticality composite structures. Further studies will be conducted once a full laminated SB specimen will be manufactured.

Material Reclamation

A defining feature of the proposed structural battery (SB) is its intrinsic disassemblability (Fig. 6), which enables efficient end-of-life recovery and reuse of its constituent materials. The SPE matrix provides physical bonding between the carbon and glass fiber plies without forming irreversible chemical crosslinks. As a result, the laminate can be mechanically dissociated. Preliminary experiments show that an ultrasonic bath (Falc Ultrasonic, 22 min at 30 °C) effectively disrupts the polymer matrix, allowing the separation of the carbon fiber and glass fiber layers. The resulting suspension contains Sepiolite, $LiFePO_4$, lithium triflate, PEO, and PEG. Subsequent centrifugation (Hermle Z326K, 15 min at 6000 RPM) enables selective precipitation of Sepiolite, $LiFePO_4$, and lithium triflate, yielding distinct solid fractions suitable for direct recovery or reprocessing. The remaining polymer-rich aqueous phase, composed primarily of hydrated PEO and PEG, can be dried to obtain a reusable polymer mixture with potential applications in various industrial sectors, particularly where low-molecular-weight polyethylene oxides are required.

Summary

This work demonstrates the fabrication and characterization of a type-III structural battery cell. Carbon fibers act as both structural reinforcement and active electrodes, while a solid polymer electrolyte ensures ionic conduction and laminate cohesion. A functionalized $LiFePO_4$ cathode, a

controlled hot-pressing cycle, and a scalable manufacturing route enabled the production of a 300×300 mm demonstrator. Electrochemical testing confirmed the cell's ability to store and deliver energy, validating the multifunctional concept. A preliminary end-of-life recovery process was also established, showing that the cell can be disassembled and its constituent materials reclaimed through mild mechanical treatments. More sustainable replacements for the acid solution required for the functionalization phase will be investigated.

Keywords: Space Exploration, Technologies, Rover, Wheel, FEM, ALM, DfAM, EB-PBF

Abstract. The continued global interest in human and robotic Moon exploration has ramped up the demand for innovative engineering solutions that can overcome the challenges of the harsh lunar environment. These challenges include extreme temperature fluctuations, abrasive regolith particles, ionising radiation, low gravity, and the constraints of transporting equipment or spare parts from Earth. In this context, the development of robotic systems and components requires a careful balance among structural performance, weight efficiency, and manufacturability. This paper presents a case study, performed in the framework of the *CIRA-TEDS Program* [1], on the design and manufacture of a lunar mini rover's wheel prototype, using *additive layer manufacturing* (ALM) and *design for additive manufacturing* (DfAM) techniques. Starting from high-level mission and environmental requirements, a reverse integration process ensures alignment between system objectives and wheel design. A hybrid design approach combining *Topological Optimisation* (TO) and *Generative Design* (GD) was applied, supported by *Finite Element Method* (FEM) analysis to evaluate structural behaviour and guide iterative improvements. The wheel was manufactured in Ti6Al4V using *Electron Beam Powder Bed Fusion* (EB-PBF). Although physical testing is planned, current results show that GD outperforms conventional designs in stress distribution and weight reduction. The study proposes a replicable framework integrating system-level requirements, DfAM, and ALM to accelerate the development of space-ready hardware for future lunar and planetary missions.

Introduction

Designing mobility systems for lunar rovers involves overcoming challenges posed by the Moon's harsh surface and environment. Lunar regolith is abrasive, electrostatically active, and offers low traction, making traditional wheel designs ineffective. Specialized wheels with flexible structures and grousers have been developed to enhance mobility, load distribution, and energy efficiency [2]. Wheel failure risks include entanglement, sinkage, and traction loss [3]. Therefore, wheel design is critical to mission success. Rover design begins with mission requirements, which guide subsystem specifications and design drivers through a structured engineering process [4]. To this end starting from a preliminary design, a hybrid approach combining topological optimisation (TO) and generative design (GD) was employed. These two tools offer complementary capabilities, TO identifies the most efficient material distribution based on constraints and applied loads [5], while GD explores different configurations that can be adapted to various manufacturing technologies [5]. Recent studies [6, 7] have demonstrated that integrating these two techniques yields superior design optimisation and efficiency. The software used to perform topological optimisation and generative design was Autodesk Fusion 360®. To evaluate structural behaviour

and support iterative improvements during the design process, Finite Element Method (FEM) analysis was conducted using Abaqus® software.

A prototype for the virtual model validation means experimental testing

In the context of lunar exploration missions, the development of mechatronic systems, such as planetary rovers, demands extremely stringent requirements in terms of reliability and predictability of operational behaviour. Space systems are launched in their final configuration, with no possibility of post-deployment intervention or correction. This constraint makes it essential to build robust numerical models capable of simulating lunar environmental conditions. The accuracy of the model is directly related to the system's ability to operate autonomously and safely in unpredictable environments [8], and the validation of the numerical model must be performed using rigorous methods, as it is the only tool available to anticipate the behaviour of the system once in mission. Representative prototype enables this correlation, particularly in the presence of complex interactions such as wheel-ground dynamics, where phenomena such as slippage, sinkage, and soil compaction significantly affect mobility performance [9]. The validation of virtual models through experimental testing is a cornerstone in the development of reliable engineering systems. Physical prototypes serve as tangible benchmarks to assess the accuracy of simulations, especially in complex domains such as aerospace, robotics, and engineering. One of the most revolutionary factors in this validation process is the ALM, which is particularly valuable in space applications [10]. In conclusion, experimental testing supported by manufacturing through ALM provides a solid framework for validating virtual models, bridging the gap between simulation and reality, and innovation through iterative design.

From the High-Level Robotic System Requirements to the Component

In the development of space robotic systems, the transition from high-level system requirements to individual components is a critical phase that ensures traceability, consistency, and technical integrity throughout the engineering process. According to ECSS-E-ST-10C, system engineering shall implement a structured requirements breakdown process to establish a validated technical framework for system-level requirements into subsystem and component-level. To formalize this derivation, a tree procedure is defined that maps system-level mobility requirements to wheel geometry parameters. For instance, the Lunar Rover Optimization Platform (LROP) developed at NASA Glenn Research Center [11] demonstrated how variations in wheel geometry and center-of-gravity positioning directly affect slope ascent capability and obstacle negotiation. Similarly, it has been demonstrated that grouser configuration significantly influences terrain deformation and traction performance, validating the reverse integration methodology through simulation and experimental testing [12]. Through reverse engineering, rover platforms are analysed to extract the needed subsystem performance and interactions. This information allows to understand the capabilities that the wheel as a component should have, such as locomotion efficiency on granular regolith, maximum permissible slope before tilting, thermal resistance during prolonged exposure to the lunar day, structural resilience during launch, landing, and soil reaction loads. From these inputs, component-level requirements for the wheel are released, such as rolling resistance, maximum drawbar-pull force, slippage, and mass and volume constraints to maintain rover stability and minimize energy consumption. Starting from the System Technical requirements, the rover classification is focused on Sub-R range [13], the procedure used incorporates Terramechanics models [14], such as Bekker’s pressure-sinkage equation, Wong-Reece shear stress models, and wheel-soil interaction model dynamic constraints as slip ratio, normal load, and soil mechanical properties, enabling parametric optimization of Wheel geometry as reported in Table 1. Titanium alloy has been selected as the wheel material, in accordance with the design heritage and performance requirements observed in both recent and planned lunar exploration missions.

Design for Additive Manufacturing

The wheel was re-designed using the Design for Additive Manufacturing (DfAM) approach to refine the preliminary geometry defined through reverse engineering of the rover architecture and maximise the advantages offered by ALM. The objective was to determine the optimal number of spokes and the best material distribution along them. The initial stage of the topology optimisation analysis involved the identification of the design space. This region was confined to the volume between the Central Hub and the Outer Rim, with the Central Hub excluded from the optimisation process in order to preserve its structural and functional integrity. This was implemented by defining it as Preserve Region. Subsequently, to ensure uniform deformation distribution in all directions, two orthogonal symmetry planes intersecting at the wheel axis were assigned. The applied load conditions were configured to simulate the operational conditions of the wheel on the lunar surface (*Table 1*). The ground-wheel tread contact was simulated by constraining the faces of the Outer Rim and Grousers over an angular sector of ±34°. The material assigned as described in the previous section is Ti6Al4V alloy. The optimization criteria adopted were the strategy proposed by the software, in particular, the maximization of stiffness and a target mass set to automatic. The decision not to set a target mass value was because the objective of topological optimization is to provide only an efficient preliminary design. The solution obtained proposed a preliminary design involving four spokes connecting the Central Hub to the Outer Rim, with a spatial distribution more concentrated towards the side of the wheel corresponding to the Central Hub assembly interface, which is the area expected to experience higher stress concentration. The preliminary configuration yielded substantial data on material distribution, which was then assessed to verify structural efficiency. Analysis revealed extremely low stress levels (a maximum Von Mises stress of 0.137 MPa) and a high safety factor of around 6500, indicating that the design was considerably oversized. These results highlighted the potential for further optimisation, leading to the development of a lighter three-spoke configuration in the subsequent Generative Design phase. Following the results obtained from topological optimization, a Generative Design study was performed with the aim of developing a geometry that would satisfy the wheel design constraints and that could be manufactured through additive manufacturing. Prior to the implementation of the generative study setup, it was necessary to prepare the functional geometries in the Autodesk Fusion Design environment. In particular, three groups of functional geometries were modelled. First, the *Preserve Geometries,* included the Central Hub and the Outer Rim with the Grousers, which were kept unaltered due to functional and interface constraints. Second, the *Obstacle Geometries,* represented the volumes in which material generation is not allowed. Specifically, an internal axial cylinder was modelled inside the Central Hub to ensure mechanical coupling, while an external cylinder concentric to the Outer Rim prevented the generation of material in the Wheel Tread and Grousers areas. Two additional lateral cylinders were also modelled on the outer faces of the wheel with the aim of limiting the growth of material along the axial direction. Finally, the *Starting Shape* was modelled on the qualitative results obtained in the topological optimization phase. This initial configuration consisted of a wheel with three solid cylinders, representing the spokes positioned radially at 120° to the axis of rotation. To ensure a

Materials Research Proceedings 69 (2026) 1438-1443 https://doi.org/10.21741/9781644904251-252

structurally balanced and symmetric outcome, three symmetry planes were defined into the model. Specifically, a primary reference plane at 0°, aligned with the vertical diameter of the wheel, and two additional inclined planes at ± 120°, introduced to further constrain material distribution along the spokes. The boundary and load conditions were assigned in the same manner as in the topological optimization analysis. The generation objective was set to minimize mass, with the production method specified as Additive Manufacturing. The Additive Manufacturing method requires the definition of a series of parameters, including the growth direction of the component (in this case, all directions were permitted), the minimum wall thickness set at 2 mm, and the overhang angle set at 45°. As in the previous phase, the material assigned for the study was Ti6Al4V. All the solutions generated by the Generative Design study followed the predefined constraints and reflected the design intent of maximising spatial efficiency. While the shapes of the spokes were different, they always kept the same connection to the areas to be preserved, respected symmetry conditions, and met the manufacturability requirements imposed by additive manufacturing technologies. Furthermore, no material was generated within the volumes defined as obstacles, ensuring clean integration with the functional zones. The new configuration obtained allowed for significant improvements in material distribution. The selected geometry features three symmetrical spokes arranged radially at 120°, connecting the Central Hub to the Outer Rim. The resulting design achieved a total mass of 23.402 grams, representing a mass reduction of 21% compared to the preliminary wheel design configuration. The wheel obtained through generative design has been referred to for the rest of the document as 3-Spoke GD wheel.

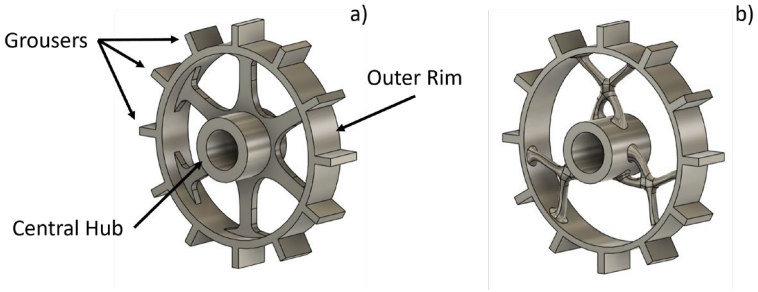

Figure 1. Preliminary Wheel Design vs GD Wheel Design

Numerical Validation of the Generative Design Prototype

The use of the FEM is of fundamental importance in the design of mobility systems for the lunar surface, where unique environmental conditions such as low gravity, vacuum, and the mechanical behaviour of the lunar regolith pose significant challenges to experimental validation. The virtual analysis strategy employed is applicable to the lunar exploration wheels and is inspired by the work done in [15]. The virtual structural assessment of the rover wheel on the lunar surface involves four steps: *Initial Step* where soil conditions are set using predefined fields, initializing vertical and horizontal stresses based on material properties and void ratio; *Gravity Step* were gravity is activated and internal soil stresses are balanced; *Attitude Step* where the wheel load is applied, establishing static equilibrium and contact patch; finally the *Rolling Step* where wheel motion is simulated with constant vertical load and ramped velocity, capturing dynamic wheel-soil interaction and footprint formation. In the initial phase of wheel design, a traditional six-spoke configuration was selected for its symmetry and structural reliability. However, applying generative design techniques, as shown in *Figure 1,* led the algorithm to converge on a three-spoke solution, which met the same mechanical and functional performance criteria. This outcome demonstrated a higher structural efficiency, challenging conventional assumptions by optimizing load paths and material distribution. Despite the radical change in geometry, both designs were developed to endure identical operational loads and conditions. The generative design maintained attitude and rolling performance while achieving a 21% mass reduction, a critical advantage in

Materials Research Proceedings 69 (2026) 1438-1443 https://doi.org/10.21741/9781644904251-252

space robotic applications due to its impact on energy consumption and inertial response. From a structural standpoint, stress analysis revealed that during the attitude step, the equivalent von Mises stress increased by 303% (*Figure 2*), attributed to a worst-case loading condition not supported by a spoke. Nevertheless, the design remained within acceptable safety margins for lunar use.

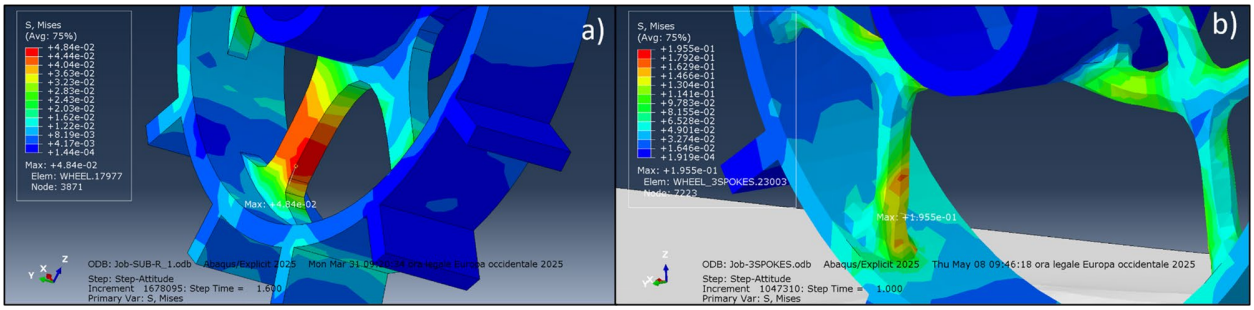

Figure 2. Wheel Stress State during Attitude Step. a) Preliminary Design; b) Generative Design

During the Rolling step, stress increased by about 30%, still within structural limits, confirming the generative design's mechanical integrity under nominal dynamic conditions (*Figure 3*). Overall, the comparison underscores how algorithm-driven approaches can reduce material usage and refine engineering assumptions, offering optimized structures without compromising performance, and paving the way for further structural innovation.

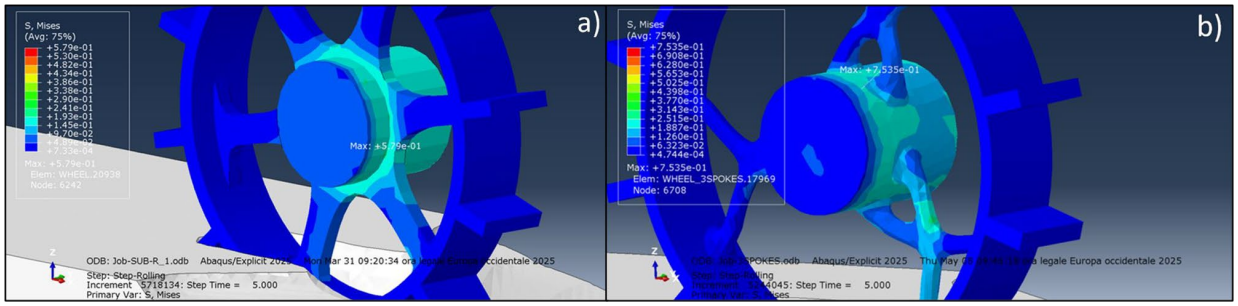

Figure 3. Wheel Stress State during Rolling Step. a) Preliminary Design; b) Generative Design

Conclusions and Perspectives

This paper presents a replicable framework for designing and manufacturing lightweight lunar rover components, integrating system-level requirements with DfAM principles and ALM technologies to optimize performance and adaptability. A conventional six-spoke wheel design was initially adopted for structural symmetry and load handling. However, generative design algorithms, through constraint-based optimization and iterative simulation, proposed a structurally compliant three-spoke configuration, minimizing mass without compromising integrity. This challenges traditional design paradigms and highlights the potential of computational design exploration. Future validation through FEM analysis and physical testing will ensure feasibility under lunar conditions.

Keywords: Additive Manufacturing, Fused Deposition Modeling, Metal–Ceramic Co-sintering, Thermal Protection Systems

Abstract. This study explores the fabrication of hybrid metal–ceramic structures for space applications using Fused Deposition Modeling (FDM) additive manufacturing. Combining metals and ceramics enables components with both high strength and thermal resistance, but property mismatches at interfaces cause stress and deformation. Numerical simulations were conducted to design optimized interfaces that minimize these effects. A three-step process involving printing, debinding, and sintering was developed for 316L steel and zirconia. Results demonstrate that engineered interfaces significantly improve bonding and mechanical reliability, offering a viable route for advanced aerospace components.

Introduction

The growing demand for materials capable of withstanding extreme environments in aerospace and propulsion systems has intensified research on advanced hybrid structures. Components exposed to re-entry or combustion conditions must resist steep temperature gradients and large thermal stresses [1]. Ceramic materials exhibit outstanding thermal stability and oxidation resistance, but their brittleness and low fracture toughness limit structural reliability. Metals, conversely, provide ductility and strength but degrade at high temperatures. Combining both in metal–ceramic hybrids could, in principle, merge their advantages; however, mismatches in thermal expansion, sintering shrinkage, and elastic modulus generate severe interfacial stresses, often causing cracking, delamination, or residual deformation [2–4].

Functionally Graded Materials (FGMs) were conceived to overcome these issues by introducing a continuous or stepwise variation in composition or microstructure between dissimilar materials. This gradual transition reduces property discontinuities and redistributes stresses generated during fabrication or thermal loading [5]. Several studies have demonstrated the feasibility of such systems—for instance, multilayer ZrO_2–NiCr composites fabricated through shrinkage-matching sintering [6] or zirconia–steel laminates optimized for compatible densification and thermal expansion [7]. Despite these results, traditional FGMs remain largely restricted to research activities. Their production is technically complex, costly, and difficult to scale. Conventional methods such as tape casting, lamination, and powder metallurgy require precise control of particle packing, sintering rates, and geometry; small mismatches can induce warping or fracture. These limitations have hindered the industrial deployment of FGMs, confining them to academic prototypes or specialized demonstrators [2,5]. The advent of Additive Manufacturing (AM) has revitalized interest in functionally graded and multi-material structures. By depositing material layer by layer, AM enables unprecedented geometric freedom and localized composition control. Among AM techniques, Fused Deposition Modeling (FDM) has attracted attention for its simplicity, scalability, and compatibility with thermoplastic feedstocks loaded with ceramic or metallic powders [8,9]. This process allows the fabrication of hybrid parts with tailored interfaces, where the local material composition can be precisely adjusted within the same build.

Materials Research Proceedings 69 (2026) 1444-1449 https://doi.org/10.21741/9781644904251-253

Recent developments in thermoplastic extrusion-based AM have extended these capabilities further. By employing paraffin- or wax-based binders with high powder loading (up to 50 vol%), it is now possible to co-deposit different materials—such as metals and ceramics—within a single printing process [10]. Careful tuning of feedstock rheology, deposition parameters, and sintering schedules enables co-sintered components that are dense, homogeneous, and free of cracks. Studies on stainless steel and zirconia composites have shown that such hybrid parts can be sintered successfully when the shrinkage and thermal behavior of both materials are properly matched [10,11]. Moreover, graded architectures combining dense and porous regions have been demonstrated, highlighting the potential of thermoplastic AM to produce lightweight and multifunctional components [12].

Alongside experimental advances, numerical modeling has become essential for understanding the thermo-mechanical behavior of such systems. Early viscous and viscoelastic formulations by Green and colleagues [3,4] demonstrated that small mismatches in densification rate can induce tensile stresses sufficient to cause warping or cracking in layered ceramics. Building on these concepts, recent finite element (FE) simulations have incorporated phase transformation, plastic deformation, and cohesive interfaces to capture the evolution of stress, deformation, and delamination in hybrid laminates [13]. These models provide predictive tools for optimizing interface design and processing parameters before experimental trials.

The present study combines thermo-mechanical modeling with extrusion-based AM to design and fabricate metal–ceramic hybrid structures suitable for aerospace applications. The objective is to exploit the geometric and compositional control of additive manufacturing to engineer graded or architected transition zones—flat, wavy, or lattice-like—that minimize residual stresses after sintering. Through the integration of modeling and experimental validation, this approach demonstrates a viable pathway to overcome the long-standing manufacturing difficulties that have limited FGMs to academic research, paving the way for structurally reliable, thermally resistant multi-material components for next-generation space systems.

Printing process

The fabrication process is based on Fused Deposition Modeling (FDM) using a Mingda MD-400D 3D printer equipped with dual extrusion and temperature-controlled nozzles and build plate. The feedstock materials are Zetamix filaments (Nanoe, France), thermoplastic compounds containing fine 316L stainless steel or 3Y-TZP zirconia powders uniformly dispersed in a polymeric binder. After printing, the green parts undergo chemical debinding in acetone using a ultrasonic bath.

Final densification of the green part is performed in a Zetasinter tube furnace, providing precise temperature and atmosphere control. According to the literature [5–7,13], 316L stainless steel and zirconia are among the most compatible pairs for co-sintering, exhibiting similar shrinkage behavior and comparable coefficients of thermal expansion (≈10–11 × 10^{-6} K^{-1}). These characteristics reduce interfacial stresses and improve bonding, enabling the production of dense and crack-free hybrid structures.

Sintering Chemo-Thermal Kinematic Model

The evolution of densification during sintering was described using an Arrhenius-type kinetic law that links temperature and time to the change in relative density. The material was considered a porous continuum in which the diffusion rate controls the reduction of porosity according to

$$\dot{\rho} = A \exp(-\frac{Q}{RT}) (1-\rho)^n,$$

where A is a pre-exponential constant, Q the apparent activation energy, R the universal gas constant, T the absolute temperature, and n an empirical exponent that accounts for the slowdown of densification as pores close. This expression, originally formulated for viscous and grain-

Materials Research Proceedings 69 (2026) 1444-1449 https://doi.org/10.21741/9781644904251-253

boundary diffusion sintering, captures the fundamental temperature sensitivity of the process [3,14].

From the calculated density evolution, the corresponding shrinkage was obtained through isotropic mass conservation, while the total deformation over the thermal cycle was determined by combining the densification-induced contraction with the integrated thermal expansion. Mechanical properties were updated stepwise as functions of density using empirical power-law and exponential relationships, which link stiffness and strength to porosity reduction.

Although simplified, assuming homogeneous and isotropic densification, the model effectively reproduces the densification and shrinkage trends observed in sinter-based additive manufacturing of both metallic and ceramic feedstocks [15].

CUF-Based Layer-wise Residual Deformation Analysis

The residual deformations induced during sintering are evaluated through a Carrera Unified Formulation (CUF) framework combined with a layer-wise modeling strategy. The thermo-mechanical problem is solved incrementally as a sequence of quasi-static states, each corresponding to a discrete time or temperature step of the sintering cycle. The approach has been developed at first for the virtual manufacturing of composite material [16] and is here extended to the sintering of metallic materials. At every instant, the stiffness matrices of the individual layers are updated according to their instantaneous elastic properties and thermal expansion coefficients. The total residual deformation is then obtained as the cumulative sum of these incremental static states over the entire thermal history.

Numerical results

The mechanical and thermal properties of zirconia (3Y-TZP) and 316L stainless steel were defined according to the model developed for this study. The resulting curves, shown in Figure 1, illustrate the progressive increase in stiffness and density as the porosity decreases during processing, while the thermal expansion coefficient remains relatively stable for both materials.

Starting from these data, the process induced deformation behavior was evaluated for a standard cantilever beam with a length of 40 mm and a width of 6 mm. The baseline configuration (Base) was modeled with a total thickness of 5 mm, composed of 4 mm of 316L steel and 1 mm of zirconia bonded at the interface. Symmetry constraints were applied on one short and one lateral face, so that the model effectively represents one-quarter of a beam twice as long and twice as wide, preserving the correct curvature and deformation behavior.

In parallel, four alternative interface configurations were analyzed to investigate the influence of geometric transitions on the global deformation:

- INT-1: interface with a zig-zag profile preserving the same volume ratio as the baseline case (4 mm metal / 1 mm ceramic).
- INT-2: zig-zag interface with an enlarged transition region, redistributing the two materials without maintaining the original thickness ratio.
- INT-3: introduction of a lamellar interlayer (4mm) between the metal and ceramic layers, composed of vertical lamellae designed to redistribute local shrinkage.
- INT-4: same lamellar interlayer (4mm) configuration as INT-3, but with the lamellae inclined at 45°, providing an oblique load transfer path during sintering.

These configurations allow direct comparison between the effect of interface morphology and the global curvature of the beam.

Materials Research Proceedings 69 (2026) 1444-1449 https://doi.org/10.21741/9781644904251-253

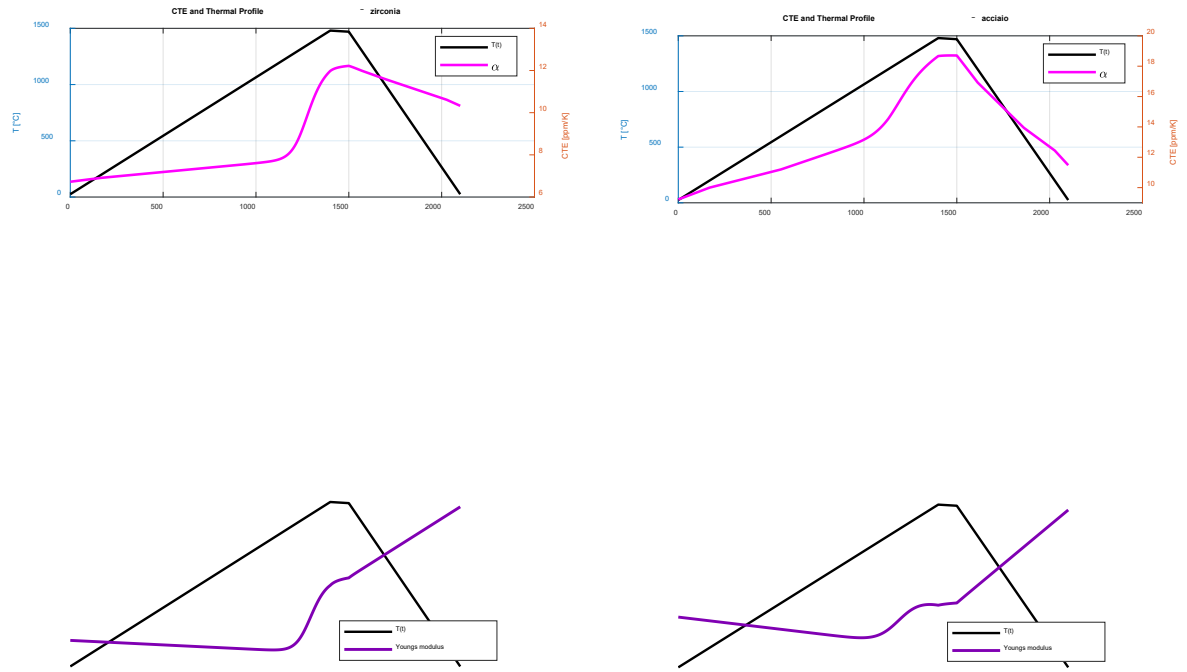

Fig. 1 Evolution of the main thermo-mechanical properties (E, α, ρ) of 316L stainless steel (right) and 3Y-TZP zirconia (left) during the sintering process.

Figure 2 compares the maximum deflection for the five interface configurations. The Base model shows the highest curvature (4.15 mm) and serves as the reference. The INT-1 zig-zag interface slightly reduces the deflection (−4.6%), while INT-2, with a wider transition zone, produces a small increase (+1.7%). The best results are achieved with the lamellar structures: INT-3 with vertical lamellae and INT-4 with 45° inclined lamellae reduce the deflection by 40.7% and 35.2%, respectively. These results confirm that introducing a lamellar interlayer is the most effective strategy for mitigating shrinkage mismatch and improving dimensional stability during co-sintering.

Conclusions

This study demonstrates that FDM additive manufacturing can effectively be combined with numerical modeling to design hybrid metal–ceramic components with improved dimensional stability. The results show that the geometry of the interface plays a crucial role in controlling the deformation generated during co-sintering. By exploiting the design flexibility of 3D printing, it is possible to tailor the interface morphology to redistribute shrinkage and thermal mismatch between materials, significantly mitigating global curvature. Although based on simplified material assumptions, the proposed approach provides a reliable framework for predicting deformation trends and guiding interface design before experimental validation. Overall, this work confirms that additive manufacturing enables functional control of metal–ceramic interfaces, opening the way to optimized, thermally stable structures for aerospace and high-temperature applications.

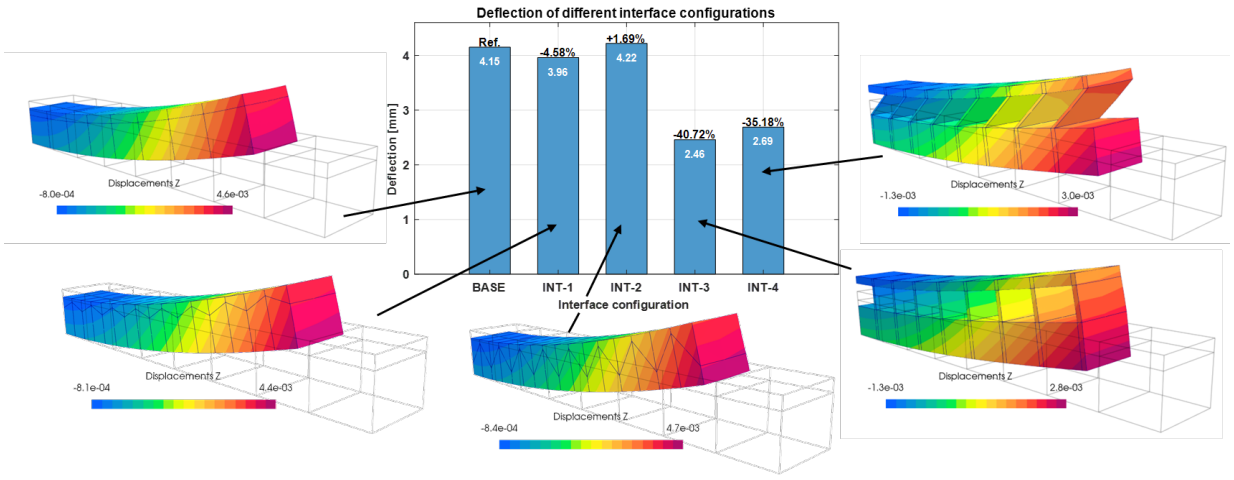

Fig. 2 Comparison of the maximum deflection for the five interface configurations: Base, INT-1, INT-2, INT-3, and INT-4. The bars show the absolute deflection values, while the percentage labels indicate the variation with respect to the Base model.

Fatigue Life Estimation in Frequency-Domain of Composite and Metallic Structures via CUF and Dirlik's Method

Elisa TORTORELLI[1,a *], Giuseppe PALAIA[1,b] and Erasmo CARRERA[1,c]

[1]MUL2 Lab, Department of Mechanical and Aerospace Engineering, Corso Duca degli Abruzzi 24, 10129, Torino, Italy

Keywords: CUF, Fatigue, Composite

Abstract. This work presents a framework for predicting the fatigue life of composite and metallic structures under random excitations. The framework combines the Carrera Unified Formulation (CUF), Dirlik's frequency-domain approach, and the Tsai–Hill criterion to evaluate fatigue damage from stress power spectral densities. Results for various laminate configurations show good agreement with FEMAP/NX simulations, demonstrating the accuracy and efficiency of the proposed CUF-based fatigue assessment.

Introduction

Fatigue is a significant contributor to the failure of structural and mechanical components. Its assessment requires evaluating stress or strain distributions resulting from the loading history and predicting the stress response under random excitations, which is crucial for estimating fatigue life. In the aerospace sector, where aircraft and spacecraft are exposed to random atmospheric loads [1], fatigue is commonly evaluated using a damage tolerance approach, focusing on the growth of existing cracks [2]. Similar strategies based on fracture mechanics under Gaussian random loading are also applied in other fields, such as mooring systems [3].

The increasing use of composite materials introduces new challenges due to their anisotropic behavior and damage mechanisms, including matrix cracking, delamination, and fiber breakage [4]. Predicting the fatigue life of composites requires advanced modeling techniques that can capture both stochastic loading and progressive damage [5]. Traditional time-domain simulations are accurate but computationally expensive, whereas frequency-domain methods, such as Dirlik's approach [6], provide efficient alternatives for fatigue estimation under random vibrations [7].

This work proposes a framework combining the Carrera Unified Formulation (CUF) [8] with Dirlik's frequency-domain method. CUF enables high-fidelity finite element modeling of multilayered laminates, capturing stress distributions across plies. Stress responses are computed in the frequency domain, with aluminum fatigue assessed via the critical stress PSD component and composite fatigue evaluated using the Tsai–Hill failure index. Dirlik's method then estimates fatigue life from the stress PSD through spectral moments, PDF evaluation, and S-N curve integration. The assessment considers the computation of fatigue life for different laminations of composite specimens under random loading via the CUF model and compares the results with those from FEMAP/NX commercial software.

The following work summarizes in the first two sections the methodology, in the third section the main results, and in the last section the conclusions.

Carrera Unified Formulation

The two-dimensional (2D) model adopted in this study is developed within the framework of the Carrera Unified Formulation (CUF). CUF enables the derivation of the governing equations for any refined structural theory using a limited set of Fundamental Nuclei (FNs). The three-dimensional displacement field of a solid plate can be represented as a general expansion of the

Materials Research Proceedings 69 (2026) 1450-1454 https://doi.org/10.21741/9781644904251-254

generalized displacements, expressed as the product of an in-plane two-dimensional shape function, $N_i(x,y)$, and a one-dimensional expansion function, $F_\tau(z)$.

$$\mathbf{u}(x,y,z) = F_\tau(x,z)N_i(y)\mathbf{u_{\tau i}} \qquad \tau = 1,\ldots,M \qquad i=1,\ldots,p \tag{1}$$

Where $F_\tau(z)$ is the expansion function modelling the displacement field, the order of the expansion function depends on the parameter M, $\mathbf{u_{\tau i}}$ is the nodal displacement unknown vector, and p is the number of nodes of each element. The results of this work are obtained using bi-quadratic (Q9) elements as shape functions $N_i(x,y)$ to discretize the in-plane geometry.

Fatigue life estimation in frequency domain

Starting from the general equation of motion and using the modal reduction strategy to reduce the computational effort, the frequency-domain formulation becomes:

$$\mathbf{X^T q_k}(\omega) = \left[-\omega^2\left(\mathbf{X^T M X}\right) + i\omega\left(\mathbf{X^T C X}\right) + \left(\mathbf{X^T K X}\right)\right]^{-1}\mathbf{X^T F_k^*} \tag{2}$$

where the modal generalized matrices of mass, damping and stiffness are $\boldsymbol{X^T M X}$, $\boldsymbol{X^T C X}$, $\boldsymbol{X^T K X}$, respectively. $\boldsymbol{F_k^*}$ is the generalized force vector; $\boldsymbol{q_k}$ is the vector that collects the degree of freedom (DOF) of the FE model and $\boldsymbol{X}$ is the matrix that collects the eigenvectors.

The power spectral density (PSD) function of a signal provides a quantitative representation of the distribution of power in the frequency domain. In the event of a given force input PSD function $\boldsymbol{G_F}(f)$, the system's transfer function can be utilised to calculate the stress output response $\boldsymbol{G_{\sigma_j}}(f)$:

$$\mathbf{G_{\sigma_j}}(f) = \overline{\mathbf{H_{\sigma_j}}}(f)\mathbf{G_F}(f)\mathbf{H_{\sigma_j}^T}(f) \quad j=1,\ldots,6 \tag{3}$$

Where $\boldsymbol{H}(f)$ is the system transfer function, i.e. a function which describes how a linear time invariant system responds (output signal) to a specific input and, in particular, $\overline{\boldsymbol{H_{\sigma_j}}}(f)$ and $\boldsymbol{H_{\sigma_j}^T}(f)$ are the complex conjugate and the transpose of this function.

The Tsai–Hill criterion has been experimentally validated for predicting failure in composite laminates under multiaxial static loading. Although fatigue may involve the same damage mechanisms observed under static loading, including matrix cracking, fiber breakage, interfacial debonding, and delamination, fatigue failure results from progressive damage accumulation rather than instantaneous failure. The Tsai–Hill criterion is therefore used here to condense the multiaxial stress state into an equivalent PSD function as in [9], which can then be used within the fatigue framework.

$$G_{\sigma_{eq}}(\omega) = \frac{\frac{1}{2X^2} + \frac{1}{2X^2}G_{\sigma_1-\sigma_2}(\omega) + \frac{2X^2 - Y^2}{2X^2Y^2}G_{\sigma_2}(\omega) + \frac{1}{S_\tau^2}G_{\tau_{12}}(\omega)}{\frac{1}{2X^2} + \frac{1}{Y^2} + \frac{1}{S_\tau^2}} \tag{4}$$

Fatigue life estimation can be computed introducing the Probability Density Function (PDF) of the equivalent stress using the Dirlik's method:

$$p(S) = \frac{1}{\sqrt{m_0}}\left[\frac{B_1}{Q}e^{-Z} + \frac{B_2 Z}{T^2}e^{-\frac{Z^2}{2T^2}} + B_3 Z e^{-Z^2}\right] \tag{5}$$

Materials Research Proceedings 69 (2026) 1450-1454 https://doi.org/10.21741/9781644904251-254

where the spectral moments are involved $m_i = \int_0^\infty f^i G_\sigma(f)\, df$. More details on the parameters are given in [6].
Finally, the fatigue life T of a composite laminate under random vibration loading is computed as

$$T = \frac{1}{\nu \int_G^\infty \frac{p(S)}{N(S)}\, dS} \tag{6}$$

where $\nu = \frac{1}{2\pi}\sqrt{\frac{m_2}{m_0}}$ is the number of the stress cycles in a unit of time and N(S) is the S-N curve of material.

Results

To validate the proposed approach, numerical results obtained via CUF-based modeling are compared with simulations performed in Femap/NX Nastran commercial software. The fatigue life is estimated for several composite laminates with different stacking sequences: $[90/-45/45/0]_s$, $[0/45/-45/90]_s$, $[0/90/0/90]_s$, and $[-45/45/-45/45]_s$. The specimen is clamped-free with geometry dimensions as in [10] and subjected to a bending excitation corresponding to a constant base acceleration PSD of 0.5 g^2/Hz. The same methodology is applied to an aluminum specimen as an isotropic reference case, which, as expected, exhibits a significantly shorter fatigue life. In Fig. 1, the root mean square (RMS) of the specimen with lamination of $[90/-45/45/0]_s$, showing that the fatigue hotspot of the composite specimen is near the hole in point P.

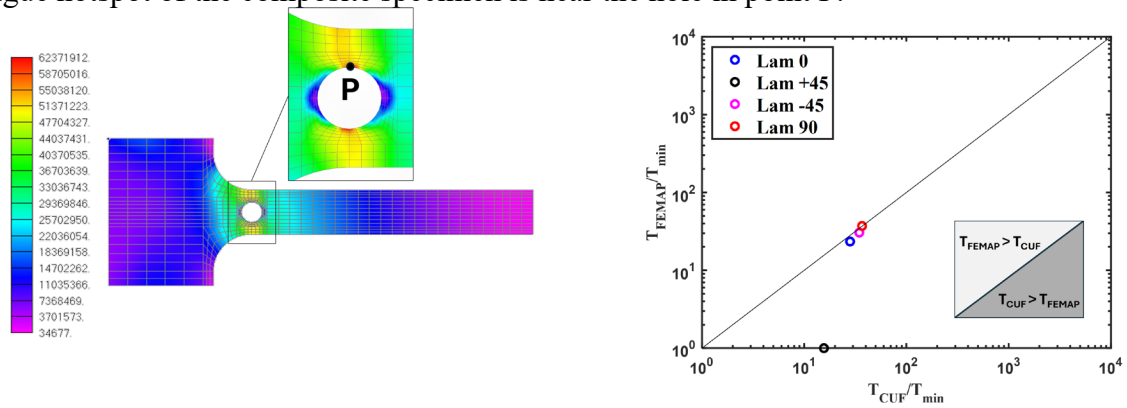

Figure 1. Root mean square (RMS) of global structure at left. Evaluation and comparison of fatigue life of specimen in point P for laminate $[0/45/-45/90]_s$ at right.

The fatigue life estimation of laminate $[0/45/-45/90]_s$ for each layer is shown in Fig. 2. In Table 1, the fatigue life and RMS of four different laminates are shown and compared with the aluminum specimen, which shows shorter fatigue life. For the metallic structure, the Von Mises criteria is applied to evaluate G_{eq}. It is important to notice that the RMS value alone is not fully representative of the fatigue life, as the PDF also plays a crucial role. This is evident from the Fig. 2, where the specimen with the lowest RMS value, corresponding to the $[0/90/0/90]_s$ laminate, does not exhibit the highest fatigue life. This highlights that the PDF has a fundamental influence on the fatigue response.

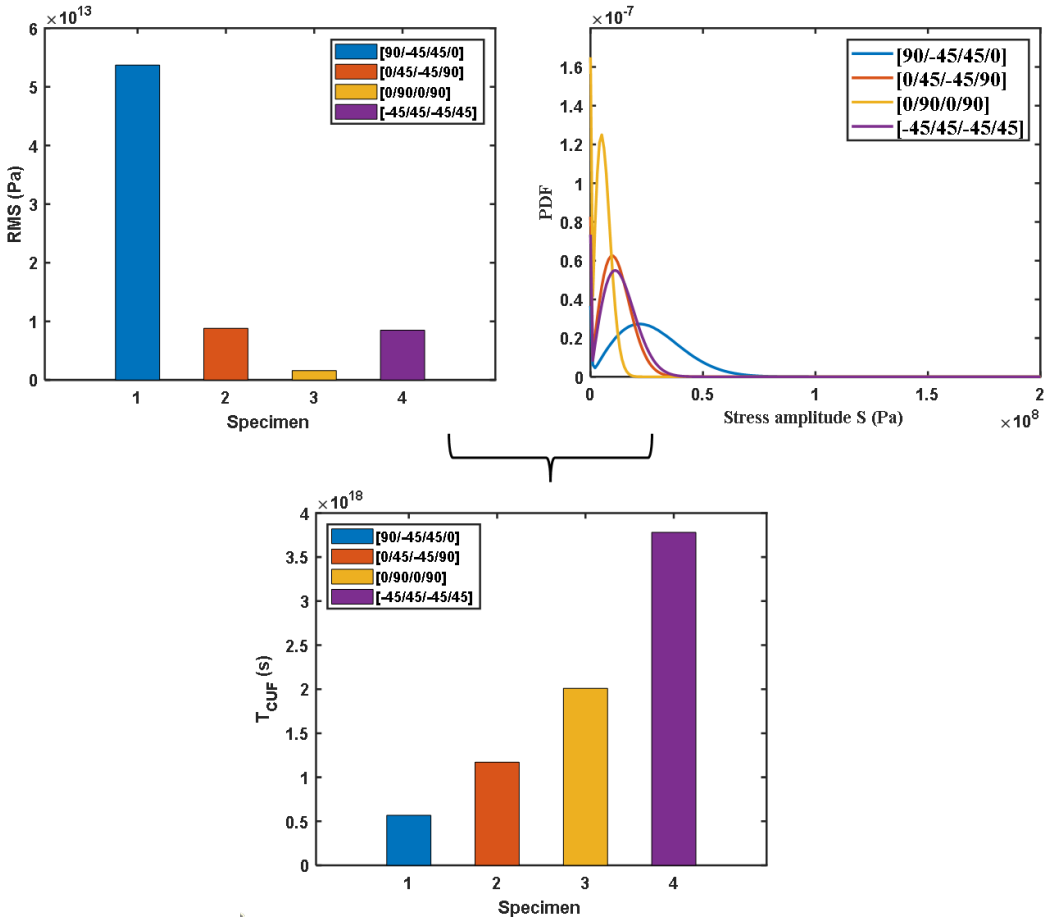

Figure 2. RMS, PDF, and fatigue life using the CUF model of composite with four different laminations $[90/-45/45/0]_s$, $[0/45/-45/90]_s$, $[0/90/0/90]_s$, and $[-45/45/-45/45]_s$.

Conclusions

This paper investigates the use of the CUF-FEM approach combined with the Tsai–Hill failure criterion to predict the fatigue life of composite structures under random excitation. The results are presented in terms of power spectral density, probability density function, and estimated fatigue life. The numerical study considered four composite specimens with different stacking sequences and compared them with an aluminum specimen. The results show good agreement with those obtained using commercial software and demonstrate that the proposed methodology, combining CUF with the frequency-domain approach based on the equivalent stress model, can be effectively applied to multi-axial fatigue analysis.

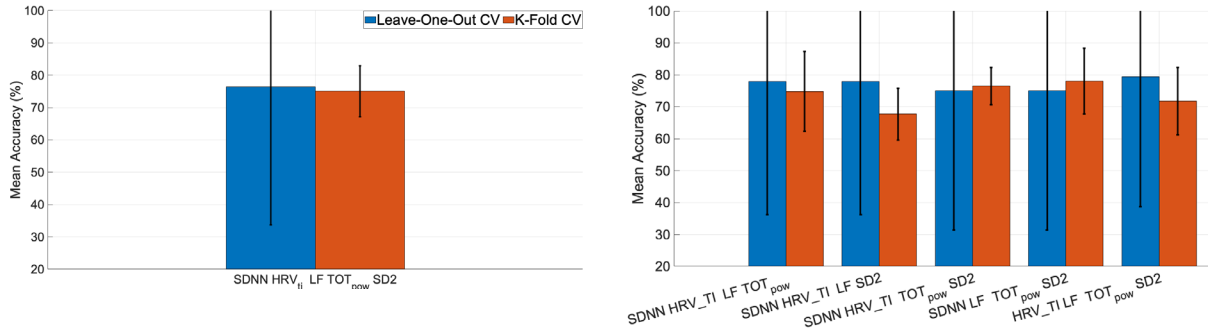
Keywords: Mental Workload Monitoring, Heart Rate Variability, Random Forest Classification, Aviation Human Factors

Abstract. In aviation, continuous monitoring of pilots' mental workload is vital to ensure safety and performance, as cognitive overload or underload can affect decision-making and situational awareness. This study explores the use of heart rate variability, a physiological marker linked to mental effort, for real-time MW assessment using wearable bio-sensors. A Random Forest machine learning algorithm is applied to classify workload levels, exploiting its robustness, interpretability, and ability to model complex feature interactions. The study evaluates RF performance across different settings to find the best configuration for the development of an embedded cockpit support system. Results are evaluated against a Kriging model to assess comparative effectiveness.

Introduction

In the high-risk aviation environment, the continuous assessment of pilots' Mental Workload (MW) is critical for maintaining operational safety and performance. Mental overload or underload can compromise decision-making, situational awareness, and reaction times. Recent advances in wearable bio-sensing technologies have opened new possibilities for non-intrusive, real-time monitoring of physiological signals, which can be used to infer cognitive states [1]. Among these signals, Heart Rate Variability (HRV) has emerged as a promising indicator due to its established links with autonomic nervous system activity and mental effort. The present study investigates the application of the Random Forest (RF) machine learning algorithm [2] to HRV data for the classification of mental workload levels in pilots, aiming at the development of a real-time, embedded system for intelligent cockpit support. This work focus on exploiting the strengths of the Random Forest algorithm, namely robustness, interpretability, and the capacity to handle complex feature interactions, to obtain a reliable classifier capable of distinguishing between multiple workload conditions. A key objective is to evaluate the algorithm's performance across various settings and identify optimal configurations for real-world deployment. The results obtained through the RF are also compared with Kriging model ones [3].



Materials and method

The RF model has been exploited in literature for pilot's MW analysis. For instance, in [4] the Electrocardiogram (ECG) signals collected for 18 pilots subjects were processed and classified in order to estimate if the pilot is in a distracted state or not. Different classification algorithms were employed, namely, the K- Nearest Neighbour (KNN), Decision Tree(DT), Random Forest (RF), Naive Bayes (NB), and Gradient Boosting Machine (GBM). The results reported by the authors have demonstrated an accuracy of the RF model of the 90 %. In [5] electroencephalogram (EEG) data were collected from ten collegiate aviation students during a live-flight scenario in a single-

engine aircraft. The data were then processed using a stacking model algorithm in which the first level was implemented by a RF algorithm. Moreover, in [6] the feasibility of a headset-based system for pilots MW has been studied. Twenty-one male pilot cadets participated in the experiment, and their EEG data were recorded and processed using different classifiers, including three SVM-based models, one KNN, and an RF classifier. The RF model has shown an accuracy of the 86.5 %. Given the promising results obtained in literature for pilot's MW analysis using RF models, in this work the application of RF purely based on HRV data is studied to preliminary assess the application of this tool in real time scenarios. The dataset for training and test of the RF was collected in a controlled environment simulating aviation tasks with varying cognitive demands. Participants were subjected to task conditions designed to induce different levels of mental workload. During these tasks, physiological data were recorded using wearable ECG devices. From the raw signals, a set of HRV features was extracted, namely SDNN, HRV_{TI} , LF, TOT_{Pow}, and SD2 [7]. First, the analyses focused on determining whether specific combinations of features can enhance the predictive accuracy of the Random Forest algorithm. To investigate this, all possible combinations of the 5 features were systematically generated and evaluated. For each combination two procedures have been explored and compared, i.e. Leave-One-Out Cross-Validation (LOOCV) and Stratified k-fold cross-validation [8].The results in Figure 1 show that among the feature combinations, the best performance was achieved using SDNN and SD2 features while the worst performance came from the combination of SDNN and HRV_{TI} .

After refining the dataset, performance studies were performed. Specifically, it has been investigated how the number of trees in the forest and the proportion of training and test data affect performance, using a stochastic approach. The evaluation was carried out using standard performance metrics: Out-Of-Bag (OOB) error, Precision, Recall, and F1-score [9]. Moreover, being defined the best combination of training percentage and number of trees in the forest the hyper-parameters maximum depth and minimum samples per split were investigated. From the analyses carried out it has been found that the best RF configuration involved 300 trees, a trees depth equal to 2, and minimum 8 samples per split. Last, the best average performance metrics obtained from the parametric studies are summarized in Table 1 and compared with those achieved using a Kriging model, highlighting that the Random Forest algorithm outperforms the Kriging one.

Table 1: Performance metrics

Model	Class	Precision	Recall	F1 Score	Test Accuracy
Random Forest	Low	0.80	0.80	0.79	83%
	High	0.77	0.75	0.74	
Kriging	Low	0.77	0.65	0.65	70.6%
	High	0.69	0.82	0.71	

Conclusions

This study explored HRV features from non-invasive ECG signals as indicators of pilots' mental WL during flight. Data were collected from certified pilots in a fully controlled flight simulator experiment. Results showed that a RF classifier outperformed a Kriging-based model in distinguishing low and high WL. The combination of SDNN and SD2 features achieved the highest accuracy (83%), demonstrating RF's robustness and reliability in capturing autonomic responses to cognitive demands.

Keywords: Pilot-Induced Oscillations, Principal Component Analysis, Convolutional Neural Network, Wavelet Transform, Flight Simulators

Abstract. This study proposes a PIO detection algorithm based on a convolutional/fully connected regression neural network that processes PCA-reduced flight data from wavelet-transformed signals. The model achieved a correlation of 0.88, according to the modified Pearson Correlation Coefficient, with Principal Component Analysis enabling a two-order-of-magnitude dataset reduction and improved training efficiency.

Introduction

Pilot-induced oscillations (PIO) remain a persistent and safety-critical challenge in the field of aircraft handling qualities. These undesired and potentially destabilizing oscillations arise from closed-loop interactions between the pilot and the aircraft, particularly during high-precision control tasks or in the presence of time delays. Despite extensive research leading to various prediction methodologies, PIOs are still difficult to detect and diagnose objectively, whether in real flight tests, operational missions, or simulator-based evaluations.

Traditionally, the detection and evaluation of PIOs have relied on the Pilot-Induced Oscillation Rating Scale (PIOR), a subjective metric assigned by test pilots during handling qualities assessments. The PIOR spans from Grade 1 (no PIO tendencies) to Grade 6 (sustained, hazardous PIOs), offering a standardized framework for severity classification [1]. However, because it depends on human perception, it introduces variability and limits reproducibility across different evaluators and test conditions [2]. To address these limitations, some objective, data-driven identification methods have been developed [3]. These techniques use control input and aircraft response signals to detect the onset of PIO. However, aligning their outputs with pilot assessments remains a significant challenge due to differences in sensitivity, interpretability, and underlying assumptions.

Machine learning techniques have also been investigated for PIO detection. In a previous study [4], a Convolutional Neural Network (CNN) was proposed to identify patterns associated with PIO within stick deflection and pitch rate signals. These signals were represented in the time–frequency domain using the Wavelet Transform. Although this approach produced outputs in the same framework of the PIOR scale, it exhibited limitations in classification accuracy and faced challenges during training due to the substantial computational time, complex network architecture, and memory requirements imposed by the dataset size.

To address these limitations, Principal Component Analysis (PCA) presents a promising complementary technique when integrated with CNNs. PCA transforms the data into a set of orthogonal components, reducing feature correlation and dimensionality, which simplifies the dataset and can enhance model efficiency and performance [5].

Accordingly, this work introduces a CNN-based method for PIO detection, leveraging a flight dataset in which stick deflection and pitch rate signals are processed using the Wavelet Transform followed by Principal Component Analysis (PCA).

The Dataset

The dataset used in this study was collected during a flight test campaign conducted in a fixed-base flight simulator. In this campaign, ten formally trained test pilots, all familiar with the PIOR scale, participated in eight variations of a pitch-angle tracking task. The task was presented as a moving target on a simulated artificial horizon. To track the target, the pilots used a centrally positioned, right-hand joystick to control a linear aircraft model representative of a FAR 25 aircraft in cruise flight at 40,000 feet and Mach 0.8. Fig. 1 illustrates the flight simulator setup used in this campaign.

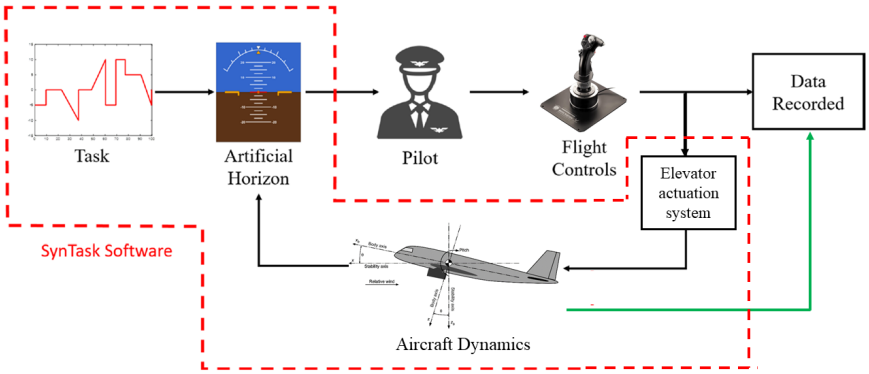

Figure 1: Flight Simulator campaign schematics [4].

Six variations of the aircraft model were generated by arbitrarily modifying the $C_{m\dot{\alpha}}$ stability derivative. These modifications allowed the pilots to experience six levels of PIO proneness, ranging from the least prone (baseline) to the most critical condition (unstable short-period) [4].

The flight test campaign thus comprised a total of 480 simulation runs. For each run, the stick deflection and corresponding pitch rate time series were recorded, together with a PIOR scale assessment assigned by the pilot at the end of the simulated flight. From a machine learning perspective, the raw dataset consists of samples comprising two-channel inputs (stick deflection and pitch rate) each associated with a corresponding PIOR label.

The Wavelet Transform

One way to enrich the information contained within time-series data is through the application of the Wavelet Transform. This is a multi-scale time-frequency transform particularly suited for non-stationary signals, which are common in piloting scenarios, including those involving PIO [4]. The Wavelet Transform was therefore applied to both the stick deflections and pitch rate time-series, generating an expanded dataset to be used by the PIO detection algorithm.

The definition of the Wavelet Transform is given by Eq. 1:

$$W(\tau, f) = \sqrt{f} \int_{-\infty}^{\infty} x(t) \Psi^*\big(f(t-\tau)\big) dt \quad (1)$$

Materials Research Proceedings 69 (2026) 1460-1465 https://doi.org/10.21741/9781644904251-256

where x and Ψ^* are the analysed signal and the complex conjugate of the wavelet function, respectively. For this analysis, the Morlet wavelet function was employed. The parameters τ and f correspond to the time and frequency axes of the transform output, respectively.

Following the transformation, each time-series produced an output matrix of dimensions 512x941. In this representation, the rows correspond to the discrete frequency axis, while the columns correspond to the discrete time axis. The absolute value of each element was then computed to represent the magnitude of the transformation.

At this stage of preprocessing, the dataset consisted of 480 samples represented as two-channel magnitude matrices, rather than time-series, with a total size of approximately 1.8 GB. As mentioned previously, this dataset format and size posed challenges during the PIO detection algorithm training process, increasing training time and constraining the network architecture in terms of complexity and efficiency [4].

Principal Component Analysis

The resulting wavelet matrices, also referred to as scalograms, were subsequently processed using Principal Component Analysis (PCA) [5]. In this analysis, each PCA sample (not to be confused with a dataset sample) corresponds to a scalogram row representing the frequency axis, while each PCA feature corresponds to a scalogram column representing the time axis.

This preprocessing stage began by calculating the mean value across the rows of each scalogram and subtracting it from the original matrix, yielding the centralized scalogram (S). The covariance matrix (C) was subsequently derived in accordance with Eq. 2.

$$C = S^T S \tag{2}$$

The next step involved computing the eigenvalue and eigenvector matrices associated with the covariance matrix. The eigenvalues indicate the proportion of variance (or influence) each component contributes when the scalogram is projected onto its corresponding eigenvector. Based on this analysis, the 31 most significant eigenvectors were selected to form the reduced eigenvector matrix ($V_{reduced}$). The scalograms were then transformed to the reduced coordinate space through a coordinate change operation, as described in Eq. 3.

$$S_{reduced} = (V_{reduced}^T S^T)^T \tag{3}$$

The new dataset, composed of the reduced scalograms ($S_{reduced}$), has a total size of approximately 60 MB, representing a reduction of two orders of magnitude compared to the wavelet data, without losing the most relevant information potentially associated with PIO signatures.

The PIO Detection Algorithm

The PIO detection algorithm was designed as a neural network that processes the PCA-transformed dataset as a two-channel input, representing the stick deflection and pitch rate signals in their PCA-reduced forms, and produces a PIOR scale grade as output. The architecture integrates a Convolutional Neural Network with seven convolutional layers, followed by a Fully Connected Network composed of three layers, as represented in Fig. 2.

Materials Research Proceedings 69 (2026) 1460-1465 https://doi.org/10.21741/9781644904251-256

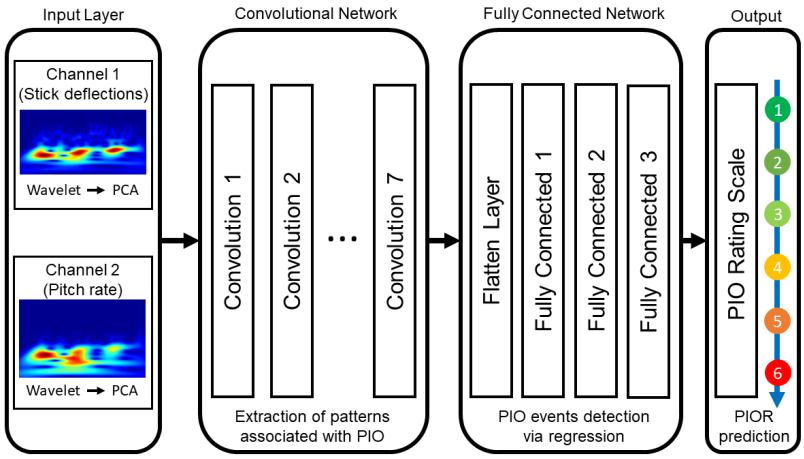

Figure 2: The PIO detection algorithm architecture.

The algorithm was trained by comparing the predicted PIOR output value with the corresponding true PIOR label for each PCA data sample. Consequently, the network functions as a regression model. Training was conducted using the Huber loss function and the Weighted Adaptive Moment (AdamW) optimization algorithm.

Before the training process, 20% of the samples were separated from the dataset to form the test set. The remaining data were used for model training through a stratified K-fold cross-validation procedure, in which the dataset was divided into training and validation folds. A total of nine folds were employed, resulting in nine independent training iterations, each performed with a distinct configuration of training and validation data.

Results

Accordingly, each model version produced a PIOR grade prediction (Y_k) for each dataset sample. The final ensemble prediction ($Y_{ensemble}$) was obtained by averaging the outputs of all model versions, as defined in Eq. 4, where n is the number of folds. This ensemble approach reduces the variance among each model version predictions and enhances the robustness of the overall estimation.

$$Y_{ensemble} = \frac{1}{n}\sum_{k=1}^{n} Y_k \tag{4}$$

To compare the ensemble predictions with the true PIOR labels ($Y_{observed}$), which were provided by the pilots in the simulator campaign, the R_{match} metric was employed [6]. This metric, defined in Eq. 5, is a modified version of the Pearson Correlation Coefficient that quantifies the degree of linear correlation between the predicted and observed PIOR grades. In essence, it evaluates the regression accuracy of the ensemble model.

$$R_{match} = \sqrt{1 - \sqrt{\frac{\sum(Y_{observed} - Y_{ensemble})^2}{\sum Y_{observed}^2}}} \tag{4}$$

Fig. 3 illustrates the PIO detection performance on the best validation set, yielding an R_{match} value of 0.95. This result demonstrates that the network effectively captured PIO-related features and established a strong correlation with the corresponding PIOR labels. For the test set, the R_{match} value decreased to 0.88, indicating mild overfitting, as this subset remained unseen throughout the training process.

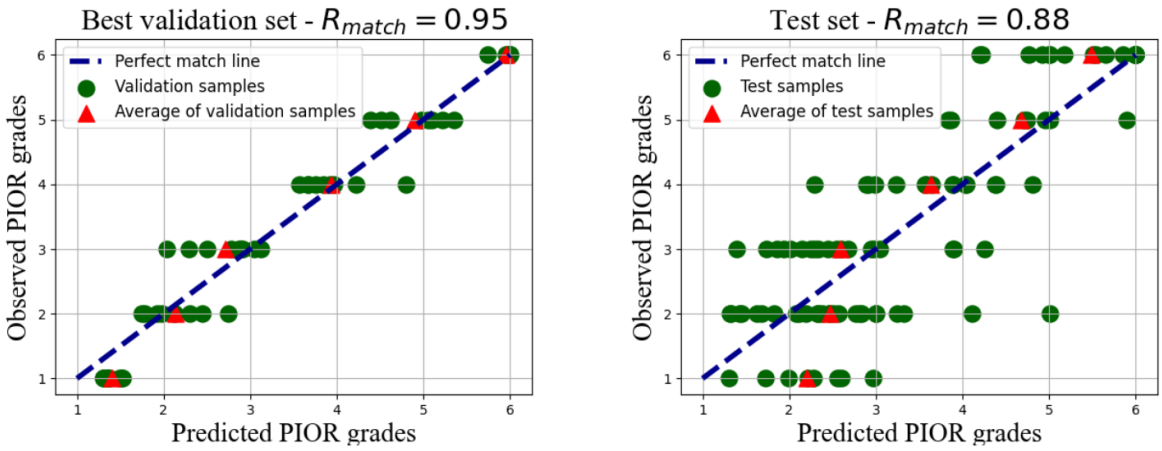

Figure 3: PIO detection results obtained from the best validation set and the test set.

It can be observed that the individual test samples exhibited larger deviations from their corresponding true PIOR labels, whereas these deviations were considerably smaller for the validation samples. However, the average predicted PIOR values for the test set were very close to the perfect match line, which explains the high R_{match} value, with the notable exception of PIOR 1. For this grade, the mean predicted value was higher than that of PIOR 2, indicating that the algorithm was unable to clearly distinguish between these two ratings. According to results obtained from pilot behaviour models reported in the literature [6], this lack of distinction between PIORs 1 and 2 is expected for datasets collected using a fixed-base flight simulator. This suggests that the accuracy of the PIO detection algorithm could be improved if real flight data were used during the training process.

The use of PCA preprocessing in this study enabled an increase in the complexity of the proposed algorithm, allowing the implementation of seven convolutional layers—compared to the four used in the previous study [4], as well as the addition of an extra fully connected layer. Because the PCA-processed dataset is two orders of magnitude smaller than the wavelet-based one, more epochs per fold could be executed during training. This reduction in data size made it feasible to employ a regression model rather than a classification model, as regression models typically require slower convergence.

Conclusion

It can be concluded that the algorithm was capable of providing moderate to high accuracy in PIO identification, with the exception of PIOR 1. As suggested in the literature, this limitation may be attributable to the nature of the dataset (fixed-base flight simulator) rather than the methodology itself, although further investigation is necessary. The PCA preprocessing offered several advantages, including enhanced model convergence during training and increased network complexity, enabling the inclusion of additional layers to more effectively extract PIO-related features.

Integrated Rotorcraft Stability through Pilot Biomechanics: A Human Factors Perspective

Andrea ZANONI[1,a] and Pierangelo MASARATI[1,b,*]

Keywords: Pilot Biomechanics, Rotorcraft-Pilot Couplings, Stability

Abstract. Aircraft- and Rotorcraft-Pilot Couplings remain a critical concern for handling qualities and flight safety. Pilots play a central role, yet fully understanding their contribution and the factors that govern it remains an open challenge. Awareness of adverse couplings and their potential impact on operations is essential for testing protocols and training syllabi.

Introduction

Aircraft- and Rotorcraft-Pilot Couplings (APCs and RPCs), undesirable interactions between pilot biomechanics and vehicle dynamics, continue to challenge handling qualities and flight safety [1, 2]. Over the past fifteen years, research has focused on modeling pilot biodynamic feedback and assessing its influence on vehicle stability and control. Building on these contributions, this paper aims at reframing RPCs from a human-centered perspective, examining how pilot biomechanics, transmitted through biodynamic feedthrough (BDFT), shape handling qualities.

Early studies showed that involuntary pilot body motion, particularly of the arm and torso, closes a biomechanical feedback loop that affects control inceptor inputs and vehicle response. For example, Quaranta et al. [3] used robust control techniques to treat pilot biodynamics as model uncertainty, quantifying proneness to RPC under collective-bounce excitation. Gennaretti et al. [4] explicitly examined BDFT in RPC onset, identifying mechanisms by which pilot body dynamics degrade damping and excite resonance modes.

Subsequent work deepened biomechanical modeling. In [5], multibody models of the spine, torso, and limbs were calibrated against experimental input data collected in passive (involuntary, control-unrelated) tasks, while [6] extended this to bioaeroservoelastic modeling, formalizing pilot body impedance contributions across flight axes. Masarati et al. [7] further investigated the role of muscular activation, showing how co-contraction patterns influence transmissibility and phase lag.

These developments, along with contributions such as [8, 9, 10]), emphasized the relevance of biomechanical modeling for pilot-vehicle system stability and handling qualities, and revealed task-dependent variability driven by posture, muscle tone, and workload.

Quaranta et al. [11] provided a comprehensive overview of aeroelastic RPC phenomena, consolidating modeling approaches, validation strategies, and classification schemes. Numerical studies of specific RPC events, such as collective bounce [12] and lateral oscillations [13], used simplified yet representative rotorcraft models, incorporating the participating rotor states and highlighting the most influential parameters.

More recently, Zanoni et al. [14] introduced a conceptual-design methodology embedding handling qualities and pilot response variability, motivating the inclusion of biomechanics early in design. This view of RPC-informed flight simulation was reinforced in simulation-focused studies such as [15].

Pilot Biomechanics as a Rotorcraft Control Subsystem

Building on these foundations, the present study treats pilot biomechanics as an active subsystem within rotorcraft control dynamics [16], with direct implications for human factors. Instead of representing the pilot purely as a command source, we model biodynamic feedthrough—anatomical impedance shaped by resonances and reflexive dynamics—as an integral component of the closed-loop response, affecting both stability and perceived handling qualities.

Pilot biomechanical models derived from experimental data and detailed multibody simulations are integrated into pilot-in-the-loop simulation campaigns that use mid-fidelity rotorcraft models of medium-lift utility helicopters and tiltrotor aircraft. Experimental data collected using the RPC testbed (Fig. 1) and robust modeling methods support an evaluation of performance metrics (RMS control input, task performance, workload) across hover, low-speed maneuvering, and obstacle-avoidance tasks inspired by ADS-33 [17] (Fig. 2). Following [14, 18], we explicitly incorporate pilot biomechanics into these investigations.

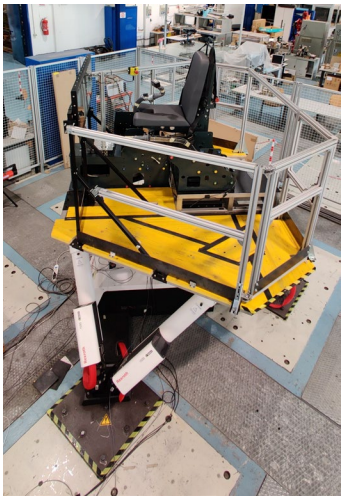

Figure 1: RPC testbed.

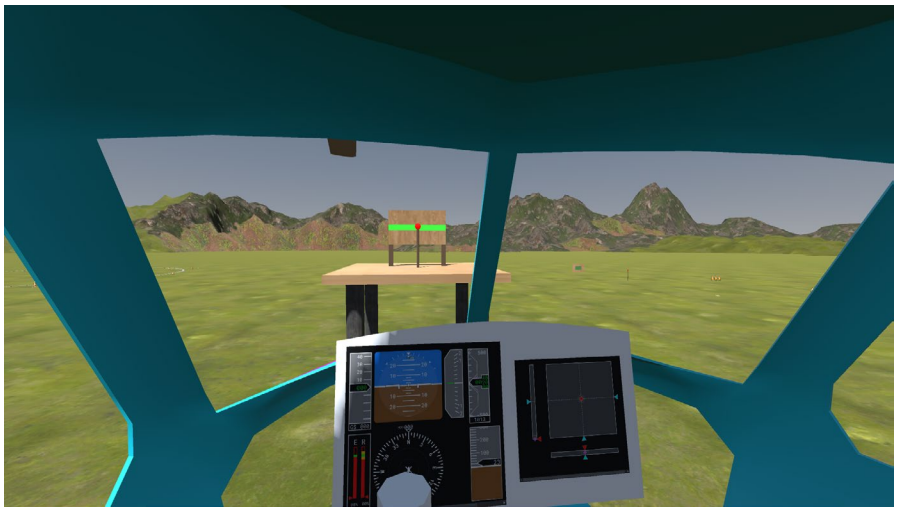

Figure 2: VR pilot view for ADS 33 vertical positioning.

A biomechanical sensitivity analysis was performed based on experimental data (Figs. 3 and 4). Key where pilot body parameters (stiffness, damping, mass distribution, reflex latency) were varied to emulate different postures and neuromuscular states. Stability margins, phase lag, axis coupling, and limit-cycle tendencies were evaluated under both linear and nonlinear control laws. Resonant modes were typically found in the 3–7 Hz range, overlapping rotor excitation frequencies (e.g., coning and slow cyclic lag modes in the non-rotating frame), thus influencing control fidelity.

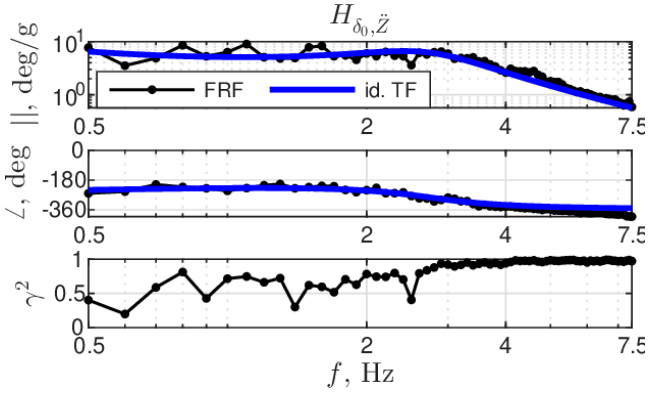

Figure 3: example BDFT identification of collective rotation due to vertical acceleration.

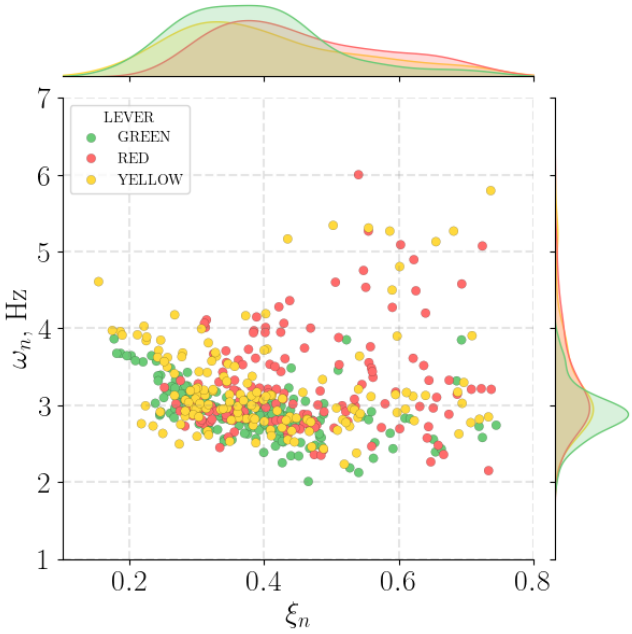

Figure 4: example of experimental distribution of BDFT dominant pole frequency ω_n and damping ξ_n for 15 subjects and 3 different collective levers.

The results indicate that anatomical resonance can reinforce lightly damped rotorcraft modes, potentially inducing instability or limit cycles, particularly under collective bounce conditions. Inter-pilot variability (e.g., BMI, posture, muscle co-contraction level) can qualitatively alter system behavior. Incorporating biomechanical modeling in early handling-qualities assessment reveals vulnerabilities not captured by conventional methods. Adaptive mitigation strategies, including seat damping, inceptor-response tuning, and control-law augmentation, can mitigate feedthrough-induced degradation while maintaining pilot authority.

The Way Forward

This perspective motivates revisiting both training and certification practices. Several questions remain open, such as:

- How do individual physical characteristics influence pilot control strategy?
- Can simulators meaningfully emulate posture-dependent biomechanical effects for training?
- Should aeromechanical stability clearance (and eventually certification) include robustness margins across a population of biomechanical models?

Introducing biodynamic sensitivity analysis into handling-quality frameworks may offer more robust design criteria by extending traditional bandwidth/phase-delay requirements. Simulator testing and pilot training should likewise incorporate posture- and stiffness-dependent modeling into protocols and syllabi, respectively, to raise awareness of involuntary control coupling.

Keywords: Single Pilot Operations, Electronic Flight Bag, Flight Deck, Human-Machine Interface

Abstract. Recently, industry has worked on concepts for reducing active flight crew in cruise while one crew member is resting (extended Minimum Crew Operations, eMCO). The project Next generation Intelligent Cockpit (NICo) of the German Aerospace Centre (DLR) aimed to develop assistance systems in the context of single pilot operations (SiPO) to support and relieve pilots in phases of high workload. To assist pilots with considering options for an alternate airport in case of urgent diversions, DLR has designed an electronic flight bag (EFB) application that calculates in-flight and landing performance and provides a ranking of suitable airports. Four criteria comprising distance, fuel on arrival, stop margin and crosswind defined suitability. In a previous pilot survey, these criteria were identified as important when deciding where to divert. The aims of a simulator study were to assess the functionalities of the EFB application and to gain pilot feedback on its usability and suggestions for further development. Focus was laid on investigating whether the equal weightings are consistent with the pilots' reasoning. Seven crews of two pilots with current or past Airbus A320 type rating performed a scenario in the DLR AVES full-motion A320 simulator. In this study, crews had to decide whether they would divert to an alternate airport when encountering a non-time-critical malfunction in adverse meteorological conditions. The pilots made use of the EFB application during their FORDEC process resting importance on its comprehensible ranking mechanism. In a preliminary analysis of results, it became evident that pilots rated the EFB application favourably and would consider using it in real operations when faced with the need to divert from the planned destination. Pilots experienced little workload throughout the scenario which shows that the EFB application is intuitive, helpful and lowers the workload in a potentially stressful situation.

Introduction

As global air traffic is forecast to grow significantly in the future and qualified aircrew is becoming scarce [1], concepts of reduced crew operations (RCO) have been investigated [2]. In recent times, the industry has been focussing on developing ideas to minimise the number of active crew members during cruise while one crew member is resting (extended Minimum Crew Operations, eMCO) [3]. Further reductions would lead to single pilot operations (SiPO) albeit neither concept is yet certified for EASA CS-25 aircraft. The project Next generation Intelligent Cockpit (NICo) of the German Aerospace Centre (DLR) aimed to develop assistance systems in the context of SiPO to support and relieve pilots in phases of high workload [4]. These systems should not only be of use for SiPO but also for common multicrew operations.

Materials Research Proceedings 69 (2026) 1471-1474 https://doi.org/10.21741/9781644904251-258

Pilots are trained to adhere to the FORDEC or similar decision-making schemes. The mnemonic acronym FORDEC abbreviates the steps of collecting Facts, generating Options, analysing Risks and benefits, making a Decision, Executing it and Checking its adequacy over time [5]. According to recent expert interviews, pilots would welcome additional support, particularly with the FORDEC decision-making steps [6]. However, the experts emphasised that the final decision and its execution must remain the responsibility of the human crew or pilot, not an automated system.

DLR has created an electronic flight bag (EFB) application to support pilot's decision-making bearing in mind the FORDEC process. It should assist mainly with the categories Facts, Options, and Risks of FORDEC when exploring alternatives for a diversion. The application calculates and evaluates in-flight and landing performance to suggest suitable airports. The suitability of airports was determined by four key factors: distance, fuel on arrival, stop margin, and crosswind. Initially, these factors were given equal weight using the multi-criteria decision-making approach TOPSIS [7]. Findings from a previous pilot survey confirmed the importance of these criteria in determining where to divert [8]. The aims of the present study were thus to assess the feasibility of the EFB application and to get pilot feedback on its usability.

Methods

Fourteen pilots which hold or held an Air Transport Pilot Licence (ATPL) and were rated on the Airbus A320 were recruited to participate in the research study. The mean age of the participants was 49.36 (standard deviation, SD = 12.38) years. The average hours of flying experience were 14740 (SD = 10870). Seven pilots were first officers or captains, respectively. Categorised by their most recent operations, five were flying long-range while nine were flying short-range flights.

For each experiment run, a crew of two pilots was seated in the Airbus A320 replica as part of the Air Vehicle Simulator (AVES) and was provided with the application under research on both EFB. After a familiarisation scenario, the main scenario flight was performed with both crew on the simulator flight deck. The pilots were free to choose who would be pilot flying (PF) and pilot monitoring (PM). Shortly after take-off upon retracting the slats and flaps, the crew would encounter a malfunction as the flaps would not fully retract but remained stuck between their 0 and 1 position. The effects of the failure included higher fuel consumption because of increased drag, and longer distance required to land the aeroplane. Due to adverse weather conditions at several airports, the pilots needed to consider carefully where to divert.

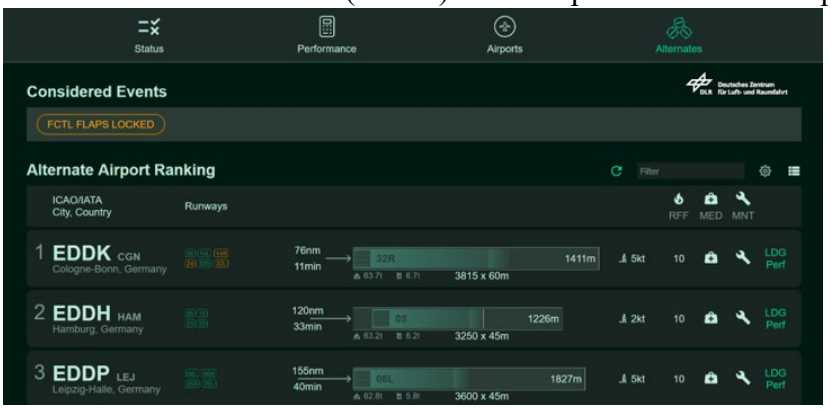

Figure 1. Alternates page

The EFB app features four main pages, i.e. a status page, a performance page, an airports page and an alternates page. The most important page is the alternates page where a ranking of airports suitable for a diversion is provided (cf. Figure 1). Suitability is defined by the four aforementioned criteria comprising distance, fuel on arrival, stop margin and crosswind. These are weighted equally by default using the multi-criteria decision-making method TOPSIS. Pilots are able to modify the weightings relatively. The status page informs the pilots about the effects of a detected failure and its influence on the app's calculations, e.g. increased fuel consumption. Also, considered Notices to Airmen (NOTAM) are shown. The other pages present the performance

Materials Research Proceedings 69 (2026) 1471-1474 https://doi.org/10.21741/9781644904251-258

calculations for each runway of a selected airport and a list of airports with prevailing weather conditions.

The underlying calculations provide the distance and remaining flight time to each airport, as well as estimates of landing performance, i.e. required landing distances and speeds that are computed failure-dependent. In the given scenario, the flaps locked fault led to higher approach speeds and increased distances needed at landing. The system also considers any predicted crosswind and potentially higher fuel consumption. On the performance page, pilots can adapt input values like the runway condition and wind speed, or indicate the use of reverse thrust. Both pilots were provided the application on their respective EFB devices that were mounted to the side-wall panels of the flight deck. The EFB were not synchronised but allowed for individual use.

The questionnaires employed in the research included one about demographics (i.e., age, gender, nationality, position, aircraft types, flight hours), one about the different features of the EFB app, one about ergonomics (i.e., situational awareness, trust, task sharing), and the NASA Task Load Index (NASA-TLX) [9].

During the scenario flight, data from the simulator as well as video and audio were recorded. The former included flight dynamics parameters, and aircraft system states, while the latter two comprised a view of the flight deck, screencasts from instruments, and communication between flight crew, simulated ATC, and researchers.

Results

The NASA-TLX questionnaire was administered upon concluding the experiment. Figure 2 shows the average weighted scores of twelve of the subjects across the dimensions mental demand (MD), physical demand (PD), temporal demand (TD), performance (PE), effort (EF), and frustration (FR), as well as the aggregate task load index (TLX). Two participants did not fill out the questionnaire and are thus not included in the results. On average, the pilots indicated a TLX of 7.41 which is fairly low on a scale from zero to 100. Partial scores of mental demand were the highest and those of frustration the lowest.

Valuable feedback on features and user interface of the application was received, including suggestions to increase button size, include a map, and provide a return button. All pilots indicated that the app's pages were intuitive to use. Many pilots affirmed that its features were useful.

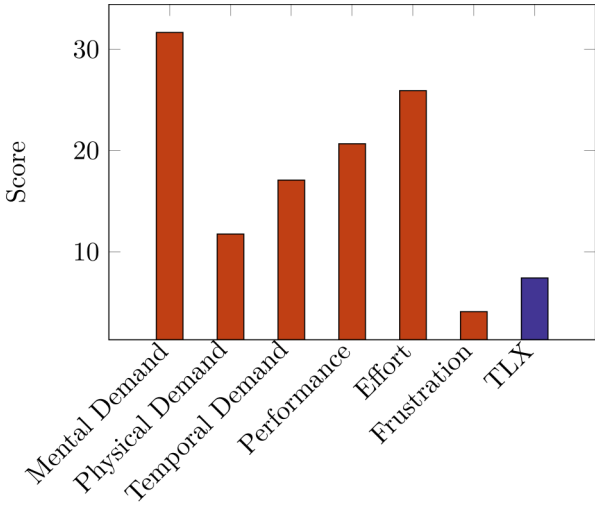

Figure 2. NASA-TLX average weighted scores

Discussion

The research aimed to assess the feasibility of a newly developed EFB application that should support pilots' decision-making when considering options where to divert. The results revealed that pilots rated the app favourably and found its features useful, particularly the alternates ranking which is based on a multi-criteria decision-making method. Pilots rested importance on the comprehensibility of the ranking mechanism.

Pilots experienced low workload throughout the scenario and were on average little demanded nor frustrated. This supports the statement that the EFB app is not an additional burden on them. For a different scenario where pilots operated spatially separated and without the EFB app, Niedermeier et.al. [4] reported that pilots felt rather overwhelmed and not able to deliver their full performance. Especially in such scenarios with high workload, the app could be of use.

The results need to be interpreted within the confines of the research. All participants volunteered, potentially leading to self-selection bias and the sample was relatively small (14 pilots). This limited number of participants does not allow any generalisation of the study results.

Conclusion

Within the project NICo, an exploratory simulator study was performed to assess the feasibility of a newly-developed EFB app in a failure scenario. Although only seven crews took part in the experiments, interesting qualitative results based on questionnaires and crew comments were obtained. Crew comments showed the app's potential for use in commercial operations.

Keywords: Cockpit Monitoring, Scanpath Analysis, Reduced-Crew Operations, Attention, A320 Flight Simulator

Abstract. The proposed reduction in commercial flight crew sizes, together with evolving cockpit operational concepts, introduces significant human factors challenges related to attention management, workload allocation, and pilot–automation interaction. Although such scenarios may be confined to specific flight phases, they highlight the continued importance of robust cockpit monitoring and have intensified interest in digital assistants to support task execution and decision-making. This study presents a comparative assessment of eye-tracking metrics and visual scanning strategies adopted by two professional pilots operating an A320 full-flight simulator. A representative short-haul mission was performed under nominal and abnormal conditions, including a hydraulic failure, in both dual- and single-pilot configurations. Gaze data were collected using Tobii Pro Glasses 3 and analyzed through an area-of-interest–based approach to characterize scanning pattern complexity. Preliminary results indicate distinct monitoring behaviors across conditions, largely influenced by the presence and modality of assistance.

Introduction

Visual monitoring is essential for commercial piloting, as it enables the continuous construction and maintenance of situational awareness through structured scan patterns, selective attention, and systematic cross-checking of cockpit information. [1] Persistent shortcomings in monitoring performance, however, continue to contribute to major incidents and crew-related operational errors. [2] This is partly attributable to the vulnerability to fatigue, which can degrade scanning strategies and impair the timely detection of safety-critical events. [3] These observations extend across diverse operational domains, with eye-movement behavior shown to reflect operators' supervisory functions and cognitive states. [4] Concerning aviation, pilots' scanpath organization varies systematically across flight phases, while different expertise levels can affect fixation distributions and visual strategy structures. [5, 6]

Recent advances in eye-tracking technology [7] have enabled precise and largely unobtrusive measurement of gaze behavior in both operational settings and high-fidelity simulation environments. [8] Consequently, these tools are now widely employed for workload assessment, training evaluation [9], and predictive modelling in human–machine interaction [10].

As flight decks progress toward higher levels of automation, the potential transition to reduced crew operations [11] is expected to redistribute attentional resources that currently benefit from cooperative scanning and shared mental models. This shift raises concerns regarding increased attentional demands on the remaining pilot, thereby motivating renewed interest in monitoring behaviors and in the potential contribution of intelligent aiding systems. Despite the valuable

insights provided, the correspondence between eye movements and attention is not perfect, as attentional shifts and peripheral information processing may occur without direct fixation. Accordingly, eye-based measures are most informative when triangulated with complementary data sources.

Experiment and Data Analysis

An experimental campaign was conducted using an Airbus A320 FNPT II MCC simulator at KKtoFly (Collegno, Italy). Two A320 type-rated male pilots each flew the same short-haul mission from Torino Caselle (LIMF) to Rome Fiumicino (LIRF) under dual- and single-pilot configurations, with a qualified co-pilot included when required. For each configuration, two scenarios were tested: (i) a nominal baseline and (ii) a Green + Yellow (G+Y) hydraulic system low-pressure failure, requiring early landing preparation, degraded flight-envelope protections, reduced system redundancy, and predominantly manual control via ECAM-directed procedures. All missions included variable weather and standard ATC interactions, handled by a dedicated operator.

Figure 1 *Single-crew configurations employed for the two pilots.*

As a starting point for single-pilot operations, tasks normally assigned to the co-pilot are assumed to be performed by the captain, although the target scenario involves collaboration with intelligent assistive entities. Two experimental variants were therefore implemented (see *Figure 1*). The first corresponds to an unassisted "all-alone" condition, in which higher workload and monitoring demands are intentionally imposed on the pilot (Pilot 2) to stress and test his condition. By contrast, the second condition provides the pilot (Pilot 1) with a custom software tool on the Electronic Flight Bag that replicates selected overhead-panel functions, executes predefined routines (e.g., overhead configuration and ECAM procedures), and provides continuous feedback. Readers can refer to the left-hand side of *Figure 2*. This assisted mode redistributes task allocation and is expected to influence monitoring strategies and eye-movement behavior.

Materials Research Proceedings 69 (2026) 1475-1480 https://doi.org/10.21741/9781644904251-259

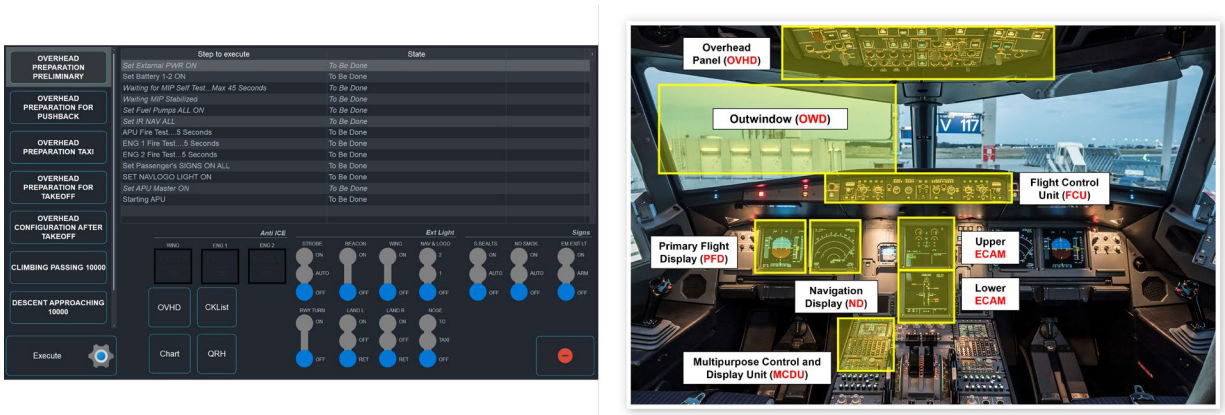

Figure 2 *On the left – A sketch from the Virtual Assistant landing page. On the right – AOI definition inside the A320 cabin.*

Pilot gaze was recorded using Tobii Pro Glasses 3 at 50 Hz and processed using Tobii Pro Lab software. Gaze samples were classified into fixations and saccades. In accordance with established eye-tracking standards [12], fixations were identified using a minimum duration threshold of 120 ms.

The cockpit was partitioned into eight Areas of Interest (AOIs) corresponding to the primary operational displays and interaction zones of the Airbus A320 (*Figure 2*). In the assisted single-pilot condition, a ninth AOI was introduced to capture gaze directed toward the tablet-based Virtual Assistant. AOI definitions were spatially consistent across participants, and samples falling outside predefined regions were excluded. Fixations were assigned to AOIs, and consecutive fixations within the same region were aggregated into dwells.

The analysis focused on a short, operationally relevant flight segment surrounding the failure event, spanning from failure onset to completion of all ECAM actions required to minimally secure the aircraft (i.e., transition to the Status page). This interval captures the critical phase requiring immediate diagnostic and procedural responses.

Results and Discussion

Two complementary analyses were conducted. The first examined scanpath dynamics via gaze transitions between AOIs to characterize the structure and temporal organization of visual scanning. The second quantified attentional allocation using fixation-based metrics, namely Total Fixation Duration (TFD) and Mean Fixation Duration (MFD). TFD reflects overall visual workload, whereas MFD captures the depth of visual processing. As shown in *Figure 3*, scanpaths are analyzed at the AOI level, whereas TFD and MFD are aggregated into functional and thematic AOI clusters to support workload interpretation in terms of general piloting functions. Analyses were conducted both across configurations and between pilots, given the fixed single-pilot condition of interest. Although the overall time window spans only a few minutes, it was sufficient to reveal meaningful differences between conditions. The pilots under analysis always acted as pilot flying, thereby retaining primary control of the aircraft and responsibility for communications.

Analysis of Pilot 2's visual behavior indicates a strong dependence on the crew configuration. In Dual-Pilot Operations (DPO), Pilot 2 directs most visual attention to the Primary Flight instruments, with a dynamic scanpath marked by frequent transitions and short fixations, consistent with shared workload and continuous monitoring on the PFD. No gaze directed toward OVHD was observed during this condition, as these tasks are typically performed by the co-pilot. Under Single-Pilot Operations (SPO), by contrast, attention shifts markedly to the Systems cluster, which dominates both TFD and MFD. Once the failure has happened, PFD monitoring becomes

Materials Research Proceedings 69 (2026) 1475-1480 https://doi.org/10.21741/9781644904251-259

sporadic, and long system-focused dwell periods emerge, especially on ECAM-UPPER and OVHD. FCU involvement decreases sharply, suggesting reduced capacity for flight-control adjustments. The mayday call was observed to occur sooner during SPO, reflecting the absence of cross-checking or probably the latent need to accelerate operations. Overall, Pilot 2's scanpath shifts from broad, high-frequency monitoring with DPO to a system-focused pattern characteristic of increased workload and reduced situational awareness (for SPO).

The same analysis can be done for Pilot 1. In DPO, attention is primarily divided between Systems and Control/Mode, with substantial engagement of Primary Flight instruments. The scanpath remains rich and continuous, supported by effective task sharing. In SPO, Systems monitoring increases—as observed for Pilot 2, yet Pilot 1 maintains recurrent transitions to PFD and ND even after the failure, preserving a more balanced monitoring loop. Scanpaths remain diversified, with short-to-medium dwell times indicative of active management of both flight-path monitoring and diagnostic tasks. The Virtual Assistant appears to redistribute, rather than intensify, workload by supporting ECAM interpretation and procedural structuring, thus reducing prolonged system-focused fixations. A notable drawback is the reduced outside-window scanning, which, although mitigated in this scenario by benign cruise-phase conditions, would not be desirable in other phases of flight. It is also relevant to remember that the pilot received minimal training with the assistant; increased familiarity may further enhance monitoring stability.

Conclusion

This preliminary study examined changes in pilot gaze behavior during abnormal event management across dual- and single-pilot configurations. Despite the limited sample, eye tracking revealed consistent shifts in visual strategies associated with increased workload and changes in monitoring responsibilities. Future work will extend the analysis to more pilots, flight phases, and failure scenarios, and integrate gaze data with performance and workload measures. Beyond reduced-crew operations, this approach may also inform cockpit interface design, assistive tool evaluation, and training for effective monitoring.

Keywords: Rotorcraft–Pilot Coupling RPC, Pilot-Assisted Oscillations PAO, Time-Varying Parameters, Kalman Filter, Parameter Identification

Abstract. This work addresses the estimation of time-varying pilot parameters within Rotorcraft–Pilot Couplings. An analytical, physics-based model with the minimum number of degrees of freedom represents the coupled pilot–helicopter dynamics. Parameter tracking uses sigma-points filtering to capture time-varying parameter characterization. Simulations under diverse conditions accurately reconstruct the trajectories of states and parameters in real time. The approach provides a practical basis for robust online identification and control strategies to mitigate Pilot-Assisted Oscillations.

Introduction

The helicopter's vibrations, inherent to rotor–airflow interactions, degrade controllability and overall safety. Pilots experience these effects as reduced control authority. Pilots' performances decrease while workload increases [1,2].

In the context of interactions between pilot biomechanics and helicopter vibratory dynamics, known as (adverse) Rotorcraft–Pilot Couplings (RPCs) [1,3], this work is focused in the 2–8 Hz range, which lies outside the pilot's intentional control bandwidth; in this regime, the pilot's biomechanical response becomes the driver of a closed-loop behavior.

Following Venrooij's framework [4], the input-output relation is defined as Biodynamic Feedthrough (BDFT). This specific case studies the vertical collective bounce [3], an RPC where vertical excitation couples with collective-lever motion through pilot biomechanics, forming a feedback loop. Since the collective lever controls the main rotor thrust, this loop can enter a self-excited limit cycle, making it one of the critical RPC phenomena to be mitigated.

Several pilot–helicopter models have been developed to capture RPC dynamics [4,5]. An analytical, physics-based approach is adopted in [6], with the minimum number of degrees of freedom and parameters, and benchmarked against prior studies and validated references. These models aim to provide interpretable representations without any loss of information about the phenomenon. The objective is to clarify how physics and geometry non-linearities shape the dynamic response.

These models simplify the parameters' tuning relative to higher order models and preserve a direct link between parameter modifications and system response. The reduced parameters set helps the deployment in control and estimation frameworks with efficient real-time execution; moreover, the provided kinematic models can be exploited for inference even in the absence of input information.

Problem

Biomechanical systems exhibit intrinsic time variance due to fatigue or sudden events. Accordingly, their parameters cannot be assumed constant over time [7]. The governing laws are not known a priori, and such variability may trigger Pilot-Assisted Oscillations (PAOs).

Materials Research Proceedings 69 (2026) 1481-1486 https://doi.org/10.21741/9781644904251-260

The goal is to identify parameters' evolution without an explicit model or direct measurements, selecting at each instant the most plausible parameters set to enable interpretation and mitigation via informed and robust control schemes, without sacrificing controllability.

Estimating time-varying parameterization is widespread across disciplines. Among others, see the work by [8, 9].

The task is inherently complex: online parameter evolution requires simultaneous state and parameter estimation. Even a simple relation $\dot{x} = w(t)\, x(t)$ becomes nonlinear here, since both w(t) and x(t) are jointly unknown and must be estimated [8]. , a probabilistic and optimization approach is adopted. The helicopter-focused literature remains limited [7], especially on sigma-point framework, which uses deterministic sampling for statistically robust linearization [9]. Two approaches are considered [8, 9], with the latter's core scheme presented.

Algorithm 1. Sigma-points Parameter Filter

Require prior $\hat{\mathbf{w}}_0 = \mathrm{E}[\mathbf{w}]$, $\mathbf{P}_{w,0} = \mathrm{E}[(\mathbf{w} - \hat{\mathbf{w}}_0)(\mathbf{w} - \hat{\mathbf{w}}_0)^\intercal]$
for k = 1, 2, … **do**
  $\hat{\mathbf{w}}_k^- \leftarrow \hat{\mathbf{w}}_{k-1}$, $\mathbf{P}_{w,k}^- \leftarrow \mathbf{P}_{w,k-1} + \mathbf{R}_{k-1}^w$
  $\mathbf{S}_{w,k} \leftarrow \mathrm{chol}(\mathbf{P}_{w,k}^-)$
  $\mathcal{W}_{k|k-1} = [\hat{\mathbf{w}}_k^-,\ \hat{\mathbf{w}}_k^- \pm \gamma\, \mathbf{S}_{w,k}]$
  $\mathcal{D}_{k|k-1} \leftarrow \mathrm{G}(\mathrm{x}_k, \mathcal{W}_{k|k-1})$
  $\mathbf{d}_k \leftarrow \sum_i \mathbf{W}_i^{(m)}\, \mathbf{D}_{i,k|k-1}$
  $\mathbf{P}_{dd,k} \leftarrow \sum_i \mathbf{W}_i^{(c)}\, (\mathbf{D}_{i,k|k-1} - \mathbf{d}_k)(\mathbf{D}_{i,k|k-1} - \mathbf{d}_k)^\intercal + \mathbf{R}_k^e$
  $\mathbf{P}_{wd,k} \leftarrow \sum_i \mathbf{W}_i^{(c)}\, (\mathbf{W}_{i,k|k-1} - \hat{\mathbf{w}}_k^-)(\mathbf{D}_{i,k|k-1} - \mathbf{d}_k)^\intercal$
  $\mathbf{K}_k \leftarrow \mathbf{P}_{wd,k}\, \mathbf{P}_{dd,k}^{-1}$
  $\hat{\mathbf{w}}_k \leftarrow \hat{\mathbf{w}}_k^- + \mathbf{K}_k(\mathbf{d}_k - \mathbf{d}_k)$, $\mathbf{P}_{w,k} \leftarrow \mathbf{P}_{w,k}^- - \mathbf{K}_k\, \mathbf{P}_{dd,k}\, \mathbf{K}_k^\intercal$
end for

The problem is decoupled [8]: a state estimation step and a parameter identification step are executed separately at each time step. This strategy lowers computational cost, and often allows each sub-problem to be treated as linear, unlike the joint formulation, [8]. In the absence of a known parameter-evolution model, each parameter follows a random walk, enabling probabilistic exploration of the parameter's space at every step. Future work will consider richer dynamics while addressing hyperparameter selection. In general, the problem can be written as:

$$\begin{cases} \dot{x} = f\big(x(t), u(t); w(t)\big) + v_x(t), \\ \dot{w} = g\big(x(t), w(t)\big) + v_w(t), \\ y = h\big(x(t), w(t)\big) + v_y(t). \end{cases}$$

Here f is the state dynamics of x, g is the parameter dynamics of w, h is the observation map for y, and v_x, v_x, v_γ are the process and measurement noise. Multiple formulations were considered: first, a second-order system to estimate both physical parameters and the state-space entries of A (a simple black-box setup).; subsequently, a formulation from prior work [6] was adopted, reported below:

$$\big[\ell^2\big(\eta^2 m_e + m_p\big) + J_\ell\big]\ddot{\theta} + \big[c_p \ell^2 cos^2\dot{\theta} + c_o\big)\dot{\theta} + \big[\ell g\big(m_e + m_p\big) - \ell^2 k_p sin\theta\big)cos\theta + \ell^2 k_p sin\theta cos\theta + k_o\theta - k_o\hat{\theta} = -\ell\big(m_e + m_p\big)cos\theta\ddot{z}$$

Materials Research Proceedings 69 (2026) 1481-1486 https://doi.org/10.21741/9781644904251-260

Where θ is the angle between the collective axis and the floor, [θ, θ̇] are the states; ℓ the lever length; η the Center of Mass relative position; m_l, $m_p(t)$ the lever and pilot equivalent mass; J_l the lever inertia; $c_p(t)$, c_o the equivalent damping; $k_p(t)$, k_o the equivalent stiffness; $\hat{\theta}$, $\bar{\theta}$ the spring preloads; and $\ddot{z}$ the base vertical acceleration. Parameters to be identified: $[m_p, c_p, k_p]$.

Simple linear systems are modeled as mass–spring–damper equivalents and can be written in two standard forms:

$$\begin{bmatrix}\dot{\theta}\\ \ddot{\theta}\end{bmatrix} = \begin{bmatrix}0 & 1\\ -\frac{k}{m} & -\frac{c}{m}\end{bmatrix}\begin{bmatrix}\theta\\ \dot{\theta}\end{bmatrix} + \begin{bmatrix}0\\ 1\end{bmatrix}\ddot{z}$$

The goal is to estimate both state-space coefficients $[a_{21}(t), a_{22}(t), b_{21}(t)]$ and physical parameters $[m_p(t), c_p(t), k_p(t)]$, which enter the equations through nonlinear terms. Despite its simplicity, the single Degree of Freedom (1-DOF) model yields a statistically grounded linearization at each step, enabling effective use of measurements, unlike purely deterministic differentiation. Equation (2), though the simplest in [6], already embeds the key nonlinearities, making it a suitable benchmark for parameter identification. Future work will extend to 2-DOF (linear and nonlinear) models as proxies for complex multibody systems, enabling rigorous model-mismatch tests. The observation model is a direct state measurement [8]; future work will include richer sensor dynamics. Algorithms from [8] (a Dual Extended Kalman Filter with recursive state-parameter coupling) and from [9] (a sigma-points Kalman filter) were tested. The latter proved to be more robust via implicit statistical linearization; therefore, the square-root Central Difference Kalman Filter (additive-noise form) of [10] is adopted. To drive parameter covariance, two options are used: Robbins–Monro adaptation and annealing of a preset constant matrix. Future work will estimate process and measurement noise online, reducing reliance on offline tuning, following [11].

Results

Several systems with distinct dynamics were simulated via an Euler–Maruyama step for stochastic dynamics and excited with inputs ranging from simple accelerations of the base to identification-oriented force signals. Noise was varied in both the process and the measurement channels.

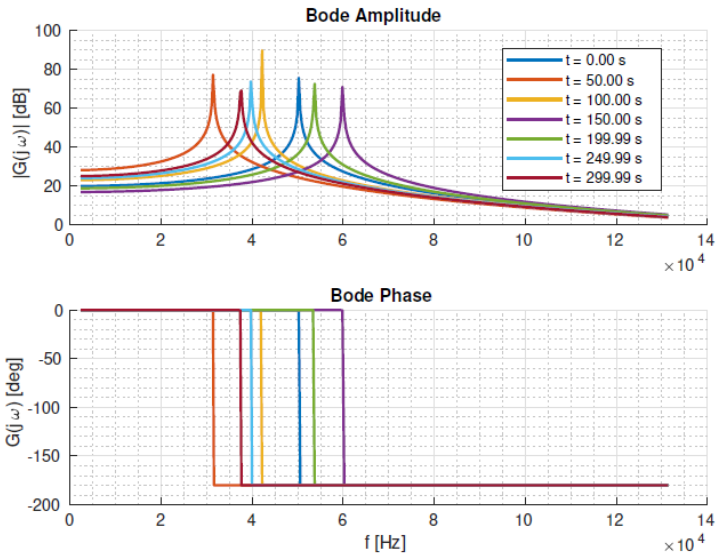

Figura 1: Time Variant Bode Graphs.

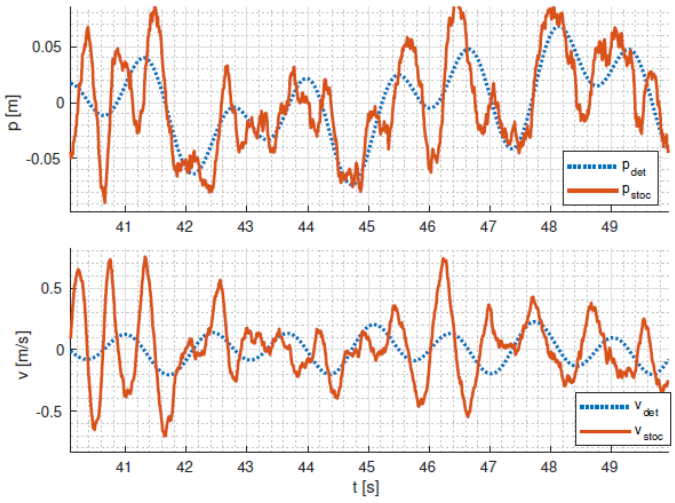
Materials Research Proceedings 69 (2026) 1481-1486 https://doi.org/10.21741/9781644904251-260

Evolving parameter dynamics produce distinct frequency-domain responses. Identifying the transfer function through linear or physics-based models enables characterization of system behavior and detection of deviation from nominal dynamics, informing control strategies to maintain robust stability (object of future work).



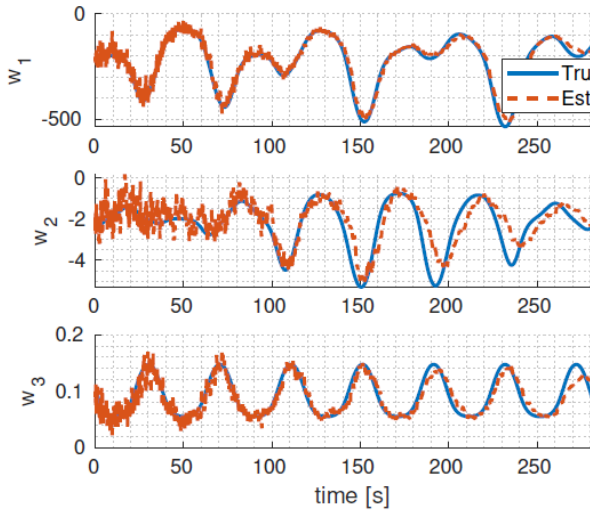


Figura 2: Linear System Process Noise.

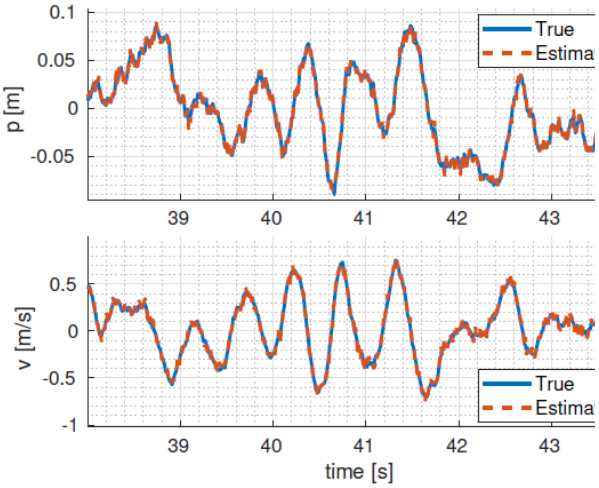
Here, the excitation profiles and the corresponding simulations of the system dynamics are shown

Results for selected noise levels show simultaneous reconstruction of the state and time-varying parameters. The main challenge is the lack of a direct measurement map for parameters such as equivalent mass, damping, and stiffness, which are not directly measurable.



Nevertheless, the approach is effective: it is equivalent to Recursive Least Squares in linear cases or (in general) to an optimization-based method (Modified Gauss Newton [8,9], but it is implemented as a Kalman filter on parameters rather than on states.

These results are illustrative. Further refinements and a broader analysis will follow.

(a) *Parameters Reconstruction.*

Figura 3: Linear Parameters Reconstruction

(b) *State Reconstruction.*

Figura 4: Linear State Reconstruction.

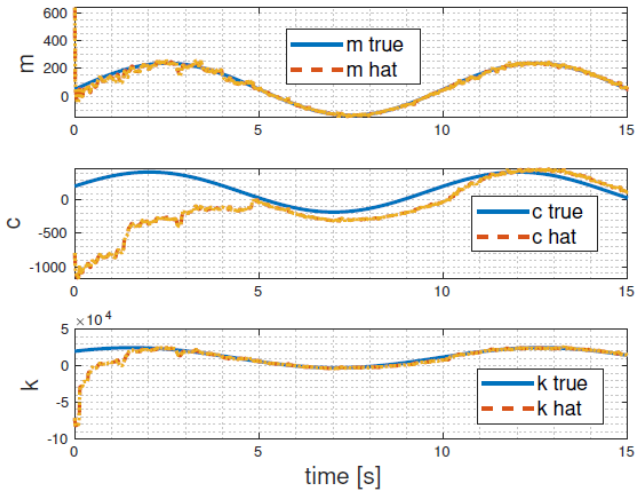


Figura 5: Nonlin Parameters Identification.

Conclusions and Future Work

The work demonstrates reconstruction over time of previously unknown pilot parameters' trajectories, from simple linear equivalents to more complex models, leveraging concise, physically consistent formulations from prior work [6] with the aim to support mitigation strategies [12] and gain better knowledge of the phenomenon. Complex, computationally demanding models can be handled by allowing time-varying components to capture unmodeled dynamics: at each instant, the simplest consistent model (e.g., mass–spring–damper harmonic oscillator) represents the system, while residual effects are absorbed by probabilistic time-adaptation of the parameter

The study is not exhaustive: limits due to process/measurement noise and parameter-rate bounds will be analyzed. Diverse parameter trajectories and increasing model mismatch will be explored and compared. The filter will be made agnostic to initial tuning by implementing methods from [11] and drawing on optimization results [8,9] also following the Linear Mean Square (LMS) approach in [12]. Upcoming work includes progressively complex tests and real-world experiments to map the method limits and define the most suitable operating range.

Navigating the New Frontier: The EU Space Act and its Impact on the European Aerospace Sector

Cecilia NOTA[1,a *]

[1]Lungo Dora Siena, 100, 10153 Torino (TO), Italy

[a]cecilia.nota@unito.it

Keywords: EU Space Act, European Space Policy, Space Safety, Space Resilience, Space Sustainability, Art. 114 TFEU, Regulatory Harmonisation

Abstract. The proposed EU Space Act aims to harmonise the Union's space governance under a single regulatory framework centered on safety, resilience, and sustainability. The Proposal introduces a system for authorisation and supervision of space activities, addresses protection of space infrastructure through a sector-specific cybersecurity regime, and mandates operators to calculate the environmental footprint of their activities as part of authorisation procedures. The Proposal marks a step forward for the European space framework, but its ultimate success will depend on balanced implementation and the EU's ability to maintain global competitiveness.

1. Introduction

The European space sector is undergoing a profound transformation, driven by the rapid commercialisation of space, the rise of "New Space" actors, and intensifying geopolitical competition [1]. This environment presents opportunities for economic growth and innovation, but it is hindered by a significant challenge: a fragmented regulatory landscape across the European Union (EU), as, currently, only 13 Member States have enacted national space laws, with others in the process of drafting their own [2]. Their varied approaches to safety, liability, and sustainability create legal uncertainty, distort competition, and erect barriers to a truly integrated single market for space services and products [3]. This fragmentation impedes the competitiveness of the EU space industry and undermines the goal of achieving strategic autonomy in a critical domain [4].

In response to these challenges, the European Commission has introduced in 2025 a Proposal for a Regulation of the European Parliament and of the Council on the safety, resilience and sustainability of space activities in the Union, the so-called EU Space Act (hereinafter referred to as 'the Proposal') [2]. This long-awaited regulation represents the first comprehensive attempt to govern the European space economy at a supranational level, aiming to create a harmonised, predictable, and competitive framework for all space operators within the EU [5]. This contribution explores the legal architecture and impact of this legislative initiative on the European aerospace ecosystem.

2. The Legal Architecture of the EU Space Act

Under the Lisbon Treaty, space is a shared parallel competence, meaning both the EU and the Member States may regulate space activities, with the latter retaining the freedom to pursue national policies alongside EU action. Indeed, Art. 189 of the Treaty on the Functioning of the European Union (TFEU), while establishing that the EU shall draw up a European space policy to promote scientific progress and industrial competitiveness, explicitly excludes the "harmonisation of the laws and regulations of the Member States" [6,7]. This caveat has historically prevented the EU from creating a unified legal framework for space activities [8,9], and it reflects the reluctance of Member States to cede sovereignty over a sector seen as strategic [10,11].

Content from this work may be used under the terms of the Creative Commons Attribution 3.0 license. Any further distribution of this work must maintain attribution to the author(s) and the title of the work, journal citation and DOI. Published under license by Materials Research Forum LLC.

The Commission addresses this limitation by grounding the Proposal on Art. 114 TFEU, the legal basis for measures concerning the establishment and functioning of the internal market [12]. Diverging national standards [13] create obstacles to the free movement of space services and distort competition, necessitating Union-level action to ensure a level playing field [2,14]. In this sense, the Proposal entails a genuine form of harmonisation, as it defines uniform technical and operational standards and introduces coordinated governance mechanisms to ensure their implementation. This legal strategy, previously employed in other sectors such as data protection with Regulation (EU) 2016/679 (GDPR) and environmental protection with Regulation (EC) 1907/2006 (REACH), represents a significant evolution in EU space governance [15]. The Commission's reasoning behind the use of Art. 114 TFEU is based on the grounds that a genuine internal market for space services and products is emerging within the Union, encompassing satellite communication, Earth observation data, and downstream applications integrated into the broader digital and industrial ecosystem. In this context, the choice of a regulation reinforces the internal market rationale because, pursuant to Art. 288 TFEU, regulations are directly applicable and binding in their entirety, ensuring uniform application across Member States [16], a necessary condition to eliminate legal fragmentation and guarantee equal market access for all operators.

It is important to note, however, that the EU Space Act has not yet entered into force. Proposed by the Commission in June 2025, the regulation is scheduled to become applicable on 1 January 2030, with the intervening period allocated for stakeholder adaptation and institutional preparation [2]. At this stage, the text remains open to amendments, as the Proposal is still in the initial phase of the ordinary legislative procedure and subject to modifications by the European Parliament and the Council, meaning that certain provisions may yet be redefined. Nevertheless, the regulatory architecture already envisioned demonstrates the Commission's intent to transcend the constraints of Art. 189 TFEU's prohibition on harmonisation by establishing binding technical and operational standards applicable across the entire EU space market through the direct applicability of regulation. This approach enables the Commission to project EU regulatory authority by conditioning participation in the EU space market on the basis of compliance with EU standards. That is to say that all operators must meet the same regulatory requirements if they wish to provide space services within the Union, thereby ensuring uniform compliance.

The Proposal's application extends beyond EU operators to non-EU operators providing space services in the Union, employing a marketplace criterion similar to the GDPR and the Digital Services Act [14]. This approach reflects the Commission's ambition to establish the Union as a global standard setter for space activities. However, this strategy carries a critical caveat for European aerospace competitiveness: the regulatory advantage depends on whether major space-faring states and global private operators voluntarily adopt or are compelled to adopt equivalent standards. If competitors operating under different regulatory regimes can undercut European manufacturers' compliance costs without losing EU market access through equivalent recognition, the competitive gains promised by harmonisation may evaporate [17].

The success of the regulation thus hinges not merely on internal EU alignment, but on whether the Union can sustain global regulatory leadership in space [2,14]. In this sense, the Proposal reflects the ambition to replicate the "Brussels effect" intended as the EU's capacity to export its regulatory standards globally through market access conditionality [18]. However, this is not without tension and the Proposal envisages a mechanism allowing the Commission to recognise third-country legal frameworks as equivalent to EU requirements (Art. 105 Proposal), facilitating international cooperation but potentially diluting the regulatory leverage the Union seeks to assert.

3. The Three Pillars of the EU Space Act and Their Implications for the European Aerospace System

The proposed EU Space Act is built on three pillars: safety, resilience, and sustainability. These pillars entail a broad regulatory transformation reshaping technical requirements and governance

structures across the space value chain [19]. This overhaul reconfigures institutional roles and establishes a harmonised framework for the authorisation and supervision of space activities (Art. 6 Proposal). The Proposal distinguishes between activities involving Union-owned space assets and those relating to non-EU assets. In the former case, authorisation and supervision powers rest with the Commission, which is supported by the European Union Agency for the Space Programme (EUSPA) in carrying out technical assessments and certification tasks (Arts. 11-13 Proposal). In the latter case, competence lies with the Member States, which must designate a National Competent Authority (NCA), eventually aided by the EUSPA, endowed with powers of supervision, investigation, and sanctioning to ensure compliance (Arts. 28-30 Proposal).

(i) The safety pillar addresses orbital congestion by setting binding rules requiring operators to ensure object trackability and reduce space debris. It introduces harmonised safety and operational standards applicable to all categories of operators carrying out space activities in the EU (Art. 6 Proposal). All operators, including non-EU entities and intergovernmental organisations, must register in the Union Register of Space Objects (URSO) to obtain EU compliance certification (Arts. 24-25 Proposal). Launch operators must implement debris control measures, fragmentation prevention, and end-of-life disposal procedures (Art. 61 Proposal), while spacecraft operators must subscribe to EU collision avoidance services (Art. 64 Proposal).

This shift from voluntary guidelines to enforceable safety protocols will affect mission design and operational procedures across the European aerospace sector; the Commission, in its impact assessment, notes that shifting from individual to constellation authorisation is projected to save operators EUR 68 million over the next decade, while extending satellite lifespans from 5 to 6 years could yield EUR 1.3 billion annually. However, these benefits must be weighed against increased manufacturing and compliance costs, with satellite operators potentially facing a 10% increase in manufacturing costs depending on mission requirements, and launch service providers incurring in additional expenses of EUR 1.5 million for heavy launchers and EUR 200,000 for small and medium sized enterprises (SMEs). Compliance will require redesign of mission architecture, enhanced engineering protocols for debris mitigation, and investment in collision avoidance systems.

(ii) The resilience pillar addresses the protection of space infrastructure from growing threats by establishing a sector-specific cybersecurity regime. Unlike the general cybersecurity frameworks established by Directive (EU) 2022/2555 (Network and Information Security - NIS2) and Directive (EU) 2022/2557 (Critical Entities Resilience - CER), which do not cover all segments of space infrastructure, the Proposal is intended to function as *lex specialis* [2], creating a bespoke resilience baseline applicable to all EU space operators (Art. 75 Proposal). In particular, the NIS2 Directive establishes cybersecurity obligations for medium and large providers of public electronic communications networks as well as for certain ground-segment operators. However, it notably excludes significant components of the space sector, most importantly space constellations owned by the Union. In addition the CER Directive is not applicable to Union-owned space infrastructures that fall within the scope of the EU Space Programme [20]. To remedy this gap, the Proposal stipulates that, for any operator already designated as “essential” or “important,” its space-specific provisions take precedence over the more general rules laid down in the NIS2 and the CER Directives (Art. 75 Proposal). Operators must implement risk management across all mission stages and conduct mission-specific risk assessments (Arts. 76-78 Proposal), enforce strict access control protocols (Arts. 81-82 Proposal), and report incidents (Art. 93 Proposal). The Proposal also creates a Union Space Resilience Network to coordinate responses to major cyber incidents (Art. 94 Proposal).

For the European aerospace sector, this represents a fundamental reorientation towards security-by-design principles, requiring aerospace manufacturers and operators to embed cybersecurity considerations into hardware, software, and communication protocols from the inception of the

Materials Research Proceedings 69 (2026) 1487-1492 https://doi.org/10.21741/9781644904251-261

design phase (Arts. 31, 58, and 73 Proposal). Risk management costs for companies are estimated by the Commission at 10% of their IT budgets, with authorisation requirements per product line costing approximately EUR 100.000, particularly affecting supply chain management, as EU space operators must establish frameworks aimed at reducing risks through software integrity controls and cybersecurity provisions (Art. 92 Proposal). Conversely, the implementation of these standards across the EU market is expected to provide significant competitive advantages; manufacturers potentially stand to save EUR 320 million per year through cybersecurity standards that reduce cyber-related risks.

(iii) The sustainability pillar introduces environmental requirements aligned with the European Green Deal objectives requiring operators to calculate the environmental footprint of their space activities as part of their authorisation applications (Art. 96 Proposal). This mandate covers all lifecycle stages, and relies on assessment methods aligned with the Commission Recommendation of Environmental Footprint (Arts. 97-98 Proposal). The requirement applies to all EU space operators except small-sized enterprises (Art. 5(26) Proposal) and research and education institutions until 31 December 2031 (Art. 96(8) Proposal). Additionally, the regulation mandates that spacecraft maintain a specific visual magnitude throughout their lifetime, including design requirements to limit pollution and minimise impact on astronomical observations, while establishing plans to reduce radio frequency disruptions (Art. 72 Proposal).

For the European aerospace industry, these sustainability requirements will drive substantial innovation in green propulsion technologies, sustainable materials, and eco-design methodologies. Implementing product environmental footprint rules is estimated by the Commission to cost EUR 4.000-9.000 per company, yet the creation of a unified environmental assessment framework provides European companies with opportunities to establish themselves as leaders in sustainable space technologies in a global market increasingly prioritising environmental responsibility. The centralised EU database for environmental footprint data, coupled with mandatory reporting of aggregated and disaggregated datasets, will facilitate informed decision-making, potentially positioning European manufacturers as pioneers in environmentally conscious space operations (Arts. 96(6) and 99 Proposal).

4. Enforcement Framework and Structural Challenges

Beyond these three substantive pillars, the EU Space Act's enforcement architecture carries significant implications for European operators.

As already mentioned, to mitigate regulatory friction with third countries, the Proposal grants the Commission discretionary power to recognise third-country legal frameworks as equivalent to EU requirements (Art. 105 Proposal). While this mechanism promotes international cooperation and reduces barriers, it also creates potential loopholes that could undermine enforcement consistency. Non-EU operators whose home countries receive equivalence decisions may bypass stringent EU compliance requirements, creating an uneven competitive landscape where some foreign competitors face lighter regulatory burdens than European manufacturers operating under domestic supervision. For the European aerospace sector, the breadth and flexibility of equivalence determinations will directly impact whether compliance costs translate into genuine competitive advantage.

Additionally, the regulation establishes a dual supervisory system: Member States supervise EU-based space operators through designated national authorities, while the Commission and EUSPA directly supervise non-EU operators, with power to impose penalties up to 2% of annual turnover (Arts. 48-56 Proposal). This division creates asymmetrical compliance pressures. European aerospace manufacturers and operators must navigate both EU standards and domestic Member State oversight, accumulating compliance costs through both levels. Conversely, foreign competitors may face Commission supervision alone, or, if their home state obtains equivalence recognition, potentially lighter oversight entirely (Art. 105 Proposal). For European SMEs, already

Materials Research Proceedings 69 (2026) 1487-1492 https://doi.org/10.21741/9781644904251-261

facing 10% manufacturing cost increases, this fragmented enforcement regime risks exacerbating competitive disadvantage relative to larger, globally-diversified competitors less dependent on EU market access.

Additionally, critical gaps and ambiguities threaten to undermine the objectives of the Proposal. First, the regulatory burdens imposed regarding compliance and certification procedures (Arts. 6-19, 41 and 46 Proposal) risk placing disproportionate strain on SMEs, the backbone of European space innovation. Although the Proposal acknowledges supportive measures (Arts. 109-111 Proposal), it provides insufficient concrete specifications, raising the prospect that under-resourced operators may be forced to curtail their activities [20]. Second, the Proposal remains notably silent on space resource exploitation, a critical omission given that certain Member States have already pursued unilateral legislative initiatives in this domain [21], potentially fragmenting the legal landscape further. Third, persistent ambiguity surrounds the dual-use character of space assets, as the preservation of Member States prerogatives on national security creates potential friction between supranational technical harmonisation and sovereign security determinations (Art. 4 Proposal).

5. Conclusion

The EU Space Act is an important step in the evolution of the Union's space governance, seeking to consolidate a unified regulatory environment underpinning EU strategic autonomy [22]. Through the three pillars, the Proposal aspires to replicate in the space domain the already mentioned "Brussels effect" [14,18]. Yet, as discussed, systemic limitations may hinder this ambition. The disproportionate compliance burdens for SMEs, the persistent legal vacuum surrounding space resource exploitation, and the unresolved tension between supranational harmonisation and Member States' security prerogatives risk constraining the reach of the Act.

Ultimately, the EU Space Act embodies both the promise and the problem underlying European integration in space: it projects regulatory authority on a global scale while remaining bound by the structural asymmetries of EU competence and enforcement capacity. Its success will, therefore, depend not only on the internal coherence of its governance architecture but also on whether the Union can translate its normative ambition into effective global influence.

Abstract. The German Aerospace Centre (DLR) acquired a Dassault Falcon 2000LX research aircraft, designated ISTAR (In-flight Systems & Technology Airborne Research), to support research in variable stability, advanced flight control concepts and pilot assistance systems. A high-fidelity flight dynamics model of the ISTAR is essential for the development of these systems and for simulator-based flight control testing. The model is based on an aerodynamic model identified through system identification (SysID) techniques using flight test data. The modular design of the aerodynamic modelling software enabled seamless integration of the identified model into the ISTAR simulator. This paper gives an overview of the model development process and an example for the application of the simulator model for the design and implementation of a yaw controller is presented.

Introduction

The development of a flight dynamics model for a simulator is a complex and time-consuming task, particularly during the design phase of new aircraft. Initially, the model relies heavily on wind tunnel measurements and computational fluid dynamics (CFD) calculations, which are later refined and validated using flight test data. The accuracy of the flight dynamics model is crucial, as it directly impacts the design of flight control functions and performance models. Furthermore, the model is an integral component of flight training devices, which are typically developed in parallel with or subsequent to the aircraft development process.

This paper provides an overview of the flight dynamics model development process for ISTAR, which is being designed as a platform for testing novel guidance, navigation and control systems. In the forthcoming years, the aircraft's control system will undergo substantial modifications, enabling researchers to integrate and test custom flight control software [1]. To facilitate this development, a cockpit simulator has been established at the DLR AVES (Air Vehicle Simulator) simulation centre, supporting the development and validation of flight control software prototypes. Consequently, an accurate flight dynamic model is essential to demonstrate to regulatory authorities that the implemented modifications and safety measures are based on a realistic model.

A key strategy for accelerating the model development process was the direct reuse of software components created during the system identification (SysID) process in the AVES simulator software. The aerodynamic model was verified through software validation during the SysID process, where model outputs were directly compared to flight data measurements. Additionally, the flight dynamics model was validated using an automated process, which enables rapid updates to the simulator model in response to significant modifications to the aircraft or to new flight test data. This approach ensures that an up-to-date 6-degrees-of-freedom model of the ISTAR flight dynamics can be maintained at all times.

Aircraft and Instrumentation

The ISTAR aircraft is a modified Dassault Falcon 2000LX with a wingspan of 21.38 m and a maximum takeoff weight of 19.4 t. The standard avionic system features two independent Air Data Systems (ADS) that measure atmospheric parameters and calculate airspeed, Mach no. and barometric altitude. To obtain more accurate air data measurements, a nose boom installation is utilized, which enables the collection of data in the relatively undisturbed airflow ahead of the aircraft nose. Three independent and one experimental inertial reference systems measure acceleration along and rotational rates around the body axis. Position sensors installed on the aircraft control surfaces record the deflections of the elevator, ailerons, and rudder. A data acquisition system is integrated into the cabin, enabling the processing and storage of all flight parameters. The aircraft cabin features two stations, allowing the flight test engineer and an experimenter to monitor flight parameters in real-time during flight operations. This configuration facilitates direct communication with the test pilots, permitting the repetition or adaptation of manoeuvres as required by the experimenter.

Flight Manoeuvres and Test Points

A comprehensive flight test campaign was conducted to gather data for the development of a model representing the flight dynamics throughout the operational envelope. The test program comprised 9 flights, performed between February and May 2022, during which a total of 26 test points were completed. These test points spanned various altitudes, speeds, and aircraft configurations, including different slat/flap settings and landing gear states. Details about the test points are shown in Table 1. The flight test campaign involved a range of SysID manoeuvrers designed to excite the aircraft's motion modes independently. Longitudinal motion was excited through multi-step elevator inputs, small step inputs, and double step inputs to the thrust lever and horizontal stabilizer. Lateral manoeuvrers included bank-to-bank turns, aileron and rudder doublets, and steady heading sideslip manoeuvrers. Additionally, level accelerations and decelerations were performed at altitudes of 30000 ft and 45000 ft. The collected dataset, which spans over 6.5 hours, includes more than 590 manoeuvres. Notably, the flight test campaign was impacted by nose boom vibration issues at speeds above 290 kt indicated airspeed (IAS), which precluded the completion of test points 5, 6, 7, and 9. These test points will be revisited once the vibration issues have been resolved. Overall, the gathered flight data provided a solid foundation for the development of an accurate flight dynamics model of the ISTAR aircraft.

Data Post-Processing and Compatibility Check

Accurate flight data measurements were crucial for developing a high-quality flight dynamics model. To ensure data consistency and accuracy, a data compatibility check (DCC) was performed [2]. The DCC is a higher-level process that detects and corrects measurement errors, and develops sensor models that provide adequate agreement between reference and measured airflow signals. A key component of the DCC is the flight path reconstruction (FPR) method, which uses inertial measurements to calculate reconstructed air data.

Materials Research Proceedings 69 (2026) 1494-1499 https://doi.org/10.21741/9781644904251-262

***Table 1**. Flight test points used for system identification manoeuvrers.*

TP	Altitude [ft]	IAS [kt]	Ma
1a	11000	120	0.22
1b	11000	135	0.25
1c	11000	145	0.27

13	37000	190	0.60
14	37000	160	0.51
15	45000	210	0.78

We applied the DCC method to our flight data measurements to ensure their accuracy and consistency [3]. Another aim of the DCC is to develop models for the aircraft air data and inertial sensors, representing the dynamic sensor characteristics. Accurate sensor models were essential for the SysID process and simulator model development, as control system designs must account for sensor characteristics such as time delays, bias, and factor errors. In preparation for the SysID process, the flight data were augmented with additional aircraft properties, including current weight, centre of gravity (CG) position and moments of inertia. These parameters were derived using a manufacturer's weight and balance model, which accounted for the zero-fuel weight and the current fuel content in each tank. Additionally, a manufacturer-provided engine model was employed to compute the thrust force as a function of Mach number, altitude and engine speed (N1).

System Identification

A crucial component of the flight dynamics simulation is the aerodynamic model, which determines the aerodynamic forces and moments acting on the aircraft. This model typically consists of equations for each aerodynamic force and moment coefficient, with each term comprising a derivative parameter multiplied by an influence variable. To estimate the aerodynamic parameters, the output error method was applied, which operates in the time domain and compares the model outputs with the measured flight data [2]. The procedure is illustrated in Fig. 2: The measured control deflections, engine thrust and current weight and balance properties were used as inputs to the model. Utilizing these inputs and the rigid body model states, the aerodynamic model calculated the forces and moments acting on the aircraft. The necessary state variables, such as flight speed, were determined using the equations of motion. Numerical integration of the equations of motion yielded the resulting model states, which served as inputs for the sensor models. The sensor models, which were previously validated through a DCC, remained fixed, and their outputs were compared with the measured flight data. An iterative process was used to minimize the calculated model error by optimizing the model parameters. This involved adjusting the structure and parameters of the aerodynamic model accordingly. The SysID process was performed using the MATLAB tool FITLAB [4] developed by the DLR Institute of Flight Systems. The kinematic model, aerodynamic model and sensor model were integrated as modular software components into a C++ library for use with the SysID process. The models and identified parameters, denoted by hatched blocks in Fig. 2 are the software components that are reused for implementing the flight dynamics model in the simulator. The results of a successful match between the flight data and the identified flight dynamics model are presented in Fig. 3. This figure displays time series plots of a sequence of lateral manoeuvres, including two bank-to-bank and two rudder doublets, followed by a steady heading sideslip and a rudder release. The input signals of the ailerons and rudder control surfaces are shown in the first two subplots, while

Materials Research Proceedings 69 (2026) 1494-1499 https://doi.org/10.21741/9781644904251-262

the subsequent subplots illustrate the corresponding responses in terms of angle of sideslip, roll rate, yaw rate, bank angle and yaw angle. A comparison between the measured flight test data (blue lines) and the simulated model responses (red lines) reveals only minor discrepancies, indicating that the model accurately captures the flight dynamics of the ISTAR aircraft. A more detailed description of the system identification procedure and an assessment of the current model quality can be found in a companion technical report [5].

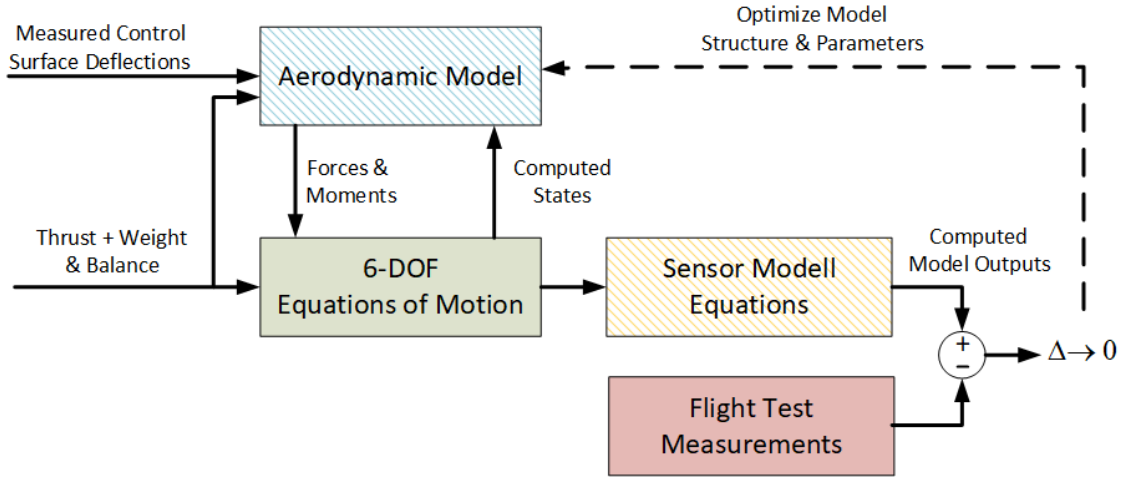

Fig. 2. *System identification process for the aerodynamic model.*

ISTAR Flight Simulator

The ISTAR cockpit simulator at the DLR AVES simulation centre is a combination of actual aircraft and reproduced hardware. All software necessary for operating the simulator is being developed completely in-house at the DLR Institute of Flight Systems. A central interface system, based on TCP/UDP communication protocols, connects the different cockpit simulator parts, like pilot control, display, vision and motion systems. The ISTAR simulation model is implemented in MATLAB/Simulink. The core of the simulation model comprises the equations of motion, supplemented by a set of sub-models for aerodynamics, sensors, weight and balance, landing gear and engine. Leveraging existing code, the aerodynamics and air data sensor models, previously employed in the SysID process, are integrated into the simulation framework via corresponding C++ S-Functions, promoting code reusability and efficiency. This extensive simulation model is being extended to include the unmodified aircraft's automatic flight control system (AFCS). As ISTAR undergoes modification to its flight control system, these changes will also be reflected in the simulation model. In order to run in real-time within the simulator, the model is compiled using Simulink Coder. When modifications are complete, the ISTAR simulator will be used to test experimental flight control software prior to flight tests. This also allows the flight test crew to gain experience with the expected flight control behaviour before flying. As the transfer between experimental flight controls and the unmodified aircraft is important from a safety perspective, relevant aircraft systems such as the AFCS must also be sufficiently simulated. Initially basic autoflight functions, such as the yaw damper and the heading and flight path angle modes, have been implemented in the ISTAR simulator, with provisions for the future implementation of more advanced capabilities [6]. As specifics of the Falcon 2000 AFCS, such as system gains or control loop structure, are not known, these needed to be estimated or inferred based on flight test data and limited system descriptions.

Materials Research Proceedings 69 (2026) 1494-1499 https://doi.org/10.21741/9781644904251-262

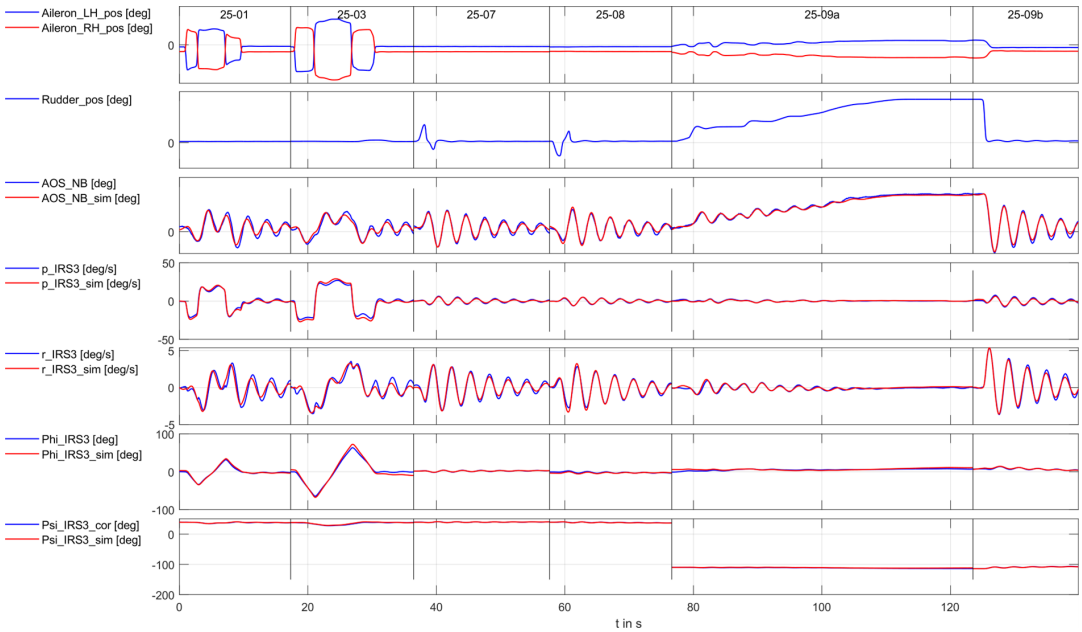

Fig. 3. *Time series plots for excitation manoeuvres in the lateral motion with measured flight data (blue) and model response (red).*

Yaw Damper Implementation

The yaw damper is the most basic form of stability augmentation found in the Falcon 2000 and is used to illustrate how the ISTAR simulation model can be used to develop flight controllers. The yaw damper was implemented using a root locus method and tuned with flight test data. Only very limited information about the yaw damper is available from the aircraft manufacturer. The functioning of the yaw damper was essentially reverse engineered using flight test data. The implementation is conventional using yaw rate feedback to the rudder and a washout filter. An offline version of the SysID determined flight dynamics model is available in Simulink. With a trimming script a state-space model of the linearized aircraft motion around a trim point of 220 kt IAS at 12000 ft was computed. This condition was chosen, because SysID test points were performed with and without the yaw damper engaged. Using a state-space model of the lateral-directional motion at this trim point, a root-locus analysis of yaw rate feedback to rudder was performed. With the yaw rate feedback and the washout filter implemented in the offline simulation, their effects were tuned to the aircraft motion measured during flight test. Figure 4 shows the effect of the yaw damper implementation on the dutch roll poles. At the trim point, a yaw rate feedback gain of 1.3 s and a washout filter time constant of 1.5 s, caused the dutch roll damping ratio to increase from 0.1 to apx. 0.4, while the natural frequency decreased (refer to Table 2) closely resembling aircraft motion. With the exception of a pole from the washout filter, located near the origin at -2.6e-3 on the real axis, the roll and spiral modes are both stabilized by the yaw damper. Particularly the spiral mode pole moves from very close to the origin further to the left along the real axis. For this yaw damper implementation to be suitable for the entire flight envelope and not just the chosen trim point, gain scheduling will be required. Subsequently, a coordinated-turn controller incorporating feedback of the lateral acceleration n_y is implemented. This leads to a marginal increase in the natural frequency of the dutch roll mode, while maintaining high damping levels.

Table 2. *Comparison of the dutch roll properties with and without the yaw damper implemented.*

Yaw Damper	Damping	Frequency [Hz]
Not Implemented	0.10	0.270
Implemented	0.38	0.073

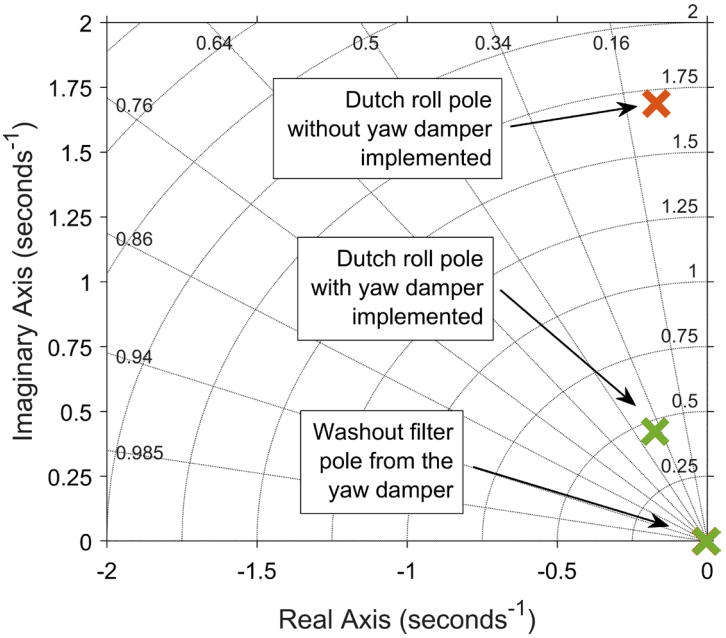

Fig. 4. *Location of the dutch roll poles with (green) and without (red) the yaw damper implemented.*

Conclusion and Outlook

In conclusion, we have successfully developed and implemented a simulation model for the ISTAR research aircraft, utilizing extensive flight test data and system identification techniques. This model has demonstrated its value in flight preparation, testing and development of control systems, such as the yaw damper controller. Future work will focus on enhancing the ISTAR research aircraft by enabling direct access to the flight control system. Additionally, the simulation model will be refined to capture a broader range of operational conditions, including high- and low-speed regimes, such as stalls, through a series of supplementary flight tests.

Keywords: Flight Simulation, Aircraft Dynamics, Education, Julia, MATLAB, Simulink

Abstract. We present a compact and user-friendly simulation package of the F-16 aircraft, which is based on aerodynamic data from the 1979 report by NASA. Developed across Julia, MATLAB, and Simulink, the package was designed for education and early research training. Priorities were given for clarity and ease-of-use over advanced functionality while preserving the full six-degree-of-freedom equations of motion and nonlinear aerodynamics. Three model variants are provided: 4th-, 8th-, and 12th-order, each progressively expanding the simulated dynamics. In addition to solving the nonlinear equations of motion, some common functions for flight dynamics analysis are provided, including trimming and linearisation, parameter sweep using parallel simulations, 3D trajectory display, and a unique real-time plotting capability in Julia. Benchmarking demonstrates excellent performance, particularly for Julia, which achieves sub-millisecond runtimes for typical time-integration tasks. The package enables learners to explore core flight-dynamics principles and nonlinear behaviours such as spins and deep stalls within a minimal coding structure. This work aims to lower the entry barrier to flight-simulation education and provide a flexible platform for undergraduate teaching and introductory research.

Introduction

The nonlinear 6-degree-of-freedom (DoF) aircraft equations of motion are a challenging topic to teach. Based on the author's experience, the reason can be attributed to the large jump from simple linear representation (transfer function and state-space) to nonlinear equations with complex coupling terms and lookup tables. Rather unfortunately, many students consider linear feedback control as one of the harder units in an aerospace engineering degree. This reduces the number of students choosing to explore aircraft dynamics further – typically as an optional unit or via a final-year research project. Students who choose this topic typically go through an 'adjustment period' of transitioning from solving handwritten equations to complex and (often) closed-source flight simulations. These software are typically constructed for a research environment that prioritises functionalities and expandability, but not necessarily user friendliness. This results in a steep learning curve and requires major effort for onboarding new lab members. Similarly, experienced control engineers from other sectors may also run into the same challenges when first introduced to atmospheric flight systems.

To address the bottleneck problem above, we propose a 'lightweight' flight simulation that prioritises simplicity over functionality – one that preserves the full 6 DoF equations of motion without advanced features that can overwhelm newcomers. This means omitting additional control surfaces (flaps, spoilers, etc.), actuator and engine modelling, atmospheric modelling, and a complex coding structure with multiple nested functions. The focus is on helping learners grasp the fundamentals behind the equations of motion for aircraft and the structure of an aircraft flight dynamics simulation—including elements such as lookup tables, time integration, and initial conditions. Other key features, such as trajectory visualisation, trimming, and linearisation, should

Materials Research Proceedings 69 (2026) 1500-1504 https://doi.org/10.21741/9781644904251-263

still be included, ideally in a way that does not overwhelm the learners. This is the opposite approach to some existing open-source flight simulations, most famously the University of Minnesota F-16 simulation [1], its recent update by one of the original authors [2], and the reduced model described in the textbook by Stevens and Lewis [3]. Furthermore, we do not favour the block-diagram approach as seen in a few Simulink examples [4], as they tend to be complex visually and may impede the user's understanding of the nonlinear equations of motion (especially if 'lazy' black box blocks are used, such as those provided in Simulink's Aerospace Blockset package [4]).

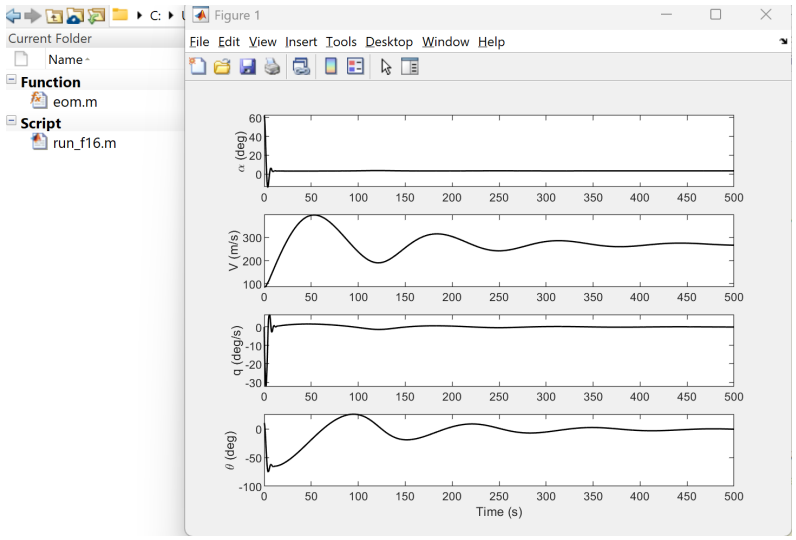

Fig. 1. 4th-order MATLAB simulation, showing the simple simulation structure with only 2 files totalling 96 lines of code.

Key features

Our simulation package, which can be downloaded from GitHub [5], is based on the F-16 aerodynamic data published in the 1979 NASA report [6]. Some well-known MATLAB/Simulink packages based on this database have been published, most notably those from the University of Minnesota [1, 2]. The package presented in this paper is a collection of 4 x 3 = 12 small simulations, which are built around the 4 coding environments used (MATLAB, Simulink, MATLAB with C-code generation, and Julia) and 3 levels of complexity in the equations of motion (4th, 8th, and 12th-order). The choice of multiple simulation environments covers a wide range of user bases. Regarding the 3 variants of the equations of motion, our rationale is:

- 4th-order: limits the aircraft motion to the longitudinal plane only. This is the ideal starting point for newcomers because the model contains all elements of a nonlinear aircraft simulation (coupled states, force and moment coefficients, and lookup table) while still being significantly simpler than the full 6 DoF equations. The 4 states modelled in the simulation are angle of attack, velocity, pitch rate, and pitch angle. The code to run the 4th-order time integration in MATLAB (including nonlinear aerodynamic tables) has only 96 lines, split between two files (see Fig. 1).

- 8th-order: expands the dynamics to include full 6 DoF. This implementation omits the 4 uncoupled equations: three representing the aircraft's location in the flat-Earth XYZ axes, plus the heading angle.

- 12th-order: contains the 4 coupled states mentioned above, along with an aircraft trajectory plotting routine.

All models assume that the air density is constant, with the default value set to 0.458 kg/m^3 (30,000 ft altitude). This assumption removes the coupling between air density and the aircraft Z-axis coordinate, thereby preventing an additional coupling term in the equations of motion. In

Materials Research Proceedings 69 (2026) 1500-1504 https://doi.org/10.21741/9781644904251-263

almost all entry-level flight dynamics texts, only the short-term dynamics is considered, which does not involve significant changes in air density. If a different altitude is desired, users can easily change the air density constant in the code.

In addition to time integration of the flight dynamics equations of motion, a few additional features are included:

- Trimming and linearisation routines to facilitate some basic open-loop analysis.
- Parallel simulation routine to run a parameter sweep. The included example determines the trim point at different stabilator deflections by running multiple simulations for a long duration, then collecting the aircraft states at the end of each simulation.
- For the 12th-order model in Julia, the code includes a plotting routine that displays the result while the differential equation solver is still running (see Fig. 2). This is similar to the 'scope' blocks in Simulink. Visualising the solutions in real-time could be useful for detecting simulations that diverge or encounter numerical instability, which tend to result in unreasonably long or infinite run time with no easy way to alert the user. To the best of the authors' knowledge, this code is the first flight visualisation package for Julia in the public domain.

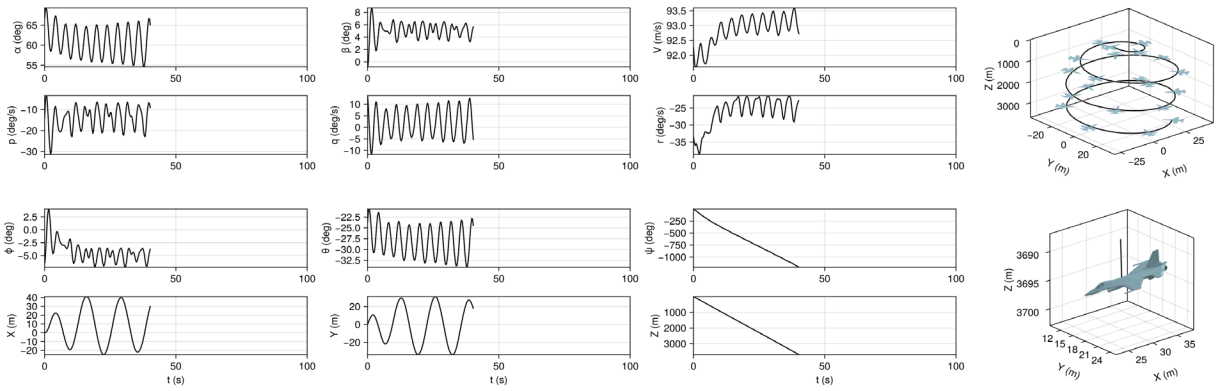

Fig. 2. 12th-order Julia simulation with plot-while-simulating feature, showing the aircraft in a spin at high angle of attack. The lower-right trajectory plot is drawn to scale.

Another notable feature is that the equations of motion are written in the wind axes instead of the typical body axis (i.e., using α, β, and V instead of body-axis velocities u, v, and w). The wind-axis representation provides an alternative reference to other simulations available. Regarding the orientation equations, we use Euler angles instead of quaternions to provide a closer link to the typical textbook equations of motion. Experienced users can easily convert the simulations to a body-axis system and/or quaternions.

Performance

Coding best practices were employed to create a light code base with high speed. The run times of two 500-second simulations (one 4th- and one 8th-order) with variable steps and 1e-4 relative tolerance are shown in Table I. Results were obtained on a laptop with a 24-core Intel i9-13950HX processor and 32 GB of RAM.

Table I. 500-second simulation run times in seconds.

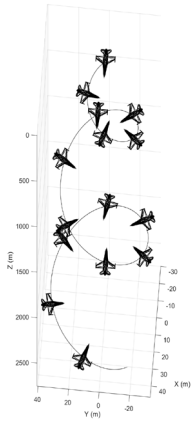
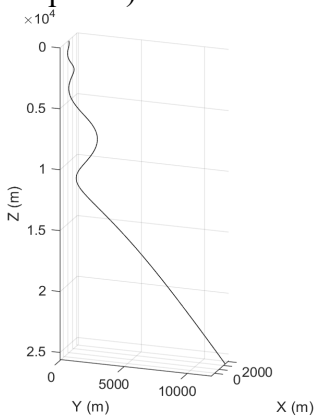
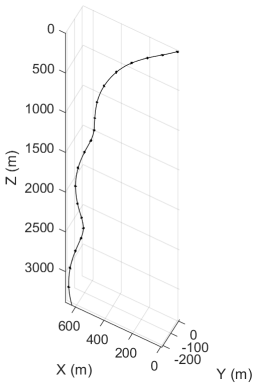
Table II shows the run times of a parameter sweep using parallel simulation, which involves 7826 simulations of duration 500 seconds split between 23 parallel workers. The same solver settings as above were used.

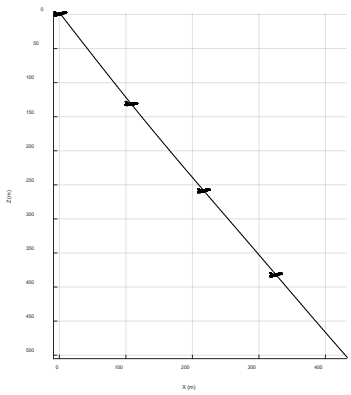
Table II. Parallel simulation run times in sec., excluding overheads and post-processing.

ENVIRONMENT	4TH-ORDER
Simulink	81.8
Julia	18.3









Key results

The 8th- and 12th-order simulations contain a set of control inputs (CI) and initial conditions (IC) that demonstrate some well-known nonlinear dynamics behaviours of the F-16. Most of these arise from the combination of nonlinear aerodynamics and aft centre-of-gravity placement. Table III summarises those cases. The airframes displayed are drawn to scale at 2-second intervals.

Abstract. In the context of human space exploration, the Environmental Control and Life Support System (ECLSS) plays an essential role in ensuring that space habitats provide and maintain life-sustaining conditions for astronauts. A long-duration human spaceflight mission necessitates the development of a highly reliable and sophisticated ECLSS, for which traditional Systems Engineering (SE) approaches, being primarily document-based, are likely to be inadequate in addressing the intrinsic complexity of developing such systems. To overcome these limitations, this work explores the applicability of Model-Based Systems Engineering (MBSE) models and tools, and discloses an integrated MBSE approach that establishes a link between the system model and analysis and simulation tools to support the iterative evaluation and refinement of the system model throughout the design process. To validate the proposed approach, the methodology is applied to the preliminary design of an ECLSS for an Analog Habitat. The results highlight several advantages, including early validation and verification of concepts, improved detection of design inconsistencies, rapid evaluation of design changes, and enhanced robustness, traceability, and efficiency of the design process.

Introduction

The Environmental Control and Life Support System (ECLSS) is a mission-critical element for human spaceflight: it supplies and regulates atmosphere, water, waste handling and, ultimately, habitability across spacecraft and surface habitats. Decades of research and flight experience have consolidated baseline functions and architectures for ECLSS and clarified their tight coupling with other onboard systems [1]. As exploration shifts from short sorties to longer campaigns, reliability, resource closure and integration constraints become the dominant drivers of systems and subsystems architecture definition and technology selection. Standards and agency practices (e.g., ECSS E-34 [2]) further frame the design space and verification needs.

Traditional Systems Engineering (SE) approach for ECLSS design has been predominantly document-centric: requirements, interfaces and verification artifacts are captured in dispersed specifications whose dependencies are difficult to maintain as complexity grows. The resulting friction (weak traceability, delayed defect discovery, and high maintenance overhead) is well documented in SE literature and practice [3]. Model-Based Systems Engineering (MBSE) addresses these limits by making a coherent model the authoritative source for requirements, design, analysis, verification and validation throughout the life cycle; this is reflected in the

Materials Research Proceedings 69 (2026) 1505-1511 https://doi.org/10.21741/9781644904251-264

INCOSE definition and subsequent studies on MBSE value [4]. Moreover, economic/operational analyses indicate that earlier validation, automated consistency, and faster change propagation provide tangible benefits on complex programs.

This paper adopts the ARCADIA methodology implemented in Capella – a MBSE tool well diffused in both Industry and Academia [5] – to structure an ECLSS architecture and its engineering data, leveraging the method's viewpoints and traceability to manage requirements, functions, interfaces and physical architecture. Capella add-ons are used to parameterize the model and expose data to analysis/simulation. In the proposed approach, an analysis and a simulation paths are complementary to provide quantitative estimations at first and then to validate the concept's performance: (i) a quantitative analysis path computing Equivalent System Mass (ESM) [6] and reliability metrics [7] – standard figures for mass, power, volume, crew-time consolidation and risk assessment – based on NASA and common practice, and (ii) a dynamic simulation path via Virtual Habitat (V-HAB) [8] to capture closed-loop interactions and operational envelopes.

The scientific contribution of this work is threefold: (i) to formalize an MBSE workflow that binds ARCADIA/Capella models to external analysis and simulation artifacts through a parameterized bridge; (ii) to demonstrate on an Analog Habitat ECLSS how ESM/reliability analytics and dynamic simulations can be executed directly from the authoritative model to inform trades, check requirements, and iterate the architecture; and (iii) to discuss the impacts on verification & validation timing and configuration control relative to document-centric baselines (NASA SE handbook framing).

The paper is structured as follows: Section 2 outlines the integration approach and model parametrization; Section 3 applies it to the Analog Habitat use-case; Section 4 synthesizes benefits and limitations and identifies extensions to later design phases.

Proposed Integrated MBSE Approach for ECLSS Design

The proposed integrated MBSE approach, described in this paper, aims to support the development of an ECLSS architecture for an Analog Habitat application throughout the entire design process. Fig. 1 provides a comprehensive overview of the main steps that constitute the proposed framework.

The approach relies on the connection between the system model and analysis & simulation tools, enabling engineers to evaluate system performance and iteratively refine the model in an automated and traceable way. In the integration process detailed in this section, the system model is initially connected to engineering analysis tools, which are particularly relevant in the early ECLSS design phases.

The proposed framework consists of four main steps: (i) model definition and parametrization, (ii) automated data extraction and tools interoperability, (iii) simulation and analysis activities, and (iv) results evaluation and requirements validation. In the proposed approach, the system model is progressively defined throughout the process using the ARCADIA methodology [5], exploiting information on the system coming from the integrated analysis and simulation tools, in an iterative process. The integration method relies on the use of the Capella's add-on Property Values Management Tools (PVMT) [9], which enables the parametrization of the model. This allows designers to generate data that can be addressed to the elements of the model, enriching it with information that support the execution of relevant analyses and definition of the system architecture.

Materials Research Proceedings 69 (2026) 1505-1511 https://doi.org/10.21741/9781644904251-264

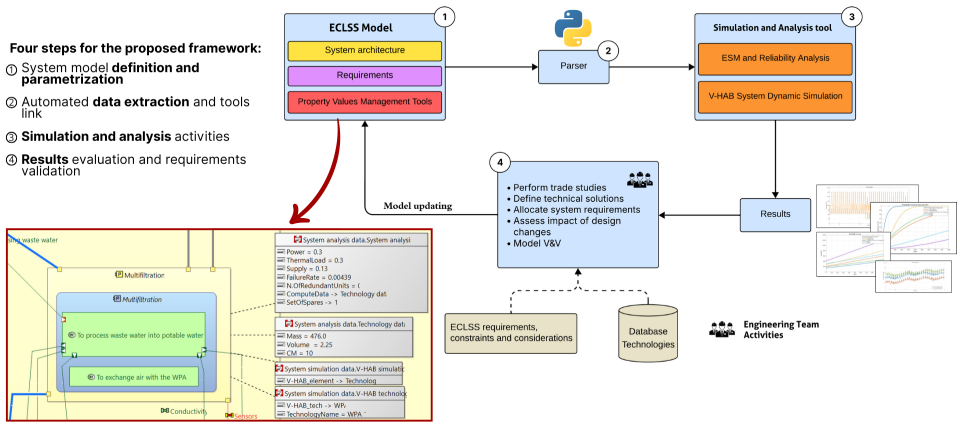

Fig. 1: Integrated MBSE approach.

The integration of the model with the analysis and simulation tools is achieved through a Python-based parser implemented in-house. This library enables the access to model elements and diagrams, as well as the extraction and manipulation of the parameters created through the PVMT. The system data that are extracted are then used to perform analyses or simulations, linking the extracted data with the appropriate external tools. This approach enables the automatic execution of system analysis and simulation, with the objective of obtaining insights into the system's characteristics and behavior. In this work, two different tools are integrated into the model to provide useful information about the system during the early design phases: an Equivalent System Mass (ESM) and reliability analysis tool, as well as the above-mentioned V-HAB simulator. The first tool, based on the parameters extracted from the model, computes two metrics that are fundamental for understanding the characteristics of an ECLSS: the system's ESM and the Probability of Loss of Crew *Pr(LOC)*.

The second tool that is integrated into the model is V-HAB, a simulation tool that simulates the dynamic behavior of an ECLSS for a specified mission scenario. In this work, a Python code is created to convert the system architectural and parametric models from Capella into the corresponding V-HAB ECLSS model. This approach enables the automatic generation of the V-HAB model and the execution of a simulation of the system for the specified mission. Each Python script that enables the extraction of system model information and the subsequent execution of analyses and simulations is imported into Capella using the *Python4Capella* add-on [9]. Once a system configuration is defined, designers can execute the scripts directly from the model, automatically obtaining the results for the system represented in Capella. Designers can exploit these results to perform trade studies, define technical solutions, verify requirements, assess the impact of design changes, and conduct continuous verification and validation of the model. Therefore, the proposed integrated approach supports the iterative evaluation and definition of the system model through the design process.

ECLSS Design for an Analog Habitat

To validate the proposed approach and obtain a more comprehensive understanding of its key advantages, the integrated approach is applied for the preliminary design of the ECLSS for an Analog Habitat. They provide a controlled, Earth-based proxy to test architectures, procedures, and human-system interactions under realistic operational constraints before flight, while offering cost and risk reduction, TRL maturation for ECLSS technologies, and high-fidelity study of human factors. An Analog Habitat campaign therefore constitutes an appropriate proving ground for an MBSE-driven ECLSS design loop: mission durations are shorter, safety can rely on terrestrial contingencies, and rapid iteration is feasible – yet the same drivers (closure vs. logistics, reliability vs. mass, ops complexity vs. robustness) still govern architecture quality [10].

Materials Research Proceedings 69 (2026) 1505-1511 https://doi.org/10.21741/9781644904251-264

The Analog Habitat is modeled with ARCADIA/Capella across its Operational, System, Logical, and Physical layers; mission objectives and requirements derive from stakeholder analysis and drive the ECLSS functions and interfaces used downstream. The Physical Architecture level (of which an example is shown in Fig. 2) serves as the authoritative source for technology choices and links (e.g., Atmosphere Control & Supply (ACS), Water Recovery & Management (WRM), Temperature & Humidity Control (THC) sub-systems), enriched with PVMT properties to capture masses, volumes, power, heat loads, consumables/expendables/spares, failure rates, redundancy/spares counts, set-points, and scenario data.

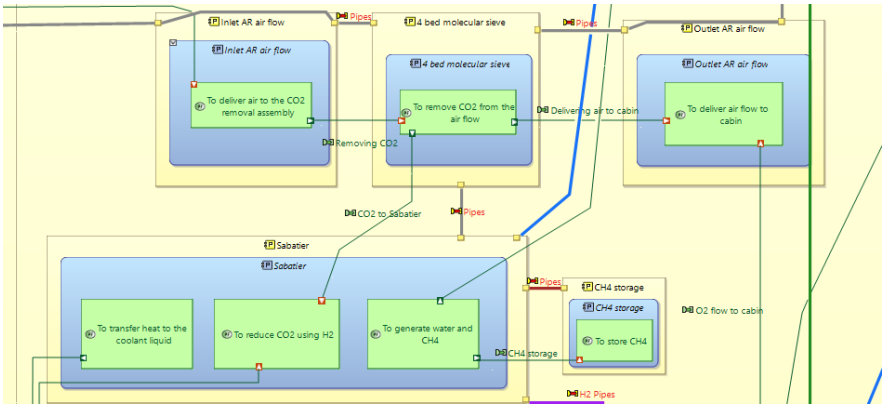

Fig. 2: Portion of the initial ECLSS architecture as represented in the PAB diagram.

A Python bridge (Python4Capella/capellambse) extracts components, links, PVMT properties (i.e., masses, flow-rates, power consumptions, simulation data, etc.), requirement links for the two tools: (i) an ESM & reliability calculator; (ii) a V-HAB model generator/runner. Execution inside Capella keeps analyses coherent with the checked-in model state.

The baseline ECLSS emphasizes the adoption of regenerative P/C technologies appropriate for long duration (eventhough in the analog they are assessed here over shorter analog missions). ESM aggregates mass, power, volume, heat rejection, and crew-time via mission-specific conversion factors per [6]; reliability uses constant-rate components with spares/redundancy treatment to estimate Probability of Loss of Crew *Pr(LOC)* [7].

The initial configuration (no spares/redundancy), results – as per Fig. 3 and Fig. 4 – show approximately linear ESM growth with duration (driven by time-dependent terms) and an unacceptably high Pr(LOC) even at ~10 days – highlighting the classic mass–reliability tension of recycling-heavy systems. The analyses show how storage-heavy architectures tend to be more reliable for short missions but incur higher ESM at longer durations; closing loops reduces ESM at longer durations but increases failure exposure unless mitigated by spares/redundancy.

Materials Research Proceedings 69 (2026) 1505-1511 https://doi.org/10.21741/9781644904251-264

The V-HAB generator creates a model equivalent to the Capella component-level model (at PA level): compartments, storages, technology instances, and controllers, with boundary conditions from PVMT (e.g., phasing, crew planners, initial inventories).

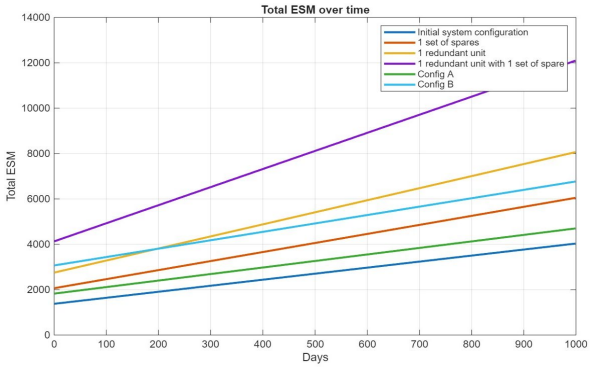

Fig. 3: Pr(LOC) over mission duration.

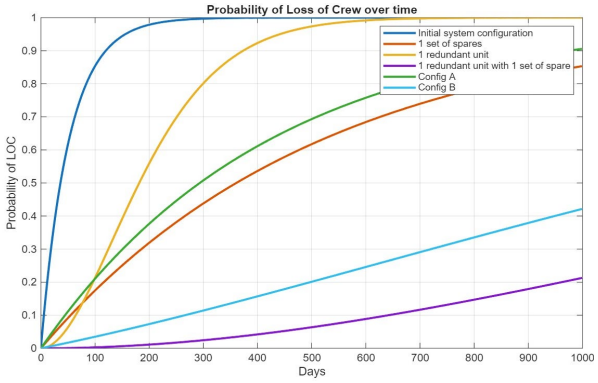

Fig. 4: ESM over mission duration.

The simulator runs closed-loop simulations (cabins, species, inventories, power) to verify requirement bounds and probe sensitivities/failure responses. Typical checks include: cabin pressure and major constituent partials recovery after disturbances; WRM throughput under crew metabolic loads; power/thermal margins; controller robustness under off-nominal inflows or component outages. Results – of which an example is shown in Fig. 5 and Fig. 6 – are fed back to requirement elements (Reviewed/WIP) to maintain traceable closure.

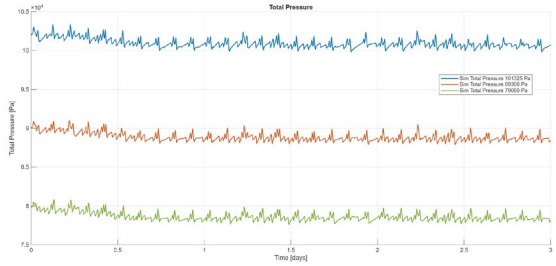

Fig. 5: Total cabin pressure over the mission duration for three different scenarios.

Materials Research Proceedings 69 (2026) 1505-1511 https://doi.org/10.21741/9781644904251-264

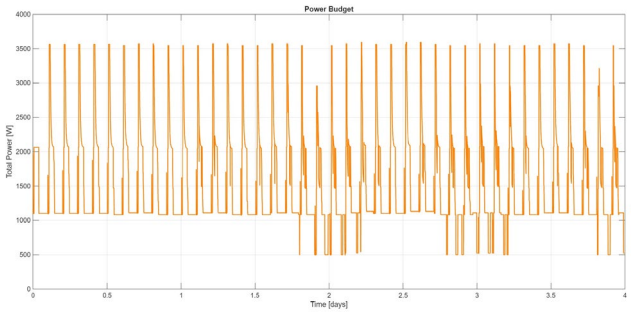

Fig. 6: ECLSS Power budget for a specified mission.

As illustrated in this section, this integrated MBSE approach establishes the model as the central source of truth for data across the entire design process, serving as a unified repository that guides requirement traceability, architecture development, analysis, and simulation throughout all phases of the ECLSS design.

Conclusion

The proposed integrated MBSE approach was developed to support the ECLSS design process. Its application to a real-world project enabled the identification of the key advantages of this approach, thereby overcoming the main limitations of the traditional methodology and leveraging the full potential of MBSE. This work demonstrated that any kind of analysis or simulation tool can be effectively integrated into a standard MBSE methodology. Indeed, a successful connection was established between Capella and an external simulation tool, as well as a custom-made analysis.

The characteristics of the proposed approach ensure consistency between the system model in Capella and the analysis and simulation tools. This guarantees that simulations and analyses are always consistent with the system model established in Capella, ensuring they consistently reflect the latest version of the model. The automatic execution of integrated tools from the model also contributes to a reduction in time and errors involved in creating the simulation each time it is required. In this integrated environment, once a system configuration has been established, analyses and simulations can be conducted rapidly, thereby providing insights into the system and enabling the rapid evaluation of the effects of design changes.

Moreover, this integrated approach facilitates the early detection and resolution of design issues by enabling verification and validation of the system from the initial stage of the design process. Furthermore, it facilitates the assessment of requirements since the initial design stages. Consequently, the proposed approach is expected to enhance the management of complexity in designing systems like the ECLSS, improving the overall robustness, traceability, and efficiency of the design process.

Future work will aim to integrate the system model with advanced engineering tools to assess the effectiveness of the approach in later design phases and further consolidate its applicability to other mission-critical systems.

Abstract. Ambitions for sustained human presence beyond Earth are accelerating, while environmental accountability and long development timelines expose limits of document-centric systems engineering approach. Crewed mission architectures integrate propulsion, communications, life support, and habitats under tight safety, performance, and sustainability constraints; decisions propagate across technologies and phases, and their impacts unfold over space and time under uncertainty. Model-Based Systems Engineering (MBSE) can manage architectural complexity, but it rarely embeds life cycle sustainability reasoning with sufficient fidelity or timeliness. This paper introduces the concept of a framework that unifies MBSE and Scenario-Based Life Cycle Assessment (SB-LCA) to perform continuous, traceable, time- and location-aware sustainability evaluation as systems' designs evolve. The framework consists of two layers: (i) a process-based LCA that quantifies the environmental impact of technologies to drive architecture trades; (ii) a transportation layer that selects payload-feasible launcher classes and partitions their footprint into static (manufacture, propellants, end-of-life) and variable (trajectory-resolved operations) contributions. Within this second layer, mission analysis couples emissions and atmospheric-response models to generate a geo-referenced inventory. Hetero-functional graphs capture interdependencies and enable reuse of SB-LCA modules across phases. The proposed approach is envisioned to identify dominant drivers, quantify sensitivities to payload growth, vehicle choice, and trajectory design, and iteratively guide lower-impact configurations – providing measurable environmental targets for responsible human space exploration.

Introduction

Designing crewed space exploration systems represents a complex system-of-systems problem: various subsystems – propulsion, communications, life support, etc. – must function coherently under harsh environments, long development timelines, and stringent safety and performance constraints [1]. Traditional, document-centric Systems Engineering (SE) has struggled to provide timely, traceable decision support across these tightly coupled design spaces. Model-Based Systems Engineering (MBSE) advances the state of practice by shifting to model-centric artifacts that improve consistency, collaboration, and lifecycle traceability [2]. Yet, even MBSE workflows rarely embed environmental sustainability with sufficient fidelity to influence early trades, despite the growing imperative to account for life-cycle impacts of space infrastructures. Life Cycle Assessment (LCA) and its broader sustainability formulations have recently been proposed to inform mission design, but adoption remains fragmented and often decoupled from architecture

models and design iteration [3]. Moreover, launcher footprint and the chemical emissions produced throughout a space mission have emerged as potentially dominant contributors to climate and atmospheric impacts, reinforcing the need to co-design payload architectures with transportation choices. Recent studies quantify large climate impacts tied to rocket exhaust and compare environmental burdens across launcher architectures [4][5], while analyses of rapidly expanding space infrastructures highlight prospective greenhouse-gas footprints at constellation scale [6]. These insights motivate sustainability assessments that are (i) scenario-aware, (ii) time- and location-resolved, and (iii) natively integrated within systems models and mission analyses. Scenario-Based LCA (SB-LCA) offers a principle-based language to represent uncertainty in future technologies, operations, and policies, enabling structured comparison of plausible pathways [7]. However, practical integration of SB-LCA into MBSE remains limited by representational gaps (how to bind LCA elements to system architecture and behavior), data gaps (how to reuse and update inventories as designs evolve), and analytical gaps (how to propagate mission analysis, emissions, and atmospheric responses into life-cycle metrics). Closing these gaps is especially important in early phases of crewed missions, where small architectural changes – mass growth, interface choices, duty cycles – can cascade into different launcher classes, trajectories, and, ultimately, different environmental profiles.

This paper addresses these gaps by introducing an MBSE ARCADIA/Capella-based Modeling & Simulation (M&S) framework [8], enriched with SB-LCA, for human exploration architectures, demonstrated on a notional Lunar Habitat mission. The framework embeds LCA constructs directly into system and mission models, enabling continuous, traceable sustainability evaluation alongside performance and safety considerations. It enforces a two-layer architecture: (i) a process-based LCA layer quantifies sustainability metrics for habitat technologies to drive architecture trades; and (ii) a transportation layer that, after preliminary habitat sizing, supports the user in selecting feasible launcher classes from payload-driven macro-categories and partitions their footprint into static (manufacturing, propellants, end-of-life) and variable (trajectory-resolved operations) contributions. The variable contribution is quantified by coupling mission analysis with emissions and atmospheric-response models to produce a geo-referenced inventory along the prescribed trajectory, which is then integrated with habitat delivery impacts for a mission-level footprint [4][5]. In doing so, it turns MBSE from a passive container of sustainability results into an active co-simulation environment where environmental objectives can be traced to architecture choices, requirements, and operational concepts [2][3].

Proposed methodology

First layer. The first layer of the proposed methodology presents as main baseline a ARCADIA/Capella-based workflow [9], with the model acting as the authoritative source for requirements, behavior, interfaces, and physical architecture. Specific Capella add-ons for creating parametric extensions (PVMT) and Python bridges (Python4Capella) [10] enable the automatic extraction of model data, the execution of external analyses and simulations, and the write-back of results, thereby maintaining configuration coherence and traceability throughout iterative trade studies and early V&V. This integration pattern has been demonstrated in previous Capella applications to quantitative assessment and dynamic simulation, establishing a reliable path for analysis-in-the-loop [8]. An example of the framework structure is presented in Fig. 1.

Within this baseline, the lifecycle and the Concept of Operations (ConOps) with associated Operating Modes are modeled as co-equal artifacts and tightly linked to the evolving architecture. Mission phases and mode logic structure the full sequence of activities from early development and verification through commissioning to nominal operations, providing the temporal scaffold required for scenario-aware assessments and allowing performance and behavior to be evaluated consistently from the earliest stages [8].

Materials Research Proceedings 69 (2026) 1512-1517 https://doi.org/10.21741/9781644904251-265

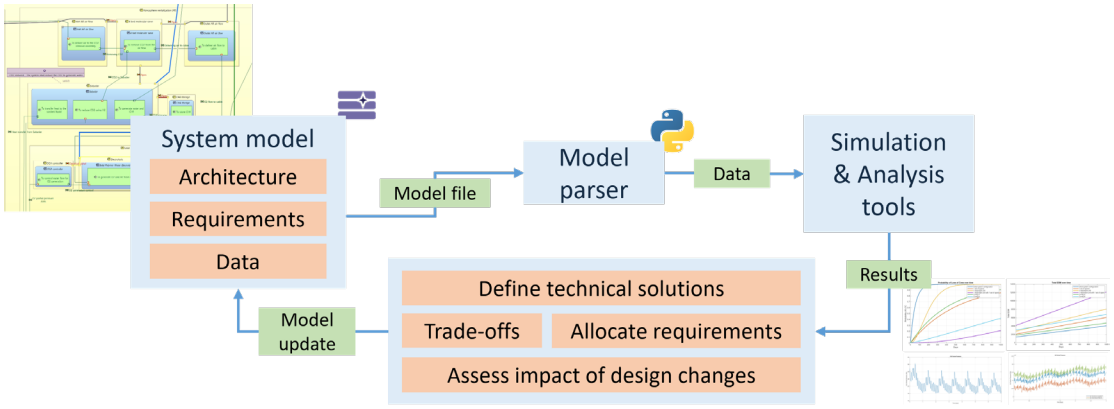

Fig. 1: First layer and M&S framework structure.

Scenario-Based Life Cycle Assessment (SB-LCA) is embedded in this environment to transform the modeled lifecycle and ConOps into quantified sustainability evidence. For a selected configuration and scenario, the Capella bridge composes the pre-operational and operational activity set from the lifecycle and ConOps, projects each activity to its planned execution year, aggregates inventories, and computes characterized impacts that are written back to the model as figures of merit alongside mass, power, reliability, and other metrics. In this way, environmental performance becomes a peer objective in model-driven trades rather than an external report, consistent with the two-layer methodology in which process-based LCA supports technology decisions at habitat level while transportation impacts are assessed separately and merged to produce a mission-level footprint. A practical bottleneck lies in building the life-cycle inventory for every component and every modeled activity. To avoid out-of-model information spread, LCA metadata are authored directly in Capella – leveraging PVMT and domain extensions – so that materials, energy, logistics, facility usage, consumables, and end-of-life assumptions are attached to components and to lifecycle/ConOps activities within the same authoritative model. This approach reuses the proven data plumbing employed for quantitative analyses and enables consistent queries by configuration, phase, or scenario; Ecodesign4Capella add-on [10] supports this in-model inventory capture and governance.

Second layer. The second layer of the framework enables the selection of a launch vehicle using outputs from the first layer – payload mass, volume, and sustainability-feasible habitat configurations – and evaluates the chosen vehicle's environmental performance on a life-cycle basis. Vehicles are drawn from a predefined pool grouped by lift capacity; once a candidate is identified, its impacts are quantified across production and operations and decomposed into: (i) a static contribution covering manufacturing of hardware and propellants and end-of-life treatment, sourced from referenced impact databases and industrial inventories [5][6][11][12]; and (ii) a variable contribution covering mission operations along the trajectory, including atmospheric responses to pollutant and greenhouse-gas emissions generated during flight [4][13][14]. The aggregation of static and variable parts yields a comprehensive, LCA-based environmental profile that supports comparative assessment and sustainability-driven trade-offs within mission design. Inputs comprise payload descriptors and a candidate set characterized by class (medium, heavy, super-heavy), stage configuration, propulsion type, propellant mass, and fairing dimensions. A selection algorithm matches requirements to a class and vehicle, within a scenario-based LCA structure that separates modeling, scenario definition, and impact evaluation for transparency and reuse [3][5][6].

Each launcher is parameterized in the MBSE environment so that mass breakdowns, propellant demand, and geometry propagate automatically to downstream assessments. This modularity enables rapid substitution of vehicles or mission scenarios with immediate updates to impacts. For

Materials Research Proceedings 69 (2026) 1512-1517 https://doi.org/10.21741/9781644904251-265

the static life-cycle portion, cradle-to-gate and launch-to-grave costs of rocket hardware and propellants are quantified and split into manufacturing/upstream propellant production and end-of-life processes; reported evidence indicates manufacturing/upstream dominates the overall footprint of launch systems [5]. Hardware inventories for structures, engines, tanks, avionics, and subsystems are taken from industry LCA studies and validated databases [15], while propellant chains (oxidizer and fuel synthesis, cryogenic processing, storage) use literature emission factors [16]. Static LCA modules are implemented as reusable elements linked to the parametric launcher model so that changes in mass, materials, or configuration are reflected automatically, preserving traceability between design parameters and impact indicators.

The variable contribution is derived from mission operations by coupling a mission-analysis tool with an emissions module that produces a time-resolved, geo-referenced exhaust profile for the selected launcher, as shown in Fig. 2. Mission analysis generates the trajectory from thrust requirements, propellant mass flow, and aerodynamic characterization. The emissions module thermodynamically characterizes the engine via a simplified propulsion model and, from propellant mass, temperature, and pressure profiles, estimates time-resolved chemical outputs using combustion-kinetic formulations. Tracked species include CO_2, H_2O, NO_x, CO, and soot (black carbon). Species-specific, altitude-dependent impact coefficients from atmospheric chemistry and radiative-transfer models capture the differing climate and ozone effects across atmospheric layers [16], with high-altitude releases receiving enhanced forcing factors to reflect disproportionate radiative and chemical effects relative to surface emissions [4]. Geospatial and temporal multipliers convert emitted masses into standardized impact units (e.g., CO_2-equivalents, ozone-depletion equivalents). Resulting inventories feed impact-assessment functions (global-warming potential, ozone effects, etc.) to yield the variable share of the launcher footprint [13][14].

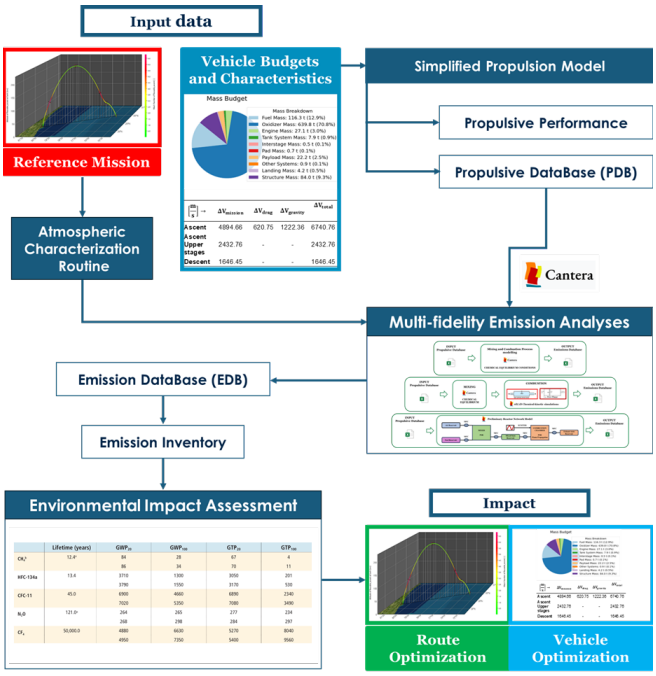

Fig. 2: Second layer dynamic contribution.

Static and dynamic contributions are then aggregated to provide the total environmental footprint of the selected transport vehicle, per mission or per kilogram of delivered habitat, expressed in standardized metrics that can be directly compared with habitat subsystem impacts from the first layer. Embedded within an MBSE/SB-LCA backbone, the process is inherently iterative: alternative vehicles, profiles (timing, trajectory), and reuse assumptions can be introduced as new scenarios, each producing updated, scenario-consistent impacts for quantitative trade-off analyses. SB-LCA principles allow systematic exploration of launch cadence, reusability rate, and technological evolution on environmental outcomes [3][5][6], while the MBSE backbone ensures consistent, traceable data flows across design iterations, inventories, and analyses [11][12][15][16].

By applying SB-LCA principles, the approach allows decision-makers to systematically evaluate how variations in key assumptions – such as launch cadence, reusability rate, or technological evolution – affect environmental outcomes, while the MBSE backbone ensures that data flows remain consistent, traceable, and fully integrated across design iterations.

In this configuration, calculated environmental impacts – time-located and scenario-consistent – serve as decision-quality figures of merit for technology selection and scheduling, while end-to-end traceability is preserved across requirements, architectural choices, lifecycle/ConOps definitions, and quantitative analyses executed from the model.

Conclusions

The presented integrated framework embeds Scenario-Based Life Cycle Assessment within an ARCADIA/Capella Modeling & Simulation workflow for crewed space systems. Lifecycle and Concept of Operations are modeled as first-class artifacts, while life-cycle inventories are authored in-model via PVMT and Ecodesign4Capella, making environmental assessment continuous, traceable, and time-located.

A two-layer formulation couples Scenario-Based Life Cycle Assessment for technology trades with a transportation layer that partitions launcher impacts into static (manufacturing, propellants, end-of-life) and variable (trajectory-resolved operations) components, ensuring delivery and pre-operational flights are captured in the mission footprint. Impact metrics are written back to the authoritative model alongside performance and safety figures of merit. The proposed approach, co-locating Scenario-Based Life Cycle Assessment with lifecycle and operating-mode models can thus expose dominant drivers early, quantify sensitivities to payload evolution, subsystem choices, launcher macro-class, and trajectory design, and support iterative convergence toward lower-impact architectures.

Current limitations center on inventory completeness, database representativeness, and uncertainty propagation across coupled analyses. Future work will emphasize uncertainty and sensitivity quantification, standardized data schemas and connectors, validation against test/flight evidence, and extensions to logistics, reuse/refurbishment, and in-situ resource utilization. With these enhancements, the framework provides a decision-grade backbone for setting – and demonstrating progress toward – measurable environmental targets in complex crewed mission design.

Abstract. The design of next-generation flight vehicles for space access and in-orbit operations requires agile and modular tools that can support the rapid prototyping of expendable and reusable vehicles. Since 2020, Politecnico di Torino has been developing the iDREAM methodology and toolset within the framework of the GSTP program under the supervision of the European Space Agency (ESA). In its initial iteration, iDREAM focused on two case studies: a Micro Launcher (ML) and a Human Landing System (HLS). The toolset is composed of three main modules to: (i) support conceptual design activities through ASTRID-H, (ii) enable early-stage assessment of economic viability via HyCost and, (iii) analyze technology sustainability through TRIS, the dedicated technology roadmapping module. Moreover, a unified and upgraded database, supported by an in-house developed Database Management Library, supports the operation of all modules within the integrated toolset. The ongoing second phase (iDREAM 2.0) marks a paradigm shift by extending the methodology to support reusable flight systems, including first and/or second stage vertical and/or horizontal landing launch vehicles (RLV), reusable re-entry vehicles (RREV), and hypersonic use cases and introducing a highly modular environment. A key innovation lies in the integration of reusable systems modelling within existing expendable-focused routines, reducing redundancy and maximizing tool adaptability. The adopted approach focuses on minimizing the number of routines required for design and analysis while maximizing the coverage of reusable configuration combinations. Following a detailed trade-off analysis, the final architecture includes six routines for ASTRID-H, three for HyCost, and a single unified routine for the technology roadmapping TRIS module. This paper presents the current status of the ongoing iDREAM 2.0 project, which is currently in the development phase and undergoing validation through a set of reference vehicles. These include reusable launch systems, with vertical and horizontal recovery, reusable re-entry capsules, and hypersonic vehicle, demonstrating the framework's versatility in supporting the design of future reusable space systems.

Introduction

The contemporary space sector faces compressed timelines, heterogeneous missions, and rising cost pressure. Early decisions must therefore couple performance, affordability, and technology maturity – yet these dimensions are still too often treated in separate loops. Multidisciplinary Design Optimization (MDO) enables fast, coupled performance trades, but mainstream practice rarely integrates cost and technology roadmapping in the same decision cycle [1]. Concurrent design teams demonstrate that time-boxed, integrated studies accelerate iteration and improve

Materials Research Proceedings 69 (2026) 1518-1523 https://doi.org/10.21741/9781644904251-266

traceability, but economic and maturation analyses are typically handed off to downstream tools [2].

Within performance, high-fidelity mission/trajectory tools (e.g., ASTOS [3]) assess launcher and re-entry feasibility but are not designed to co-evolve with cost or roadmap logic in early trades. In parallel, cost estimation spans agency and commercial traditions – from TRANSCOST and NAFCOM [4] to subsystem-level CERs for small-launcher markets [5] – yet these models are seldom wired directly to the conceptual sizing variables that drive mass and configuration sensitivities. Subsystem-granular CERs and "theoretical first unit" logic are most useful when fed by design data rather than spreadsheets; classic systems texts (e.g., SMAD [6]) similarly argue for considering affordability from day one.

On the technology side, roadmapping aligns stakeholder needs, capabilities, and enabling technologies. Phaal et al. [7] frame it as a flexible planning method. Building on this literature and ESA practice, TRIS introduced a rational, systems-engineering process that prioritizes technologies, quantifies schedule/cost implications, and plans maturation activities – moving beyond purely expert-driven roadmaps [8].

What was missing was a single, modular environment that (a) makes design, cost, and roadmapping talk natively; (b) keeps stakeholder needs in the driver's seat; and (c) preserves consistent data across loops. iDREAM 1.0 addressed this gap within ESA's GSTP framework (with ASI support), unifying ASTRID-H (conceptual/preliminary design), HyCost (early life-cycle cost), and TRIS (technology roadmapping) on a shared HyDat database and in-house management library [9].

This paper presents iDREAM 2.0, which generalizes that baseline for reusability and hypersonic missions. The architecture embeds recovery and operations within the same loop as sizing, cost, and roadmaps, while minimizing routine duplication. Concretely, it consolidates six ASTRID-H routines, three reuse-aware HyCost flows, and a single unified TRIS routine, all backed by an upgraded HyDat for traceable, one-source-of-truth parameters and automatic exchange of mass, cost, and roadmap evidence.

The paper is organized as follows: §2 summarizes iDREAM 1.0; §3 details the iDREAM 2.0 architecture and reusable-system extensions; §4 concludes with key findings and future work.

iDREAM 1.0 toolset and capabilities

iDREAM 1.0 integrates three pillars – ASTRID-H for conceptual/preliminary design, HyCost for early life-cycle cost assessment, and TRIS for technology roadmapping – on top of a shared database (HyDat) and an in-house Database Management Library, as shown in Fig. 1. ASTRID-H extends a decade of multi-fidelity sizing research at Politecnico di Torino from aircraft into microlaunchers and lunar landers, retaining a structured workflow that supports both *"sizing from scratch"* and assessment of existing configurations. It exchanges mission analysis data with ASTOS to refine closure: preliminary sizing (mass, dimensions, aerodynamics, propulsion) is iterated with an internal mission design routine, then re-optimized in ASTOS, and reintegrated into ASTRID-H to sharpen propellant and payload allocation. The microlauncher workflow implements both a restricted staging algorithm for feasibility checks and an optimal Lagrange-multiplier staging

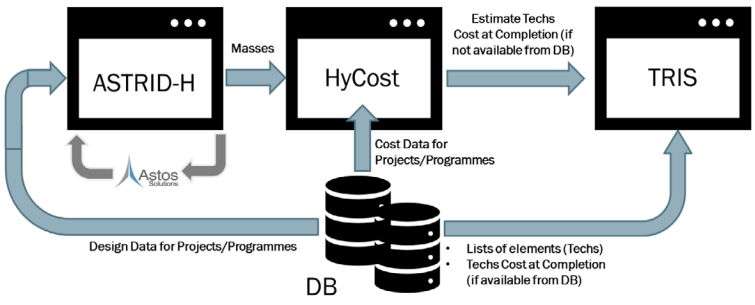

Fig. 1: iDREAM 1.0 structure.

scheme to minimize mass given payload and burnout velocity, with structural-ratio ranges linked to propellant type.

HyCost complements ASTRID-H by estimating development, manufacturing, and operating costs – as well as cost and price per flight – directly from design variables and performance outputs or from user databases. At its core are subsystem-level cost-estimation relationships, tuned with reduction factors for commercial applications and learning curve options for innovative manufacturing. The adopted approach builds on an ESA methodology for small and commercial launch vehicles based on *"recurring first unit"* logic and linear factors at subsystem/equipment level, extended in iDREAM to include process/manufacturing considerations so that estimates remain transparent and updateable as new commercial data emerge. HyCost also aggregates results by technology families to provide cost-at-completion inputs for TRIS.

TRIS closes the loop by converting the coupled design–cost view into a rational, stakeholder-driven roadmap. The methodology proceeds through five steps – (i) stakeholder analysis, (ii) elements definition (operational capabilities, technologies, building blocks, and mission concepts/activities), (iii) prioritization, (iv) planning, and (v) results evaluation – implemented with mathematical and logical models and supported by database-curated lists and resource estimates for TRL transitions. Recent updates improve allocation of budget/time in the planning algorithm and enable "non-ideal" roadmaps under constrained scenarios, reflecting ESA practice across hypersonic, re-entry, and exploration contexts.

These modules operate on a common data backbone. HyDat – a MySQL database originally developed with ESA to support technology roadmapping for hypersonic transportation and reusable access-to-space systems – now feeds and records parameters across design, cost, and roadmaps through a dedicated Database Management Library. The entire stack is implemented in Python with an integrated GUI; each module can be used stand-alone or in the fully coupled flow, ensuring traceable, bidirectional data exchange and repeatable studies.

With such structure, iDREAM 1.0 enables rapid *"what-if"* exploration where a design change immediately propagates to affordability and maturation plans – and vice versa. A validation on Rocket Lab's Electron [10] illustrates the approach: starting from public mission and configuration data, ASTRID-H/ASTOS converge on masses and dimensions within ~10% of reported values – consistent with conceptual-design expectations – while HyCost produces a subsystem breakdown aligned with reference costs and TRIS organizes a time- and budget-aware development path to TRL 9 over the program timeline. Methodologically, iDREAM sits alongside MDO/PIDO integration frameworks but takes a deliberately domain-opinionated stance: aerospace-specific routines and a shared database minimize setup friction and brittle file hand-offs while preserving the agility of early-phase trades. That foundation proved particularly useful as reusability became mainstream – where recovery constraints, refurbishment, and cadence-driven operations tightly couple trajectory, structures, and cost – setting the stage for the generalized, modular extensions presented in §3.

iDREAM 2.0 updated toolset and capabilities

iDREAM 2.0 generalizes the 1.0 framework to cover reusable systems and hypersonic use cases while deliberately minimizing the number of routines needed to span a wide configuration space. The guiding principle is to embed reuse logic inside the same expendable-focused workflows wherever possible, avoiding duplicate code paths and brittle hand-offs. After a trade-off on alternative decompositions, the architecture converged into six routines for ASTRID-H, three for HyCost, and a single, unified routine for TRIS. This structure keeps data consistent across modules and concentrates model complexity where it adds coverage rather than redundancy.

ASTRID-H. As shown in Fig. 2, the ASTRID-H module now supports both expendable and reusable configurations through four core routines – Expendable/Reusable Vertical Launcher (ER-

Materials Research Proceedings 69 (2026) 1518-1523 https://doi.org/10.21741/9781644904251-266

VT), Expendable/Reusable Horizontal Take-Off (ER-HT), Re-entry Vehicle (REV), and Human Landing System (HLS) – augmented by two supplementary landing routines for Vertical Landing (VL) and Horizontal Landing (HL).

1. Take-Off and Landing Strategies: Module Definition

	ASTRID-H					
	Configuration (T/O)			Landing		Case Study
Categories	Winged	Vertical Launcher	Lifting Body	HL	VL	
Micro Launcher		1		N/A	N/A	ML
Medium Launcher		1		N/A	N/A	MED L
Heavy Launcher		1		N/A	N/A	HEA L
Reusable Launch Vehicle 1st stage		1			4	RLV1 VTVL
		1		5		RLV1 VTHL
	2				4	RLV1 HTVL
	2			5		RLV1 HTHL
Expendable Vehicle 1st stage		1		N/A	N/A	EXP1 VT
	2			N/A	N/A	EXP1 HT
Reusable Launch Vehicle 2nd stage	2			5		RLV2 HL
		1			4	RLV2 VL
Expendable Vehicle 2nd stage		1		N/A	N/A	EXP2
Exp. Re-entry*			3	N/A	N/A	EREV
Reusable Re-Entry Vehicle *			3	5		RREV HL
					4	REV VL
Hypersonic Vehicle	2			5		HYPER
Lunar Lander		6			6	HLS

Combining the stage from Table 1 shows that the routine methodologies (ASTRID-H, HyCost) can be combined in the same way of vehicle stages.

2. Potential Vehicle Combinations (RLV - EXP): Module Blend

First Stage	Second Stage: EXP2	Second Stage: RLV2 VL	Second Stage: RLV2 HL	Combination	Name	Reference vehicle

Fig. 2: iDREAM - ASTRID-H routines modularity overview.

The landing routines compute propellant consumption and the additional equipment/mass required for controlled descent, then feed those increments back into the sizing loop. This structure lets a single vehicle study switch from expendable to reusable assumptions by toggling landing logic rather than swapping entire design flows; it also keeps hypersonic, wing-assisted take-off cases within the same ER-HT backbone. Complementing this architecture, the modularity approach was derived from a survey of target categories – RLV first/second stages (VTVL/VTHL/HTHL or VL/HL), E/REVs, hypersonic vehicles, and medium/heavy launchers – so common take-off/landing strategies and reuse features are handled by shared sub-models rather than case-specific branches.

Methodologically, ASTRID-H retains the multi-fidelity conceptual/preliminary design stack established in 1.0 and continues to exchange mission analysis data with ASTOS for closure. The same design estimation logic and mass estimation workflow used for expendable microlaunchers is now re-used for RLVs, with landing increments and recovery constraints injected through the VL/HL supplements before trajectory re-optimization. This preserves the tight ASTOS-ASTRID-H loop that proved effective for 1.0 while expanding coverage to reuse-driven constraints.

HyCost. To parallel the generalized design layer, HyCost consolidates early-phase LCC into three approaches: (i) an Expendable Launchers (EXP) flow; (ii) a Reusable Space & Point-to-Point Transportation and Re-entry (RST) flow covering reusable first/second stages, HTHL/VTHL concepts, and E/REVs; and (iii) a tailored Human Landing System (HLS) routine. The RST logic introduces refurbishment, inspection/maintenance, turnaround assumptions, and cadence effects while preserving the subsystem-granular CER philosophy adopted in 1.0 so estimates remain transparent and updateable as new commercial data emerge. All three flows ingest ASTRID-H outputs directly (masses, counts, propellants, equipment) to keep architectural sensitivities intact.

TRIS. In 2.0, TRIS operates through a single roadmapping routine applied uniformly across case studies. It keeps the five-step, systems-engineering process while incorporating the recent upgrades to time/budget estimation and to resource-constrained planning that allow realistic, non-ideal roadmaps. Technologies tied to reuse (e.g., Thermal Protection System (TPS) durability, landing systems, rapid turnaround operations) can therefore be prioritized and scheduled with budget/time constraints and demonstration-asset logic, consistently across RLVs, RREVs, and hypersonic cases.

HyDat. All modules share an upgraded HyDat-backed database accessed through the in-house Database Management Library, ensuring one-source-of-truth parameters and automatic exchange of mass, cost, and roadmap evidence across studies. The same backbone that linked ASTRID-H, HyCost, and TRIS in 1.0 now anchors reuse-specific fields (e.g., landing equipment, refurbishment tasks, inspection intervals) without fragmenting the schema, which is crucial for rapid, cross-module *"what-if"* iterations.

Validation set and current status. iDREAM 2.0 is being validated against a reference vehicle set spanning vertical and horizontal recovery launchers, a reusable re-entry capsule, and a hypersonic vehicle. These cases exercise the combined ER-VT/ER-HT/REV/HLS workflows and the VL/HL landing supplements, while the corresponding EXP/RST/HLS cost flows and the unified TRIS routine are used to verify consistent propagation of design changes into affordability and maturation plans. This staged validation is intended to demonstrate that the *"few routines, broad coverage"* strategy yields AGILE prototyping across reusable and expendable regimes.

Conclusions

This paper has presented iDREAM 2.0, an integrated methodology and toolset that brings conceptual design, early cost assessment, and technology roadmapping into a single, data-consistent environment, extending the scope of iDREAM 1.0 to reusable launch systems, reusable re-entry vehicles, and hypersonic applications. The core architectural choice – few routines, broad coverage – keeps early-phase studies agile while introducing the hooks required by reusability. Concretely, ASTRID-H now organizes sizing and mission analysis through four core routines (expendable/reusable vertical launcher, expendable/reusable horizontal take-off, re-entry vehicle, and lunar lander) complemented by two landing supplements (vertical and horizontal) that inject recovery physics and landing equipment into the loop. HyCost offers three reuse-aware flows (expendable, reusable/point-to-point/re-entry, and a tailored HLS routine) to keep subsystem sensitivities visible as assumptions evolve. TRIS operates through a single, unified methodology that prioritizes and schedules maturation activities using the same evidence base as design and cost. All modules exchange parameters through an upgraded HyDat database and the in-house management library, ensuring traceability and rapid *"what-if"* propagation across the stack.

The result is a domain-opinionated environment that maintains the speed of conceptual trades while reflecting operational realities – landing increments, refurbishment and turnaround, reuse-dependent reliability and maintenance, and cadence-sensitive economics – without multiplying bespoke tools or brittle hand-offs. Current limitations are those inherent to early-phase modeling: bounded fidelity for certain subsystems, uncertainty in commercial cost data, and the need for richer representations of refurbishment policies and inspection intervals. Near-term development will focus on uncertainty propagation across design-cost-roadmap strands, deeper reliability and maintenance modeling for reusable elements, tighter links to trajectory optimization and aero/thermal pre-design and expanded sustainability metrics. With these enhancements, iDREAM 2.0 offers a practical foundation for fast, defensible decisions across a broader class of future reusable space systems.

Keywords: Spacecraft Health Monitoring, Solar Panels Incipient Damage Identification, Onboard Fault Diagnosis, Signals Compression, Bayesian Inference

Abstract. Spacecraft solar panels are among the most failure-prone subsystems, requiring onboard health monitoring to ensure reliable operation in harsh space environments. This work demonstrates and validates the FREEDOM digital twin for onboard near real-time health management of spacecraft solar arrays under limited computational resources. The twin is trained offline through a two-stage data-assimilation process, and operates online to predict degradation via inverse Bayesian optimization. Validation performed on a solar panel integrating AZUR SPACE 3C44 cells under incipient damages across a ten-year geostationary-orbit mission scenario yielded a mean damage-prediction error of 5.2 % with a computational time of 62 s.

Introduction

Spacecraft solar panels represent the dominant source of unrecoverable faults within the electrical power system (EPS) [1]. Fault detection and isolation (FDI) for these systems remains particularly challenging due to their coupled electrothermal dynamics, limited sensing capability, and continuous exposure to the harsh space environment [2]. Solar panels are subjected throughout their operational life to radiation, micrometeoroid and debris impacts, and ultraviolet (UV) darkening, which induce gradual and often coupled degradation in the photovoltaic materials and interfaces [3]. These effects alter the current–voltage response in subtle ways, producing variations in telemetry that remain within nominal limits until significant power loss occurs [2]. The detection of such incipient degradations is further complicated by the need for near real-time monitoring in geostationary and deep-space missions, where long communication delays prevent continuous ground supervision [4].

State-of-the-art FDI methods for spacecraft solar panels are not yet capable of meeting these requirements. Hardware redundancy and threshold-based limit checking [5] lack sensitivity to progressive incipient degradation, while analytical model-based approaches [6] rely on high-fidelity physics models whose computational cost exceeds the capabilities of flight-qualified processors. Moreover, the scarcity of in-orbit fault data limits the applicability of purely data-driven methods, which typically depend on extensive labeled datasets to generalize effectively [7]. These constraints highlight the need for data-efficient FDI frameworks able to operate autonomously onboard, extract fault-relevant information from sparse telemetry, and detect early degradation before functional losses become critical.

In recent years, digital twin technologies have emerged as a promising alternative for health monitoring of complex engineering systems [8]. By maintaining a dynamic virtual counterpart of the physical asset that evolves in parallel with flight operations, digital twins enable continuous synchronization between measured and simulated responses to infer system health and predict degradation trends [9]. To address the challenges of fault diagnosis in spacecraft solar panels, this work demonstrates the FREEDOM digital twin - Fast Reliability Estimate and incipient fault

Detection Of Multiphysics aerospace systems-, a computational framework tailored for onboard near real-time health monitoring of complex multiphysics systems subject to incipient damages [10]. The FREEDOM digital twin combines offline data assimilation and online inference in a unified, computationally efficient architecture. Offline, it employs Dynamic Mode Decomposition and Self-Organizing Maps to compress high-dimensional telemetry into a fault-informative representation; online, it assimilates new data and predicts evolving degradation states via inverse Bayesian optimization, continuously updating the virtual counterpart of the physical system. The twin is validated for a spacecraft solar panel composed of AZUR SPACE 3C44 triple-junction cells operating in a 10-year geostationary-orbit mission scenario, and considering multiple concurrent incipient damages.

Digital Twins Requirements for FDI of Spacecraft Solar Panels

Extending the digital twin concept to spacecraft solar panels presents unique challenges arising from the panels' coupled electrothermal behavior and limited sensing capability. Their electrical response depends on complex interactions between environmental and material effects, yet only a few low-rate telemetry channels - typically voltage, current, and temperature - are available for monitoring. At the same time, onboard processors impose strict computational limits, and the scarcity of in-orbit fault data restricts the use of supervised learning approaches. To operate effectively under these conditions, a digital twin for spacecraft solar arrays must meet three key requirements:

1. *Efficient data assimilation and compression*: extract and compress fault-relevant features from sparse low-rate telemetry while retaining sensitivity to early degradation signatures.

2. *Incipient fault prediction*: accurately predict multiple co-occurring early-stage degradation mechanisms whose effects are weakly observable in the measured signals.

3. *Computational tractability*: ensure near real-time operation within the strict processing and memory constraints of flight-qualified onboard hardware.

Methodology

The FREEDOM digital twin enables near real-time onboard health monitoring of spacecraft solar arrays by maintaining a continuously updated virtual representation of the physical subsystem. The framework is organized into two complementary phases: an offline efficient data assimilation and compression stage, and an online prediction stage, in which the twin operates onboard assimilating telemetry to predict the evolving degradation state. The division between offline and online stages ensures that the computationally demanding tasks are performed on the ground, while the flight implementation remains lightweight and data-efficient. Fig. 1 illustrates the conceptual interaction of the FREEDOM digital twin with the real solar panel. In the following, we outline the mathematical foundations of the FREEDOM framework. A complete description of the digital twin is provided in [10].

Materials Research Proceedings 69 (2026) 1524-1529 https://doi.org/10.21741/9781644904251-267

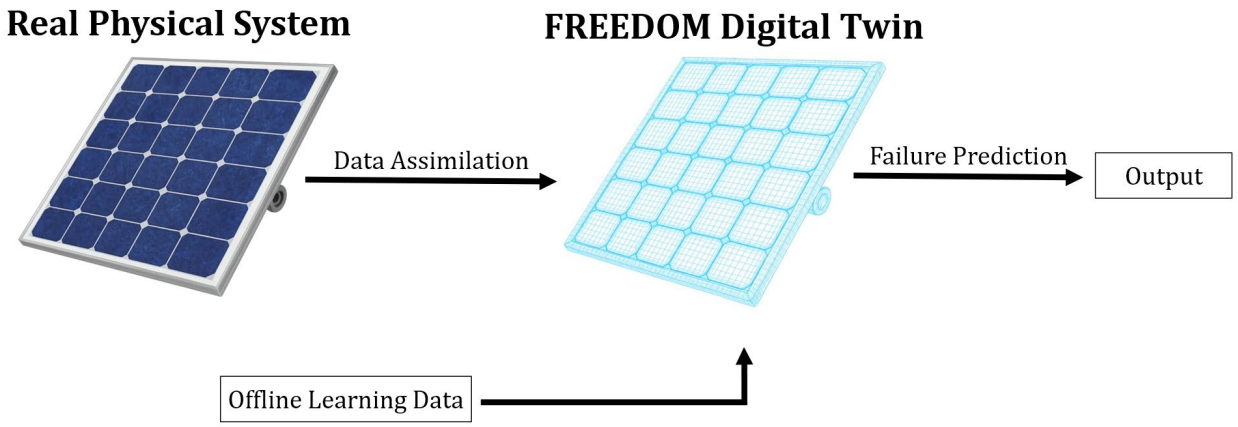

Figure 1: FREEDOM digital twin conceptual interaction with the real physical system

Offline Learning. In the offline phase, FREEDOM learns a reduced-order representation of the system encoding the essential system dynamics and fault sensitivity in a compressed form that minimizes onboard computational requirements. Time-series voltage signals $v(t,k)$ are generated from a high-fidelity model of the solar array under varying degradation parameters k. The first stage applies Dynamic Mode Decomposition (DMD) to extract the dominant temporal modes of the system response: $v(t+\Delta t) \approx A\, v(t)$, where A is the best-fit linear operator capturing the system's coherent dynamics. The DMD decomposition yields modal structures and eigenvalues (ϕ_i, λ_i) that form a reduced basis:

$$v(t) \approx \sum_{i=1}^{r} b_i\ \phi_i e^{\omega_i t}, \tag{1}$$

where r is the retained rank determined by the cumulative energy criterion, and $\omega_i = \ln(\lambda_i)/\Delta t$ represents the modal frequency content. The resulting modal amplitudes are processed using a Self-Organizing Map (SOM) to cluster similar degradation signatures, and identifies the most informative temporal points $\hat{x}$ defining a compression mask that preserves diagnostic information. The outcome of this stage is a mapping function $\mathcal{C}: v(t) \rightarrow \hat{v}(\hat{x})$, where $\hat{v}$ is the low-dimensional fault-informative projection of the original signal. This compression significantly reduces the dimensionality of the inverse problem to be solved during onboard operation.

Online Prediction. During the mission, the FREEDOM digital twin operates continuously updating its internal state based on incoming telemetry. The objective is to predict the current health status k^* of the solar panel. The health estimation problem is formulated as an inverse optimization task:

$$k^* = \arg\min_{k} \delta\left(\hat{\boldsymbol{v}}_{meas}, \hat{\boldsymbol{v}}_{sim}(\boldsymbol{k})\right) \tag{2}$$

where $\hat{\boldsymbol{v}}_{meas}$ is the compressed voltage measurement obtained from telemetry, $\hat{\boldsymbol{v}}_{sim}(\boldsymbol{k})$ is the corresponding twin-predicted signal. Eq. (2) is addressed through Bayesian Optimization (BO) with a Gaussian Process (GP) surrogate model [11] to approximate the discrepancy function, $\delta(k) \sim \mathcal{GP}\left(\mu(k), \sigma^2(k)\right)$, where μ and σ^2 represent the mean and uncertainty of the GP model prediction. The next query point k_{n+1} is selected by maximizing a non-myopic acquisition function $k_{n+1} = \arg\max_{k} \alpha(\boldsymbol{k}; \mu, \sigma)$ [10]. This iterative process converges to the optimal degradation vector k^* while minimizing the number of model evaluations. The resulting k^* defines the twin's current health state, which is continuously updated as new telemetry becomes available.

Materials Research Proceedings 69 (2026) 1524-1529 https://doi.org/10.21741/9781644904251-267

Experimental Setup

We simulate a representative mission scenario to validate FREEDOM using a detailed solar cell model subjected to multiple evolving degradation mechanisms. The model employs the AZUR SPACE 3C44 triple-junction GaAs solar cell, widely used in geostationary and deep-space missions [12]. Implemented in the Simulink/Simscape Electrical environment, it reproduces the electrical behavior of a solar panel element through an equivalent-circuit (EC) representation. We estimate the EC parameters - photocurrent, series resistance, shunt resistance, diode saturation current, and ideality factor - from manufacturer datasheet values, defining the nominal healthy condition of the system. We model three primary degradation mechanisms: micrometeoroid and debris impacts (k_1), radiation damage (k_2), and ultraviolet (UV) darkening (k_3). We simulate (i) radiation-induced effects using ESA's SPENVIS toolkit [13], (ii) micrometeoroid and debris impacts using empirical relations from NASA's Handbook for Designing MMOD Protection [14], and (iii) UV darkening with an empirical factor that reduces photocurrent over time [15]. These effects combine into a time-dependent parameter set that captures realistic in-orbit degradation over a ten-year GEO mission. In particular, we focus on modeling and predicting incipient damages define as $k_i < 0.1$ for the k normalized damage variable. Within this range, damages generate subtle and hardly detectable variations in the current–voltage curve, providing a challenging test of FREEDOM's sensitivity to early fault signatures. We generate the input measurement set for the FREEDOM offline learning phase by running 10000 high-fidelity simulations, each corresponding to a unique degradation vector $k = [k_1, k_2, k_3]^T$ determined using a scaled Latin hypercube design with a scaling exponent of 1.5.

Results and Discussion

Fig. 2(a) shows thirty informative temporal points identified for data assimilation by the offline learning phase over a representative voltage signal. The density of informative points increases toward the end of the simulated mission, where the dominant dynamic modes extracted by DMD exhibit greater divergence between health states, indicating that FREEDOM allocates computational resources to the temporal regions carrying the highest degradation informative content. Fig. 2(b) reports the evolution of the mean Relative Parameter Error (RPE) over twenty runs for each degradation mechanism during online inference. The FREEDOM digital twin accurately tracks the evolution of incipient degradations across all modes. Radiation-induced damage (k_2) is estimated with negligible error, while micrometeoroid and debris impacts (k_1) and ultraviolet (UV) darkening (k_3) show consistently low RPE values. The overall mean estimation error of 5.2% demonstrates the accurate prediction of multimodal failures under realistic mission conditions. All evaluated cases fall within the incipient degradation regime targeted for prediction by FREEDOM during operation. The high accuracy achieved in this range demonstrates the framework's ability to capture the subtle electrical signatures of early-stage damage, well before measurable power loss occurs. In addition, FREEDOM completes the entire prediction phase in 62s, confirming its computational efficiency.

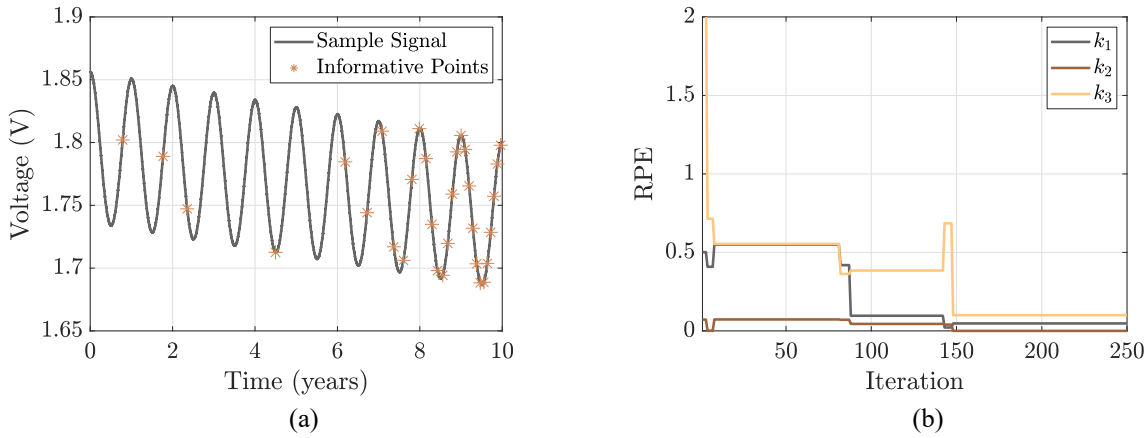

Figure 2: (a) Offline learning output showing the informative temporal points extracted by the DMD-SOM compression. (b) Online predictive performance showing the mean Relative Parameter Error of the damage prediction.

Concluding Remarks

This work demonstrated the FREEDOM digital twin for autonomous health monitoring of spacecraft solar arrays, addressing the challenges of data efficiency, incipient fault prediction, and onboard computational limits. FREEDOM combines offline data assimilation through Dynamic Mode Decomposition and Self-Organizing Maps with online Bayesian inference to identify multiple degradation mechanisms in near real-time. Validation on a solar panel composed of AZUR SPACE 3C44 cells over a ten-year geostationary-orbit scenario achieved a mean relative parameter error of 5.2% with a runtime of 62s, confirming its capability for accurate, data-efficient, and computationally tractable onboard degradation diagnosis.

Abstract. Cyber-Physical Systems—such as aerospace systems—increasingly rely on multi-physics co-simulation, yet data exchange and orchestration strategies across black-box FMUs can erode accuracy and wall-time performance. This work exploits physical and logical delays—captured through Transmission Line Modeling insights and Logical Execution Time semantics—to segment model coupling graphs into temporally independent sub-system groups. Benchmarks of weakly coupled groups show that an increased macro time step, while respecting signal delays, can preserve system dynamics while reducing model invocations and enabling parallelization without breaking causality.

Introduction and Background

Modern Cyber-Physical Systems (CPS) in aerospace, automotive, and infrastructure integrate multi-physics, embedded computers, and communication networks. Their scale and tight coupling create demands for sophisticated modeling and simulation techniques for design, verification, and validation [1, 2, 3, 4, 5, 6, 7]. Co-simulation has emerged as the dominant solution, enabling the coupling of sub-system models from diverse disciplines and tools through black-box encapsulation [6, 8, 1, 9, 10, 11]. However, this approach introduces significant challenges, particularly concerning accuracy, numerical stability, and performance, especially in hybrid systems—integrating both continuous-time and discrete events—that may demand real-time or faster-than-real-time execution for hardware-in-the-loop integration or large design-space exploration [5, 12, 2, 3, 13, 14, 9, 6, 15, 16].

A critical limitation in achieving credible and wall-time efficient co-simulation originates from data exchange and orchestration strategies. The black-box nature of many sub-system models, for example Functional Mock-up Units (FMUs), restricts the visibility of internal dynamics, sometimes hindering the design of optimal orchestration algorithms necessary for reliable execution [11, 17, 14, 18]. Current approaches often rely on time-triggered communication with Zero-Order Hold (ZOH) sampling strategies that can introduce artificial delays and unwanted high frequency dynamics [12, 19, 3, 17, 4, 20]. These effects can significantly degrade results when dealing with weakly coupled sub-systems that naturally function semi-independently over extended periods [2, 3, 16, 4, 13].

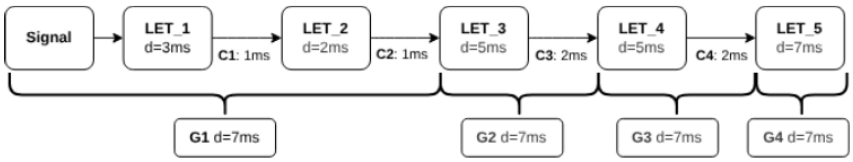

Figure 1: Temporal decoupling of sub-system group G1, G2, G3 and G4. Arrows show information propagation within the system. *d* shows the sub-system or connections signal delay.

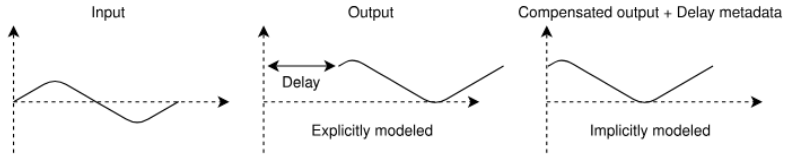

Figure 3: Comparison between *explicit* and *implicit* modeled delay

Structured segmentation of systems into weakly coupled sub-systems enables information-dependent yet temporally independent operations to be executed concurrently without violating causality [21]. This capability is crucial for multi-rate co-simulations, where different sub-systems are allowed to operate at different communication steps and therefore demand sophisticated synchronization for correct data exchange [22, 6]. Two paradigms are utilized as a basis for enabling this: first, the Logical Execution Time (LET) paradigm [23, 24, 25], which decouples a model from its actual execution time; and second, Transmission Line Modeling (TLM), which utilizes physically motivated information delays (e.g., control signal latencies, sensor sampling periods, component response times, or fluid propagation speed) between sub-systems to decouple them for stability [12, 21, 26].

The criterion for safe decoupling is whether the chosen macro/communication time step exceeds the propagation delay across a sub-system. When this condition holds, the sub-system behaves temporally independent within a step, eliminating algebraic constraints and enabling robust parallel scheduling; if the step exceeds the effective delay, discretization can introduce a numerical error that manifests as phase distortions and system instability. In TLM it is common that the temporal independence that can be utilized for parallelization within a system is equal to the smallest delay that is present between a system's models [26]. By introducing a grouping mechanism of signal delays, the temporal independence between groups can be increased without sacrificing validity and independent groups can be simulated in parallel, see Figure 1.

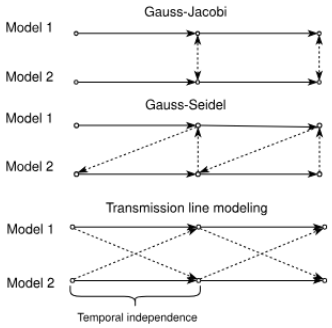

Figure 2: Comparison between orchestration methods, Dashed lines are information propagation.

Signal delays can either be explicitly or implicitly modeled. When delays are explicit, the model itself compensates for the phase shift introduced by the intrinsic delay, see Figure 3 for minimal overview of the concept. When delays are implicit, and not represented in the model, the co-simulation layer must compensate to ensure the system's true propagation characteristics, in this case by introducing an artificial phase shift. Utilizing the known phase shift allows the co-simulation engine to map the information into the future, thereby creating weakly coupled—and temporally independent—sub-systems as long as the time step does not exceed the model delay; Figure 2 illustrates how TLM applies this insight.

Contributions. This paper advances delay-aware co-simulation beyond established TLM and LET practices through three contributions:

1. Delay-aware grouping scheduler, a method that fuses LET semantics with TLM-style delays to execute groups of weakly coupled subsystems in parallel without violating causality.

2. FMI 2.0 orchestration workflow, a deterministic orchestration algorithm, based on (1.), that utilizes implicit signal delays to increase parallelization of Functional Mock-up Interface (FMI) 2.0 components while emulating FMI 3.0 Intermediate Update Mode (IUM) via sub-stepping (Algorithm 1).

3. Quantitative evaluation, a controlled benchmark that quantifies phase shift for common orchestration algorithms, and for the proposed approach, using first zero-crossing metrics (Figures 5a–5).

Scope and Limitations. This short paper targets delay-aware scheduling for weakly coupled CPS co-simulations. The requirements are originating from aeronautical systems with tightly integrated mechanical, hydraulic, and control subsystems. The scope is limited to systems where intrinsic signal delays can be removed from the models and replaced by metadata. This initial study intentionally scopes the evaluation to a single, well-understood benchmark to isolate the interaction between explicit and implicit delays and a comparison between a custom, tailored scheduler and the two commonly used master algorithms, Gauss-Jacobi and Gauss-Seidel.

Methodology

A controlled benchmark composed of sub-systems with predefined information delays, see Figure 1, is realized as a monolithic system in the Modelica tool Dymola [27] to establish a reference that is free from co-simulation emergent behavior. The system is designed to enable grouping of sub-systems and connections and to enable testing at a predefined “large” macro time step. The signal passed through the system is a sine wave with constant frequency and amplitude; the models contain only a pure phase shift to enable easy visualization of changes. Using this monolithic realization as ground truth ensures that any deviations observed after export are attributable to the co-simulation strategy and implementation rather than to modeling or coupling inconsistencies. From the monolithic reference, the system is exported as a System Structure & Parameterization (SSP) where each sub-system and connection is an FMU to enable utilization within the co-simulation environment.

To verify the export and coupling of the system, a co-simulation applying both Gauss–Jacobi and Gauss–Seidel master algorithms with a small (relative to the test system dynamics) communication step (0.01ms) is used to replicate the monolithic results. Both the sub-systems and the connections remain explicitly modeled just as in the reference system. The same configuration is then simulated using larger time steps (1ms, 2ms, and 3ms) to observe signal characteristics and the phase shift caused by the orchestration method. Because the benchmark introduces only phase shifts (no amplitude distortion), the resulting phase shift is computed by locating the time of the first zero crossing of each signal and subtracting the corresponding reference time.

Finally, to validate that temporally independent groups can be executed concurrently without degrading validity, the sub-systems are clustered into the groups defined in Figure 1 and advanced with a 7ms macro step tailored to the system delays. Enabling the grouping and concurrent execution requires removing phase shifts from the sub-system models, making the delays implicit; metadata describing the delay characteristics is provided to the tooling. FMI 3.0 offers Intermediate Update Mode (IUM) to mitigate effects from sparse model invocation by exposing data between communication points [12, 28]. Because the experiments rely on FMI 2.0, which lacks equivalent functionality, each model executes repeated sub-steps internally to emulate richer data propagation of IUM; the complete orchestration algorithm is shown in Algorithm 1.

Materials Research Proceedings 69 (2026) 1530-1536 https://doi.org/10.21741/9781644904251-268

Algorithm 1: Grouping orchestration Pseudocode

```
in sequence foreach macro step H do
    in parallel foreach Group G_k do
        in sequence foreach Model M in G_k in signal dependency order do
            // Emulate intermediate updates inside the macro step
            t ← 0
            while t < H do
                Execute M for a sub-step h
                t ← t + h
```

Result

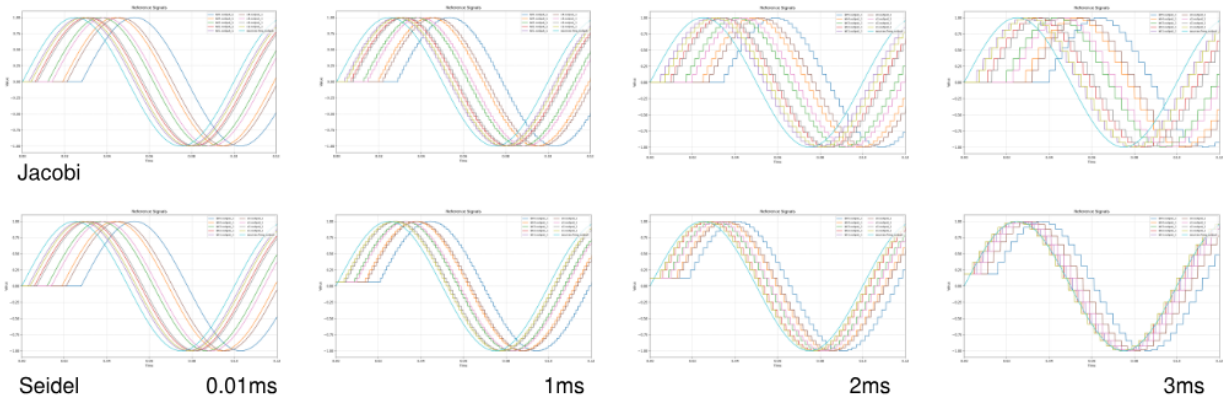
To observe distortion caused by orchestration algorithm selection and step size, the accumulated phase shifts of the signals are visualized. In Figure 4, the resulting signals corresponding to the commonly used master algorithms Gauss–Jacobi and Gauss–Seidel are compared across step sizes. For small steps, both algorithms closely match the Dymola monolithic reference, while larger steps introduce increasing distortion. Figure 5a summarizes the resulting accumulated phase shifts for both master algorithms; the results indicate that system design influences how phase shift scales with the time step, complicating general conclusions in regard to phase shift and step-size increases. Figure 4 also highlights the zero-order-hold staircase effect, where the plateau length equals the macro time step, in effect degrading signal quality.

Figure 5 shows the system simulated using emulated IUM. Gauss–Jacobi does not benefit from IUM because the algorithm is inherently parallel, meaning information can only be exchanged deterministically at communication points. Gauss–Seidel, on the other hand, benefits from the serial execution order, which allows intermediate updates to reduce phase shift. Both Gauss–Seidel and the proposed approach (temporally independent sub-systems), when combined with emulated IUM, yield higher signal quality without staircase artifacts. Compared to Gauss–Seidel, the proposed approach maintains parallel execution while keeping the resulting phase shift small and enabling larger macro time steps.

Discussion and Conclusion

This work is intentionally limited as a proof of concept. Future work should extend the comparison to other solutions, for example adaptive step-size co-simulation and other decoupling techniques. Additional benchmarks are needed to evaluate how the concept scales to more realistic systems in terms of accuracy and stability. These comparisons will quantify how delay-aware grouping may complement existing FMI master algorithms and highlight opportunities for hybrid schedulers. A key requirement for applying the grouping mechanism to high-fidelity models is the ability to externalize delays from the sub-systems; how broadly this assumption holds must be evaluated.

To enable usage and adaptation of these principles, since delay information is seldom included explicitly in FMU or SSP metadata, it should be considered how to identify system delays post-export through data-driven estimation or optimization. That said, estimating delay information is only the first step: selecting an effective graph segmentation and step size is non-trivial and likely depends on factors such as system design, model design, operating system scheduling, background load, and hardware. A limitation of the current solution is that it accounts only for static delays



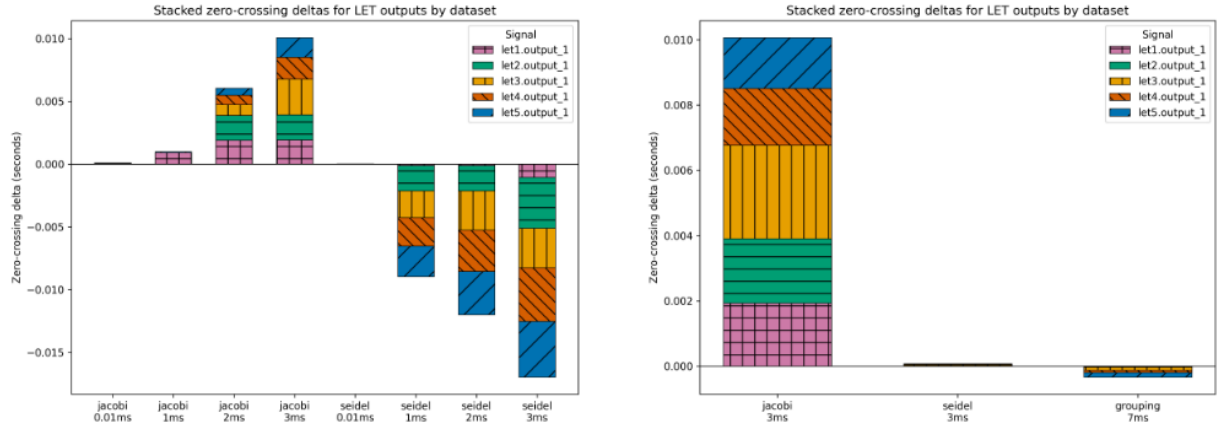


Figure 4: Comparison between Jacobi and Seidel phase shift depending on time step

Figure 5: Reference simulation results and phase shift comparison across orchestration strategies and step sizes.

within the system. Extending the approach to dynamic attributes, for example using model Jacobians to estimate online delay variations, could unlock additional optimization opportunities such as adaptive loop breaking during execution.

As a side note, explicitly defining information delays may also provide benefits to commonly used orchestration algorithms. For example, on how to break loops in the signal dependency graph with minimal impact, prioritizing the slowest (largest-delay) links as cut points to minimize artificial decoupling, or to ensure that the step size does not break the Nyquist–Shannon sampling theorem by providing guidance to where step refinement could be applied locally along the most restrictive links.

Abstract. This paper presents an experimental co-simulation engine designed to study scheduling strategies and performance trade-offs in complex Cyber-Physical Systems (CPS). The engine offers a modular, graph-based architecture with deterministic execution semantics, lightweight configuration, and built-in measurement. These features enable fair comparisons across orchestration algorithms and parallelization strategies. We outline the design, document determinism and performance mechanisms, and benchmark against a reference setup to support rigorous evaluation and future digital-twin deployments.

Introduction

The escalating complexity of modern Cyber-Physical Systems (CPS)—ranging from nuclear power plants to aerospace—necessitates more advanced design, operation, and maintenance methodologies [1, 2, 3, 4, 5, 6]. These systems couple physical processes with software and electronics, often with some computation controlling dynamics via feedback loops [4, 7, 5]. Traditional monolithic simulation struggles with CPS heterogeneity, where sub-systems often are developed by different teams, or even sub-contractors, using disparate tools and formalisms [8, 9, 10].

Co-simulation addresses these challenges by coordinating multiple sub-systems to reproduce the behavior of a coupled system [5, 11, 8, 12, 13, 14, 15, 16, 17]. It lets domain experts work in their preferred tools while maintaining a holistic system view [5, 18]. The Functional Mock-up Interface (FMI) [19] has become the de facto standard for tool-independent model exchange and co-simulation, packaging models as black-box Functional Mock-up Units (FMUs) [3, 5, 8, 20, 21, 22, 23, 24, 25].

In addition to FMI, the System Structure and Parameterization (SSP) standard [26] complements co-simulation workflows by describing the architecture of a system-of-systems, including how FMUs are interconnected, their parameters, and configurations. SSP separates concerns by defining system topology, parameter sets, and simulation settings independently of the FMUs themselves, enabling modular, tool-independent reuse and configuration of co-simulation setups. This standard facilitates exchange of system designs between different engineering tools and supports scalable system integration, versioning, and automation in CPS development pipelines [27, 28].

Despite broad adoption, co-simulation still faces challenges in numerical stability, accuracy, and performance, especially for strongly coupled and hybrid systems [1, 8, 29, 14, 10, 16, 5, 17, 30]. Achieving credible results [31] depends strongly on the orchestration/master algorithm, its

role to dictate signal exchange strategies [25, 10, 15]. Selecting an appropriate algorithm is context dependent and hinges on the characteristics and implementations of the individual simulation units [10].

Table 1: Comparison of simulation engines over characteristics relevant for the presented work

Software	Open	FMI	SSP	RT/HiL
OMSimulator [32]	Yes	Yes	Yes	Soft RT
FMI Go! [33]	Yes	Yes	Yes	Soft RT
Notes: strong focus on distributed simulations.				
Open Simulation Platform [34]	Yes	Yes	Partial	Soft RT
Notes: strong focus on maritime.				
FmPy [35]	Yes	Yes	Partial	No
Maestro2 [36]	Yes	Yes	No	Partial
DACCOSIM NG [37]	Yes	Yes	No	Partial
Mosaik [38]	Yes	Yes	No	Partial

A focused experimentation co-simulation engine that combines the transparency and modularity of lighter simulation engines with determinism, SSP model management, and HiL readiness would provide a base for reproducible multi-domain experiments, transparent orchestration semantics, and the ability to integrate into real-time hardware campaigns and would fit into aerospace digital twin development at Saab [28]. Table 1 compares open-source engines over attributes relevant for the presented work. The top entries provide full compliance with both FMI and SSP standards as well as support soft real-time execution modes. The lower portion illustrates complementary engines: such as FmPy, Maestro2, DACCOSIM NG, and Mosaik, that address specific application areas but only cover subsets of the FMI/SSP stack and rarely extend beyond partial real-time requirements.

Across these products, there is limited focus on determinism, real-time constraints or Hardware-in-the-Loop (HiL) integration. Many of the products both support Model Exchange (ME) and Co-Simulation (CS), inferring architectural limitations that could be avoided in a pure co-simulation engine with the added benefit of limiting code base size and complexity. Adapting an existing platform is possible, but the two that look most promising out of the box (OMSimulator and FMI Go!) are both large and mature projects and would require substantial effort to tailor and adapt. Thus the decision was made to design and implement a small, purpose-built experimental engine for testing and evaluation of CPS co-simulation orchestration methods leveraging FMI and SSP. Its primary goals are:

- A lightweight and simple experimentation platform for credible co-simulation of CPS models that provides a basis for scheduling experimentation and enable comparison of established orchestration methods such as Gauss–Jacobi and Gauss–Seidel [12, 30], alongside novel, tailored algorithms [15] to study impacts on accuracy, stability, and performance.
- Enable deterministic co-simulation with controlled propagation of information between models [14, 29, 39, 5] of physical, logical, and software models, reflecting the multi-domain nature of CPS.
- Enable evaluation of multi-core parallelization methods [17, 40, 23, 41], variable step sizes and adaptive scheduling [42, 24, 7, 17], and efficiency techniques such as advanced algebraic loop handling [10, 15, 43, 17], creating enablers for extensive design space exploration and HiL integration, both vital for industrial applications and digital-twin development [23].

Materials Research Proceedings 69 (2026) 1537-1543 https://doi.org/10.21741/9781644904251-269

Scope and Contributions. Compared to OMSimulator, FMI Go!, and related applications, the proposed engine purposefully narrows scope to pure co-simulation with SSP-managed composition and real-time optimized execution paths. The design emphasizes (1.) determinism via explicit data selection and integer time, (2.) transparency of orchestration semantics for comparisons, and (3.) a compact codebase that lowers the barrier for implementing and testing scheduling variants. Its main contributions are:

- An open-source modular, simple, graph-based simulation engine that enables comparison of orchestration algorithms, SSP4SIM.
- An open source SSP and FMI XML parsing library for C++, SSP4CPP.
- A benchmark against OMSimulator to quantify correctness and performance under standard Gauss–Jacobi orchestration utilizing an environmental control reference system.

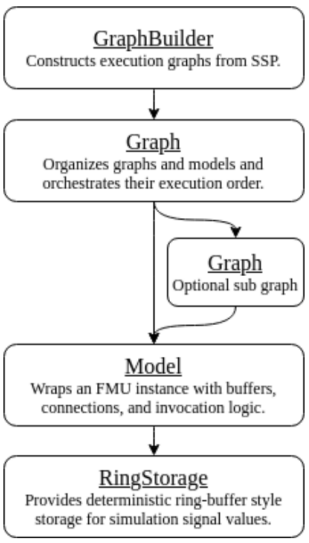

Figure 1: Solution architecture

Simulation Engine Architecture

This section introduces the overall layout of the simulation engine. The architecture emphasizes modularity, repeatability, and performance, enabling comparisons across orchestration algorithms and different degrees of parallelism.

Modularity. The implementation separates the workflow into clear assembly stages. The first step (Figure 1) interprets SSP metadata and produces an intermediate dependency graph closely aligned with the SSP representation. The intermediary graph is then processed into a ”simulation graph” specialized for efficient execution and traversal. In this representation both models and graphs are nodes that can be connected and nested, where each layer may employ different orchestration algorithms, see Figure 3. To further simplify testing and evaluation of strategies, orchestration algorithms and analysis passes are handled in separate layers to ensure they do not interfere with FMU integration or storage layers.

Determinism. The runtime enforces repeatable execution through two mechanisms. First, a small but essential solution, time is represented as integer nanoseconds (seconds in int64_t) instead of floating-point, avoiding comparison pitfalls. Second, each model maintains a ring-buffered data store (RingStorage) for its outputs, see Figure 2, to enable access to a number of past outputs. This allows orchestrators to select data to propagate deterministically between models, thus avoiding hidden race conditions in parallel and multirate execution. This strictness incurs one extra copy of all data passed between models but allows different orchestration algorithms to select data according to their requirements or data interpolation/extrapolation. The buffer size is selected to fit with the algorithm selected, certain algorithms may require several iterations of output values to be stored while simple ones like Gauss–Jacobi need only a small set. Together, these two mechanisms improve the possibilities for deterministic results even under parallel and multirate execution.

Materials Research Proceedings 69 (2026) 1537-1543 https://doi.org/10.21741/9781644904251-269

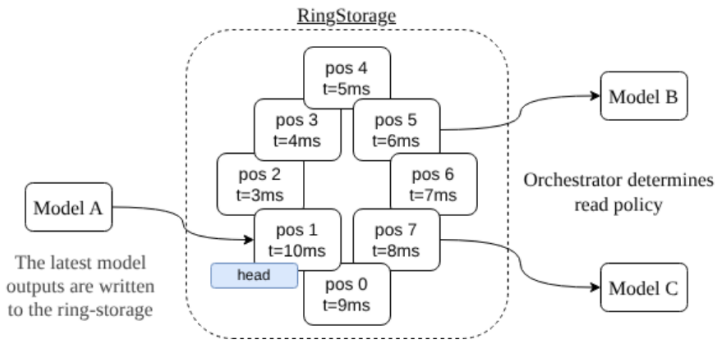

Figure 2: Schematic overview of the output ring buffer solution

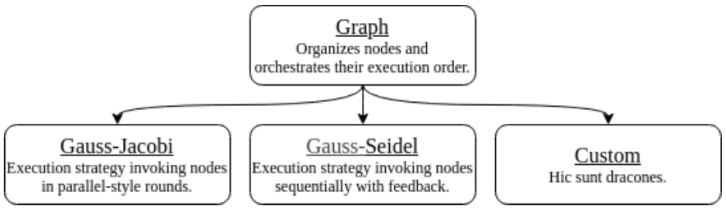

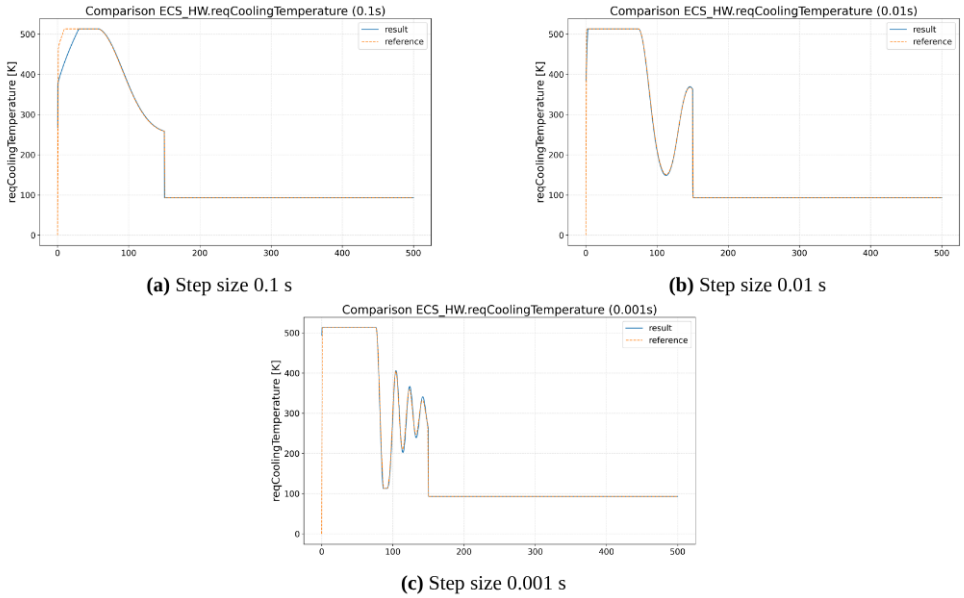

Figure 3: Execution algorithms

Performance. To meet demanding performance constraints, (1.) precomputing and deferring work away from time-critical simulation loops minimize repeated operations. As shown in Figure 1, the GraphBuilder parses and evaluates the SSP System Structure, establishes model connections, and streamlines the Graph and Models for inexpensive execution. (2.) separating the simulation path from result recording ensures that slower disk read/write does not bottleneck execution. A dedicated worker thread continuously samples results from signal ring buffers and writes them to disk, independent of the critical simulation path. A note here is that there is a trade-off for this speed increase, even if the internal simulation is fully deterministic, the externally recorded data may vary slightly between runs depending on how the operating system schedules the recorder. (3.) the runtime embeds quantitative feedback via timers around experiments and critical components, collecting cumulative statistics to provide the evidence needed to compare scheduling variants, assess parallel scaling, and validate HiL readiness to identify bottlenecks and enable further optimization.

Configuration and Logging. Other noteworthy attributes are: (1.) A lightweight JSON-backed configuration service provides a single source of truth for runtime options. Core components query this service for model selection, timing, solver tolerances, orchestrator selection, and various toggles, enabling simple scenario changes by switching profiles. (2.) A dedicated logging utility supplies thread-safe, severity-filtered diagnostics that logs to file or network target using an established JSON format compatible with common viewers.

Benchmark results. The initial benchmark compares against OMSimulator (OMS) using an open reference system [44] for simple benchmarking: an environmental control loop with a heat source, a heat sink, and a controller [45]. Since OMS uses Gauss–Jacobi for co-simulation the comparison will utilize the same algorithm. Three different time step sizes are compared using the same reference system to see if behaviors are overlapping. There behaviors between the two engines is very similar, Figure 4a, 4b, and 4c, and to a large extent the verification of the implementation is successful, there is a slight diff in the initial stages of Figure 4a that need to be evaluated further.

(a) Step size 0.1 s **(b)** Step size 0.01 s

(c) Step size 0.001 s

Figure 4: Reference vs result responses under different macro step sizes.

Conclusion and Future Work

To support further verification of the simulation engine, future work includes: (i) completing further comparisons across multiple SSPs against multiple reference engines, (ii) expanding the set of scheduling policies and parallel executors, and (iii) quantifying determinism trade-offs under mixed real-time loads. We will use these results to guide robust digital-twin deployments in safety-critical CPS.

Keywords: System-of-Systems Engineering, System-of-Systems Architecture, Communication, Software Architecture, Agent-Based Modelling and Simulation

Abstract. System-of-Systems Engineering (SoSE) studies how independent constituent systems interact to generate emergent capabilities. However, it is challenging linking the study operations and SoSE to software implementation and agent-based simulations. This paper considers communication as the primary architectural concern and examines how software architectures can improve SoS modelling and simulation. In particular, by relating software architectures to Observe–Orient–Decide–Act (OODA) loops, which are a promising structure for aligning communication, decision logic, and agent interactions with modular and traceable agent architectures. The goal of this work is to explore how communication within SoS architectures can be better structured, represented, and analysed through software engineering and agent-based modelling frameworks in the context of hierarchical and cooperative operational environments, where information exchange directly influences system performance and emergent outcomes.

Background

System of Systems Engineering (SoSE) studies the methodologies for developing assemblies of systems in such a way that the collective brings new capabilities [1]. These systems operate independently but also as a part of an overarching System of Systems (SoS) architecture designed to form a collaborative and communicative network. The communication and interaction between systems are what makes the new capabilities emerge [1]. It is difficult, however, to provide an architecture for the SoS without being aware of the emergent capabilities beforehand, for that reason, modelling and simulation is used for finding these unforeseen capabilities. However, when using software for implementing a simulation tool for the SoS, not knowing the overall architecture represents a challenge that could make the models diverge from reality. The present work proposes the use of communication as the starting point for proposing a software architecture that could be easily relatable when considering options for the SoS architecture. By considering communication early in the process, issues related to communication in the form of delays, scalability, traceability, or interoperability can be addressed so they do not become an issue later.

Systems Engineering as Starting Point

There have been attempts to connect the Systems Engineering (SE) Vee Model to SoSE [2], but SE design and analysis assumptions are not always suitable for every SoS case [1]. There are accepted heuristics for architecting an SoS that can be found in the literature [3], being considered the correct modelling of interactions as the most critical one for capturing emergence. A very interesting approach for defining system architectures is heuristic extrapolation [4]. This method is particularly relevant as it is context sensitive and abstraction is removed iteratively in the design representation. The heuristic extrapolation method takes a general descriptive heuristic to derive domain-specific heuristics and rationale for decisions.

Adopting Software Engineering

The process of modelling and analysis of SoS architectures is inherently iterative. For SoSE studies, the development of a simulation model is going to depend on the software architecture chosen for representing interactions during an operation. However, the goal of implementing such model to be used during SoSE processes is to be able to make decisions for defining the SoS architecture and interactions. Moreover, for a proper analysis, if the decided software architecture is representative of the SoS architecture, obvious parallelisms between them will rise, and engineers should be able to extrapolate from one another more easily and intuitively. This coupling usually requires an iterative process with numerous trade-off discussions. For parallelisms, considering similar architectures that are already in use simplifies the process. Shown in Fig. 1 is a simplified hierarchy for wildfire suppression operations, and by using these established structures, it is possible to choose amongst the already defined software architectures. Many of them are well-known [5] and provide guidance for implementing the models required for SoS analysis. Moreover, many of these software architectures have well-defined layers, a clear structure of how the information is propagated, and whether a layer can access resources from other layers. Using these software architectures as a starting point for discussing SoS architectures is considered optimal, as they are well defined and they can be used directly for the implementation of models while keeping traceability of the reasoning behind the decisions taken. To improve the process, one of the most recent methods proposed combines mathematical formulations with model theory, which has been validated and used for system and software design bringing numerous advantages [6].

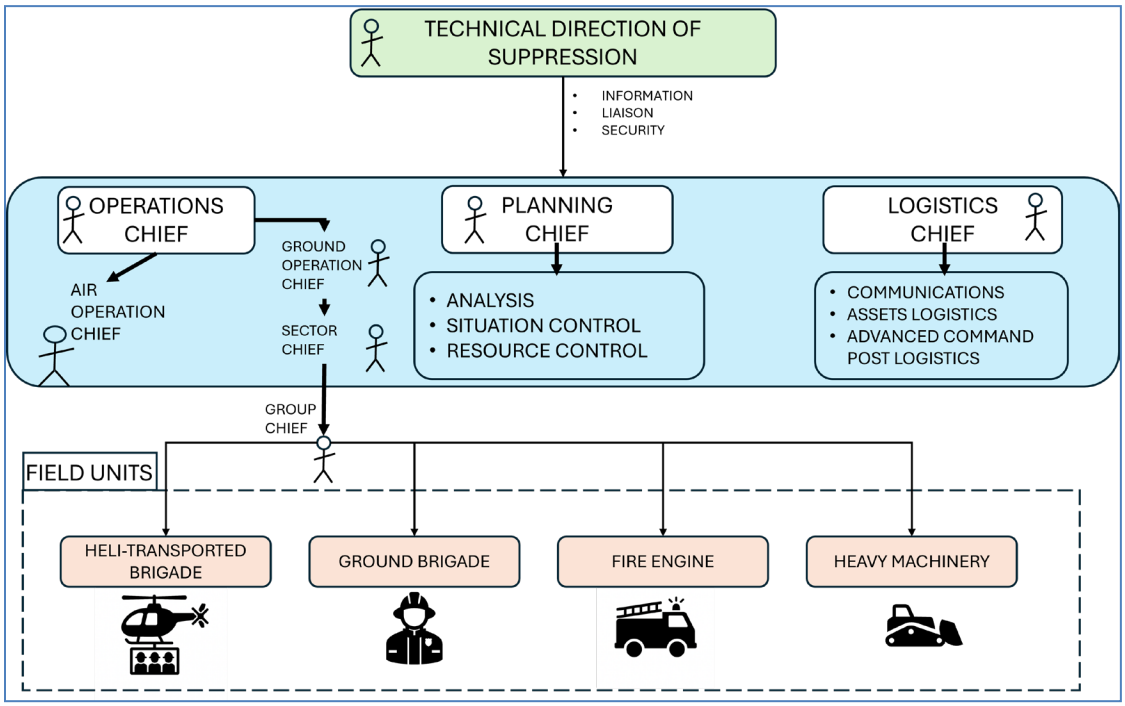

Figure 1: Incident Command Structure for Wildfire Suppression. Adapted from [10].

In terms of modelling and simulation for SoSE, agent-based models are usually used [1]. They focus on the interactions of agents, both between them and with their environment, for finding emergent behaviours or missing capabilities that could define requirements for designing new constituent systems. A traditional high-level software architecture of an agent separates the functions for observation of the environment and the functions for acting upon the environment [7], as shown in Fig. 2. However, this architecture is insufficient when trying to represent agents

Materials Research Proceedings 69 (2026) 1544-1548 https://doi.org/10.21741/9781644904251-270

with more advanced interaction capabilities, such as an incident commander agent in a wildfire suppression operation whose interactions are roughly represented in Fig. 3.

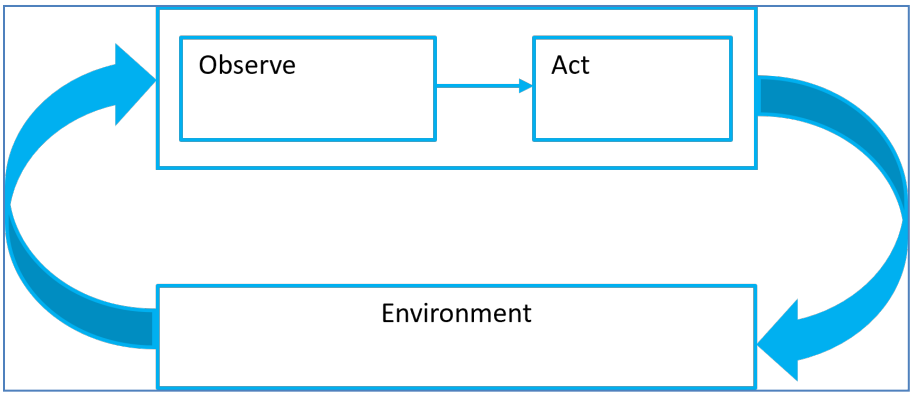

Figure 2: High-level agent architecture.

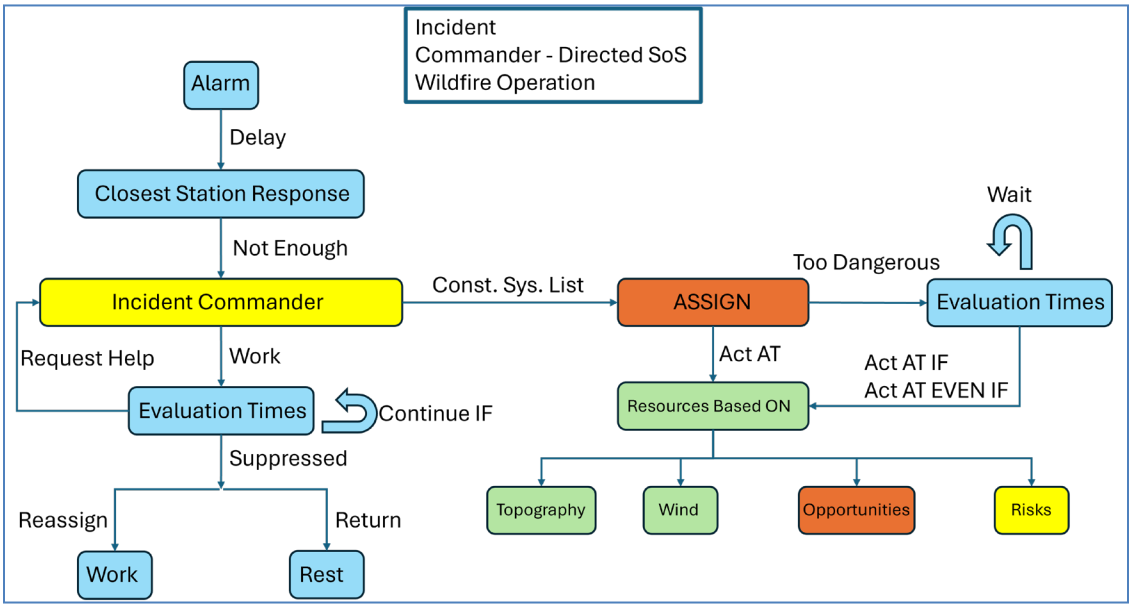

Figure 3: Figure 3: Incident commander agent interactions.

The goal behind these agent architectures and agent-oriented programming is to perform all the coding considerations as if they were mental states [9], being the difference with object-oriented programming that agents can choose whether to perform a task, and objects cannot. The agent could also be implemented with beliefs and commitment rules.

Agents then could be defined in terms of being communicative or not [7]. For the specific case of SoS, an interesting option for implementing agents would be to adopt an architecture based on Observe-Orient-Decide-Act (OODA) loops, which would allow to compartmentalise the implementation of the agents' behaviour in each part of the loop, define clear flows of information and how it is shared, and include interactions in the Decide and Act steps of the loop. This architecture could include forms of artificial intelligence and even be extended with agent intentions [8].

Conclusion

Despite the ongoing research about SoSE and software architectures, there seems to be no method considered standard for linking SoS architectures and software implementation, especially through

communication logic. The method of extrapolating heuristics and the consideration of software structures do not fully relate to how information flows, transforms, and supports decisions during an SoS operation. Software architectures have well-defined communication layers, but those layers do not fully represent SoS decision dynamics. To address this disconnection, this paper has proposed communication-centred architectures as the starting point, considering OODA loops particularly relevant, as they can relate system behaviour during real operations directly to agent implementations in simulation models. The OODA loops have structured information flow and a traceable and modular separation of concerns, which maps in a straightforward manner to both software implementation and SoS interactions, and how information evolves into decisions. These reasons make the loop valuable for SoSE applications where coordination and communication fidelity are necessary to find any emergent system performance. While OODA loops alone do not solve all SoSE challenges, their simplicity, modularity, and operational clarity provide a framework for agent-based models.

Future work should therefore focus on implementation and verification of an OODA-based framework with special attention to the communication layer for SoS simulation. Particularly relevant topics for future research are the definition of messaging (to represent human communication), evaluate the scalability and interoperability in a model with heterogeneous agents, and verify that the OODA loops do indeed improve traceability between SoS architecture decisions and software implementations.

Keywords: Public Acceptance, Extended Reality (XR), Urban Air Mobility (UAM), Human Factors (HF)

Abstract. The aviation sector is currently moving towards the integration of Urban Air Mobility (UAM), a new, safer and more sustainable aerial domain. UAM uses electric vertical take-off and landing (eVTOL) technology and Unmanned Aerial Systems (UAS) to transport goods and people at very low altitudes. However, technological and social sustainability challenges still need to be addressed before it can be fully developed. One of the main challenges is public acceptance of UAM and how to assess levels of acceptance. Acceptance frameworks that have already been successfully exploited in the aviation field can be implemented in the UAM context to investigate such social acceptance of UAM services. Since these methodologies are largely based on subjective perceptions, Extended Reality (XR) technologies have the potential to increase public acceptance of UAM systems, as they offer an immersive visualization of the relevant aspects. In this context, this work presents insights from a literature review on the state of research into the application of XR technologies to public acceptance of UAM. Previous studies have identified future users of UAM as clients of services and infrastructures, air taxi passengers, and pedestrians. Some of the use cases conducted include the development of operational concepts and the design of vertiports and air taxi interiors, as well as visual and auditory perception. Understanding how different aspects of acceptance are addressed can help us to appreciate the potential of XR to enhance such applications.

Introduction

UAM leverages the use of electrical take-off and landing (eVTOL) aircraft and UAS, also called drones, to very-low airspace level aerial applications such as package delivery, air taxis, traffic monitoring, surveillance and emergency [1]. Being an innovative transportation technology, there are still some implementation and operational challenges to be considered before its full deployment. Thus, a holistic and collaborative approach is required to address technological aspects such as propulsion systems, vehicle design and network connection, ground and air infrastructure development, services and policies development [2]. Beyond technical challenges, social factors play an important role in the deployment of UAM services [3]. Within the aviation context, acceptance methodologies such as Technology Acceptance Model (TAM) have already been exploited to address aviation risk assessment methods [4], to evaluate students' acceptance of AR instructions in aviation maintenance training [5] and to assess costumers' experience in the context of airport self-services [6]. In 2019, EASA ser the foundational brick for human stakeholders in UAM by investigating, at European level, public opinion and acceptance of UAM missions, with results demonstrating that 83% of respondents have a positive attitude towards such innovative aerial transportation system, with 71% ready to try out its services [7]. In the next

Materials Research Proceedings 69 (2026) 1549-1553 https://doi.org/10.21741/9781644904251-271

sections, a preliminary view on the State of the Art of XR applied to the Public Acceptance of UAM will be presented, with a special focus on the identification of potential users of such systems and what aspects of XR Technology have been employed to assess social acceptance.

Public Acceptance of UAM services

Studies founded on TAM and applied to UAM have been extensively conducted, with results reflecting positive perceptions and attitudes towards UAM services [8-10]. However, these studies are mostly conducted via surveys, online questionnaires and telephone interviews, lacking in offering realistic perceptions of the addressed concepts. While such traditional methods allow for rapid dissemination and completion of data acquaintance, they lack realistic visualization of the users' experience. Thus, the results are mainly based on the subjective opinion of participants. When thinking about understanding public perceptions of UAM, it is fundamental to expose citizens to realistic environmental conditions that replicate real features considering future UAM scenarios. Therefore, simulation platforms capable of enabling such requirements are utmost required. Immersive simulations can facilitate the involvement of stakeholders in the development and implementation of UAM services by providing realistic UAM experiences.

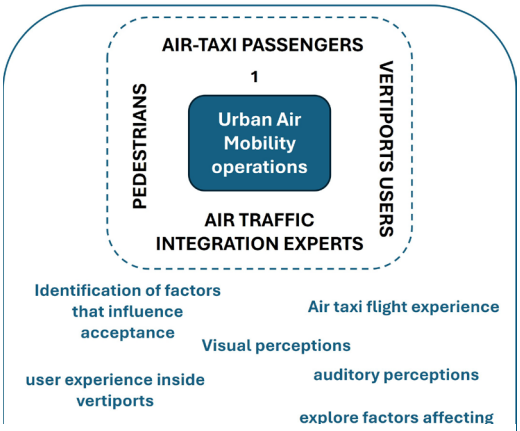

Fig. 1 Overview of Social Acceptance applications identified in the literature review. (1) Users addressed in existing studies. (2) Use-cases implemented.

Preliminary Literature review on XR Technologies and acceptance of UAM services

XR is a promising technology for facilitating stakeholders involvement in UAM deployment. In order to understand how the intersection between XR Technologies and acceptance of UAM services has been addressed, a preliminary comprehensive literature review has been conducted on existing works. A combination of keywords such as *"UAM"*, *"Acceptance"*, *"Public Acceptance"*, *"XR Technologies"*, *"Virtual Reality"*, *"Augmented Reality"*, *"Mixed Reality"* and *"drones"* as input in major scientific databases was used, with a total of 11 works selected. The use-cases addressed, technologies used and which part of acceptance is targeted in such works are summarized in Table 1. By understanding how different aspects of social acceptance are addressed, we can better appreciate the potential of XR to enhance such applications.

Table 1 Collection of works considered for the present study.

Reference	XR Technology	UAM social stakeholders	Aim of work conducted	Country and sample size

Conclusion

UAM is an innovative and growing concept in the aviation field and, before its full integration, some aspects such as social acceptance of these systems should be addressed. Acceptance frameworks such as TAM have been successfully applied to different aviation areas, allowing for its transversal application to address acceptance in UAM. Since such traditional methods rely on two-dimensional visualization, XR Technologies comes as an enabling technology to address acceptance since it offers immersive simulation interfaces. In this context, this paper highlights a literature study on XR technologies applied to Public Acceptance of UAM systems aiming at identifying main aspects addressed. Some of the use-cases identified were vertiport and aircraft interior design, visual and auditory perceptions, operational concepts development, and exploratory studies on underlaying acceptance factors. The users addressed in previous studies are pedestrians, future UAM and vertiport users and air taxi passengers.

Keywords: Urban Air Mobility, Advanced Air Mobility, Business Models, Sustainable Mobility

Abstract. This paper provides an overview of the emerging trends and business models in the Advanced Air Mobility (AAM) sector, with a particular focus on the Urban Air Mobility (UAM) segment [5] in the European and Italian contexts. The work presents a multidimensional analysis aimed at identifying the main demographic, technological, industrial and regulatory trends. After that, it examines the current Italian scenario, the main recognizable business models, and offers some considerations on UAM's ability to create, capture and distribute value.

Introduction

UAM generally refers to an innovative transportation segment that uses aerial vehicles such as drones and electric vertical take-off and landing (eVTOL) aircraft for both passenger and cargo transport within urban and suburban environments [9]. The purpose of this transportation system is to enhance safety, sustainability and accessibility [14] through the use of renewable energy sources, automation and digital infrastructure [1]

Scenarios

In order to understand the context and economic potential of UAM, this study identifies the main demographic, technological, industrial and regulatory trends. From a demographic perspective, UAM is driven by rapid urbanization in both developed and developing countries [13]. It is estimated that by 2050, more than 70% of the European population and more than 80% of the North American population will live in urban areas [11]. This urban growth is expected to exacerbate traffic congestion and pollution [11], [12]. In this scenario, UAM emerges as key solution to mitigate these issues, with the potential to reduce emissions by up to 80% compared to traditional cars [14].

Table 1. Summary of main UAM trends

Demographic	*Technological*	*Industrial*	*Regulatory*
Urbanizations driving UAM demand	Innovations in eVTOL and drone technologies	Initiatives by major companies (Boeing, Airbus, etc.)	FAA and EASA as major authorities
Impact of urban congestion and pollution	Advancements in battery technology	Initiatives by major delivery companies (Amazon, UPS, etc.)	European Green Deal

Economic implication of traffic congestion	Integration of 5G for communication	European Drone Regulation
Factors influencing public acceptance	Autonomy and AI in UAM systems	

From a technological standpoint, the main trends involve innovations in vehicle design, electric or hydrogen propulsion, autonomous flight and advanced communication systems [11]. These technologies enable UAM applications for both cargo and passenger transport [19].

At the industry level, UAM promises to generate a new market, with projections reaching up to $9 trillion by 2050 [10]. The sector is also anticipated to have a significant impact on employment, particularly in fields such as engineering, aviation, software development, and logistics.

At the regulatory level, the Federal Aviation Administration (FAA), in collaboration with NASA, is leading the development of operational standards in the United States [9]. In China, the regulatory framework relies largely on existing civil aviation regulations [11]. In Europe, the European Union Aviation Safety Agency (EASA) has published special conditions for authorizing the use of VTOLs, with the aim of positioning the European industry as a global first mover [6]. These efforts align with the European Union's broader strategy to foster smart and sustainable mobility [2], [7].

Business models

As with technology, business models in the UAM industry are evolving rapidly, reflecting the potential and challenges of a fast-growing market. These models are generally classified into three categories, each with their own specifications and dynamics [15]: passenger transport; cargo; hybrid solutions. The latter includes models that do not fully fall into the first two categories, such as the concept of overhead warehouses.

Within the UAM landscape, passenger transport represents one of the most promising areas, with several emerging business models that aim to revolutionize urban mobility. Unlike what is observed in the automotive and traditional aviation sectors, passenger UAM vehicles do not yet adhere to standard designs, as demonstrated by wide variety of eVTOL configurations. Initially, these services are likely to target high-income users due to high costs. However, from an economic point of view, technological maturation and computational advances are expected to drive economies of scale, reducing production costs and gradually increasing the affordability and accessibility of these services [16].

Based on the types of consumers targeted, three main business models for UAM passenger transport can be identified [4], [8]:

- *Air taxis*. Urban Air Mobility promises to significantly alleviate congestion in urban areas through a non-stop on-demand flight service that allows citizens to move from one landing pad to another within a defined area. This service will operate over short distances, typically between 15 and 50 km, covering the diameter of the entire urban center.
- *Airport shuttles*. Airport shuttles are designed to cover similar and longer distances than air taxis. These flights would operate between various landing pads distributed throughout the city and the main airport. In this context, flights would not be on demand but regular.
- *Intercity flights*. Intercity flights are designed to operate between cities that are too close to justify traditional flights, but far enough away to benefit from air travel. The distance covered will vary between 50 and 250 km [4].

UAM technologies have also found important applications in the cargo sector [3]. For over a decade, several companies have been developing cargo models that rely on drones for so-called

last-mile deliveries [18], [3]. Unmanned aerial vehicles (UAVs), which include drones, are extremely versatile tools with applications across various domains. The drone-based *delivery of goods and food* items represents the first major frontier in aerial cargo. In recent years, many companies – such as Amazon - have invested significant resources in the developing services for the delivery of goods and groceries. Cargo in the context of UAM also includes the distribution of critical *medical supplies and healthcare equipment*. The ability to reduce delivery times and operational costs presents a substantial advantage for the healthcare sector. Drones, capable of flying autonomously and covering long distances, provide a solution to geographic accessibility challenges, particularly in remote or underserved areas. As healthcare systems face rising labor costs and fluctuating fuel prices, the automation of transport processes becomes an effective strategy to reduce costs and minimize delays typically associated with traditional delivery services [17].

The Italian market. The Italian UAM market is still in its early development phase. It is estimated that the entire AAM sector, which includes UAM, could reach a market value of € 1.8 billion by 2030, with a compound annual growth rate (CAGR) of about 20.6% between 2025 and 2030. The segment with the greatest growth potential is passenger transport, with a growth of 36% by 2030, followed by cargo with a growth of 18.5% [12]. Investments in research and development are expanding. In 2022 they amounted to € 16 million in cargo and € 8 million in passenger transport, with a projected CAGR in 2030 of 11% and 30% respectively [12]. The Italian industrial landscape is currently dominated by startups, with limited involvement from medium and large companies. In fact, only 1% of companies operating in the AAM sector in Italy report an annual turnover exceeding € 5 million [12].

Value creation. In the Italian context, value creation through the UAM sector is still in its early stages. Italy has begun laying the groundwork for future positioning, particularly in cargo segment, with a focus on medical logistics. In this segment, value is primarily created through improved efficiency, speed and reduced lead times for critical deliveries. In the passenger transport segment, value creation is similarly driven by efficiency and speed, in particular for air taxi services and airport-to-city connections. However, significant additional opportunities could emerge in the tourism sector, leveraging the silent and environmentally friendly nature of electric UAM vehicles. This could enable unique air tours over historic cities such as Rome, offering a new, sustainable form of experiential tourism.

Value capture. Value capture in the Italian UAM sector is currently limited by a fragmented regulatory environment. Most companies are still in the investment phase and have yet to establish commercial services. At present, revenue streams are largely limited to the cargo segment, including drones and software sales for specific industrial applications. Initial business models are expected to rely primarily on B2B partnerships, which offer more predictable revenue streams than B2C approaches. For instance, UAM companies could establish partnerships with airports and other operators to provide regular and scheduled services. Additionally, companies involved in the development of UAM infrastructure may capture value through take-off and landing fees, as well as ancillary passenger services. However, the introduction of such innovative and advanced technologies must be carefully managed to ensure they remain inclusive and accessible to the broader public.

Value delivery. Effective value delivery in the UAM sector depends on two key strategic priorities: regulatory and institutional collaboration, and the development of supporting infrastructure. In Europe, unlike the approaches taken in America and Asia, regulation often acts

as a barrier to rapid technological development, largely due to stringent safety standards and rigorous certification processes. However, regulation is a key aspect in ensuring that UAM services are safe, reliable and socially accepted. This highlights the importance of limited, step-by-step pilot projects to demonstrate the practical benefits of UAM and gradually build public trust. The goal is not simply to convince the public of the value of UAM, but to actively engage them in the development of a sector with significant societal and economic potential.

Contribution

The study is presented as a review of the current economic scenario of the UAM, contributing to enriching the UAM literature, which is still limited. In particular, it places a greater focus on the European and Italian contexts, moving from a multidimensional framework and the use of updated data. The work thus highlights the main trends, challenges and opportunities in the sector, offering a useful basis for policy makers and other stakeholders.

Abstract. Urban Air Mobility (UAM) is currently emerging as innovative mobility solution for urban transport. To ensure its seamless integration into existing systems, advanced simulation frameworks are strongly needed. Extended Reality (XR) technologies offer powerful tools to support such simulations. This paper presents a suite of Extended Reality-based integrated simulation and interaction platforms for multipurpose testing of UAM through Digital Twins of missions and scenarios. The platforms combine various hardware and software infrastructures and components, including the IRIS Cave Automatic Virtual Environment (CAVE), an eVTOL passenger simulator, and an Augmented Reality application for drone-based aircraft maintenance. Developed within the framework of the MOST – Sustainable Mobility Project, these platforms aim to support diverse use cases and contribute to the safe and efficient integration of UAM systems.

Introduction

In the context of rapid technological advancements and increasing digitalization of systems, the airspace domain is moving towards new solutions such as Advanced Air Mobility (AAM) and Urban Air Mobility (UAM). AAM is enabled by electric take-off and landing (eVTOL) aircraft and Unmanned Aerial Systems (UAS) and UAM refers to its implementation in urban scenarios [1]. These innovative aerial operations are expected to enhance the overall efficiency and sustainability of airspace systems. However, their integration into existing environments poses significant challenges related to safety, infrastructure development, and public acceptance. To address these challenges, a collaborative approach among the various stakeholders involved in this emerging transportation ecosystem is essential for achieving full-scale deployment. One key aspect of this process involves sharing information and data within realistic visualization and interactive environments. In this regard, the use of Extended Reality (XR) technologies for visualizing Digital Twins (DT) of aircraft and/or operational scenarios offers a promising path to support stakeholders, providing comprehensive, high-fidelity environments for prediction,

Materials Research Proceedings 69 (2026) 1559-1562 https://doi.org/10.21741/9781644904251-273

monitoring, and decision-making [2]. In the aerospace domain, DT applications have already been carried out across different areas such as aircraft design and development, manufacturing, operation and maintenance [3]. Further applications have been proposed in the context of Urban Air Mobility, such as exploring ground infrastructure location and aerial corridors [4] and supporting airspace management [5]. Although there exists no consensus on the formal definition of a DT, most reputable research shares the commonality that a DT is a cyber-physical system consist of at least three components: a physical system, a virtual model and their interactions [2][6][7]. Extended Reality (XR) Technologies, including VR (Virtual Reality), AR (Augmented Reality) and MR (Mixed Reality), enable seamless human–Digital Twin interaction by blending real and digital content, integrating high-fidelity simulation modules, and fostering collaboration among users [9]. Building upon these concepts, this work presents a modular and collaborative XR-based platform for Digital Twin visualization and interaction, developed through close cooperation between academic and industrial partners within the framework of the MOST – Sustainable Mobility Project.

XR-based Simulation Platform for Digital Twin applications in AAM and UAM

In the MOST Project, an XR multisensory simulator supports the need of a convergence place for safe AAM and UAM simulation and interaction and has ultimately two main goals: i. to integrate multi-layered DT capabilities in three-dimensional DT models of UAM and AAM missions; ii. To enable a realistic, collaborative and interactive user experience through simulation platforms designed to the analysis of DTs. The proposed simulation framework has been deployed, in both software and hardware infrastructure, to different facilities of project partners and has the capability to support and simulate multiple use-cases including eVTOL passenger transport, AR drone-enhanced aircraft maintenance and public acceptance. The overall hardware-software architecture of the XR multisensory simulator is depicted in *Figure 1*.

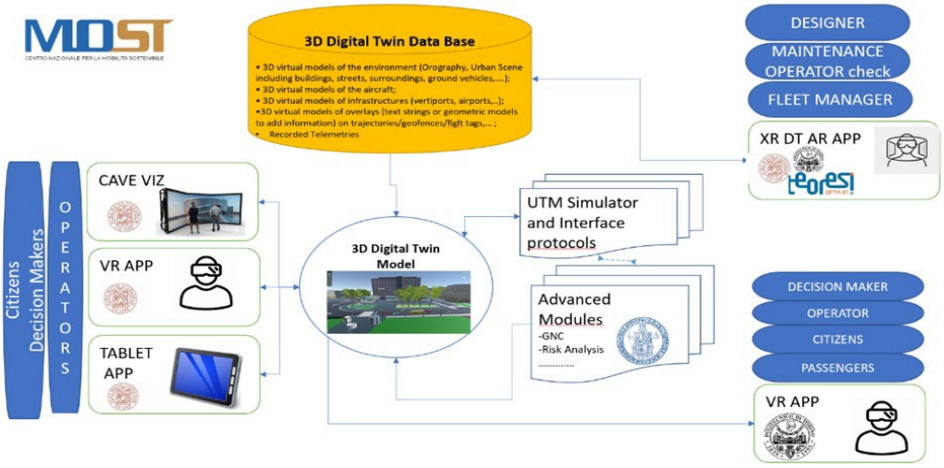

Figure 1 *The overall suite XR-based simulation platforms for Digital Twin visualization and interaction developed in the framework of MOST - Sustainable Mobility Project.*

The architecture of such XR Platform follows a modular design and is built upon the creation of a virtual scene composed of different data layers that can be combined between themselves and deployed according to the desired application. These layers are the Digital Twin Model layer, in which the three-dimensional models of the individual objects for each layer are integrated, including high-fidelity 3D models of eVTOLs and drones, urban environments and its components (e.g. buildings, streets, ground vehicles, terrain data), infrastructure dedicated to UAM (known as *vertiports*), overlays (text strings or geometric models to add information) and the recorded trajectories and paths database; The XR Visualization layer, that provides the XR Human Machine

Materials Research Proceedings 69 (2026) 1559-1562 https://doi.org/10.21741/9781644904251-273

Interface through which the application will be experienced and interacted to by the user and the Integration and Simulation Engine layer: responsible for managing layer interaction logics and data communication with external simulators or telemetry sources.

The MOST XR Platform modules

IRIS – Immersive Reconfigurable Innovative System is a unique cutting-edge immersive simulation infrastructure that allows users to experience Virtual Reality applications within an environment projected onto the walls of a room-sized cube (See Figure 2). The facility installed at the University of Bologna site in Forlì, leverages key features such as *immersion*, enabled by multiple projectors displaying high-resolution three-dimensional environments and *interaction*, enabled by input devices (e.g. tracking systems). A simulator aiming at replicating onboard flight experience from the point of view of passengers was developed by the Polytechnic of Turin (See Figure 3). The simulator reproduces an autonomous or piloted UAS mission under different visibility conditions (e.g. clear daylight, clear nighttime, cloudy with rain and foggy scenarios), during which other UAM traffic is visible to the user.

Figure 2 Immersive Reconfigurable Innovative System (IRIS) Cave platform in its open configuration displaying the Digital Twin model of Fuorigrotta, Naples, developed within MOST Project.

Figure 4 Passenger view from the UAV Passenger Simulator.

Aircraft maintenance activities can benefit from Augmented Reality interfaces due to the high level of interaction intrinsic of such procedures [10]. An AR interface to enhance drone-based maintenance and inspection procedures was proposed by Teoresi (See Figure 4*)*. The system primarily focuses on enhancing real-time situation awareness by leveraging Augmented Reality to display telemetry data (e.g. battery status, aircraft position and key metrics) to remote drone operators while executing predefined aircraft inspection activities. As the operator can visualize key information to support efficient and informed decisions. The ultimate goal is to boost precision, responsiveness and overall effectiveness of airport inspection and maintenance tasks through AR-enabled workflows. To demonstrate the capability of supporting the smooth integration of AAM and UAM into the current airspace scenario, the various infrastructures and components of the XR framework were tested through a series of pilot cases integrating advanced simulation modules, such as and the risk analysis framework developed by the University of Naples and the Unmanned Traffic Management simulator provided by TopView through Cascade Funding. A further module is the Simultaneous XR simulator for airport scenarios immersive experience provided by TXT through cascade fundings.

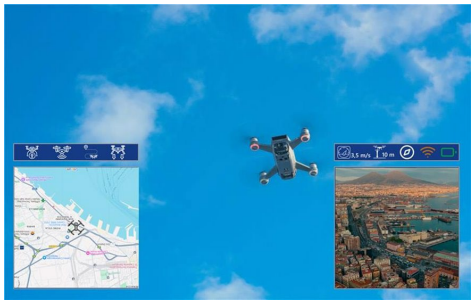

Figure 3 The AR for AR-enhanced aircraft maintenance.

Conclusion

AAM and UAM are promising concepts for the future of aerial transportation; however, further efforts are still required to ensure their effective integration into existing airspace systems. To this end, this paper has presented an XR-based platform designed for Digital Twin (DT) applications in UAM and AAM simulation. Three hardware components have been developed: the IRIS immersive system, the eVTOL passenger simulator, and an AR enhanced, drone-based maintenance application. The proposed simulation framework demonstrates the potential of bridging XR technologies and DTs, not only as tools for visualization and interaction but also as a foundation for informed decision-making among UAM and AAM stakeholders.

Abstract This paper introduces the design of FORTUNA, a modular rover aimed at enabling robotic operations and exploration on planetary surfaces. The work entirely developed by students of team DIANA from Politecnico di Torino. FORTUNA's goal is to explore the planetary surface by interacting with other platforms (forming a fleet of rovers) and surviving the environment. The project is part of an ever-growing vision of an established presence on the moon, which would require many robotic platforms to perform various tasks, from maintenance to exploration. The rover, developed following the experience gained on the team's previous rover ARDITO [1], it is designed to be smaller, faster, and more cost effective. These improvements are achieved through its high degree of modularity and its capability to host different payloads. In September 2025, FORTUNA took part to the European Rover Challenge (ERC) in Poland, where the platform accomplished all competition tasks achieving a 4th place overall. In May 2026 the platform will compete in the University Rover Challenge (URC) in the Mars Desert Research Station The Fortuna rover offers a lightweight and cost-effective platform specifically designed to support maintenance operations at lunar base as well as exploration missions on the Moon and Mars. Its modular architecture and advanced autonomous[2] system enable adaptability to diverse mission requirements, from routine infrastructure inspection to complex surface exploration. By integrating a 6-DOFrobotic arm and supporting both autonomous and remote-controlled modes, Fortuna enhances operational flexibility while reducing mission costs. This combination of features makes Fortuna an optimal candidate for sustainable surface exploration and long-term human presence on planetary surfaces.

Introduction

DIANA (Ducti Ingenio Accipimus Naturam Astrorum) was born in 2008, in Politecnico di Torino, prompted by the AMALIA project, a space-grade rover, aiming at participating in the Google Lunar X-Prize and land on the Moon.

In 2015, the team shifted its focus to student competitions, with project TO-RO the team had the opportunity of participating in its first rover series competition. In 2019 a new rover, TRINITY, was presented and from 2021 to 2024 ARDITO was built but it had reached it's operational limit, taking into consideration past experiences and valuable advices given by the judges, DIANA has decided to design a brand new rover.

FORTUNA (Fortuna Operans Res Terrarum Universi Navigatio Astrorum) is DIANA's latest prototype of a robotic space rover aimed at student competitions. It is a brand new concept of rover for the team, being a lightweight and agile platform, able to quickly overcome obstacles and manipulate objects, rocks, and regolith.

Materials Research Proceedings 69 (2026) 1563-1567 https://doi.org/10.21741/9781644904251-274

FORTUNA is an end-to-end project developed in STARLab [3], the team was required to design a full platform of a space rover prototype while following ERC requirements. This approach is consistent with the team's philosophy of using as much in-house solutions as possible and keeping a close eye to the space industry. The whole project is being followed by a group of system engineers that ensures the compliance of the project with all requirements and performs functional analysis based on ERC tasks.

Design Approach

From an early stage, a V-Model [4] approach was adopted for the FORTUNA project. This model describes a clear representation of the sequence of steps that have been taken during the project life-cycle development. At the beginning of the year, a project timeline has been defined to schedule the major project tasks, outlining the progression from the design phases to integration and testing. Following the ECSS Standards [5] (ECSS-M-ST-10C Rev. 1), several milestones have been set to monitor the progress of the main activities and their completion: the Preliminary Design Review (PDR) for the evaluation of consistency between the preliminary design and system requirements, the Critical Design Review (CDR) to confirm that the design is at stable point meeting the technical requirements in order to proceed to the manufacturing phase, the Qualification Review (QR) for the system validation under specific operational conditions and the Operational Readiness Review (ORR) to determine the readiness of the Rover for operations and mission execution.

Throughout all the project phases, a dedicated group of System engineers is responsible for ensuring the compliance with the requirements defined at the beginning and conducting a first assessment of the risk analysis. Due to time constraints and a strict timeline the V-model was adopted without much possibility for many iterations. A dedicated group of system engineers followed the project from its early-phase, using ERC Appendix 3 and rule-book as stakeholder needs to write all Rover requirements following the ECSS Standards.

FORTUNA's requirements have been divided into:

- Mission
- Functional
- Interface
- Physical
- Environmental
- Operational
- Design
- Configuration
- Human Factors

FORTUNA Design

Together with requirement definition a Concept of Operations (ConOps) study and a Functional Tree were developed. The functional analysis aimed to create a list of every function the rover must perform in order to complete all the assigned tasks. A function-equipment matrix was also made, which assigns to each rover function its assigned equipment. This approach is crucial to identify mission critical equipments and to enable the early implementation of redundancy where needed. All system engineering work was done during concurrent engineering sessions during which Functional Table, ConOps and requirements were updated simultaneously.

FORTUNA's mobility system is based on a double-bogie configuration composed of four independent driving wheels made of a TPU outer skin and an aluminum alloy outer plate. The system is composed of two mirrored structures made of carbon tubes profiles joined with aluminum plates and structural glue. At both ends of each mobility are placed steering BLDC MyActuator motors with an integrated control board. The two halves of the mobility system are linked together through a differential system that allows the rover to safely overcome obstacles up to 250 mm while maintaining the stability of the rover. The two bogies are connected through a dual-pivot differential system, increasing the available volume within the avionics module while significantly reducing the overall system mass. To ensure the rover's capacity to overcome obstacles the whole system has been validated and simulated through various runs on HEXAGON ADAMS [6] software. COSMOS is the software module responsible for managing the rover's

Materials Research Proceedings 69 (2026) 1563-1567 https://doi.org/10.21741/9781644904251-274

mobility, receiving as input a target linear velocity and steering angle and processing them through algorithms that calculate, in real time, the optimal velocity and steering angle for each actuator. Since each wheel is powered by independent motors, COSMOS can assign different commands to each wheel, enabling complex and adaptive maneuvers. The system supports multiple operational modes designed for specific locomotion scenarios. The Idle mode sets the rover in a static state, while the new Translation mode allows motion in any direction with fixed orientation, enhancing maneuverability. For curved paths, COSMOS implements Ackermann and Double Ackermann modes based on Ackermann steering geometry. The single Ackermann mode replicates car dynamics, while the Double Ackermann mode, with all four wheels steerable, improves precision; the Spinning mode allows rotation in place. COSMOS ensures full and flexible mobility control by selecting the proper mode and calculating individual wheel commands.

The Avionics bay [7] is designed to pack all the main platform avionics into a single compact structure. All the control logics are fitted into a 9U CubeSat form factor box, designed with handles to be easily swappable in case of malfunctions, with two identical avionics bays prepared to hot-swap if needed. The battery is placed under the avionics bay to lower the center of mass, and a payload interface plate at the back provides power, data, and structural connections. The structure, made from folded aluminum sheets (Al5754), ensures strength and lightness, while the PMU controls all subsystems, allowing remote shutdowns through the CAN-bus line. The Raspberry Pi 5 and Jetson ORIN Nano handle communication, control, and AI tasks, with STM32 H7 boards running FreeRTOS for a more robust firmware system.

DIANArm Mk2 is FORTUNA's six-degrees-of-freedom robotic arm, enabling interactions such as grabbing objects, using tools, and collecting samples. It is made from carbon fiber tubes joined by aluminum plates and 3D printed parts, with each joint actuated by BLDC Cubemars motors with integrated control boards and mechanical reduction for torque and precision. The control logic is stored in the avionics bay, all boards and motors communicate through CAN-bus, and the total weight has been reduced to 8 kg, with improved accuracy for manipulation and autonomy. The Arm Control Unit runs FreeRTOS and the GrippyGrabby logic offers four control modes, while AUTOGrabby and SISMA provide autonomous operation through AI-based detection and trajectory planning with fail-safe mechanisms. The End Effector, made of CNC-machined aluminum plates, includes sensors, camera, TOF sensor, and Dynamixel motor driving a differential mechanism, with modular TPU fingertips for grasping and tactile feedback.

The main structure of a Deep Sampler consists of a precision linear guide with a worm screw actuated by a stepper motor, allowing the sampling mechanism to rise and lower by activating the screw. Collected sand is stored and weighted in a separate 3D printed container at the bottom of the structure, enabling safe deep sampling operations up to 30 cm. The payload is mounted on the back of the rover using aluminum profiles, with an additional thicker 20x40 mm profile added for structural integrity and stress reduction. As with all other rover payloads, the Soil Sampler carries its own control logics and connects to the Main On-Board Computer through CAN-bus communication as defined in the interface document.

Materials Research Proceedings 69 (2026) 1563-1567 https://doi.org/10.21741/9781644904251-274

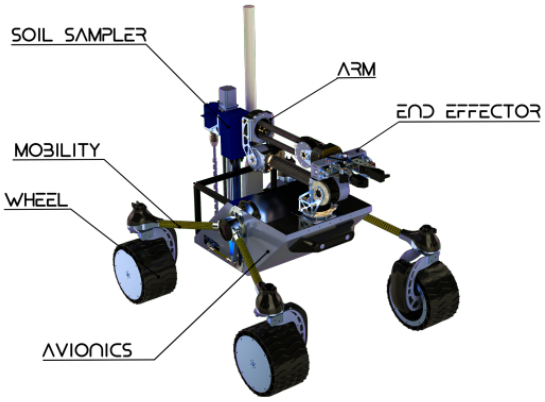

Figure 1: FORTUNA Rover

Test Approach

A well-structured test verification plan employs a layered approach. Four types of test have been defined in order to cover each phase of the FORTUNA project. After the Design Validation team undergoes a temporary reorganization into cross-functional groups focused on integrating and testing specific systems.

FORTUNA Design (DEV): This first layer is the Design Validation, conducted internally by each department. During the development stages, each component is verified independently, with a different strategy according to its nature: mechanical structures are mainly validated through FEM analysis and discussions with our suppliers; electrical hardware undergoes analyses and breadboard testing; software is tested during development, following a test-driven development approach. This kind of verification is crucial, but it is not formally included in the test plan, which accounts system and sub-system, leaving the departments dealing with components validation. This approach ensures a more balanced distribution of validation responsibilities among technical development leaders and the test manager.

Reduced Functional Tests (RFT): This kind of tests have a threefold function:

- Validate the system once integrated;
- Acting as a control point, verifying essential functions before proceeding with more extensive testing;
- Verify rover state after a system upgrade or a transportation.

This test has to be performed once the Rover has been integrated and the components are already verified. To understand the status of each system tests are performed excluding as much as possible dependencies from other part of the Rover. The goal of this layer is to obtain full knowledge regarding the system's operative status.

Full Functional Tests (FFT): Full Functional Tests will be performed once the Rover is stable to assess the correct integration of FORTUNA and its payloads in each configuration. These tests can be performed in non-operative conditions and has to cover every function of the Rover.

Mission Test (MST): Finally, mission-oriented tests simulate real task scenarios, providing a comprehensive check of the system's performance under realistic conditions. These tests will be conducted both in a simulated martian scenario in collaboration with ALTEC S.p.A [8].

(Aerospace Logistics Technology Engineering Company), a sponsor of the Team which grants the access to their facilities, and on the newly developed SimVISION simulator.

Abstract. A method for generating an aircraft cabin from Large Language Models (LLM), ontology, and Singular Value Decomposition is presented in this paper. An initial aircraft outer geometry from previous work is used as a starting point for the concept generation of the cabin design. ChatGPT, Claude, and Copilot were used to generate the initial ontology of the aircraft cabin along with requirements, functions, and design alternatives. The ontology is refined through chain-of-thought prompting and later modified to obtain the required ontology. The data of the aircraft cabin was also collected similarly and used in the Singular Value Decomposition (SVD). Because ontology representations have limited numerical computation capabilities, the collected data are processed with SVD to obtain quantitative estimations. Statistical analysis further enriches the knowledge extracted from the ontology. A case study validates the proposed methodology by generating a cabin configuration that satisfies the stated requirements.

Introduction

Passenger aircraft design is a complex and multidisciplinary task that involves the integration and consideration of numerous systems, requirements, and constraints. The need for tools that can manage such complexity grows together with the demand to find more efficient and sustainable solutions. The recent rise of LLMs, as well as an increasing interest in semantic technologies, introduces new opportunities for improving and evolving the existing procedures of today in the search for new solutions.

Among the many subsystems involved in the design of large passenger aircraft, the cabin plays an important role that often determines the required fuselage dimensions and influences the aircraft layout. The cabin is often one of the very starting points in an aircraft sizing procedure [1] and involves considering the trade-offs while balancing regulatory requirements with spatial constraints and passenger-centered considerations. The purpose of this paper is to present a method that utilises LLMs, ontology, and statistical SVD analyses for ultimately generating aircraft cabin design concepts. The method thereby enables quick evaluations and trade-off analyses of different aircraft cabin concepts.

A case study for the cabin design of a conventional large passenger aircraft is used to illustrate the various steps of the presented method. Finally, an outlook on possible future improvements of the said method is presented.

Theoretical Background

This section gives a brief theoretical background for the foundational principles used in the proposed method of this paper. The presented work is an extension of the work performed in [2], which describes a method by which an ontology description can be used to generate a geometrical representation of a concept aircraft. Consequently, this previous work forms the foundation for the present study; therefore, background related to Ontology, Matrix of alternatives, Interactive Reconfigurable Matrix of Alternatives (IRMA) and SVD, Effective Parameterisation for Geometry Build-up can be referred to the previous paper [2].

Aircraft and Cabin Design

Aircraft Interiors are a major component of the Aircraft Design process. Cabin space should be used intelligently to maximise its potential, to identify and incorporate factors that contribute to passenger comfort, and to accommodate the required maximum number of passengers. The design of the cabin complies with FAR 25 regulations.

Large Language Models

Based on advanced forms of Statistical Language Models, Large Language Models the estimated likelihood of words appearing in a given sequence [3]. Different forms of machine learning have been used over the years, including recurrent neural networks or reinforcement learning [4]. The result is a Large Language Model that undergoes training with feedback, reducing the output error to a value close to, but never equal to, zero, in accordance with the *Universal Approximation Theorem*.

Method

This section introduces and explains the method for generating aircraft cabin concepts based on the foundational principles mentioned in the previous section. An illustration of the method and corresponding steps is shown below in Figure 1. The method is intended to apply to domains other than just aircraft cabin design and has therefore been kept agnostic to promote reuse in other engineering endeavours. LLM is used to generate an initial ontology with entities and relationships from the desired domain. The ontology can, from there, be expanded or modified based on the initial requirements to give a desired and correctly structured knowledge representation. Description logic reasoning can help ensure that the ontology is consistent and logically sound. Once the desired ontology is established, information about, for example, functions and design alternatives can be extracted and used to create more common and condensed conceptual design tools for added decision support, such as a matrix of alternatives, or a more advanced IRMA as shown in [2]. The outcome of the ontology part in Figure 1 is a qualitative description of the generated concept's characteristics.

As ontologies are limited in terms of numerical calculation capabilities, a parallel track with numerical data generated through an LLM and later processed with SVD is seen in Figure 1. The SVD model is used on the numerical data to give initial quantitative estimations of the intended concept based on the most important requirements for the design in question. Here, Quality Function Deployment (QFD) is a means for prioritising requirements if needed. Ultimately, the outcome from the SVD analysis is numerical estimations for the intended concept properties based on statistical data. The qualitative estimations from the ontology and the quantitative estimations from the SVD analysis can be synthesised into a complete initial estimate of the concept. The concept must be verified against the requirements and adjusted or negotiated if it does not meet them.

Materials Research Proceedings 69 (2026) 1568-1573 https://doi.org/10.21741/9781644904251-275

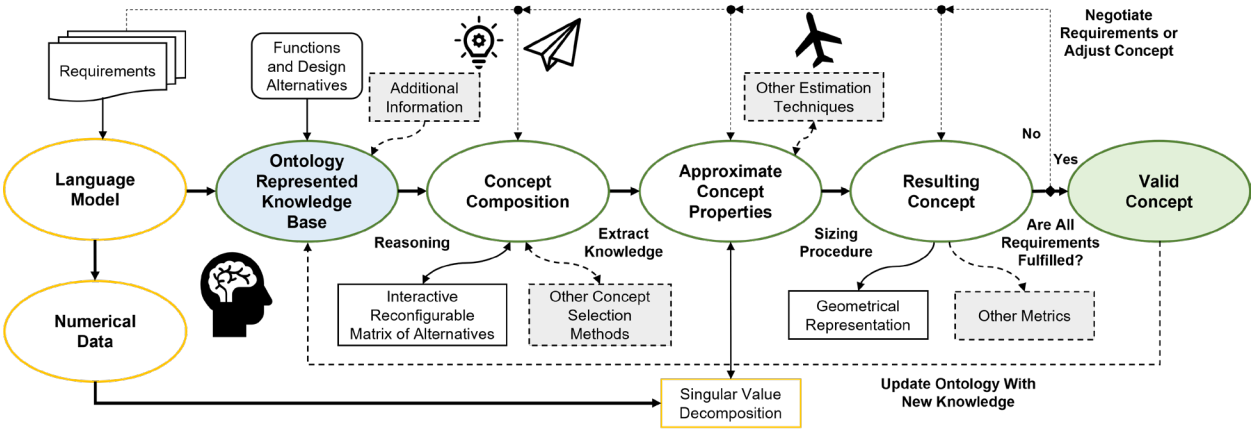

Figure 1 An illustration of the presented method and its corresponding steps.

Use Case: Aircraft Cabin Design

This section describes how the proposed method from Figure 1 is used to generate an initial aircraft cabin design based on basic requirements.

LLM-based Ontology Creation and Usage

The ontology used in this case study was initially generated with LLM. The ontology has thereafter been refined in the Protégé ontology editing software [5] to include proper relationships between cabin design functions and their potential design alternatives. The ontology also includes a hierarchy of general cabin design considerations and components. These range from basic considerations such as cabin seating arrangements to amenities such as potential entertainment systems. Figure 2 shows an extract of the used ontology. As shown on the right-hand side of Figure 2, the Seating Alternatives individual has three object property assertions linking it to three different design alternatives through the hasAlternative relationship. A similar structure is applied to all function individuals within the ontology to establish the connections to their respective design alternatives. Consequently, the ontology acts as an overarching knowledge base for the cabin design procedure and may also include potential incompatibilities between design alternatives.

LLM-based Numerical Data Collection

The numerical dataset was generated through data retrieval using state-of-the-art models (GTP-5 and Claude). The input prompt used with both models was: “Make a table of Figure 2 – The ontology class hierarchy (left) and the definition for a Seating Alternatives individual (right). Aircraft name, Manufacturer, Passenger capacity, No. of seating classes, No. of seats in First, Business and Economy classes, No. of lavatories, No. of galleys, No. of aisles and No. of exists for the following aircraft” followed by a list of aircraft available from a single manufacturer. It was noticed, during the process that mixing manufacturers in the prompt led to misleading data due to the issues of hallucination that these kinds of models still experience even after their latest improvements [6]. The data generated when requesting a single manufacturer in the prompt was of good quality, yet not completely correct and still requires human review.

Materials Research Proceedings 69 (2026) 1568-1573 https://doi.org/10.21741/9781644904251-275

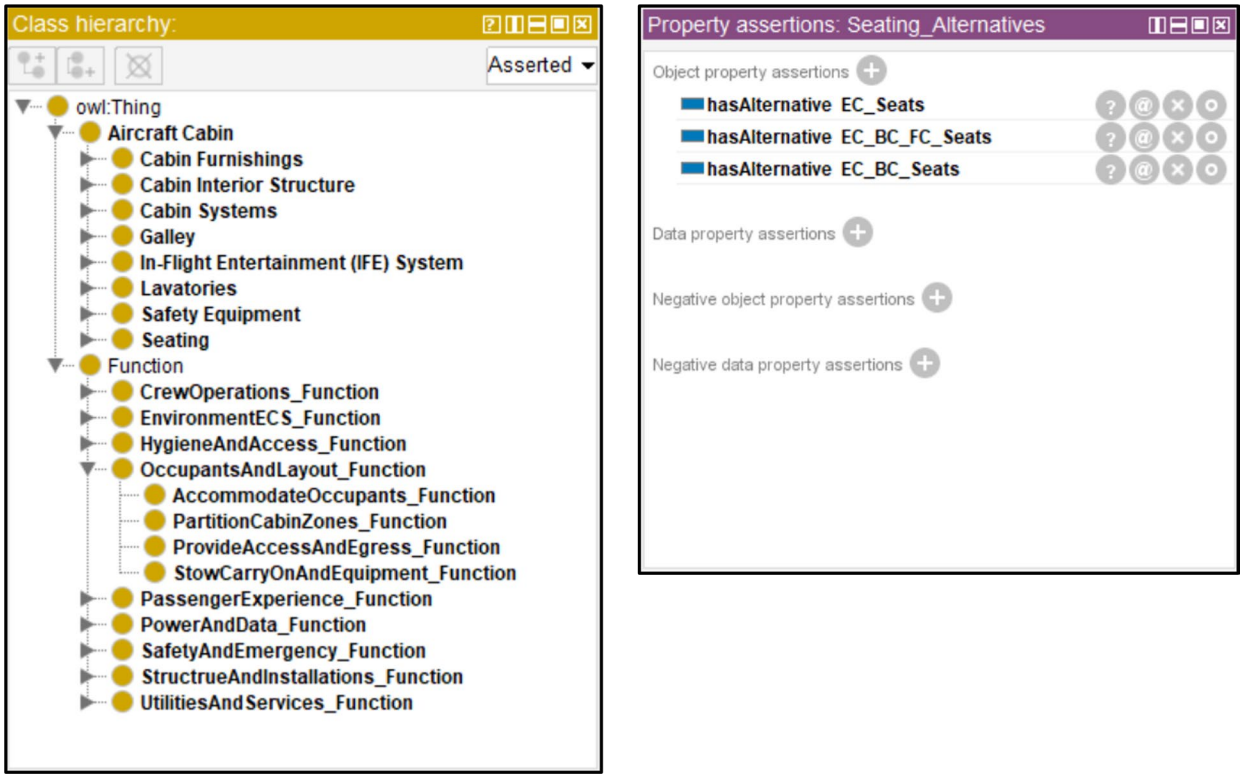

Figure 2 The ontology class hierarchy (left) and the definition for a Seating Alternatives individual (right).

Singular Value Decomposition Analysis

The generated numerical data was converted into logarithmic values to gain a more linear model structure for the SVD analysis [7]. The analysis itself, and the required matrix operations, were performed using an Excel-implemented macro. The outcome of this macro is an SVD model with determined SVD-variables [2]. If the model is used to predict the values for an Airbus A220 by using only 2 variables (3rd-rightmost column for reference), and the model inputs are respectively 132 passengers and 2 seating classes, it can be seen in Figure 3 that the predictions show a relative error of 63% (2nd-leftmost column) with respect to the estimated values by the model (4th-leftmost column). This is due to the higher number of 3-class aircraft in the dataset, which skews the prediction. If the same procedure is done again but only using 2-class aircraft for generating the SVD model, the relative error is drastically reduced to 37% as shown in Figure 4.

Figure 4 Unbiased model for prediction of aircraft cabin using two variables.

Concept Geometry Layout

The resulting concept is thoroughly evaluated against the requirements, ensuring its validity. The values of Passenger Capacity and Number of Seating classes obtained from the SVD are used in PreSTo (Figure 5 - Top) along with the previous values from outer geometry design [2]. The values for cabin layout from PreSTo are then imported to the Enhanced User Interface (Figure 5 - middle) and later exported to the Knowledge Based Engineering (KBE) tool RAPID [9] (Figure 5 - Bottom). Insights from the SVD analysis and geometrical sizing will be used to update the ontology and the corresponding individual with new data properties.

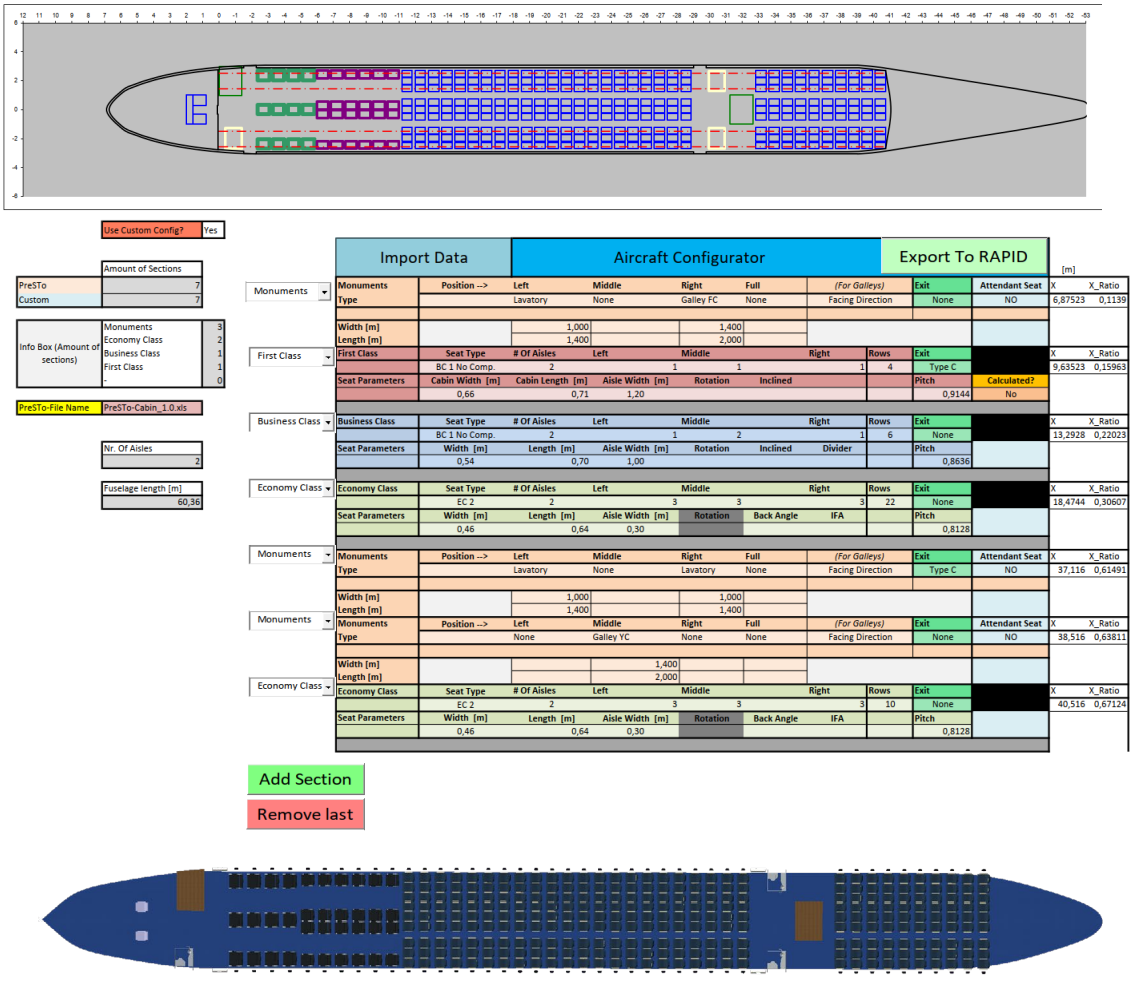

Figure 5 Representation of the results along with the flow process for a 3-Seating classes. Top to Bottom, Preliminary Sizing Tool (PreSTo), Enhanced user interface [8] and generated concept in Robust Aircraft Parametric Interactive Design (RAPID) [9], [10].

Conclusions and Outlook

In this paper, a method for generating an aircraft cabin using LLM, ontology, and SVD is presented. The extraction and enhancement of relevant information using approaches such as a statistical SVD analysis have narrowed down the number of parameters needed for estimation. The resulting information was used as input for an initial geometric sizing step that generated initial-sized versions of selected concepts using PreSTo and finally representing the 3-dimensional model of the aircraft in RAPID. The initial ontology generation produced difficulties in capturing the requirements, functions, and design alternatives, necessitating additional manual refinement. Further manual work was needed in updating the same. Knowledge graphs, combined with an AI agent, could replace much of the current manual effort. An AI agent specifically trained for Aircraft Concept generation and Cabin Design, would be valuable for both in research and academic applications.

Keywords: Flight Simulation, Aircraft Design, Pilot Studies, Aircraft Modelling

Abstract. This paper describes the development and use of a new, flexible flight modelling and simulation environment based on Alsim's engineering pack simulation tool with their AL250 simulators, recently installed at the University of Hertfordshire. This capability provides the necessary performance and flexibility to support the university's aerospace engineering and pilot studies programmes, along with supporting the breadth of ongoing research activities. Two key developments are highlighted: pilot studies assessment, and a modelling framework for general fixed wing aircraft for design testing. Examples of research activities currently in planning and development are also briefly presented, including work on emission modelling for general aviation aircraft. The outcomes from these activities have had notable improvements on previous facility capabilities in all areas.

Introduction

Access to increasingly high-quality and higher-fidelity flight simulation environments is crucial for universities running aerospace degree programmes to be able to provide effective laboratories for active learning. A great amount of flexibility is often required to be able to utilise the same simulator for multiple different learning objectives and avoid the cost and space requirements of multiple specialised systems. This flexibility is also crucial for supporting research and development activities that could encompass investigations in topics ranging from human factors studies to flight control design and testing. The technical performance of many affordable flight simulators is now at the point where they are ubiquitous in most universities running aviation, pilot studies, or aerospace engineering degree programmes [1]. However, not all simulator offerings provide the necessary flexibility for all of these, in addition to requirements for research activity.

As part of a recent upgrade to new facilities the University of Hertfordshire (UH) has recently invested in three Alsim AL250 flight simulators. The AL250 is a reconfigurable single and twin engine piston FNPT II[1] aircraft simulator, designed to meet the training requirements of PPL/CPL/IR/MEP[2]. The cockpit multi-function displays can be switched between traditional instrumentation in a T arrangement and a conventional electronic flight instrument system (EFIS). The base flight models are notably accurate and whilst the simulators can be certified, of more interest to the university is the engineering design and analysis capabilities afforded by its 'engineering pack' (E-Pack) software. These features make it an increasingly attractive tool for many other universities. Waterloo University has used its AL250 extensively for eye tracking, cognitive load, and human factor studies since 2023 [2–5]. A variety of applications in taught programmes have already been explored at Nottingham [6] whilst Portapas [7], also at Nottingham, has used the AL250 with the E-Pack to implement a model of an eVTOL for both teaching and research applications. Such applications are similarly planned at UH throughout the undergraduate and postgraduate programmes. These activities have previously been achieved using a Merlin

MP520 and X-Plane based simulators. The greater flexibility and accuracy of the AL250 enhances these activities through the integration with MATLAB/Simulink which is also taught throughout the degree programme.

System overview

Two of three AL250 simulators recently installed at the university, shown in Fig. 1, can send and receive data to and from a MATLAB/Simulink client operating from a networked computer running the E-Pack software. This is achieved with a network datastore that acts as a CAN bus to share and push data between each of the simulator's subsystems. This includes, when connected, the client running the MATLAB/Simulink E-Pack software. The E-Pack is implemented as MATLAB and Simulink toolboxes that facilitate the communication with an AL250 unit and its various subsystems. As many of the data variables driving the simulator can be read from and/or sent to the simulator a substantial variety of applications is possible: from simple data logging to flying completely new, bespoke aircraft flight and systems models. Administrators access the simulator configuration controls through an instructor station whilst pilots may access similar controls, particularly for flight data recording, via a tablet device in the flight deck which also serves as an electronic flight bag (EFB).

The simulators have three primary use cases: i) pilot studies training and assessment, ii) aircraft design simulation, iii) research applications. Each of these is briefly discussed in the subsequent sections.

Pilot studies assessment

A pilot studies pathway of aerospace engineering is offered to undergraduate students who, in addition to core modules on all aerospace engineering pathways, undertake specialised pilot studies modules in topics such as air law, navigation, meteorology, planning, communications, flight performance, avionics, and human factors. Graduating from the programme requires completion of 20 hours of flying (instructed or solo). The flight simulation facilities at the university have long been used to allow students to develop confidence and skills to support this, in addition to more authentic sessions and assessments. This is enhanced with the new flight simulators which provides a highly accurate flight model, high-fidelity flight deck and controls, and easier access to data logging commands through the EFB.

An example of one of the more complex assessments on the programme is a flight planning exercise requiring students to plan a route via multiple local waypoints, including two short-stop landing/takeoffs, avoiding class D airspace (Fig. 2). Students must then fly a minimum 20 nautical

Figure 1. Alsim AL250 simulators.

Materials Research Proceedings 69 (2026) 1574-1579 https://doi.org/10.21741/9781644904251-276

mile portion of this route to demonstrate sufficient flight control and navigation skill. A significant enhancement with the AL250 compared to previous simulators is an integrated, physical GPS navigation unit for the students to use.

Other notable enhancements with the AL250 simulators are greater weather setting controls and a higher fidelity flightdeck which provides a more realistic environment for radio communication lessons and tests (Fig. 3). This enables both the actual flight and radio equipment to be used as part of the assessment to enhance the training transfer.

Aircraft design tool

Many aerospace degree courses will incorporate some form of aircraft design capstone project [8–11]. One of the fundamental aims of this kind of project is to replicate the industrial working environment of (and subsequently build students' skills and confidence in) cooperative design and systems integration. Consequently, these projects are typically undertaken as group work which reflects the nature of industrial work. An important element of the design process, or more generally as part of the feedback loop for developing students' knowledge and understanding, is for students to quickly generate a flight model of their design to analyse and evaluate it.

Fast generation of flight models from preliminary design parameters is a relatively mature topic owing to the wealth of knowledge and information on this topic. As such, there is a wide variety of methodologies that can be programmed to generate these flight models (Fig. 4), which trade accuracy for complexity and timeliness. The requirements of a tool for student-focused aircraft design activities are:

1. Fast generation of flight models from a basic geometry and mass specification.
2. Generation of simulated flight data to support performance, stability, and control analysis.

High fidelity models are not crucial for this task so analytical and semi-empirical models for computing the aerodynamic and stability parameters can be readily computed in MATLAB/Simulink for easy implementation with the E-Pack software. This is being done using methods from DATCOM, ESDU datasheets, and various well-known texts [12,13] to create a general template to model a generic fixed wing aircraft.

For example, Fig. 5 shows an electric-powered acrobatic aircraft designed by one group of students on the final year capstone group design module. In previous years we have used parametric modelling tools using a Merlin MP520 two-axes motion simulator and/or X-Plane software, both requiring some geometric data as well as propulsion performance data. Propulsion

system models with these systems were limited to conventional types (piston and gas turbine-based), with limited capability of electric propulsions systems in X-Plane. With the flexibility offered by the MATLAB/Simulink environment detailed models of more modern and advanced propulsion systems can now be explored and implemented. This includes more comprehensive modelling for batteries and hydrogen-based fuel cell systems for a variety of electric and hybrid propulsion models. This is in addition to the capability of modelling more complex systems, e.g., variable cycle engines.

The use of MATLAB/Simulink also means that higher fidelity models and different vehicle configurations with the design tool can be supported with an inherent modularity in its implementation. Additional functionality is planned as future module updates.

Research applications

Research capabilities with the new AL250 simulators include:

1. Nonlinear and unconventional configuration flight dynamics modelling.
2. Control inceptor evaluation.
3. Human-machine interaction studies.
4. Flying and handling qualities evaluation.
5. Flight control design and analysis.
6. Designing flight recovery techniques.

Most of these rely on the flexible modelling and data-reading functionality provided by the E-Pack software. The use of the simulators to enhance two example research projects are described below.

In the first example, an autonomous take-off system is implemented as an assistive autopilot. Such a system has potential applications in autonomous short takeoff/landing aircraft and in single pilot operations. A section of the system is presented in the Stateflow state machine of Fig. 6. This is combined with a low-level attitude autopilot as well as a thrust asymmetry control law which regulates the lateral deviation in engine-out scenarios. This system has been assessed in a purely software environment but the added benefit of running it on the AL250 simulator, via the E-Pack, means the human interaction with the system can be evaluated through the representative flight deck and autopilot panel controls.

The second example relates to the modelling of aircraft emissions of fixed wing aircraft to support a research project in the decarbonisation of general aviation airports. The project aims to define the exemplar framework for small airfields to approach and achieve decarbonisation and sustainability targets through a variety of approaches. One approach is better understanding and management of airfield emissions from the aircraft that operate from it, which are predominately

training school flights. One approach to emission modelling is to consider the fuel consumption multiplied by the specified emission species index. To achieve a baseline model a set of simulated training sorties are flown in the AL250 simulator, with the fuel consumption extracted and recorded through the E-Pack. In particular, the fuel consumption at different phases of flight is obtained from the simulated aircraft and used to obtain flight phase benchmarks for the emissions. Fig. 7 illustrates the simulated fuel consumption and mass of various emission species (carbon monoxide, CO; carbon dioxide, CO_2; Hydrocarbons, HC; Nitrogen oxides, NO_x) throughout a circuit for a twin-engine aircraft flight model, using emissions factors derived from [14]. The trends are consistent with experimental measurements from literature [14,15]. The data is also useful to compare the accuracy of metamodels that rely solely on flight hour date from trainer flights.

Conclusions

An overview of recent developments and uses with Alsim AL250 flight simulators in university taught and research programmes has been presented. These simulators provide improvements and capabilities for the three key uses: i) pilot studies assessments, ii) modelling for aircraft design activities, and iii) a wide range of research activities. Examples of these have been presented. The greater fidelity of the simulated flight deck environment, along with the wide-ranging capabilities from the MATLAB/Simulink E-Pack, has enabled more authentic piloting assessments, more

detailed aircraft system modelling capabilities, and more accurate simulation environments for research, compared to previous facilities. This is achieved in a smaller footprint than previously possible due to the flexibility of the Alsim simulators.
