CEAS - AIDAA Conference 2025

Proceedings of the 10th CEAS Aerospace Europe Conference
and 28th AIDAA International Congress.
Held December 1-4, 2025 at the Lingotto Congress Center,
Turin, Italy

Edited by
Erasmo Carrera and Matteo Filippi

M|R|F

CEAS - AIDAA Conference 2025

Proceedings of the 10th CEAS Aerospace Europe Conference 28th AIDAA International Congress. Held December 1-4, 2025 at the Lingotto Congress Center, Turin, Italy

Editors

Erasmo Carrera and Matteo Filippi

Politecnico di Torino
Mechanical and Aerospace Engineering Department, Turin, Italy

Peer review statement

All papers published in this volume of "Materials Research Proceedings" have been peer reviewed. The process of peer review was initiated and overseen by the above proceedings editors. All reviews were conducted by expert referees in accordance to Materials Research Forum LLC high standards.

Table of Contents

Preface
Committees

1. Artificial Intelligence, Machine Learning & Data Driven Methods

Detection of Aircraft Spoofing Using the GVA Parameter in ADS-B Data
Jakub TRÝB, Jakub HOSPODKA 2

Immersive Virtual Reality Framework for Lunar Pressurized Rover Training and Interaction
Dario Zamani, Mehran Bahojb Ghalibafan, Marco Crestini, Matteo D'Aquila, Magesh Chandramouli, Alfonso Pagani, Marco Petrolo, Erasmo Carrera 9

Single Controller for Multiple Aircraft by Deep Reinforcement Learning
Fatih Ahmet SARIGUL, Ismail BAYEZIT 15

Comparative Analysis of Generative Data Augmentation Techniques for Aircraft Damage Detection Algorithms: A Case Study
Salvatore MEROLA, Aditi MHATRE, Ann-Kathrin KOSCHLIK, Michele GUIDA, Francesco MARULO 21

Enabling Physics-Based Deep-Learning Thunderstorm Nowcasting for Critical Decision Making in Innovative Air Mobility
Niklas WARTHA, Grigory ROTSHTEYN, Christoph METZL, Tobias BÖLLE 25

Neural Network-Based Prediction of Bursting Events in a Turbulent Channel Flow
Enrico SACCAGGI, Gaetano Maria DI CICCA 31

Deep-Learning-based Dent Detection of Aircraft Surfaces using Synthetic Data
Aditi MHATRE, Salvatore MEROLA, Ann-Kathrin KOSCHLIK, Rebecca RODECK, Gerko WENDE 37

Improving GNSS Positioning Accuracy through Adaptive Weighting and Multipath Isolation
Sebastiano CHIODINI, Andrea VALMORBIDA, Giovanni ANESE, Marco PERTILE, Giada GIORGI, Claudio NARDUZZI, Bortolino SAGGIN 42

Lunar Descent and Landing Via Fusion of Deep Learning-Based Visual Navigation and Moonlight Signals
Michele CERESOLI, Floor MELMAN, Yoann AUDET, Richard SWINDEN, Francesco CAPOLUPO, Michèle LAVAGNA 48

Numerical Assessment of Convective PGMs
Giada COLOMBO, Umberto IEMMA 54

Modelling the Correlation Function of Wall Pressure Fluctuations Under Turbulent Boundary Layers with Machine Learning Methods
Marika DI MEO, Alessandro CASABURO, Arthur Diniz FLOR TORQUATO FERNANDES, Francesco FRANCO 60

Use of Convolutional Neural Networks for Multifidelity CFD Problems
Sebastiano Geremia Isidoro MARCI, Luca MUSCARA, Lorenzo FOLCARELLI, Andrea FERRERO, Filippo MASSENI, Dario Giuseppe PASTRONE 66

Vision-Based Relative Pose Estimation of Space Objects for Proximity Operations Using Lab-Validated Deep Learning
Matteo FORASASSI, Giordana BUCCHIONI, Lorenzo POLLINI 72

Minimum-Energy Trajectory Generation for Quadrotor UAVs Using Basis Functions and Gradient-Based Optimization
Fabio CELANI, Dennis LUCARELLI 78

Tuning Machine Learning Outcomes for Airfoil Aerodynamics Seed Sensitivity in Predictive Performance
Diana-Andreea STERPU, Daniel MĂRIUȚA, Grigore CICAN, Ciprian-Marius LARCO, Lucian-Teodor GRIGORIE 84

Modular OODA-Based Agents for Scalable and Adaptive AI in System-of-Systems Modelling and Simulation
Jorge L. LOVACO, Karl ZUBER, Raghu Chaitanya MUNJULURY, Christopher JOUANNET, Petter KRUS 88

Comparing UAM Demand, eVTOL Design, and Profitability across Metropolitan Regions using Simulation and Optimization
Ansgar KIRSTE, Eike STUMPF 94

2. Aerodynamics & Fluid Mechanics

Wind Tunnel Investigation of Vertical Stabilizer Wedging Angles on the Aerodynamic Performance of a Modular Aircraft Model
Valeria VAVALÀ, Ambra GIOVANNELLI, Tomasz ŁUSIAK 100

Design of a 3D-Printed Modular Airframe with Interchangeable Vertical Stabilizers for Experimental Applications
Valeria VAVALÀ, Ambra GIOVANNELLI, Tomasz ŁUSIAK 106

Effects of Airfoil Trailing Edge Thickness on the Generation of Secondary Tones
Giorgio SANTANATOGLIA, Richard D. SANDBERG, Elnaz HAJIZADEH 112

Computational Analysis of a Multistage Nose Spike to Reduce Drag on a Conceptual Supersonic Transport Aircraft
Joseph Ciano Pinto, Siva Marimuthu, Parvathy Rajendran, Rajadurai Murugesan 119

Computational Analysis to Improve the Aerodynamic Performance of NACA 0012 in Transonic Flow Using Raw Riblet Patterns
Siva MARIMUTHU, Sheikh ISLAM, Parvathy RAJENDRAN, Rajadurai MURUGESAN 125

Advanced Numerical Modeling for Calibration of Heat Flux Sensors for Space Applications
Armando MAIELLO, Orsola PETRELLA, Angela VOZELLA 130

Influence of Variable Camber by Differential Flap Setting on the Aerodynamic Performance in Off-Design Flight Conditions
Katharina Alt, Victoria Schmitz, Jochen Wild, Daniel Reckzeh 136

An Unsteady Lifting-Line Model for Rotors in Forward Flight
Gregorio FRASSOLDATI, Beatrice DE RUBEIS, Giovanni BERNARDINI, Massimo GENNARETTI 142

When Propellant Controls the Spin: Two-Phase Fluid Dynamics and Their Impact on Spacecraft Rotational Stability
Gianni CASSONI, Gianmarco COVETTI, Fabrizio GENNARI, Jacopo SERAFINI 148

Improving Post-Stall Airfoil Performance Using Synthetic Jet-Based Flow Control
Baris GUNGORDU 154

A Comparative Study of Flow-Induced Vibrations by Circular and Polygonal Cylinders Using Lattice Boltzmann and Immersed Boundary Methods
Alessandro TROTTA, Esmaeel MASOUDI, Stefano MELONI, Mahdi AZARPEYVAND, Djamel REZGUI, Stefano UBERTINI, Andrea Luigi FACCI 158

Hot-Wire Velocity Measurements in Subsonic Nozzle Flows: Experimental Test Campaign
R. Camussi, E. De Paola, A. Talamelli, L. Lazzarini, S. Palazzo, F. De Gregorio, K.-S. Rossignol 164

Lattice Boltzmann Simulation of Cylinder-Induced Loads on a Lamina
Alessandro TROTTA, Riccardo GIANSANTE, Stefano MELONI, Carlo AQUILINI, Roberto CAMUSSI, Stefano UBERTINI, Andrea Luigi FACCI 172

Image Segmentation for Leading Edge Experiments of Rocket Fins in an Arc-Heated Wind Tunnel
Oliver ASSENMACHER, Oliver HOHN, Alexander RÜTTGERS, Ali GÜLHAN 177

Assessment of a CFD Solver for Detonation Wave Simulations
BONELLI Francesco, MILIA Davide, NINNI Davide, PASCAZIO Giuseppe, LAERA Davide 183

Comparison of Far-Field Methodologies for Unsteady Low Reynolds Number Flows
Dameon WESTLEY, Lelanie SMITH, Drewan SANDERS, Manuel CARREN˜O RUIZ, Domenic D'AMBROSIO 187

Implicit-Mesh Discontinuous Galerkin Methods for Solving Multiphysics Flow in Lid-Driven Cavities
Niba KAINAT, Vincenzo GULIZZI 193

Analysis of the Wake Vortex Encounter Risk Under Reduced Vertical Separation Enabled by Geometric Altimetry
Tobias BAUER, André KOLOSCHIN 199

Assessment of RANS Turbulence Models for Swept Shock Wave–Boundary Layer Interactions
Andrea PALUMBO, Sergio PIROZZOLI 205

Numerical Simulation of the Effect of Extreme Accelerations on the Sonic Boom Generated by a Circular Cylinder
Roberto Francisco Bobenrieth MISERDA, Braulio Gutierrez PIMENTA, Vinicius Coutinho DA SILVA, Ana Luisa Pereira MALDONADO 211

Numerical Simulation of the Transition from Regular to Mach Reflection of Oblique Shocks
Davide RUOCCHIO, Alberto GUARDONE 217

Use of Matching Pursuit Algorithm for Identification of Aircraft Aerodynamic Coefficients
Mateusz PILECKI, Manfred GAWLAS, Jacek GRZEGORZEWSKI 221

Blockage Effects in Wind Tunnel Experiments of Turbulent Wakes: A Numerical Study
Gianluca PORPORA, Andrea PALUMBO 227

Numerical Simulation of Wall-Bounded Flows with Thermally Perfect Gases
Alessandro AIELLO, Andrea PALUMBO, Gennaro COPPOLA 233

Assessment of Structure-Preserving Methods for LES of Compressible, Wall-Bounded Flows
Giuseppe ILLIANO, Francesco DE VANNA, Gennaro COPPOLA 239

Static and Dynamic Derivatives Estimation of an Image Guided Rocket Using Computational Fluid Dynamics
Karol Bielaszka, Radosław Kamiński, Olgierd Skromak 244

Instability Mechanisms in the Compressible Falkner–Skan Boundary Layers with A Cooled Wall
Hao Li, Franco Auteri 250

Far-Field Exergy-Based Drag Decomposition of a Turbulent Blunt-Body Wake with Hybrid-LES
Justin DU PLESSIS, Drewan SANDERS, Tamas JÓZSA, Tom-Robin TESCHNER 254

The impact of Staggered Fins on Aerodynamic Drag of a Transonic Sounding Rocket
Jakub Antoni JANKIEWICZ, Manfred GAWLAS, Urszula WASILEWSKA 260

3. Aeroacoustics & Noise Control

High-Order Vibroacoustic Modal Analysis of Fluid-Loaded Plates with Simply-Supported and Free Edges
Dario MAGLIACANO, Matteo FILIPPI 267

Noise Robust ML Sunspot Forecasts for Cycle Aware Space Weather Operations in the Cycle 25 Era
Esraa Zeki Mohammed, Ahmed Ghareeb, Mohammed Rashad Baker 271

Aspects Regarding the Implementation, Capture and Measurement of Noise on the Măgurele Air Test Stand
Radu Cristian GABOR, Grigore CICAN, Mihnea GALL 275

Local Noise Dissipation Mechanism and Flow Impedance in Acoustic Liner Grazed by Turbulent Flow and Acoustic Wave
Francesco AVALLONE, Angelo PADUANO, Francesco SCARANO 281

A Novel Multipolar Expansion for Acoustic Footprint Reduced Order Modeling
Giorgio PALMA, Stefano MELONI, Christophe BOGEY, Lorenzo, BURGHIGNOLI, Caterina POGGI, Jacopo SERAFINI 287

Labyrinthine Acoustic Metamaterials for grazing Sound Waves
Giuseppe PETRONE, Alessandro CASABURO, Giuseppe CATAPANE..... 293

Wavenumber-based Reconstruction Methof for the Vibroacoustic Response of Plates under Distorted Similitude
Alessandro CASABURO, Giuseppe PETRONE, Francesco FRANCO, Sergio DE ROSA 298

Effects of Pre-Stressed Conditions on the Dynamic and Acoustic Behavior of Composite Sandwich Panels
Piero CHIAIA, Matteo FILIPPI, Alfonso PAGANI, Erasmo CARRERA 303

The Ffowcs-Williams and Hawkings Analogy for Full Aircraft Noise Prediction
Emanuele STICCHI, Damiano CASALINO, Daniele RAGNI, Francesco AVALLONE..... 308

Multi-Fidelity Numerical Acoustic Optimization of UAV Propellers
Roberto NAVARRO, Luis Miguel GACÍA-CUEVAS, Jorge GARCÍA-TISCAR, Federico Nahuel RAMÍREZ, Marco LAUDATO, Mihai MIHAESCU 314

Auralization and Subjective Evaluation of Air Taxi Noise Events
Teresa MOSES, Michael SCHMÄHL, Mirko HORNUNG 319

Optimal Impedance for Acoustic Liners: From Cremer to Nonlocal Concepts
Emanuele De Bono, Alessandro Casaburo, Giuseppe Petrone, Manuel Collet, Sergio De Rosa 325

Vibration and Noise Analyses of eVTOL Tilting Propeller with Different Anhedral Angles in Low-Speed Flight
Gi-Jeong Park, Hyeok-Jin Son, Jaeheon Jeong, Jae-Sang Park 331

Acoustic Liners for Low-Frequency Sound Absorption: A Preliminary Study
Luigi Maria CARDONE, Giuseppe PETRONE, Alessandro CASABURO, Francesco FRANCO, Sergio DE ROSA 335

Numerical Vibro-Acoustic Characterization of Aerospace Structures Made of Miura-Ori Origami Metamaterial
Martino Carlo MORUZZI, Vasilena Petrova KRALEVA, Matteo FILIPPI, Maria CINEFRA 341

Acoustic Comfort Evaluation in the Passenger Cabin and Cockpit Through a Mixed-Reality Environment
Andrea ALAIMO, Sara BAGASSI, Francesca BRACAGLIA, Erasmo CARRERA, Antonio ESPOSITO, Tommaso FADDA, Matteo FILIPPI, Martino Carlo MORUZZI 346

4. Aeroelasticity & Structural Dynamics

Set-Up of a Generic Aeroelastic Simulation Model for Demonstration and Software Testing Purposes
Francisco CARVALHO, Arne VOSS, Raffaello MARIANI 352

Periodic Ground Resonance Analysis with Harmonic Decomposition
Andrea BASSI, Giuseppe QUARANTA 358

Whirl Flutter: An Experimental, Numerical, and Analytical Study on a Small-Scale Demonstrator
Giusi MAGLIOCCO, Francesco MARULO, Michele GUIDA, Giovanni MARULO, Emilio DI LORENZO 362

Fault Tolerance Analysis of a Double Ailerons Based Adaptive Flutter Suppression System
Carmelo Rosario VINDIGNI, Giuseppe MANTEGNA, Calogero ORLANDO, Andrea ALAIMO 366

Aeroelastic Modeling of Deformable-Airfoil Wings Through Unsteady Lifting-Line Theory
Riccardo GIANSANTE, Giovanni BERNARDINI, Massimo GENNARETTI 370

Aeroelastic Modelling of Highly Deformable Wings in Compressible Flows
Edoardo LEVATI, Igor PAOLINI, Giovanni BERNARDINI, Massimo GENNARETTI 375

Propeller-driven Vibration Testing of Aircraft Wings
Gabriele DESSENA, Alessandro PONTILLO 380

Coupled Thermal-Mechanical Behaviour of Ventilated Brake Discs with Radial Vanes and Lattice Cores: A Preliminary Comparison
Giuseppe MANTEGNA, Calogero ORLANDO, Davide TUMINO, Carmelo Rosario Vindigni, Andrea ALAIMO 384

Trim Analysis of Highly Flexible Aircraft via a Coupled DG-VLM Framework
Elisa TESTAQUATRA, Vincenzo GULIZZI 390

Mid-Fidelity Approaches for the Non-Linear Aeroelastic Assessment of The Pazy Wing
Alessia BOVE, Giuseppe QUARANTA 396

Aeroelastic Evaluation of Dry Wing Effects for Hydrogen Aircraft
Fanglin YU, Mirko HORNUNG 402

Dynamic Modeling of Rotor Damper Configurations for Aeroelastic and Ground Resonance Analysis
Matteo CROCI, Pierangelo MASARATI 408

Investigation of Lift-offset Effect on Performance and Vibratory Loads of a Rigid Coaxial Rotor
Jae-Hee HWANG, Jae-Sang PARK 414

Analysis of Morphing Trailing Edge Flap Effects on Dynamic Stall of the NACA 13112 Airfoil for Helicopter Rotor Blade Applications Using CFD and Experimental Methods
Dorin-Madalin FERARU, Daniel MARIUȚA, Grigore CICAN, Ciprian-Marius LARCO, Lucian-Teodor GRIGORIE 418

5. Aircraft Design, MDO & Performance

A Survey of Advanced Air Mobility Use Cases and Implementation Challenges in Japan: A Systems Approach Perspective
Yusuke Mihara 425

Fire Fighting System Integration on C-27J Aircraft
Francesco GIUGLIANO, Fabio CHIACCHIO, Pierpaolo BORRELLI, Marco DI GIFICO, Rosalia GRAZIANO, Salvatore PANICO 431

Conceptual Design for Uncrewed Combat Aircraft through a Modular Low-Fidelity MDO Workflow
Lorenzo VISCONTI, Giovanni ZIPPA, Paolo BADER 436

Most Promising Technologies and Aircraft Concepts for Environmental Performance Improvements: A Systematic Review
Lukas SÖFFING, Elise SCHEERS, Helen SZÖKE-ERÖS, Lukas WEBER, Pascal BERTRAM, Patrick RATEI 442

Co-design of Aircraft Configuration and Flight Profile for Match-range Operation
Lijing LIU, Christian REYNER, Rhea P. LIEM 448

Design and Optimization of Thin Membrane Tensioning for Deployable Space Antennas
Lorenzo MARTINAZZOLI, Mena PALMIERI, Susanna LAURENZI 453

Aero-Propulsive Modeling and System Identification of a Distributed Electric Propulsion Flying Model
Giorgio FILIPPOLI, Niko TERZAROLI, Beniamino M. PERRI, Lorenzo MASSA, Stefano CACCIOLA, Lorenzo TRAINELLI Carlo E. D. RIBOLDI 457

Exploring Box-Wing Configurations for Next-Generation Firefighting Aircraft
Giuseppe Palaia, Karim Abu Salem, Andrea Fasolis, Erasmo Carrera 463

Systematic Aircraft Propulsive System Generation for Sizing, Evaluation and Selection
Enzo DELLA BELLA, Valérie POMMIER-BUDINGER, Scott DELBECQ, Joël JEZEGOU, Marija JANKOVIC, Alain LEFEBVRE 469

Aerodynamic Efficiency of Longitudinally Unstable Tailless Aircraft
Stefan RIETHAUSEN, David LUNDSTRÖM, Petter KRUS 475

An Energy-Centric Approach for Evaluating Climate Impact Levers in Conceptual Aircraft Design
Kristina MAZUR, Mirko HORNUNG 481

A Modular Life Cycle Assessment Framework for Novel Aircraft Configurations and Sustainable Aviation Fuels
Kristina MAZUR, Katrin BISTRECK, Christina ERBSKORN, Mirko HORNUNG 487

Validation of High-Fidelity Multidisciplinary Maneuver Simulations with Flight Test Data from DLR Dassault Falcon 2000LX ISTAR
Martin BAUER, Johan Moritz FELDWISCH, Philipp MÜHLMANN 493

A Simulation-Coupled Concurrent Engineering Approach to Next-Generation Low-Cost Counter-UAV Missiles
Vincenzo Jr. DI ROSA, Francesco GASPERINI, Matteo GIANNITTI, Michele GUIDA, Simone GUBBIONI, Emanuele COFANI 499

Enhancements in the Aircraft Preliminary Design Methodologies: Adoption of Sustainable High-Fidelity Simulations
Federico CARLINI, Marco BASAGLIA, Luca BATTAGLIA, Elisa GARBI, Simone GENOVESE, Rocco GENTILE, Chiara LA GUARDIA, Angela SCARDIGLI, Lorenzo VISCONTI, Giovanni ZIPPA 504

Wind Gust Spectral Analysis with Aeolus Observations: Insights from a Transatlantic Route
Marianna VALENTE, Giuseppe PALAIA, Alfonso PAGANI, Erasmo CARRERA 510

Preliminary Design of Advanced Wing for an Ultra Efficient Regional Aircraft
Giovanni Marco CAROSSA, Elena RONCOLINI, Tomás Eugenio CÁRDENAS MUTIS, Francesco TOFFOL, Sergio RICCI 516

Investigation of the Influences of Different Booster Recovery Methods on Air Traffic
Antonio DEPARDON, Jonas LANGNER, Thomas FEUERLE, Carsten WIEDEMANN, Simona SILVESTRI 522

Assessing Synergies Between Truss-Braced Wings, Liquid Hydrogen Propulsion, and Open Rotors in Conceptual Aircraft Design
Lucas KUGLER, Michael KOTZEM, Sebastian WÖHLER, Thomas ZILL 528

Development of a Flying Platform to Study Three-Surface Configurations with Redundant Longitudinal Control
Stefano Cacciola, Carlo E.D. Riboldi, Carlo Fazioli, Leonardo Filippello, Francesco Rosato 534

Analysis of LTO Cycle Emissions as Results of Aircraft Operations in the Vicinity of Torino Caselle Airport
Edoardo Blanco, Davide Ferretto 540

Analysis of CO_2 Emissions and Cost Resulting from the Adoption of Sustainable Aviation Fuels by Medium Range Aircraft in Different World Regions
Angela Bozzaotre, Davide Ferretto 546

Synthesizing Aircraft System Specifications with Document-Managed Large Language Model Outputs from One-Shot System Inquiry Prompt Chain
Vinicius Kaster MARINI, Petter KRUS 552

AI-Driven Pre-Design Predictions of a 90-Passenger Hybrid-Electric Aircraft
Erick ESPINOSA-JUÁREZ, Álvaro GÓMEZ-RODRÍGUEZ, Felix MARTINEZ-RIOS, Christopher JOUANNET, Kristian AMADORI 558

GPU-Accelerated CABARET Simulations of Distributed Propulsion for UAM
Hussain A. ABID, Igor SOLNTSEV, Andrea RAPISARDA, Hassan A. ABID, Sergey A. KARABASOV, E. DE PAOLA, Luana Georgiana STOICA, Giorgia CAPOBIANCHI, Alessandro DI MARCO, R. CAMUSSI 564

6. Propulsion, Energy & Combustion

Experimental Characterization of Ageing Phenomena in Li-Po Battery Packs for Lightweight UAV Applications
Aleksander SUTI, Gianpietro DI RITO, Aurélien REYSSET 572

Comprehensive Modelling for Electric Machine Sizing and Performance Estimation in Aerospace Applications Enhancing Static and Dynamic Simulation
Victor J. BAHRS, Katharina KOLO, Stefanie DE GRAAF 577

Modelling the Transient Behavior of Heat Exchangers in Aircraft Engine Preliminary Design
Aytunc YILDIRIM, Marc SCHMELCHER, Alexander GÖRTZ 583

Suitability Assessment and Potential Use Case Definition for the Application of Electric Energy Carriers in Electrified Aircraft
Maurice Lucas DOERNTE, Florian FRANKE, Stefan KAZULA 589

Experimental Study of Vibration Levels in Microjet Engine Prototype Considering Venturi Intake Influence
Cornel-Mihai TĂRĂBÎC, Andrei-George TOTU, Grigore Cican 595

The GREEN FOXFIRE Project: Sustainable Hybrid Propulsion for CubeSats Based on Paraffin/HTPB
Daniele TORTORICI, Sasi Kiran PALATEERDHAM, Antonella INGENITO, Alessandro MONTANARO, Daniele PIAZZULLO, Luigi ALLOCCA 601

Off-Design Performance Consequences of Design Payload and Range Requirements for SPPH Hybrid-Electric Aircraft
Maurice F.M. HOOGREEF 607

Engineering Polyimide Materials for Moon Exploration Missions: Intrinsic Self-Healing and Shape Memory Properties via Supramolecular Interactions
Francesca BLONDELLI, Elisa TOTO, Guido SACCONE, Nunzia FAVALORO, Maria Gabriella SANTONICOLA 614

Sustainable Hydrogen-Rich Polymer Blends for Advanced Space Radiation Shielding
Elisa TOTO, Francesca BLONDELLI, Lorenzo FERRI, Susanna LAURENZI, Maria Gabriella SANTONICOLA 620

Numerical Investigation of the Applicability of a Single Ramp Supersonic Inlet for Ramjet Propulsion
Franciszek Dominik TOMCZAK 626

Operational Envelope of an EAD Thruster Under Varying Pressure and Humidity
Davide USUELLI, Andrea AVALLI, Raffaello TERENZI, Stefano TROVATO, Marco BELAN 632

Advanced Mesh Grid Geometries for EAD Thrusters: An Experimental Approach
Stefano TROVATO, Raffaello TERENZI, Davide USUELLI, Marco BELAN 638

Sustainable Aircraft Propulsion with Four Energy Sources
Salvatore Trepiccione, Giuseppe Grazioso, Fabrizio Nicolosi 644

Automated Flight Testing of a Distributed Electric Propulsion Flying Model
Lorenzo TRAINELLI, Giorgio FILIPPOLI, Niko TERZAROLI, Beniamino M. PERRI, Stefano CACCIOLA, Carlo E. D. RIBOLDI 650

Development of an Autonomous Flight Control System for a Distributed Electric Propulsion Flying Model
Giorgio FILIPPOLI, Beniamino M. PERRI, Niko TERZAROLI, Lorenzo TRAINELLI, Stefano CACCIOLA, Carlo E. D. RIBOLDI 656

Preliminary Sizing of Airport Infrastructures for Refuelling Hydrogen-Powered Aircraft
Lorenzo Trainelli, Gabriele Sirtori, Carlo E.D. Riboldi, Giorgio Filippoli, Stefano Cacciola 662

A Breguet Range Formulation for Liquid Hydrogen-Powered Aircraft
Giuseppe PALAIA, Karim ABU SALEM, Erasmo CARRERA 666

Defining Control Loops for a Fuel Cell Powered Aeronautic Propulsion System
Rudy CEPEDA-GOMEZ 672

Analyzing the Eco-Design Approach for an Innovative In-Space Propulsion System
Daniele Ferrara, Michele Trovato, Angelo Minotti, Antonio Casimiro Caputo, Paolo Cicconi 677

Reduced-Order Dynamic Modelling of the Wankel Engine Employed in the Hybrid Propulsion System of a Lightweight Helicopter UAV
Gianpietro DI RITO, Alessandro MAZZONE, Andrea NESCI, Eugenio ROVERA, Valerio BONINI 683

Preliminary Safety Assessment of the Propulsion Power Management System of a Hybrid-Electric Regional Aircraft
Gianpietro DI RITO, Aleksander SUTI 689

Hydrogen-Enriched and Plasma-Assisted Flames for Lean Blow-Out Control in a Swirl-Stabilized Burner
Maria Grazia DE GIORGI, Pasquale DI GLORIA, Sara BONUSO, Ekin Can KARASU 695

Numerical Modeling and Validation of a Water Electrolysis Propulsion System for CubeSats
Raviteja VEMULA, Pratyush Kumar SINGH, Maria Grazia DE GIORGI 701

Propeller Aerodynamics Under Non-Uniform Inflows
Sara MONTAGNER, Manuel ZANNONE, Jacopo SERPIERI, Gioacchino CAFIERO 707

Thermo-structural Design of Composite Pressure Vessels for Hydrogen Aircraft
Luigi Maria CARDONE, Vittorio MEMMOLO 713

Configuration Analysis and Impeller Design for an Oxidizer Pump in Small Liquid Rocket Engines
Miłosz KOZYCZ1 718

AI-Driven Inverse Constrained Design for Turbine Optimization
Francesco PORTA, Sergio LAVAGNOLI 724

Enabling Aerospace Electrification by means of Scale-Resolved Battery Simulation
Max OKRASCHEVSKI, Janina DREWS, Steffen REHSE, Dana SCHONVOGEL, Ralf SCHMIDT, Tom BOENKE, Holger ALTHUES, Arnulf LATZ, Timo DANNER 730

Experimental Flow Characteristics of Turbine Stator Well with Honeycomb and Labyrinth Structures
Jiahua LIU, Zeyu WU, Dongdong LIU, Nan CAO, Xiang LUO 735

Development and Characterization of Solid Propellants Based on Environmentally Friendly Sugar and Oxidants for Aerospace Applications
Gerardo Raúl CABALLERO MORALES, Italo Paolo AMBROSIO HUANAY 741

Design of a Low Power Anode Layer Hall Thruster
Ivana SETTEMBRE, Davide PICCIAU 747

Comparative Analysis of Copper Hairpin Motors and Cryogenic Pure-Aluminum Litz-Wire Motors for Hybrid-Electric Aircraft Propulsion
Xinjun Liu, Thomas Schriefer, Andreas Lindner, Maximilian Hofmann 751

Retrofitting a Hairpin Stator Winding Aircraft Propulsion Motor with a Superconducting Rotor
Andreas Lindner, Xinjun Liu, Daniel Walch 757

7. UAV, UAM & Rotorcraft Systems

Shuttle Drone Control with Airflow Disturbance Compensation for Cooperative Target Capture
António S. Costa, Bruno J. N. Guerreiro 765

Towards Cooperative Guidance in Air-Defense: Extending Weapon-Target Assignment into the Mid-Course Phase
Ole OSTERMANN, Johannes AUTENRIEB, Carsten SCHWARZ 771

Simulation-Based Development of a Forward-Motion Mid-Air Deployment System for Fixed-Wing UAVs from Quadrotor Platforms
Paul Olanifimihan OKE, Yingsong GU 777

Electric Powered Helicopter: From Concept to Feasibility
Elif Hazal ÇELİKCAN, Ahmad HAMMAD, Michail TSAGKARIS 782

Application of Control Barrier Functions to Avoid Vortex Ring State in Unmanned Helicopters
Emilia ISBONO, Mark SPILLER, Philipp SCHITZ 788

Anti-Windup Compensator Design for Fixed-Tilt Multirotors with Interaction Capabilities
Dharani JAYANNA, Davide INVERNIZZI, Daniele MAGLIORE, Simone PANZA, Marco LOVERA 794

Ground Effect in Thrust-Lift Conversion using the Deflected Slipstream Concept in Martian Conditions
Wei HAN, Manuel CARREÑO RUIZ, Domenic D'AMBROSIO 800

Learning-Based Quadrotor Tracking Control Using Recursive Gaussian Processes
Alessandro LUPATINI, Giovanni GOZZINI, Alessandro NAZZARI, Roberto RUBINACCI, Marco LOVERA 806

Perception Aware Quadrotor Control: An Experimental Evaluation
Lidia PEREZ, Alessandro NAZZARI, Roberto RUBINACCI, Davide INVERNIZZI..... 812

eVTOLs in Inter-Hospital Medical Transport: A Simulation Based Scenario Analysis for Bavaria
Benedikt M. DREYER, Sophie F. ARMANINI 817

An Extensible Drone Framework for In-flow Disturbance Analysis
Benedetta NOVELLI, Stefano MELONI, Diego PENNINO, Alessandro TROTTA..... 822

Aerodynamic Performance Characterization of UAV Propellers via Blade Element Momentum Theory including Post-Stall Behaviour
Marco LUCARINI, Gianpietro DI RITO, Simone CAMARRI, Marco NARDESCHI..... 827

Assessing the Technical-Economic Feasibility of Unmanned Airships: Methodology and Case-Studies
Carlo E.D. RIBOLDI, Luca FANCHINI 833

Identification of Airship Aerodynamic Models from Flight Data: Preliminary Investigation and Identifiability Analysis
Carlo E.D. RIBOLDI, Stefano CACCIOLA, Yan POZHANKA, Mostafa HASSANALIAN 839

Reinforcement Learning-Based Bezier Airship Hull Optimization: A Data-Driven Framework for Shape Adaptation Under Aerodynamic Constraints
Qian ZHAO, Carlo Emanuele Dionigi RIBOLDI..... 846

CFD-Based Estimation of Added-Mass and Aerodynamic Derivatives in Heave Motion for a Hybrid Closed-Wing HAPS
Eleonora RICCIO, Alessandro CERESA, Vincenzo Rosario BARANIELLO, Giuseppe PERSECHINO, Francesco TUFANO, Domenico COIRO..... 850

A Novel Approach to Quantify Counter-Drone System Effectiveness Against UAS Swarms
Dani HOTTERS, Nikolaos KALLIATAKIS, Felix KUHNERT, Prajwal Shiva PRAKASHA, Ries VAN HEUR, Buse KAYA 856

8. Guidance, Navigation & Control

Performance Assessment of a Multi-Step Guidance and Control Architecture for Approach and Capture of a Tumbling Space Target
Agostino MADONNA, Giuseppe NAPOLANO, Alessia NOCERINO, Roberto OPROMOLLA, Giancarmine FASANO, Michele GRASSI 862

Enhancing Incremental NDI Control with L1 Adaptive Augmentation in a Longitudinal Autopilot
Giorgio RAOS, Giovanni GOZZINI, Davide INVERNIZZI 868

Adaptive Augmentation of Incremental NDI Laws with Systematic H∞ Synthesis
Giulio FRANCESCHINI, Giorgio RAOS, Giovanni GOZZINI, Davide INVERNIZZI 874

From Strain Measurements to Rotor Blade Shape and Loads Reconstruction: The BeSaME Project
Pierangelo MASARATI, Emanuele CASCIARO, Alessandro COCCO, Roman SUTOV, Paolo BETTINI, Alex ZANOTTI, Giovanni BERNARDINI, Francesco LIGUORI, Jacopo SERAFINI, Claudio PASQUALI 880

Hierarchical Task-Priority Tracking Control in Space Robots
Pietro BRUSCHI, Davide INVERNIZZI 885

Enabling Onboard Analytical Batch Filtering for Angles-Only Navigation to Non-Cooperative Space Targets
Alessandro SCALVINI, Giacomo BORELLI, Gabriella GAIAS 891

Hardware-in-the-Loop Implementation of a Fixed-Point Controller for Boresight Stabilization of Magnetorquer-Only Satellites
Emre SAYIN, Stefano CARLETTA, Fabio CELANI 897

Single Agent On-Orbit Inspection: Energy-Awareness, Data Down-linking and Orbital Exploration via Deep-Q-Learning
Augustin DAY, Francesco Paolo SALZO, Gabriele GEMIGNANI, Stéphanie LIZY-DESTREZ, Giordana BUCCHIONI 902

A Decentralized Cluster-based Approach for Multi-Agent On-Orbit Inspection
Francesco Paolo SALZO, Pasquale FERRARA, Giordana BUCCHIONI 908

Nonlinear Simulation of Aircraft Terminal Maneuvers Including Gear Dynamics and Ground Effect
Stefano CACCIOLA, Andrea CALABRIA 913

Precise Orbit Determination of Satellites with Low-Cost, Single Frequency Receivers in raPPPid
Hoor BANO, Marcus Franz WAREYKA-GLANER, Gregor MÖLLER 919

9. Space Systems, GNC & Orbital Operations

GeoScout: Architecture for Piggyback Interplanetary CubeSats
Lorenzo OLIVIERI, Alessandro FRANCESCONI, Matteo MASSIRONI 926

Mission Design and Enabling Technologies for a LEO-to-MEO Dual-Phase CubeSat Mission: The BOREALIS Platform
Lorenzo Nardi, Fabio Curti, Stefano Carletta, Parsa Abbasrezaee, Lorenzo Thomas Contessa, A. Di Serafino, Vahid Omrani, Domenico Caputo, Giovanni Palmerini, Nicola Lovecchio, Sahithi Sriramoju, VS Siva Sankaram Emani, Nunzio Burgio, Giulia Petrucci, Riccardo Mazzotti, Mara Mirasoli, Fabio Lorenzini, Matteo Mergé, Augusto Nascetti 930

Autonomous Detection of Satellite Orbital Anomalies Through Statistical Behavioural Analysis
Pietro RUSSO, Giorgio ISOLETTA, Roberto OPROMOLLA, Giancarmine FASANO..... 936

Enhancing Space Manipulator Fault Tolerance for In-Orbit Servicing through Meta-Reinforcement Learning
Matteo D'AMBROSIO, Michèle LAVAGNA 942

Estimating the Probability of Close Approaches Generated by an In-Orbit Fragmentation via Monte Carlo-Based Approach
Yeerang Lim, Camilla Colombo 948

Multidisciplinary Design and Optimization of Suborbital Transatmospheric Vehicles
Pierluigi DELLA VECCHIA, Luca FALCONE, Agostino DE MARCO, Fabrizio NICOLOSI, Giulio AVANZINI, Mario DI RENZO, Donatella PASSIATORE, Danilo ZONA 954

A Modular and Scalable Validation Framework for Planetary Rovers: Application to the ARDITO System

Preface

The CEAS/AIDAA Conference 2025 was held in Turin, Italy, from December 1 to 4, 2025, co-organized by the Council of European Aerospace Societies (CEAS) and the Italian Association of Aeronautics and Astronautics (AIDAA).

The conference provided an international forum for researchers, engineers, and professionals to present and discuss recent advances in aerospace science and engineering. The program covered a broad range of topics, reflecting the diversity and evolving challenges of the aerospace sector.

The editors wish to thank the authors, reviewers, and members of the organizing and scientific committees for their valuable contributions to the conference's success.

Turin, Italy
December 2025

Committees

Conference Chairs

- Cornelia Hillenherms, German Aerospace Center – CEAS President
- Erasmo Carrera, Politecnico di Torino – AIDAA President

Executive Committee

- Andrea Alaimo – CEAS Director General
- Riccardo Augello – AIDAA Member
- Erasmo Carrera – AIDAA President
- Rosanna Daly – Conference Lead and UK Director, Advanced Business Events
- Nunzia Favaloro – Chair of the AIDAA Communication Committee
- Matteo Filippi – Politecnico di Torino – AIDAA Member
- Cornelia Hillenherms – German Aerospace Center, CEAS President
- Lukasz Kiszkowiak – Acting Editor-in-Chief, CEAS Quarterly Bulletin
- Erika Manis – Piemonte Agency
- Philip Nickenig – CEAS Vice-President Finance
- Giuseppe Palaia – Politecnico di Torino – AIDAA Member
- Beata Wierzbińska-Prus – CEAS Secretary

Keywords: GNSS Interference, ADS-B, GVA, Aircraft Navigation, Spoofing

Abstract. GNSS interference, including jamming and spoofing, represents a growing challenge to aviation safety. These disruptions critically impact systems reliant on accurate positional and altitude data, such as Enhanced Ground Proximity Warning Systems (EGPWS). Spoofing, in particular, can cause severe anomalies in aircraft position and altitude data, leading to erroneous system responses. This paper investigates the potential application of the GVA (Geometric Vertical Accuracy) parameter, derived from ADS-B data, as a means of detecting GNSS interference, with a specific focus on its relevance for EGPWS functionality. More than 110 flights were analysed, comparing GVA parameter behaviour in regions with and without reported GNSS interference. Regions of suspected interference were identified using NOTAMs, reports, and algorithms from SkAI Data Services. The analysis focuses on the correlation between GVA anomalies and known GNSS disruption events, examining altitude discrepancies (GNSS versus barometric altitude) and positional anomalies (e.g., erratic movements, off-route positioning, and sudden location shifts). The methodology includes data preprocessing to isolate flights affected by interference, statistical analysis of GVA fluctuations, and graphical representation of observed trends. Flights from interference-free areas served as a baseline for comparison. The results indicate that GVA anomalies are consistently associated with regions of reported GNSS spoofing. Spoofing events manifest as significant discrepancies in aircraft position and GVA altitude. The discussion highlights the implications of these findings for operational safety. The study emphasizes the potential for integrating GVA-based detection methods, enabling these systems to act as supplementary indicators of GNSS interference. Limitations of the study, including a gap in critical coverage that partially limits the completeness of the analysis and the reliance on available ADS-B data, are acknowledged, along with suggestions for future research. This study demonstrates the feasibility of using ADS-B parameters, the GVA, as an indirect method for detecting GNSS interference. Future work will focus on expanding the dataset to include flights from additional regions, refining detection algorithms, and exploring the integration of these methods into operational aviation systems. By addressing GNSS interference at a system level, this research aims to contribute to the development of robust solutions that enhance aviation safety in an increasingly challenging navigation environment.

Introduction

Global Navigation Satellite Systems (GNSS) form the backbone of modern civil aviation, supporting safety-critical applications such as ADS-B and RNAV [1], [2]. This strong dependence, however, introduces vulnerabilities to radio-frequency interference, particularly jamming and spoofing [3], [4]. While jamming typically results in a denial of service, spoofing is more hazardous as it generates counterfeit signals that mislead receivers without necessarily triggering immediate alarms [5]–[7]. Recent reports confirm that large-scale GNSS interference has become an active and globally relevant aviation safety issue [8], [9].

ADS-B broadcasts include integrity indicators defined in RTCA DO-260B and EUROCAE ED-102A standards [11], [12], such as the Geometric Vertical Accuracy (GVA). While parameters

such as NACp have been investigated for interference detection [13], [14], the behaviour of GVA during GNSS spoofing remains insufficiently explored. A robust consistency reference can be obtained by comparing GNSS-derived geometric altitude with barometric altitude, which is independent of GNSS and therefore immune to spoofing effects [15].

This paper investigates the combined use of altitude discrepancy between barometric and GNSS-derived altitude and the GVA parameter as indicators of GNSS spoofing. Using ADS-B data from over 110 flights obtained from the OpenSky Network, nominal operations are compared with flights affected by suspected spoofing. The objective is to assess whether GVA provides meaningful supplementary information, particularly in subtle spoofing scenarios where altitude discrepancies remain small, thereby enhancing situational awareness of GNSS integrity degradation.

- **Data Source and Flight Selection**

ADS-B data were obtained from the OpenSky Network, a large-scale open air-traffic surveillance infrastructure composed of distributed ground-based receivers [16], [17]. The dataset covers the period from January 2024 to January 2025 and consists of more than 110 anonymized commercial flights operating in multiple airspace regions. The analysed dataset was divided into reference flights operating under nominal GNSS conditions and flights suspected of GNSS spoofing based on independent operational reports and the SKAI Data Services monitoring platform [18]. All aircraft identifiers and operational details were fully anonymized. Each ADS-B message provides barometric altitude, GNSS-derived geometric altitude, quality indicators, and precise time tags, forming the basis of the vertical-consistency analysis.

- **Altitude Consistency Metric**

The detection approach is based on the physical independence between barometric altitude and GNSS-derived geometric altitude. While barometric altitude is derived from onboard pressure sensors and is immune to GNSS interference, the geometric altitude directly depends on the integrity of the satellite navigation solution [15].

For each ADS-B message, the instantaneous altitude discrepancy was computed as

$$\Delta h(t) = h_{baro}(t) - h_{GNSS}(t) \quad (1)$$

where h_{baro} represents the barometric altitude and h_{GNSS} the geometric altitude derived from GNSS. Based on reference-flight behaviour and standard operational tolerances [1], a conservative detection threshold of $|\Delta h| > 200$ft was adopted.

- **Geometric Vertical Accuracy (GVA) Parameter**

The Geometric Vertical Accuracy (GVA) parameter transmitted in ADS-B Version 2 messages was analysed as a supplementary indicator. According to the RTCA DO-260B / EUROCAE ED-102A standard, GVA is a 2-bit indicator expressing the 95% confidence bound of the GNSS-derived vertical position [11], [12].

***Table 1** – GVA parameter encoding (95% confidence bound)*

Encoding	Meaning
0	Unknown or ≥ 150 m
1	< 150 m
2	< 45 m
3	< 15 m

Since GVA is derived from the internal receiver figure-of-merit models, it may not directly reflect malicious spoofing scenarios. Therefore, GVA is evaluated strictly as a complementary indicator and always interpreted jointly with the altitude discrepancy Δh.

- **Data Preprocessing and Quality Control**

All data processing was performed using MATLAB R2024b [19]. ADS-B messages with missing altitude or time information were removed. All timestamps were converted to Coordinated Universal Time (UTC), and both barometric and geometric altitudes were converted to feet to ensure consistency with aviation standards [1], [20]. The altitude discrepancy Δh was then computed for each time step using (1). For each flight, three synchronized time series were evaluated: barometric altitude, GNSS-derived geometric altitude, and $\Delta\, h$. These quantities were jointly visualized to assess the magnitude, duration, and temporal evolution of vertical inconsistencies. In parallel, GVA time series were analysed to evaluate their response to detected altitude anomalies. The classification of spoofed flights was validated by cross-comparison with independently reported spoofing intervals from monitoring services [18]. This external information was used solely for validation and not as a primary detection criterion.

Results – Altitude and GVA Analysis

The results of the combined analysis of altitude discrepancies and the ADS-B-reported GVA parameter are presented in this section. The results are organized from reference flights under nominal GNSS conditions to progressively more pronounced spoofing scenarios, highlighting both strong and subtle manifestations of GNSS integrity degradation.

- **Reference Flights – Nominal GNSS Operation**

Reference flights unaffected by spoofing or other forms of interference are used to establish a baseline for nominal GNSS behaviour, characterized by close agreement between barometric and GNSS-derived geometric altitude and stable GVA values throughout the flight.

Figure 1 – Reference flight under nominal GNSS conditions showing close agreement between barometric and GNSS-derived geometric altitude and stable GVA values.

Materials Research Proceedings 69 (2026) 2-8 https://doi.org/10.21741/9781644904251-1

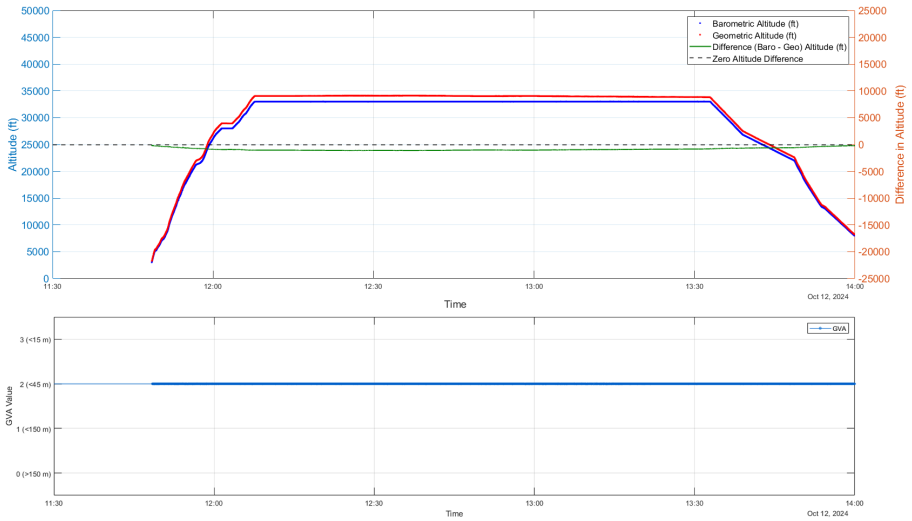

***Fig. 1** – Reference flight under nominal GNSS conditions*

- **Strong GNSS Spoofing – Large Vertical Discrepancies**

Flights affected by strong GNSS spoofing exhibit pronounced and persistent separation between barometric and GNSS-derived geometric altitude. These events are characterized by a sudden onset of large altitude discrepancies Δh, typically exceeding the 200 ft detection threshold, and persisting over extended time intervals.

Figure 2 – Spoofed flight A showing a large and persistent vertical discrepancy between barometric and GNSS-derived altitude, accompanied by a temporary interruption of ADS-B reporting during the cruise-to-descent transition.

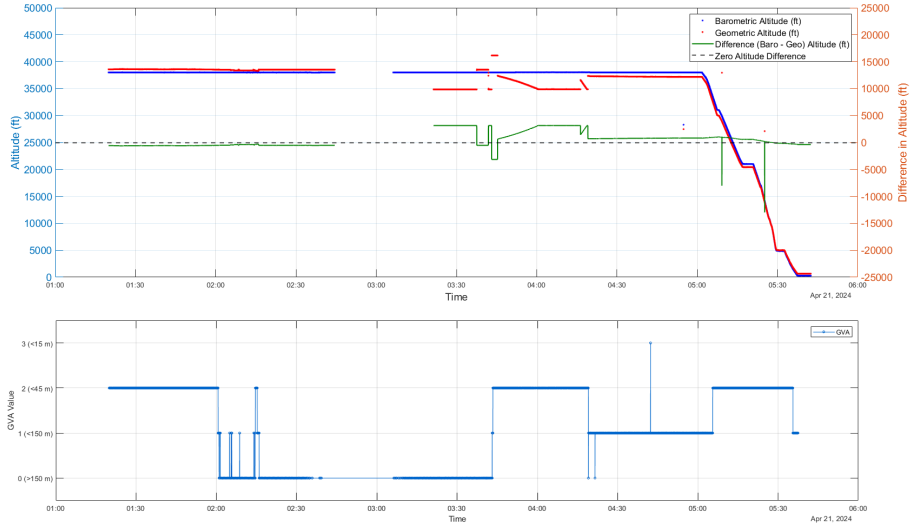

***Fig. 2** – Spoofed flight A (strong vertical discrepancy)*

Figure 3 – Spoofed flight B illustrating intermittent and discontinuous GNSS-derived altitude behaviour, visible as increased scatter and reduced temporal continuity, followed by the development of a sustained vertical discrepancy during descent.

Materials Research Proceedings 69 (2026) 2-8 https://doi.org/10.21741/9781644904251-1

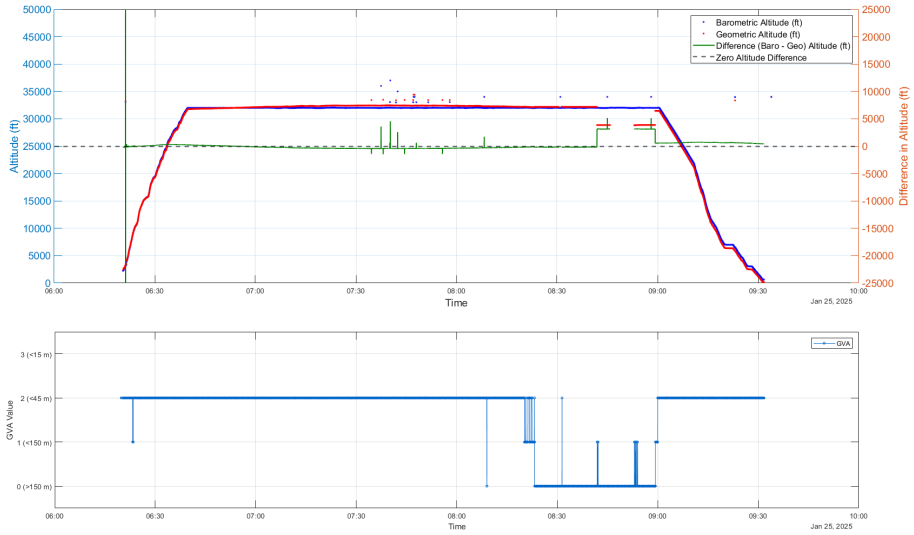

***Fig. 3** – Spoofed flight B (intermittent GNSS behaviour)*

- **Directional Properties of Altitude Discrepancies**

A consistent directional tendency in altitude discrepancies was observed across the analysed spoofed flights. In most strong spoofing cases, barometric altitude exceeded the GNSS-derived geometric altitude during peak discrepancy intervals, indicating a systematic downward bias of the spoofed GNSS solution. In a smaller subset of cases, the opposite behaviour was observed, with geometric altitude exceeding barometric altitude, suggesting upward manipulation of the GNSS solution. This directional asymmetry indicates that spoofing scenarios are not random but follow specific interference patterns.

- **Subtle Spoofing – GVA Response Below the Δh Threshold**

Not all spoofing events produce large vertical deviations. A subset of affected flights exhibits altitude discrepancies that remain below the 200 ft detection threshold throughout the flight. In these cases, the primary indication of degraded GNSS integrity is provided by changes in the GVA parameter rather than by Δh alone.

Figure 4 – Spoofed flight C exhibiting minimal vertical discrepancy remaining below the 200 ft threshold, while GVA indicates degraded GNSS integrity during the affected interval.

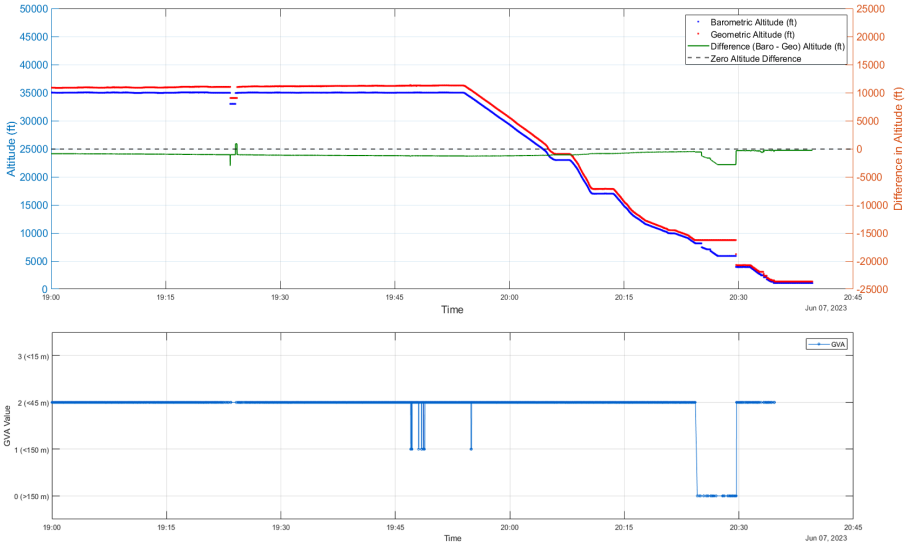

***Fig. 4** – Spoofed flight C (subtle spoofing)*

Discussion

The presented results demonstrate that vertical consistency analysis based on barometric and GNSS-derived geometric altitude provides a physically interpretable indicator of GNSS spoofing. Large spoofing events are clearly manifested as persistent altitude discrepancies exceeding the selected 200 ft threshold. In these cases, the onset of spoofing is typically abrupt and remains detectable over extended time intervals. More importantly, the analysis shows that the GVA parameter provides complementary information in cases where altitude discrepancies remain below the detection threshold. In such subtle spoofing scenarios, GVA degradation often precedes or accompanies minor vertical inconsistencies, indicating a deterioration of GNSS solution integrity that would otherwise remain undetected using altitude comparison alone. The results further indicate that spoofing-induced altitude deviations exhibit non-random directional properties, suggesting structured interference mechanisms rather than stochastic navigation errors. While GVA is not a direct spoofing detector, its joint interpretation with altitude consistency significantly improves situational awareness regarding GNSS integrity. It should be noted that ADS-B-based detection methods are inherently limited by message availability, update rates, and receiver-dependent quality indicators. Consequently, the presented approach is intended as a supplementary integrity-monitoring tool rather than a standalone detection system.

Conclusion

This study evaluated the feasibility of using ADS-B-reported Geometric Vertical Accuracy (GVA) in combination with barometric–GNSS altitude consistency as an indirect indicator of GNSS spoofing. The analysis of more than 110 operational flights demonstrated that strong spoofing events are reliably detectable through large and persistent vertical discrepancies, while subtle spoofing scenarios can be identified through characteristic changes in the GVA parameter.

The results confirm that GVA does not act as a standalone spoofing detector but provides valuable complementary information when interpreted jointly with physically independent altitude sources. This combined approach enables the detection of integrity degradation even in cases where altitude discrepancies remain within nominal operational limits. Future work will focus on expanding the dataset to additional geographic regions, refining quantitative detection thresholds, and integrating other ADS-B quality indicators to improve robustness. The presented methodology contributes to the development of passive, data-driven GNSS integrity monitoring techniques that can enhance aviation safety in environments affected by satellite navigation interference.

Keywords: Virtual Reality, Lunar Pressurized Rover, Immersive Simulation, Digital Twin, Astronaut Training, 3D Modeling

Abstract. This work presents an immersive Virtual Reality framework integrated into a digital twin architecture for the Lunar Pressurized Rover (LPR). The system enables both dynamic simulation of rover operations on simulated lunar terrain and static exploration of its internal layout. Users can interact in real time with cockpit controls, onboard systems, and functional subsystems such as navigation, power, and life support. The framework supports astronaut training, ergonomic assessment, and early design validation, offering a human-centered, cost-effective tool for developing and testing future lunar exploration vehicles.

Introduction

The development of Lunar Pressurized Rovers (LPR) necessitates innovative approaches to design, validation, and training, given the absence of prior operational experience, test campaigns, or physical prototypes [1-2]. To address these challenges, this work presents an immersive virtual environment integrated into a full digital twin architecture, enabling human-centered design exploration, interactive control simulation, and early design insight [3-4].

The virtual platform supports two complementary modes: dynamic simulation and static exploration. In the dynamic simulation mode, users operate a fully interactive digital replica of the LPR within a simulated lunar terrain (Fig. 1). The interface includes cockpit-mounted VR menus for real-time interaction with rover systems. The primary control panel allows users to initiate the rover, toggle between gear modes (Park, Neutral, Drive, and Reverse), and activate auxiliary systems, including Cruise Control and All-Wheel Steering (AWS). A secondary menu enables in-depth interaction with navigation, lighting, onboard cameras, power management, and telemetry displays, including speed, battery status, oxygen level, acceleration, wheel torque, and center of mass tracking. These features provide a realistic operational environment for astronaut and operator training, system diagnostics, and scenario testing [5-6].

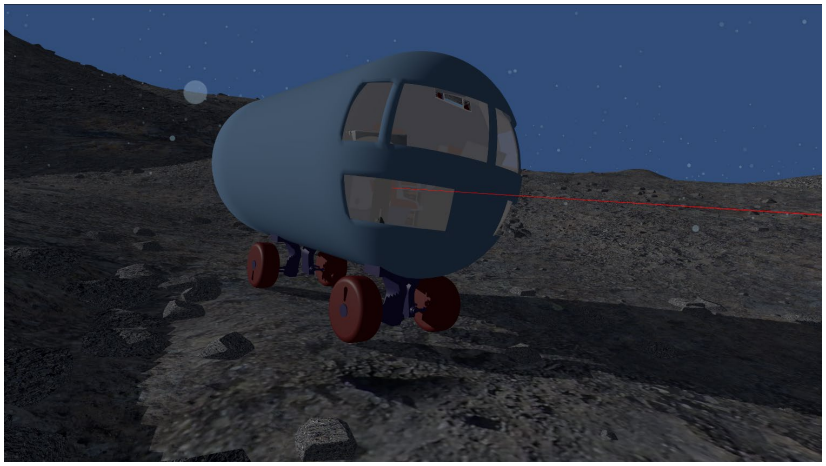

Figure 1. Simulated lunar terrain used in the dynamic mode for immersive operation of the Lunar Pressurized Rover (LPR), enabling real-time interaction with rover systems and environmental navigation.

The static exploration mode focuses on internal layout and functional inspection. Based on a functional flow diagram depicted in Fig. 2, the LPR is decomposed into five subsystems: cockpit, scientific workspace, EVA interface and airlock, crew and utility section, and emergency systems. Each subsystem is modeled with interactive elements and associated tasks, allowing users to explore the internal environment, interact with displays and equipment, and assess ergonomic configuration [7]. The cockpit section includes two reclining seats, multi-functional displays for navigation and system control, and a panoramic viewing system with integrated cameras (Fig. 3). The scientific workspace enables procedural interaction for tasks such as lunar sample handling, analysis, and storage.

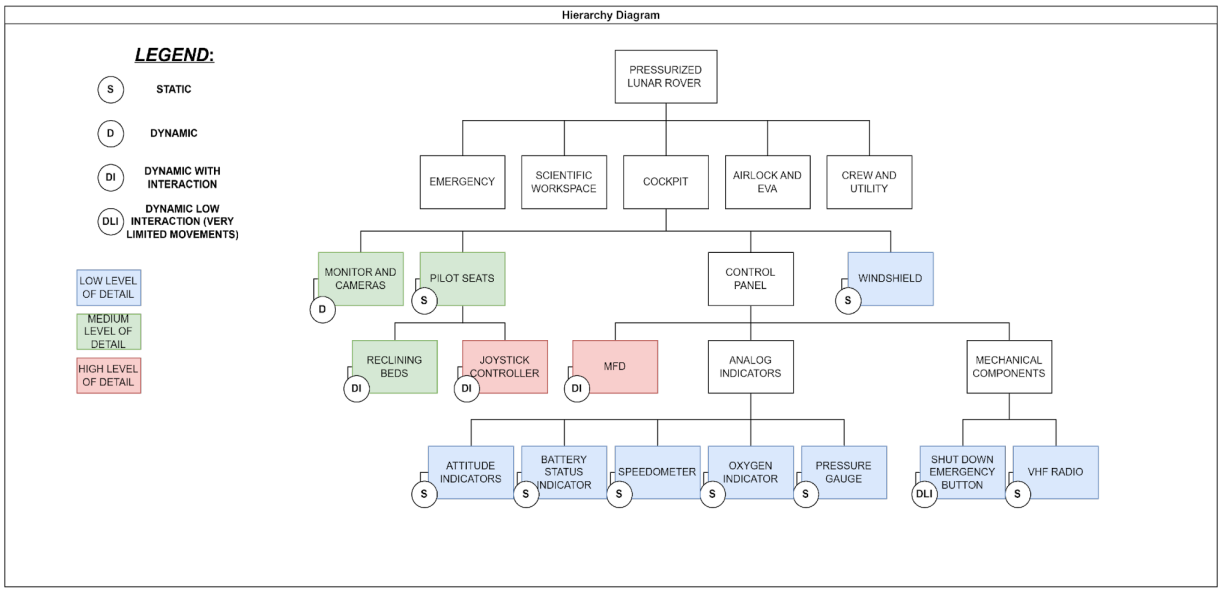

Figure 2. Hierarchical functional diagram of the pressurized lunar rover, showing subsystem decomposition and classification of components by interaction type (static, dynamic, interactive) and simulation detail level.

Together, these two modes provide an integrated environment for both system-level prototyping and mission-specific training [8]. The use of VR from the early stages of design provides a precise spatial perception of volumes and interfaces, which is critical in the absence of physical mock-ups. Human factors are integrated directly through spatial interaction and real-time feedback,

Materials Research Proceedings 69 (2026) 9-14 https://doi.org/10.21741/9781644904251-2

improving the placement and accessibility of control systems [9]. Moreover, the virtual model can serve as the front end of a complete digital twin, enabling predictive maintenance through the real-time overlay of telemetry and diagnostic data [10]. This supports fault detection, system health monitoring, and mission planning with a proactive approach to rover operations.

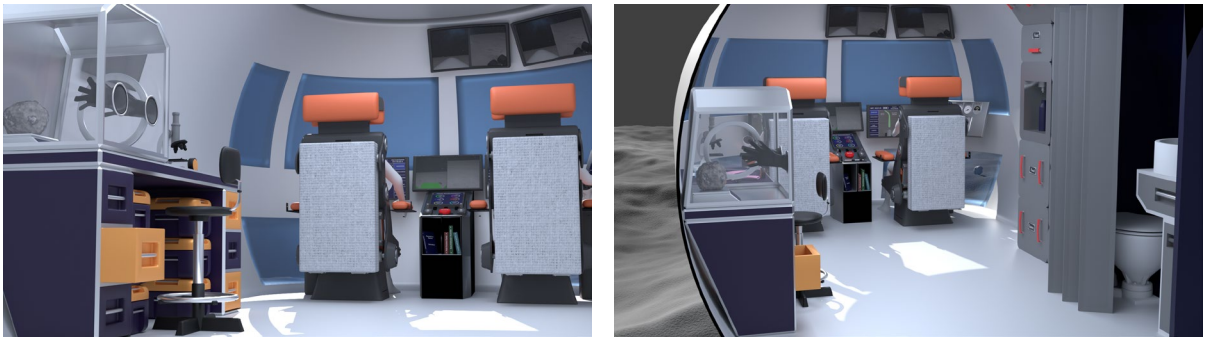

Figure 3. Interior rendering of the pressurized lunar rover showing the cockpit and scientific workspace. The configuration displays ergonomic seating, panoramic screens, multifunctional displays, and a dedicated area for lunar sample analysis and storage.

Cockpit Virtual Environment

One important section of the static exploration mode is the cockpit. In this area, users perform a sequence of tasks aimed at preparing the system for the lunar surface exploration mission. The first step is to perform a functional analysis to break down the cockpit into subsections; after a few iterations the component level is reached. The modeling phase is based on the items identified in the previous step, using aircraft and space systems as a reference for the necessary mesh detailing. Another important topic is the arrangement of elements around the seats: the first inspiration comes from a plane control panel, with a very high level of redundancy, then followed by a more automotive-centered layout, with less redundant components and with a higher distinction between the two crew members' functions. It is also essential to add ergonomic considerations to ensure that every object the crew must interact with is within reach and the configuration is guided by a principle of priority and frequency of use. The last important point is the creation of materials, aiming at reproducing the look and feel of a real environment to increase the sense of immersion. Before focusing on the actual software implementation, extensive preproduction work must be done to identify the precise input-output sequence that users will perform. This process has major impact on the time spent developing the simulation: very detailed studies for every single subtask to be achieved lead to a smoother implementation job. Virtual reality development focuses on establishing an effective interaction between users and the system's interface in front of them. C# scripts are the main way to bring models into life. The simulation is organized as follows: a script, called user interface manager, rules over the instruction messages that show up to guide the players; a second key script is the multi-functional display manager, it controls the navigation within the main interactable display. Additional scripts are created to provide specific methods needed during certain tasks or special out-of-nominal conditions. The result of this work is a sequence of five tasks, with instructions following the users along their path and marking the completion of each single required activity. The first one asks users to turn on the multi-functional display for the first time and to perform a check of the life-support system's status; two problems arise during the inspection of the menu, but users have the necessary support to solve them. The second task focuses on setting up the external camera views in the screens located in the cockpit around the pilot seat, serving as aid during the driving. The third guides the trip planning via the navigation menu and teaches users how to display all the critical data to be accessed during the

rover's movement. Other two tasks demonstrate the configuration of the sleeping area and how to handle an emergency.

Unity Simulation

Unity was selected as the development environment due to its real-time rendering capabilities, integrated physics engine, VR compatibility, and versatility in simulating interactive systems. Given that stakeholder training represented a primary project objective, Unity's C# scripting environment enabled the development of customized interaction logic to enhance user engagement, manoeuvrability, and system responsiveness. A dedicated simulation terrain was constructed to evaluate rover performance under lunar like operational conditions. As illustrated in Fig. 4 an interactive menu system designed for a better manipulation. The system includes a main menu, where user can monitor the speed, time, energy level and Oxygen level. A lighting setup designed to imitate the lighting conditions on the Moon, with three groups of lights: wheel lights, interior lights, and headlights. A multi-camera system is also implemented, giving the user side-mirror views, wheel-mounted camera views, and a 360-degree camera for better awareness of the surroundings. In addition, a power-management panel allows the user to adjust the rover's power based on the situation, with numeric input controls to improve accuracy. A navigation display shows the path already travelled by using the stored movement data, and the data-logging system records important values such as position, velocity, acceleration, and each wheel's torque. The user can start or stop the simulation at any time, and the recorded data are exported as a .xlsx file for further analysis. All features are integrated into a VR interactive menu, where the right-hand controller is used for acceleration and braking, and the left-hand controller is used to interact with the menu, giving the user intuitive and efficient control during the simulation. These sections are integrated into an interactive menu accessible through the Meta Quest 2 VR headset. To ensure effective control of both the menu and the rover, the VR controllers are configured to provide maximum ease of use and operational efficiency. The right-hand controller is assigned to control the rover's acceleration and braking, while the left-hand controller is used to interact with the on-screen menu and its functions.

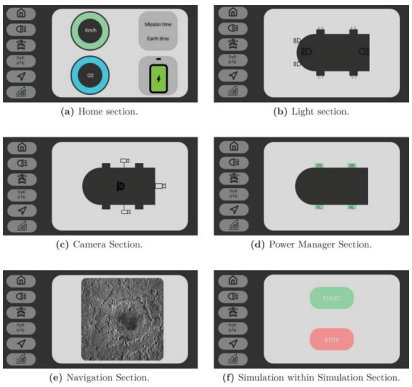

Figure 4. The interactive menu of the Roover.

Scientific Workspace Virtual Environment

The scientific workspace is the LPR's onboard workbench used in static exploration to inspect internal layout, equipment, and conduct moon sample analysis experiments. In this mode, users can explore the laboratory and interact with instruments to complete the related tasks. The workspace is modeled around a workbench equipped with different useful tools for measurement and inspection, a microscope, and a local monitor for task prompts and readouts. A sealed chamber (glovebox) with integrated gloves enables manipulation of regolith while preventing dust

dispersion inside the rover (Fig. 4). Visual fidelity focuses on highly interactive tools, including baked textures for regolith to preserve surface detail in real time. As with the cockpit, the scientific workspace was first decomposed through a functional analysis. Before implementation, a detailed input–output storyboard was created for each subtask (inputs: grabs, button presses, tool contacts; outputs: UI prompts, instrument readings, state changes). This upfront mapping shortened implementation time and ensured that every interaction in VR corresponds to an explicit, verifiable outcome. As seen in the previous section, the task sequence is implemented in Unity through C# scripts that manage state transitions and user interactions. A VR storyboard shows the workspace as a sequence of tightly scoped training tasks whit event-driven scripts that handle collisions, grabs and UI prompts:

- Sample selection & setup: The user opens the sealed box UI, selects a sample/object set, and confirms to lock into glovebox view with the chosen items inside.
- Weighing, sizing, and subdivision: Inside the glovebox, the trainee weighs the sample (balance readout on UI), measures dimensions, fractures it with a hammer, and repeats measurements on fragments—all with immediate UI feedback.
- Microscope analysis: After exiting glovebox view, a selected fragment is placed in the microscope; here it's possible to zoom/rotate controls for close inspection and to gather more data.
- Data capture & verification: Results are recorded in a notebook UI; a "Check Answers" step flags correct/incorrect entries and reports a score on the bench monitor.
- Emergency drill (workspace-linked): If an onboard alert triggers, the trainee leaves the bench, wears a suit in a prescribed order, and returns to diagnose the fault via the workspace monitor, reinforcing cross-section readiness while remaining anchored to lab operations.

Figure 4. VR rendering of the sealed-box interior showing the sample measurement and tool selection. The configuration displays interactive hands, various instruments, and a panel for choosing what to bring inside the box.

Conclusions

By integrating immersive simulation, functional modeling, and predictive analytics, the proposed framework reduces development time and costs, enhances system reliability, and facilitates real-time operational decision-making in planetary surface missions. The developed virtual environments for the cockpit and scientific workspace demonstrate how VR can effectively support human-centered design, procedure validation, and astronaut training. The approach enables early evaluation of ergonomics, system accessibility, and task sequences before physical prototypes exist. Future developments will extend the framework toward a fully integrated digital twin with real-time telemetry, haptic feedback, and interactive mission simulations.

Keywords: AI-Based Control, Generalized Flight Control, Deep Reinforcement Learning (DRL), Fixed-Wing Aircraft Control

Abstract. This study introduces a DRL-based controller for multiple fixed-wing aircraft without model-specific tuning. The proposed system is trained using Proximal Policy Optimization (PPO) and is enhanced by algorithmic strategies such as multi-model training and kinematics-based reward shaping to ensure generalization across diverse platforms. It is compared with a conventional method to see if the generalized controller maintains high control performance at the level of an aircraft-specific design. This approach presents an adaptable alternative to conventional control design, offering resilience to configuration changes, and providing reduced dependency on the model.

Introduction

This work proposes a new approach to flight control by making it more general rather than being aircraft-specific. In this sense, a single controller can handle multiple aircraft's control by itself without any reconstruction or recalibration. It is expected that such a controller can be used like a plug-and-play system across aircraft platforms that are distinct in many ways. In other words, this controller is not specific to any of the aircraft worked on but general for all of them.

The generalized control concept can offer numerous advantages over conventional methods such as scalability, adaptability, reduced maintenance and tuning, lower development costs, and reduced dependency on specific models. This new design logic, unlike conventional aircraft-specific control system design, provides two important innovations to flight control. First, such a control system can be used for more than one aircraft. Second, such a controller can show good control performance even in the face of unknown or previously unseen flight dynamics. On the other hand, this approach may raise questions about optimality, which is the main advantage of aircraft-specific control design.

Background

As an initial step, to construct a testbed environment for the proposed control system design, five distinct fixed-wing aircraft models shown in Fig. 1 have been selected.

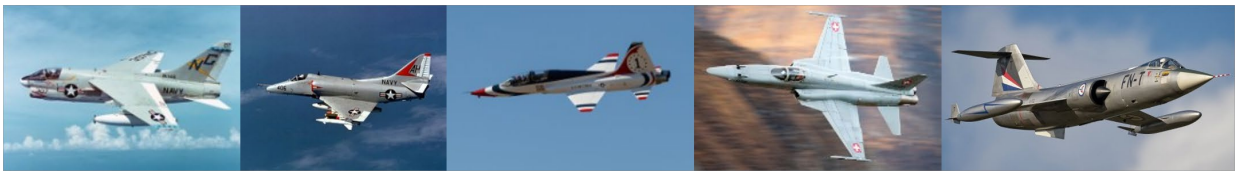

Figure 1: Five aircraft models

These models provide a good base for the multiple aircraft definition since they clearly present different dynamics, and also for generalization concept because they are similar due to being military aircraft. Besides that, they have already been subjected in a valuable work called "Aircraft

Content from this work may be used under the terms of the Creative Commons Attribution 3.0 license. Any further distribution of this work must maintain attribution to the author(s) and the title of the work, journal citation and DOI. Published under license by Materials Research Forum LLC.

Materials Research Proceedings 69 (2026) 15-20 https://doi.org/10.21741/9781644904251-3

Stability and Control Data" conducted by Gary L. Teper in 1969 [1]. This paper contains useful data including aerodynamic derivatives and coefficients obtained from mostly wind tunnel tests. This facilitates the aircraft modeling process and increases the fidelity. However, this paper is not the only source of the data because there are some missing parts. Therefore, computational tools such as DATCOM [2] and OpenVSP [3] have also been used in compiling the required data. Table 1 shows the data sources for the aircraft models;

Table 1: Main source of aerodynamic data for aircraft models

Aircraft	Data Source
A-7A	Teper
A-4D	Teper
T-38	Teper + DATCOM
F-5A	OpenVSP
F-104	Teper + OpenVSP

Other missing parameters which will be used in the flight simulation have been estimated by using standard analytical methods [4, 5]. Using low fidelity computational tools and analytical estimation methods can cause loss in fidelity for the modeling process. However, this is not important in the sense of this work because these models will be sufficient as long as they properly represent aircraft dynamics and they are different. Different sizes, shapes, and body-wing-tail configurations shown in Fig. 2 ensure that these are distinct models, and they will show different flight behaviors.

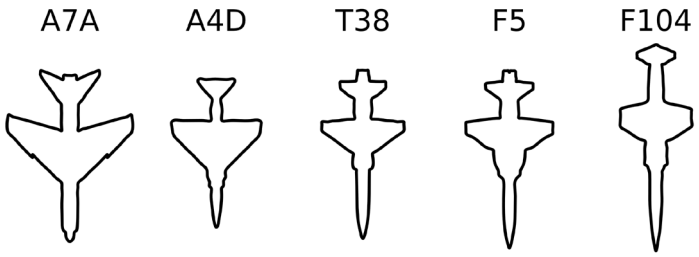

Figure 2: Five models at the same length scale

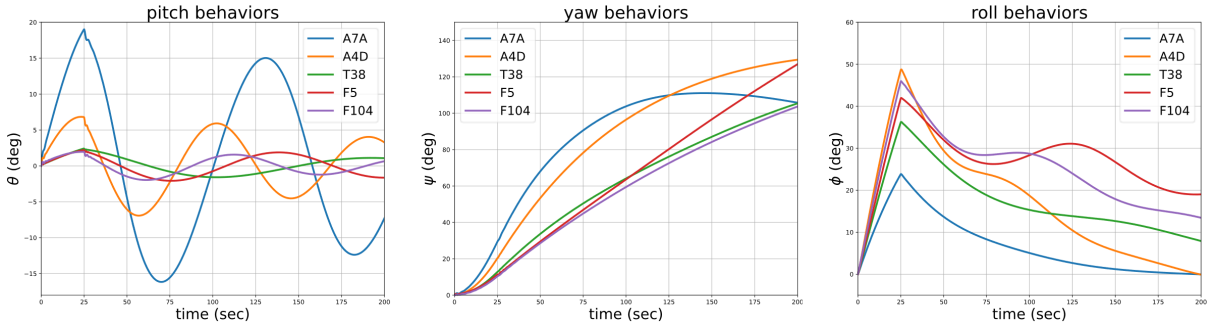

Figure 3: Aircraft behaviors in terms of Euler angles

How different these aircraft behave either in the presence or absence of control input can be seen in Fig. 3 where first 25 seconds the elevator, rudder and ailerons are held at 5, 5, and 3 degrees deflections, respectively and then released. These plots show that neither natural behaviors nor the control input reactions are the same for all the models nevertheless there is a general pattern.

Materials Research Proceedings 69 (2026) 15-20 https://doi.org/10.21741/9781644904251-3

Methodology

In this work, a DRL-based control approach is used in which a control agent is trained by using the PPO algorithm [6]. The learning procedure as an Markov Decision Process MDP [7] is integrated with the flight simulation where the aircraft's equation of motion with 6 degree of freedom is solved by Runge-Kutta [8] integration. This process can be seen below in Fig. 4;

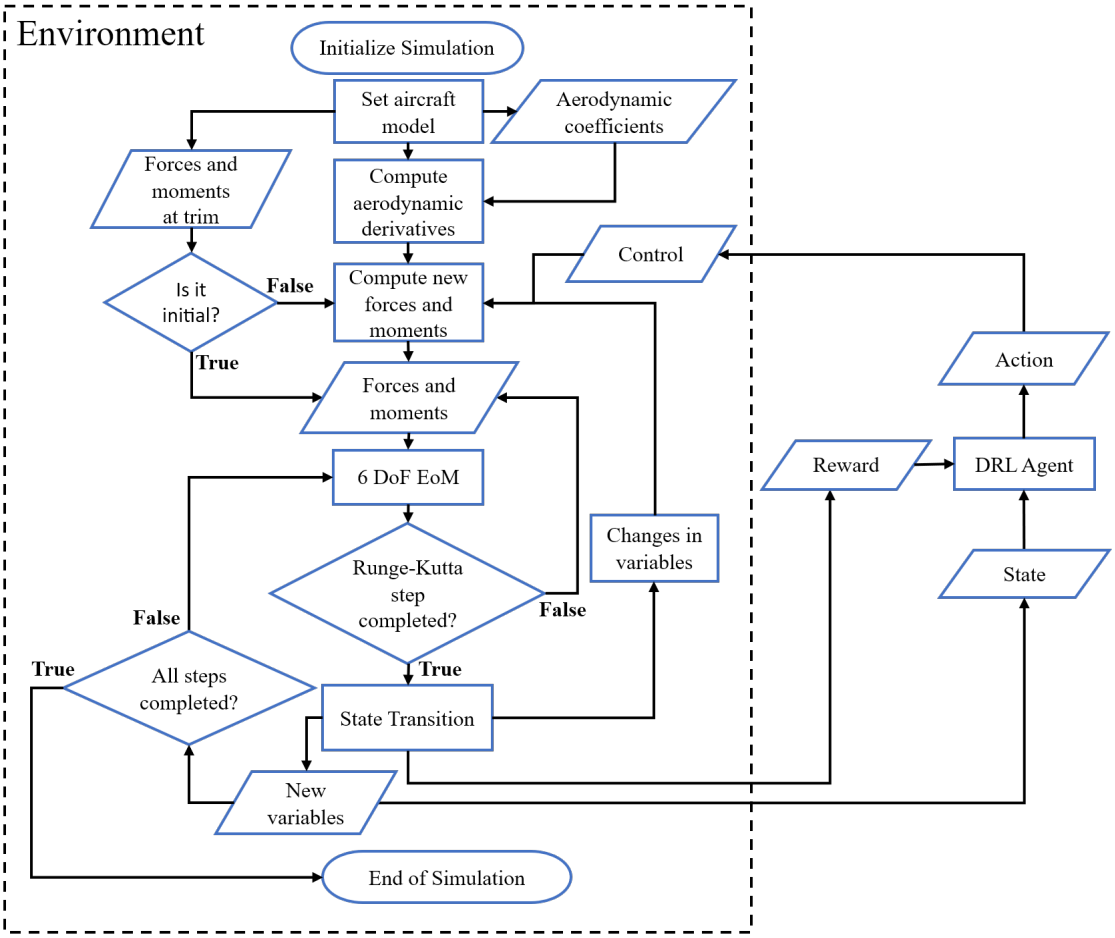

Figure 4: MDP with flight simulation environment

Since the task is attitude control, the difference between Euler angles and reference (desired) angles are used as state parameters. It becomes directly Euler angles themselves where the reference values are zeros. However, this state definition is too instantaneous and does not give much information about the kinematics. For this reason besides the current Euler angles, previous Euler angle values are also added as state parameters to get information about direction and the change of angles. Also, action space is already predetermined as control inputs which are elevator, throttle, aileron and rudder change. The reward function is defined in terms of norm of the state vectors since this vector gives us the proximity to the desired values.

$$S = [\theta_c \quad \psi_c \quad \phi_c \quad \theta_p \quad \psi_p \quad \phi_p] \tag{1}$$

$$A = [\delta e \quad \delta T \quad \delta a \quad \delta r] \tag{2}$$

Materials Research Proceedings 69 (2026) 15-20 https://doi.org/10.21741/9781644904251-3

$$R = \left(\frac{1}{s}\right) - s \quad \text{where} \quad s = \text{norm}(S) \tag{3}$$

Results

The results are obtained for two tasks which are leveling and turning. In leveling, the aircraft start with deflected Euler angles from trim point and the controller tries to bring them back to zero. It can be considered as stabilization and thus the controller fulfills the stability augmentation task here. When the aircraft are left to their own devices for 10 degrees distributed angles, they behave as shown in Fig. 5;

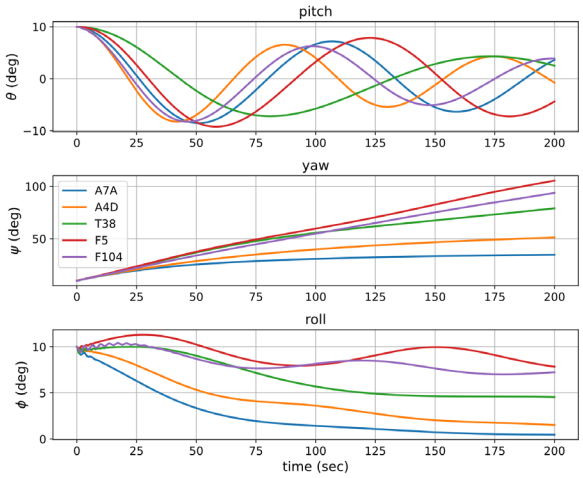

Figure 5: Stick-free motion in the presence of distribution

When the single DRL control agent steps in, it works for all five aircraft as shown in Fig. 6;

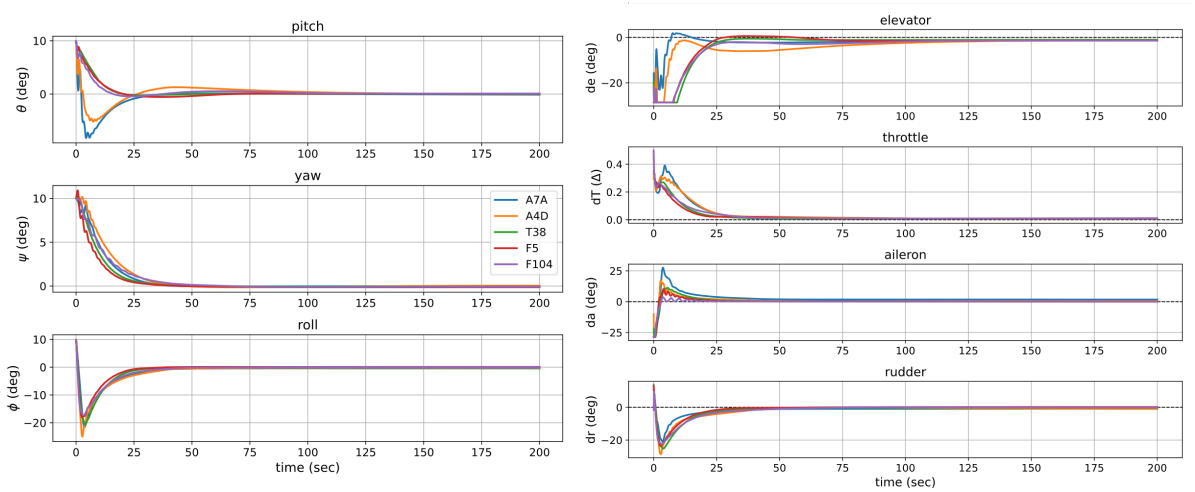

Figure 6: Stability augmentation with DRL controller

The controller is also tested for a task where the agent needs to bring Euler angles to predefined values and hold them there. This makes the aircraft turn their heading to a certain direction.

Materials Research Proceedings 69 (2026) 15-20 https://doi.org/10.21741/9781644904251-3

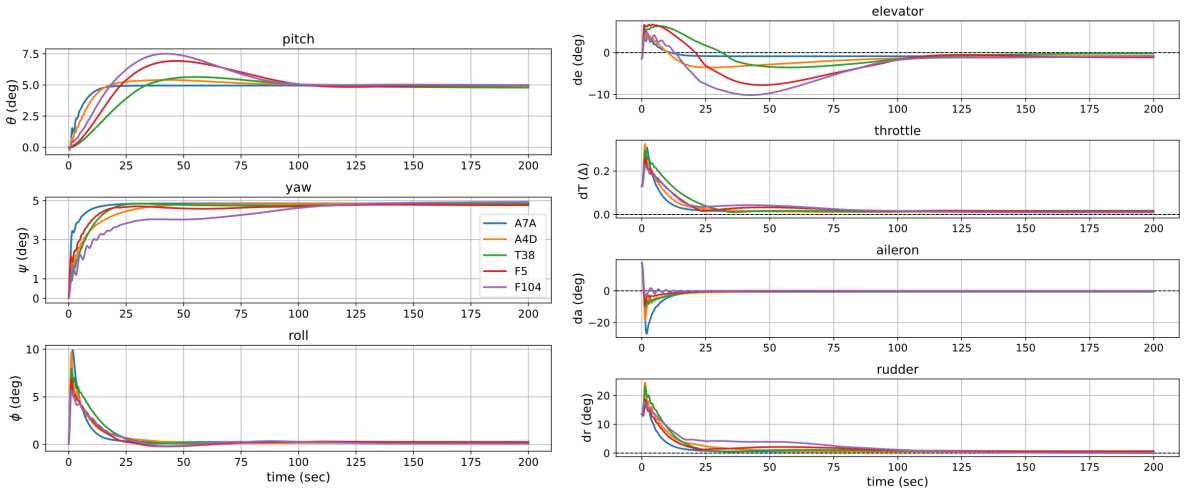

Figure 7: Turning control with DRL controller

The above results in Fig. 7 show that a single control agent can be used for control of multiple aircraft. On the other hand, we also need to test control performance for the DRL agent. For this reason, the A7A aircraft is taken as the sample and the DRL based controller is compared with an LQR controller. As seen in Fig. 8 the DRL-based controller can show performance at the level of the LQR controller, however making it generalized for multiple aircraft has caused some changes in performance. This trade-off between optimality and adaptability can be considered acceptable when taking account that a single controller can handle five aircraft.

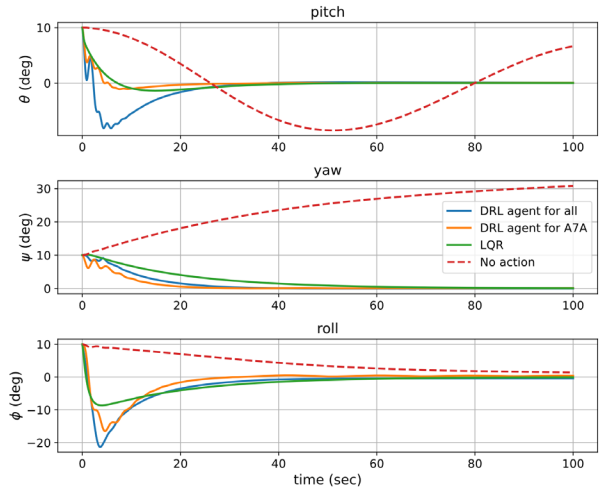

Figure 8: Comparison with LQR for A7A

Conclusion

This study has demonstrated that a single DRL-based controller trained via multi-model learning can effectively manage attitude control tasks for multiple fixed-wing aircraft without making model-specific adjustments. Though the generalized controller has exhibited a compromise in optimality compared to an aircraft-specific LQR controller, this trade-off is acceptable given the significant gain in adaptability and scalability. Overall, the results confirm that DRL offers a promising path toward generalized flight control that reduce dependence on individual models.

Abstract. This study addresses the challenge of limited annotated data in aircraft surface damage detection by evaluating generative models for data augmentation. Conducted within the CINNABAR 2 project with DLR MRO institute in Hamburg (DE), it compares Generative Adversarial Networks (GANs) and Diffusion Models for producing realistic synthetic images. Real data are collected from smartphones, DSLRs, and robotic camera systems. Image quality is assessed using the Learned Perceptual Image Patch Similarity (LPIPS) metric and visual inspection. Results indicate that Diffusion Models outperform GANs, achieving a lower LPIPS score and better detection metrics, demonstrating superior realism, diversity, and suitability for enhancing deep learning model training.

Introduction

A major limitation affecting the accuracy and generalization of deep learning algorithms in object detection tasks, such as aircraft surface damage detection, is the scarcity of annotated training data [1]. In industrial applications, particularly in safety-critical fields like aerospace, creating large, high-quality datasets is both costly and time-consuming. The diversity of defect types, materials, lighting conditions, and imaging perspectives further complicates data collection, as these factors significantly impact model performance [2]. When datasets are insufficient or unbalanced, AI algorithms often fail to generalize beyond their training domain. Therefore, developing comprehensive datasets that capture a broad spectrum of damage appearances and acquisition conditions—such as variations in illumination, resolution, surface texture, and viewing angle—is essential for effective model training. However, achieving such diversity manually is often impractical. To address this challenge, recent research has explored the use of generative models to address the lack of annotated data in structural damage detection [3] to augment limited datasets for multiclass structural damage classification, obtaining limited results in terms of accuracy in the subsequent testing phase for damage detection algorithms.

Methodology

This study investigates two different generative strategies for augmenting training datasets to make a comparison between them. First, Generative Adversarial Networks (GANs) [4] employ a dual-network architecture where a generator produces synthetic images, and a discriminator learns to distinguish between real and fake samples. The process begins with configuration and initialization, where the generator (G), discriminator (D), and perturbation module are initialized along with key hyperparameters (learning rate, number of steps, perturbation strength). The training loop iterates until convergence; within each iteration, the discriminator update phase

Materials Research Proceedings 69 (2026) 21-24 https://doi.org/10.21741/9781644904251-4

(performed for multiple steps per loop) involves generating fake images, sampling real images, performing adversarial training on real data, and computing the discriminator loss on both real and fake samples. The adversarial training component introduces perturbations to real images to enhance discriminator robustness and reuses the perturbed data efficiently across discriminator updates. In the generator update phase, the generator produces fake images to fool the discriminator, and its weights are updated based on the discriminator's feedback. The loss and stability emphasize training balance, combining discriminator and generator losses without requiring additional normalization or large batch sizes. The convergence/termination stage monitors performance metrics such as FID and IS, stopping training once convergence or saturation is reached.

The second approach, Diffusion Models [5], synthesizes images by iteratively denoising random noise, effectively reversing a diffusion process that gradually corrupts data. As the previous algorithm setup, the process begins with configuration, including specification of training parameters, dataset paths, and device selection. The pretrained model is then loaded, comprising components such as the Stable Diffusion pipeline, CLIP tokenizer, U-Net network with Low Ranking Adaption (LoRA) layers, Variational Auto Encoder (VAE), frozen text encoder, and DDPM scheduler. Next, LoRA configuration defines which attention layers to adapt and sets hyperparameters such as rank and dropout. The dataset and dataloader stage involve loading and augmenting image–prompt pairs for training. The training setup specifies optimization settings, including the AdamW optimizer, learning rate scheduler, and early stopping. During the training loop, images are encoded using the VAE, prompts are tokenized, noise is added and predicted by the U-Net, and model weights are updated based on MSE loss between predicted and target noise. Finally, the model saving stage stores the best-performing model, including the trained U-Net and LoRA configuration files.

As a case study, this work is conducted within the scope of the CINNABAR 2 [6] project, in collaboration with the DLR Institute of Maintenance, Repair and Overhaul – Department of Process Optimization and Digitalization in Hamburg, Germany. The test study focuses on a representative structural component of a commercial aircraft — specifically, a section of a medium-range commercial aircraft wing — used to simulate real-world inspection scenarios. To assess the impact of different image acquisition conditions, three imaging systems are used to collect real data:

- *Smartphone camera*, representing low-cost, flexible field inspections.
- *Digital Single-Lens Reflex (DSLR) camera*, providing high-resolution, professional-grade imagery.
- *Robotic arm* with a mounted camera

The images collected are used to build a dataset of 50 images with different subjects; the main goal is to have an *Image-to-Image (*Img2img*)* model able to generate new damage starting from existing ones in different poses, colors, illumination, and scenes. To do so, both algorithms previously described are trained using similar training options (Table 1).

Image size [pixel]	512x512	512x512
Learning rate	0.0001	0.0002

Materials Research Proceedings 69 (2026) 21-24 https://doi.org/10.21741/9781644904251-4

Results

The LPIPS metric is used to compare the performance of the two algorithms. The Learned Perceptual Image Patch Similarity (LPIPS) metric is a perceptual measure designed to quantify the similarity between two images in a way that aligns more closely with human visual judgment than traditional pixel-based metrics. LPIPS evaluates differences in feature representations extracted from intermediate layers of convolutional neural networks pretrained on large-scale image datasets. These deep features capture structural and semantic content that humans are sensitive to, such as textures, edges, and object parts. A lower LPIPS score indicates higher perceptual similarity between two images, while higher values suggest greater visual differences. This makes LPIPS widely applicable in the evaluation of generative models, image restoration, and data augmentation tasks. The results obtained are reported in Fig. 1 and Fig.2. The synthetic images generated by Diffusion Models are more suitable for data augmentation purposes, as indicated by their LPIPS average score of 0.2707 (versus GAN model LPIPS average score: 0.5797). For this reason, it is decided to use a diffusion model to generate 100 synthetic images to compare the performance of a damage detection algorithm trained on a mixed dataset (real images + synthetic images) with the performance of the same algorithm trained only on real images. YOLOv11 is chosen as the damage detection algorithm. YOLOv11 is the latest iteration in the You Only Look Once (YOLO) series, developed by Ultralytics [7]. It is designed to offer high performance across a range of computer vision tasks, including object detection and image classification. Two datasets are therefore prepared: the first containing 50 real images (real dataset) and the second containing 50 real images and 100 synthetic images (real + fake dataset). Both are split into 80%/20% for the training/validation phase, using only real images for the validation phase in both cases. The results are evaluated in terms of Precision, Recall, mean Average Precision at 50% Intersection over Union (mAP50), and mAP50-95 (Table 2). More details about its use for Damage Detection can be found in [8].

Table 2 - Evaluation metrics for real image dataset and real + fake image dataset

	Box P	**Box R**	**mAP50**	**mAP50-95**
Real	0.81	0.85	0.837	0.421
Real + Fake	0.978	0.889	0.951	0.586

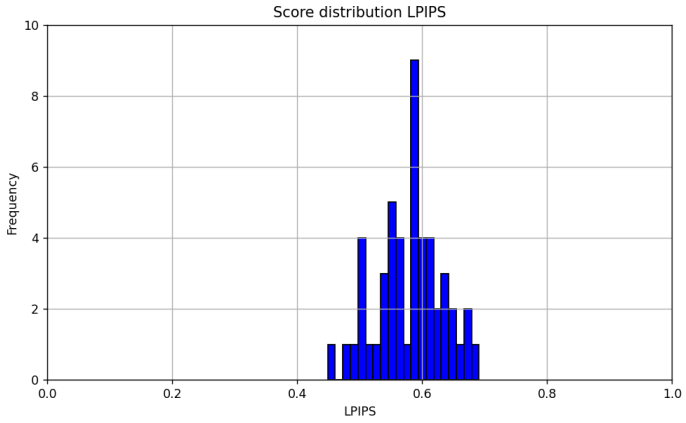

Fig. 2 - Score distribution LPIPS for GAN model

Conclusion

The comparison between the two training strategies demonstrates the clear benefit of augmenting real data with synthetic samples. The model trained exclusively on real images achieved a reasonable balance between precision and recall but struggled with bounding box accuracy. In contrast, the model trained on the mixed dataset showed a notable improvement across all metrics: it is more reliable in its predictions, slightly more sensitive in detecting true cases, and produced more accurate localizations. These results show that synthetic data can effectively complement limited real datasets, minimize false positives while improving overall detection performance, and generalize to real-world circumstances.

Keywords: Nowcasting, IAM, Thunderstorms, Deep Learning

Abstract. Adverse weather events constitute a major contributor to delays of aircraft. Thunderstorms, and accompanying effects, are frequently considered most hazardous to aircraft. Spatiotemporally highly resolved short-term forecasting of thunderstorms is possible from remote sensing data and has previously proven beneficial for commercial aircraft operations. This work demonstrates the potential of thunderstorm nowcasting in the innovative air mobility (IAM), by incorporating a physics-based deep-learning approach in an operational IAM flight planning platform. Operators benefit from more accurate and higher-resolved thunderstorm information, translating into smarter, safer, and more efficient operations and flight planning. Ultimately, a higher number of safe IAM operations can be realized.

Introduction

Atmospheric phenomena play a major role in air traffic management and flight planning, significantly contributing to delays. EUROCONTROL reports a 48%-increase in weather related delays in their civil aviation network from the years 2023 to 2024, resulting in a total of nearly 7 million delay minutes [1]. Commonly, numerical weather predictions (NWP) are employed to anticipate weather events. However, recurrently their spatiotemporal resolution proves insufficient. Furthermore, computational complexity of NWP models disallows frequent forecast updates, particularly hindering accurate predictions for short lead times. The need for accurate and very short-term forecasts, also called nowcasts, of aviation-relevant weather phenomena has been established throughout the past years [2]. With climate change, the frequency and severity of extreme weather events are expected to increase [3], further emphasizing the need for nowcasting. Besides civil aviation, the demand for Innovative Air Mobility (IAM) is expected to grow in passenger and cargo transportation [4]. To this day only few weather nowcasting studies have been performed for the IAM. For instance, Chrit and Majdi [5] performed wind and turbulence nowcasting. Particularly the IAM is expected to benefit from weather nowcasting: their operation is tied to versatility, short flight times and routes. Thus, the spatiotemporal scales are significantly smaller than global NWP can offer today. Thunderstorms and accompanying effects are particularly hazardous for small air vehicles, e.g., drones (here analogous to IAM). Lightning strikes, heavy precipitation, strong winds, and hail may affect drones far more than experienced by conventional aircraft.

To the authors' knowledge, for the first time this paper investigates the operational potential of nowcasting thunderstorms for IAM-sector in comparison to NWP implementations. A particular focus is put on the automatization of flight planning and increasing its efficiency. A physics-based machine learning (ML) model, the advection-informed neural network (AINN) [6], and the flight

planning platform NOVA [7] by Unisphere are employed. The nowcasting model is prototypically integrated into the NOVA platform. NWP and nowcasting forecasts are compared via representative case studies, which confirm the added value of nowcasting for IAM. The remainder of this paper is structured as follows: the two main methods, NOVA and the AINN, are detailed. Afterwards, two case studies validate the potential of thunderstorm nowcasting in an IAM flight planning platform. Lastly, conclusions are provided.

Methods

NOVA [7] for planning IAM flights. The NOVA platform, developed by Unisphere, is a simulation-based digital co-pilot for IAM operations, offering advanced automation in flight planning, risk assessment, and regulatory compliance. NOVA applies Smart 4D Trajectory technology to evaluate weather impacts, battery performance, and global navigation satellite system reliability along planned flight paths, thereby supporting scalable and safe beyond visual line-of-sight operations. Within NOVA, aircraft performance, route geometry, and user-defined operational limits are combined with meteorological data to assess flight feasibility over a planning horizon of up to seven days. The system presents results through an automated traffic-light scheme (green/yellow/red) that compares forecast conditions against configurable thresholds for parameters such as wind, precipitation, temperature, visibility, and other operator-defined limits. Presently, weather-related risk assessment in NOVA relies on NWP data provided by the European Centre for Medium-Range Weather Forecasts (Integrated Forecast System) at a horizontal resolution of approximately 9 km resolution (≈ 0.1 deg), with new hourly forecasts issued every six hours. Because NWP data alone has limited ability to represent rapidly developing convective phenomena, operators complement NOVA's automated evaluation by inspecting radar imagery, which is available as an integrated visualization layer within the platform. This manual review of thunderstorm activity currently informs final go/no-go decisions. Integrating nowcasting into NOVA will replace this manual radar interpretation with an automated, short-term convective risk assessment, enhancing the reliability and efficiency of mission planning. Satellite-based thunderstorm nowcasting is embedded into NOVA as illustrated in Fig. 1 - this enables global nowcasting coverage (unlike radar).

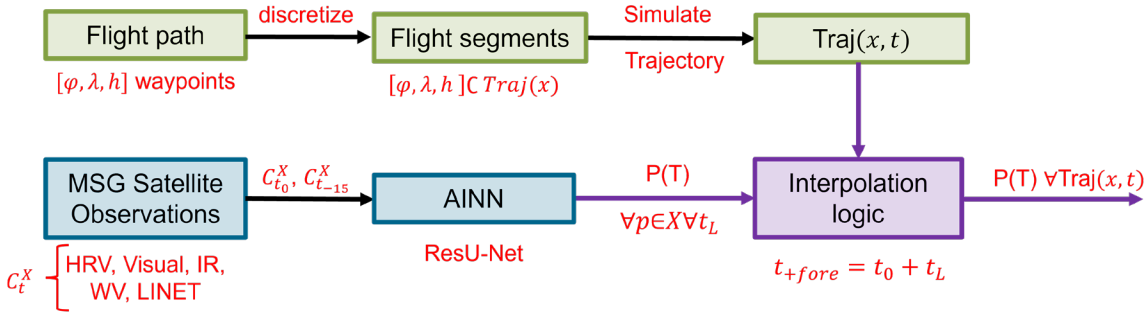

Figure 1 - AINN (blue) integration into NOVA (green). Purple represents the integration.

NOVA components are marked in green, first defining the desired flight path according to the latitude (φ), the longitude (λ), and the altitude (h), after which the complete flight path is discretized into flight segments. Along these segments, the flight trajectory (Traj) is simulated i.e., a time component is added.

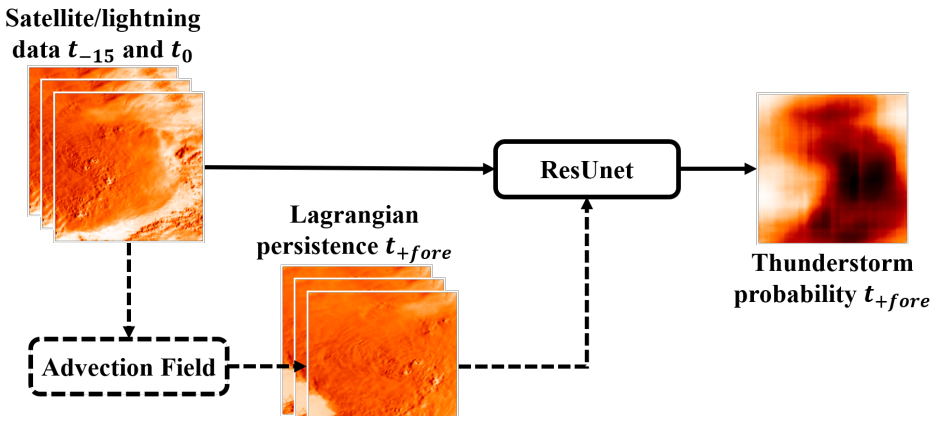

Figure 2 - AINN value chain. The employed BNN is represented by solid arrows only. [6]

Physics-based ML thunderstorm nowcasting [6]. Conventional operational nowcasting algorithms rely on advection and empirical rules from optical flow considerations in remote sensing imagery [8]. In recent years data-driven nowcasting, particularly ML models, achieved promising results. Metzl et al. [6] developed the AINN model depicted in Fig. 2. It is based on geostationary satellite and ground-based lightning data. The input for our task are the latest two observations (at t_0 and t_{-15}) of four Meteosat Second Generation (MSG) satellite [9] channels (C: HRV, VIS008, IR108, WV062) with a minimum temporal and spatial resolution of 15 min and ≈ 3 − 5 km (the HRV channel has a resolution of ≈ 1 km), respectively, aggregated lighting observations from the lightning detection network (LINET) [10], and the Lagrangian persistence advection field of all input channels for the desired forecast time (dashed arrows in Fig. 2). A ResU-Net [11] constitutes the heart of the AINN, delivering pixel-wise (p) calibrated thunderstorm probabilities P(T) as output. It solves a semantic segmentation task with binarized LINET data as ground truth, given its detection efficiency of over 95% and the 150 m spatial accuracy. For both the input and ground truth, each lightning stroke is grouped into 15-min bins and covers a disc with a 15-km radius. For each lead time t_L, i.e., 30 min, 60 min, 90 min, 120 min, 150 min, 180 min, one ResU-Net is trained for a 1024 × 1024 grid with a 0.0125-deg spacing (≈ 1 km) centered around the European Alps (25 crops of size X: 256 × 256 are individually processed). Data from May to October in 2018 and 2019 are employed for model training, validation, and testing. Metzl et al. [6] differentiate between the AINN (all arrows in Fig. 2) and the so-called baseline neural network (BNN) (only the solid lines in Fig. 2). They find that for lead times (fore in Fig. 2) up to 2 h, the difference in nowcasting skill between the AINN and BNN is negligible, with only a minor skill deficit by the latter for larger lead times. For the present study we thus consider the BNN sufficient. At present NOVA interpolates thunderstorm probabilities in a nearest-neighbor and linear fashion for the spatial and temporal domains, respectively.

Case Studies

June 18, 2019: Nowcasting solves NWP uncertainty. We demonstrate how nowcasting can automatically support NWP forecasts in NOVA. A drone is scheduled to fly across Lake Constance as drawn in Fig. 3 (≈ 30 km distance, ≈ 20 min duration) with a take-off time t_{TO} at 19:40 UTC from Constance. Forty minutes prior (19:00 UTC) the drone operator wishes to make a go/no-go decision for the flight and runs NOVA to obtain a flight recommendation. At that time, LINET observations of the past three hours (see Fig. 4 left) reveal large thunderstorm cells approaching from the south-west of Lake Constance. NOVA's NWP forecasts predict a thunderstorm probability between 40% - 50% along the flight distance D_F (see Fig. 5). These values do not allow

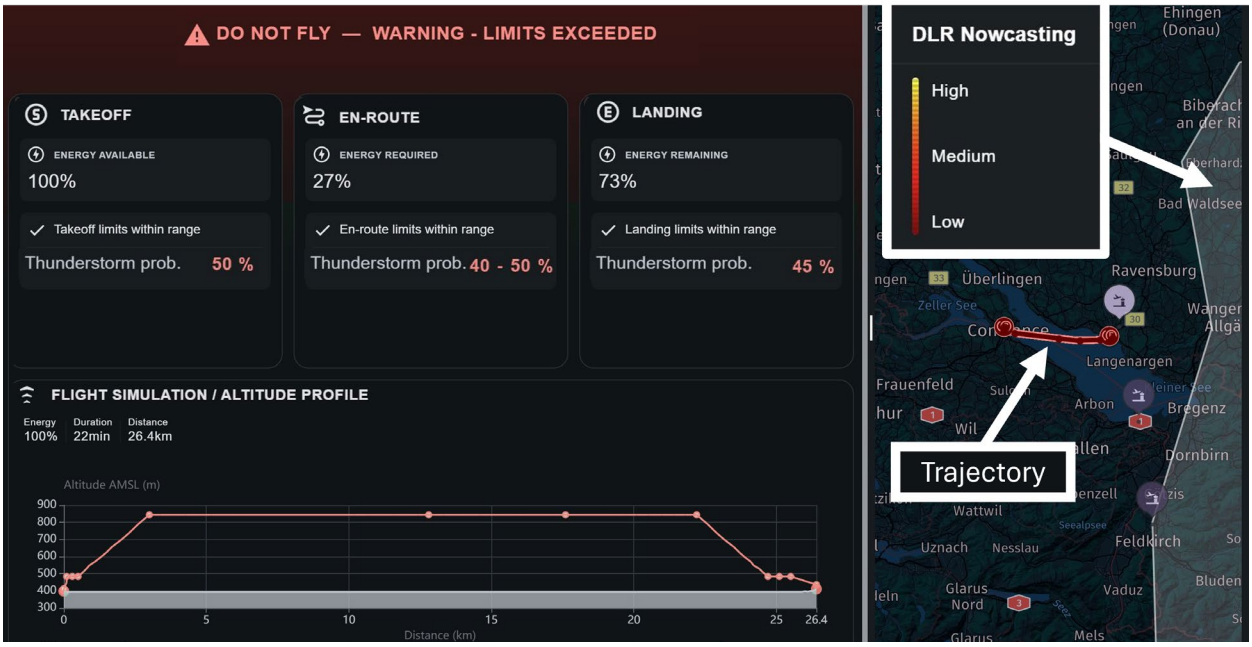

Figure 3 - NOVA interface. Overview of the critical simulation parameters (left) and the drone flight trajectory across Lake Constance, Germany (right).

for an obvious go/no-go decision and thus NOVA recommends to not fly. Instead of canceling the flight, we additionally run our nowcasting tool (NWC). Precise thunderstorm nowcasts are provided for t_{TO}, as plotted in Fig. 5 - a near zero thunderstorm probability is predicted along the complete flight distance. Thunderstorms predicted by the nowcasting are drawn on the map in Fig. 3. The right of the map is marked as very dangerous (white layer), the flight trajectory is clear. These results align well with lightning observations (Fig. 4 right) from post-analysis. At already 19:00 UTC our nowcasts predict that the thunderstorm cells will morph around the south-east of Lake Constance, while the north-west area of the lake (the area containing the flight trajectory) remains safe to fly. The NWP model is unable to resolve the convective cell as necessary and instead marks the complete lake area as potentially containing thunderstorms. The added value of the automatic nowcast is evident: tactical planning of drone flights is increased.

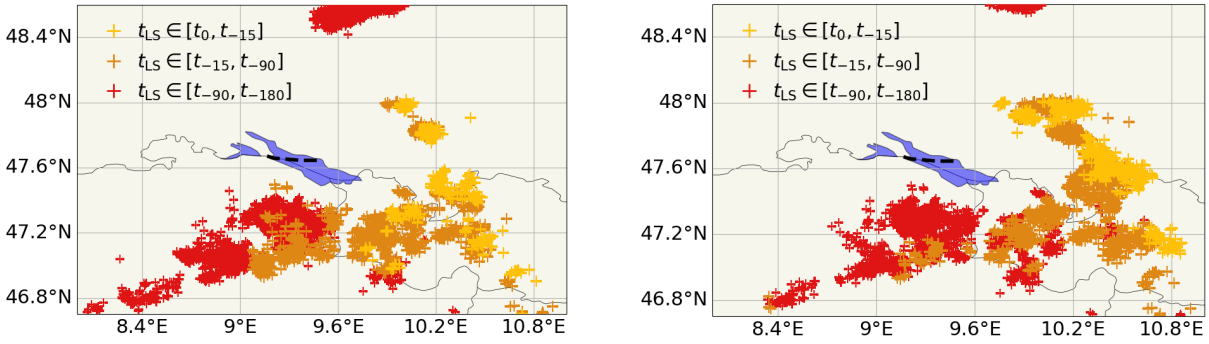

Figure 4 - Lightning strikes (LS) at 19:00 UTC (left) and 19:40 UTC (right) near the flight trajectory (dashed line). Symbols represent lightning strikes during the past 15 − 180 min.

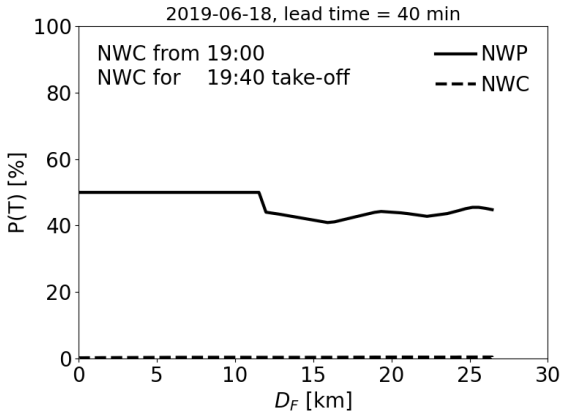

Figure 5 - Thunderstorm probabilities for DF by NWP (solid) and NWC (dashed) estimated 40 min ahead of t_{TO}. NWP and NWC probabilities are not directly comparable.

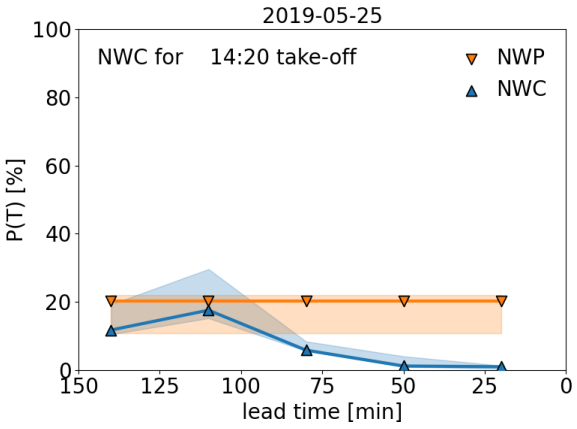

Figure 6 - Median thunderstorm probabilities for the flight trajectory (with 5% and 95% percentiles) by NWP and NWC, which are not directly comparable.

May 25, 2019: High spatiotemporal resolution enables reliable flight planning. The same flight trajectory is assumed. NOVA, with our nowcasting tool, is run at 30-min intervals prior to take-off planned for 14:20 UTC, given that a first run indicated the possibility of thunderstorm occurrence. Indeed, a significant convective cloud front is observed to approach from the north-west at these early times. While NWP continues to provide uncertain thunderstorm probabilities, Figure 6 illustrates the advantage of the nowcasting (lead time here refers to the nowcast computation time prior to take-off). As take-off approaches, the nowcasting thunderstorm probabilities diminish, which is owed to the high temporal resolution of the data. Just under one hour prior to take-off, the thunderstorm probability is near zero. Post-analysis of observations confirm that no thunderstorm occurred for the planned flight trajectory and time - the main cell re-routed north of Lake Constance. This study emphasizes the necessity for high temporal resolution in weather forecasts for the IAM.

Summary

A first investigation and feasibility study to automatize thunderstorm nowcasting for the IAM was presented. A novel machine learning nowcasting model was embedded in an IAM flight planning platform. Case studies showcase the benefit of thunderstorm nowcasting for the IAM. Flights that previously had to be canceled can be conducted safely with our automatic nowcasting. It is also expected that hazardous flights are avoided by detecting thunderstorm cells in regions marked as safe-to-fly by NWP forecasts. Manual monitoring of radar imagery is no longer necessary for flight operators. A great potential is seen for thunderstorm nowcasting to improve flight planning. In future, dynamic flight re-routing is also considered plausible with this high-resolution nowcasting tool.

Keywords: Wall Turbulence, Flow Control, Machine Learning

Abstract. This study investigates the use of a hybrid architecture of a Feed-forward Neural Network (FNN) combined with the Proper Orthogonal Decomposition (POD) to estimate the effect of control on sweep events within the context of an opposition control strategy. The experiments were carried out in a fully turbulent channel flow with a friction Reynolds number of 365. The POD was conducted to reduce the database dimensionality, and then a FNN was trained to predict the non-normalized spatial modes matrix, subsequently allowing the reconstruction of the Conditionally Averaged Sweep Event (CASE). The results demonstrate that the hybrid neural network is capable of reproducing the control signature for different actuation parameters with an accuracy comparable to a conventional neural network, while requiring approximately 90 times fewer trainable parameters.

Introduction

Choi et al. [1] through direct numerical simulations, demonstrated that the opposition control technique can achieve skin-friction reductions up to 25% by applying wall blowing and suction with velocities equal in magnitude but opposite in direction to those at a prescribed wall-normal location. Wind tunnel experiments reported in [2, 3] further demonstrated that real-time opposition control, implemented through wall-normal jet actuation to block high-speed fluid motions during sweeps, effectively mitigates the intensity of these events. In recent years, data-driven models have shown success in estimating the response of control systems to given actuation parameters. A FNN was implemented in [4] to predict the effect of actuation parameters on the CASE. The objective of the present work is to extend that study by reducing the dimensionality of the FNN by changing the model architecture. Furthermore, the possibility of further reducing the dimensionality is explored through the use of a hybrid POD-FNN, which first predicts the non-normalized spatial modes matrix of the POD and then reconstructs the CASE, while maintaining nearly the same accuracy.

Experimental setup

The experiments were conducted in an 8-meter-long duct with a 7 cm x 30 cm rectangular cross-section (aspect ratio equal to 4.28). The center-line velocity was set to $U_0 = 3.22$ m/s corresponding to a friction velocity of $u_\tau = 0.16$ m/s and a resulting friction Reynolds number of $Re_\tau = 365$. Two hot-wire probes were employed, each connected to a Dantec 55M10 CTA Standard Bridge anemometer. Both probes featured a sensitive tungsten wire with a diameter of 5 μm and a length of 1.25 mm. The upstream probe, a Dantec 55P11, was positioned at $x^+ = -65$ and $y^+ = 15$, while the downstream probe, a Dantec 55P15 boundary-layer type, was mounted on a two-axis stand. The superscript + denotes quantities in wall units. Following [3], sweep events were detected in real time using the velocity-gradient technique applied to the streamwise velocity signal acquired from the upstream probe. An analog differentiator computed the gradient from the hot-wire anemometer voltage output, and a comparator identified events

when the time derivative exceeded a threshold. The threshold was calibrated to match the event count from the variable interval time averaging method [5] with k=1.0 and averaging time T^+=10. A detected sweep event generated a TTL signal sent to an Arduino Uno Rev3 board, introducing a delay ΔT to take into account convection time and actuator response time. The delayed TTL signal triggered a signal generator to produce a single-period sine wave of frequency f and voltage amplitude $\hat{A}$, amplified to drive a loudspeaker. The loudspeaker produced a jet through a 1 mm diameter orifice (corresponding to about 11 viscous units). The rear probe velocity signal was acquired and conditionally averaged to visualize the sweep event.

Database description and model creation

The database used in this study is the one presented by [4], constructed by varying the control parameters. The objective is to predict the longitudinal component of the velocity signal for the controlled CASE, $\hat{u}_c \in \mathbb{R}^{1\times n_t}$, using as inputs the actuation parameters and the longitudinal component of the velocity signal for the uncontrolled CASE, $\hat{u}_{nc} \in \mathbb{R}^{1\times n_t}$, where $n_t = 750$ is the number of points in the conditionally averaged window and corresponds to 139 viscous units. Let the control triplet be denoted as θ, characterized by actuation frequency f, voltage amplitude $\hat{A}$, and delay time ΔT. A total of $n_d = 130$ control triplets were sampled to construct the input part of the dataset using a Latin Hypercube Sampling technique within the space 30÷60 Hz, 50÷75mV_{pp} and 0.15÷3ms for frequency, voltage amplitude and delay time respectively. For each dataset sample, $\hat{u}_c(\theta)$ was experimentally evaluated after a conditional sampling of the rear probe velocity signal acquired at $x^+ = 65$ and $y^+ = 15$. The resulting dataset was divided into training and validation subsets, containing 80% and 20% of the data respectively, and normalized to have all the features in the range between 0 and 1. A FNN with a reduced number of trainable parameters compared to the model proposed in [4] was adopted to predict the control effect on the CASEs.

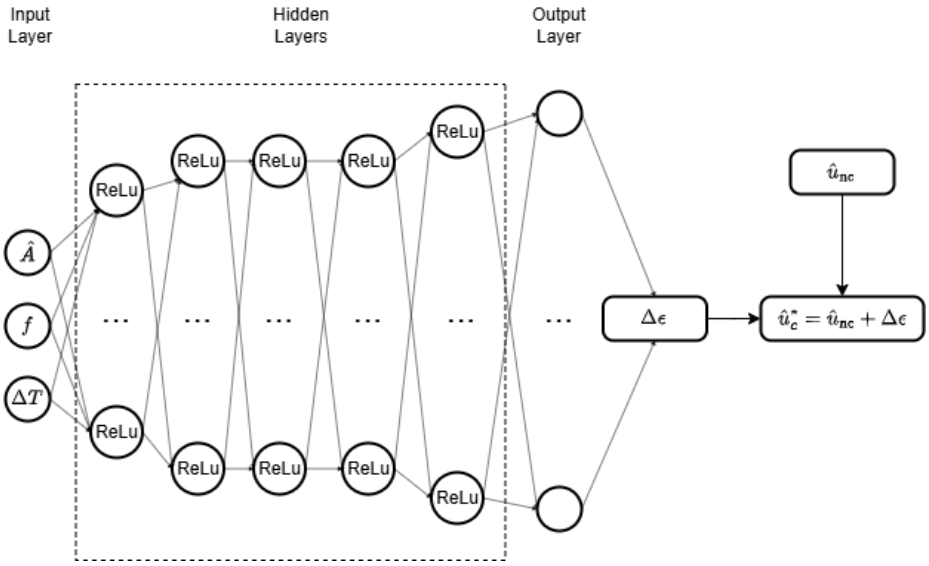

Figure 1. FNN structure used to predict the longitudinal component of the velocity signal for the controlled CASE $\hat{u}_c^*$ based on the control parameters and the longitudinal component of the velocity signal for the uncontrolled CASE, $\hat{u}_{nc}$.

The network architecture here implemented, is illustrated in Fig. 1 and comprises 5 hidden layers of dimension (16, 32, 32, 32, 64) followed by an output layer which produces as output $\Delta\epsilon$. $\Delta\epsilon$ is then added to $\hat{u}_{nc}$ to give the predicted controlled CASE signal, represented as $\hat{u}_c^*$ for a given triplet θ. The hyperparameters of the network, including learning rate, batch size, and activation

Materials Research Proceedings 69 (2026) 31-36 https://doi.org/10.21741/9781644904251-6

functions, are the same as [4]. This network will be referred to hereafter as $\mathcal{N}$. Similar results to those obtained with the network presented in [4] were achieved using $\mathcal{N}$, which features a deeper architecture with fewer neurons, leading to a reduction in the number of trainable parameters from approximately 225,000 to 53,000 (over four times fewer).

Hybrid POD-FNN model

To further reduce the size of the model, it is possible to decrease the dimensionality of the output part of the dataset. The first step is therefore to compress this dataset from $\widehat{\boldsymbol{U}}_{\boldsymbol{c}} \in \mathbb{R}^{n_d \times n_t}$ to $\widetilde{\widehat{\boldsymbol{U}}}_{\boldsymbol{c}} \in \mathbb{R}^{n_d \times n_r}$ where $n_r \ll n_t$ denotes the reduced temporal dimension of the output part of the dataset. POD [6] was then applied to decompose the dataset according to:

$$\widehat{\boldsymbol{U}}_{\boldsymbol{c}} = \boldsymbol{\phi}\boldsymbol{\Sigma}\boldsymbol{\psi}^{\boldsymbol{T}}, \quad (\mathbf{1})$$

where $\boldsymbol{\phi} \in \mathbb{R}^{n_d \times n_d}$ denotes the matrix of pseudo-spatial basis vectors, $\boldsymbol{\Sigma} \in \mathbb{R}^{n_d \times n_d}$ is the singular value matrix, and $\boldsymbol{\psi} \in \mathbb{R}^{n_t \times n_d}$ is the matrix of the temporal modes. A reduced-order approximation of the dataset, retaining only the first n_r most energetic modes, is given by:

$$\widetilde{\widehat{\boldsymbol{U}}}_{\boldsymbol{c}} = \widetilde{\boldsymbol{\phi}}\widetilde{\boldsymbol{\Sigma}}\widetilde{\boldsymbol{\psi}}^{\boldsymbol{T}}, \quad (\mathbf{2})$$

where $\widetilde{\boldsymbol{\phi}} \in \mathbb{R}^{n_d \times n_r}$, $\widetilde{\boldsymbol{\Sigma}} \in \mathbb{R}^{n_r \times n_r}$ and $\widetilde{\boldsymbol{\psi}} \in \mathbb{R}^{n_t \times n_r}$ contains only the first n_r columns or singular values. Analysis reveals that retaining only the first 7 modes (n_r = 7) is sufficient to capture more than 99% of the total energy. A reconstruction of $\hat{u}_c$ taking into account only the first 7 modes is presented in Fig. 2.

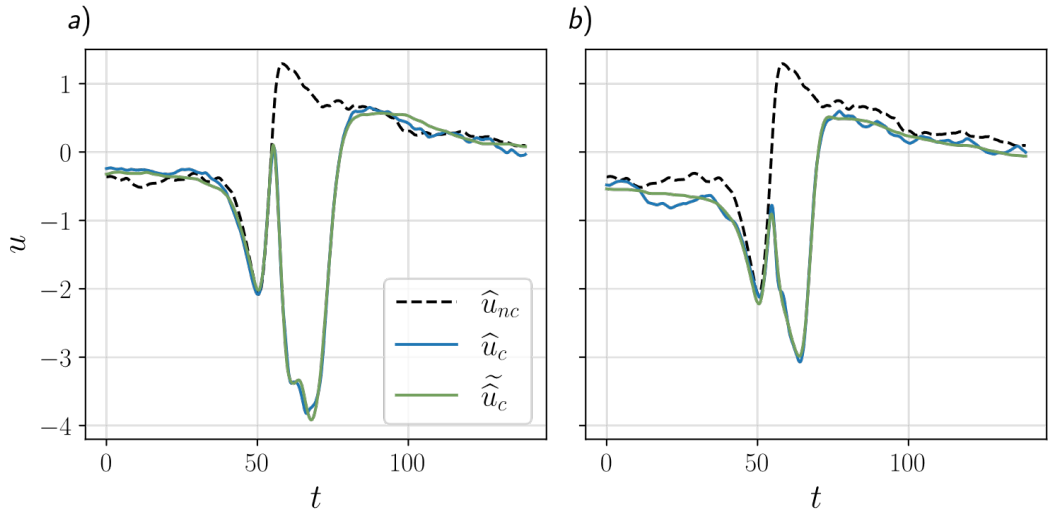

Figure 2. Longitudinal component of the velocity signal (in viscous units) for the CASEs. The superscript + is here omitted for both u and t. The black dashed lines and the blue continuous lines represent the experimentally sampled uncontrolled and controlled CASE, respectively. The green lines indicate the reconstructed CASE with the first 7 POD modes.
a) $\theta = [33.3\ Hz,\ 56.44\ mV_{pp},\ 0.65\ ms]$, *b)* $\theta = [52.49\ Hz,\ 61.59\ mV_{pp},\ 0.95\ ms]$.

Relying on this low-dimensional representation, it becomes possible to predict $\widetilde{\boldsymbol{\alpha}} = \widetilde{\boldsymbol{\phi}}\widetilde{\boldsymbol{\Sigma}} \in \mathbb{R}^{n_d \times n_r}$ from the input-parameter dataset $\boldsymbol{X} \in \mathbb{R}^{n_d \times n_i}$, where n_i=3 denotes the number of control parameters, and subsequently reconstruct $\tilde{\hat{u}}_c$ using regressors such as decision trees [7] or XGBoost regressors [8]. Although this strategy is computationally lightweight, it suffers from significant issues related to the regularization of the cost function when predicting the coefficients of $\widetilde{\boldsymbol{\alpha}}$ since each coefficient must be weighted. An alternative approach that avoids a direct regularization is to predict the coefficients of $\widetilde{\boldsymbol{\alpha}}$ using a FNN, then reconstruct $\tilde{\hat{u}}_c$ and compare the reconstruction with $\hat{u}_c$ within the loss function. In this case, the regularization is implicitly

Materials Research Proceedings 69 (2026) 31-36 https://doi.org/10.21741/9781644904251-6

enforced by the training procedure. A schematic of this hybrid POD–FNN architecture is shown in Fig. 3**.** Different architectures of the hybrid POD–FNN model were evaluated by varying the number of neurons per layer and the number of hidden layers. The learning rate and weight decay were kept identical to those used to train $\mathcal{N}$, while a greater number of training epochs (30000 vs 10000) was adopted since the model contains fewer trainable parameters. In addition an early stopping criterion was implemented to avoid overfitting [9].

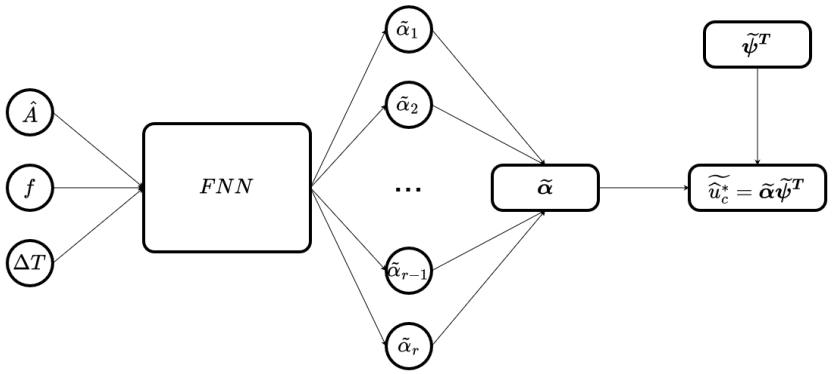

Figure 3. Schematic of the hybrid POD-FNN model. Inputs are the actuation parameters and the temporal modes. Outputs are the predicted controlled CASEs.

Models were assessed on the validation dataset using R^2 and the adjusted R^2 named R^2_{adj} as metrics [10]. R^2_{adj} accounts for the number of trainable parameters and thus penalizes excessively large networks. In Table 1, the metrics R^2 and R^2_{adj} are reported for the tested architectures identified through the sequence (*a, b, c*) where *a* is the number of neurons in the first hidden layer, *b* in the second, and *c* in the third. As expected, R^2 increases with the number of parameters. Conversely, R^2_{adj}, increases up to the architecture (8, 16, 16), named $\widetilde{\mathcal{N}}$, and then slightly decreases, even though the R^2 continues to improve. This behavior reflects the penalization term included in R^2_{adj}, whose denominator increases more rapidly than the improvement in the R^2 value due to the higher amount of trainable parameters. A comparison between the CASEs predicted by $\mathcal{N}$ and $\widetilde{\mathcal{N}}$ for the inputs in the validation dataset is shown in Fig. 4. The measured quantity to be approximated by the FNN, $\hat{u}_c$, is represented by a solid blue line, while the solid red and green lines correspond to the predicted controlled CASE obtained by $\mathcal{N}$ and $\widetilde{\mathcal{N}}$, denoted as $\hat{u}_c^*$ and $\tilde{\hat{u}}_c^*$, respectively. The comparison between the two curves indicates that both networks successfully capture the dynamics of the system, providing an accurate representation of the controlled sweep event. While $\mathcal{N}$ is slightly more accurate than $\widetilde{\mathcal{N}}$, as reflected by its R^2 value of 0.977 compared to 0.976 for $\widetilde{\mathcal{N}}$, this marginal improvement comes at the cost of a model over 90 times larger in terms of trainable parameters.

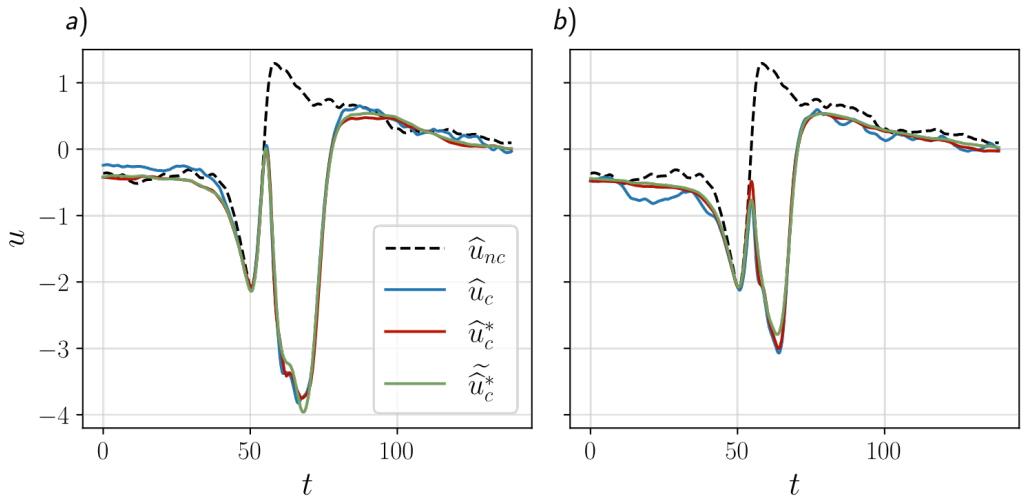

Figure 4. Evaluation of $\mathcal{N}$ and $\widetilde{\mathcal{N}}$ in the validation dataset. The black dashed line represents the uncontrolled CASE. The blue lines corresponds to the experimentally sampled controlled CASEs. The red and green lines indicate the predicted controlled CASEs with $\mathcal{N}$ and $\widetilde{\mathcal{N}}$ respectively. a) $\theta = [33.3\ Hz,\ 56.44\ mV_{pp},\ 0.65\ ms]$, b) $\theta = [52.49\ Hz,\ 61.59\ mV_{pp},\ 0.95\ ms]$.

Conclusion

In the context of opposition control, and with the goal of predicting the controlled CASE more efficiently, the first step consisted in improving the network architecture used in [4], thus reducing the number of trainable parameters by a factor of approximately four. Subsequently, aiming for an even more lightweight model, a POD analysis was performed, revealing that only 7 modes are

sufficient to capture 99% of the output dataset energy. Building on this insight, a significantly smaller FNN was trained, featuring roughly 90 times fewer trainable parameters than those adopted in $\mathcal{N}$ while achieving a comparable R^2 value.

Acknowledgments
This publication is part of the project PNRR-NGEU which has received funding from the MUR – DM 118/2023. We acknowledge the work of the student Arthur Pierre Philippe Nuvoloni for his help in defining the architecture of network $\mathcal{N}$.

Abstract. Detecting and localizing dents on aircraft surfaces is crucial for maintaining their structural integrity. However, this task can be challenging for humans as dents are not very prominent to the naked eye and require the assistance of light reflections to reveal the damages across the surface. Latest state-of-the-art technologies such as lasers or cameras digitize this step, however the workload is shifted to identifying the dents in the virtual image. The integration of deep-learning methodologies can help automate dent detection. This study compares two object detection architectures: You Look Only Once (YOLOv11) and RealTime DETection TRansformer (RT-DETR) for dent detection. A high-quality dent dataset is prepared, consisting of real and synthetic images of common long- and mid-range aircraft fuselages, to train and test the models. The results indicate that YOLOv11 marginally outperforms RT-DETR in detecting dents with a mean accuracy precision (mAP50) score of 0.66 against the mAP50 value of 0.57 for RT-DETR.

Introduction

Dents are one of the most common damages found in aircraft surfaces that are caused by external forces and affect the structural integrity. These dents need to be classified based on their size, shape, and location to assess their severity and guide maintenance decisions [1,2]. This inevitable inspection process is performed manually by technicians, and requires a significant number of work hours. Unlike other types of defects like scratches or corrosion, dents are more difficult to detect visually as there is usually no prominent change in colour [3]. Inspectors must rely on close observation and additional lighting, which can lead to eye fatigue and missed detections. Introducing deep-learning methodologies offers a promising solution by automatically detecting dents on large aircraft surfaces with high accuracy, reducing human errors and inspection time. However, most existing studies focus on larger dents and are constrained by limited training datasets for dents, which hinders the models' ability to learn diverse dent features [3,4]. This study aims to identify the most suitable approach for detecting dents with the help of light reflections, serving as the Region of Interest (ROI) for further damage assessment and decision-making. This case study focuses on dent detection on aircraft structures using visual images. In addition to the accuracy of the models, it is required that the algorithms are fast and efficient, enabling them to operate in real-time. To address this, our study implements and compares the object detection architectures, YOLOv11[1] and the RT-DETR [5]. One of the key contributions of our work is the generation of an enriched dent dataset, consisting of both real images of dents and synthetic images generated with the help of generative AI models, improving the overall results

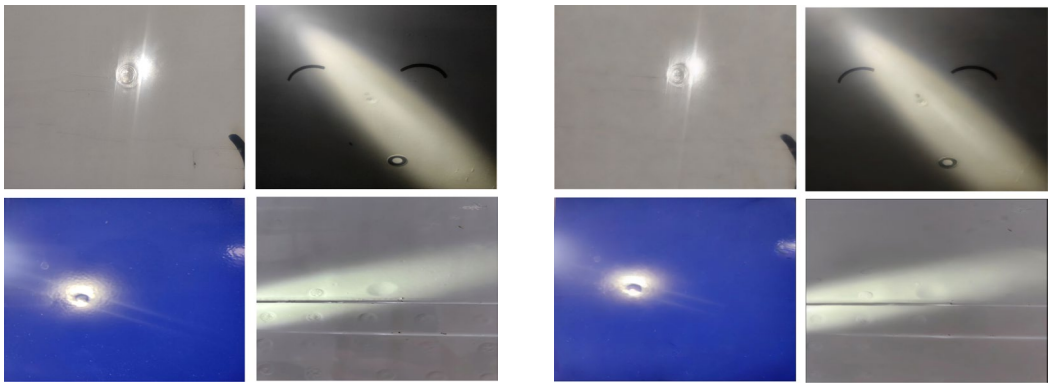
Methodology

The YOLOv11 is a versatile foundational model that is adept at object detection and instance segmentation, and suitable for real-time applications. It is available in different model sizes allowing it to cater to diverse computing environments. Similarly, RT-DETR is another state-of-the-art model in this domain, which is an end-to-end Transformer-based detector. These models are the current state-of-the-art in real-time object detection, which provide a good trade-off between accuracy and speed, making them suitable for aircraft inspection. To train the models, we prepared a high-quality dent dataset, which contains 1166 annotated images of dents across various aircraft parts including wing sections of B737 and A380. The dataset is prepared by combining the 614 real images and 552 synthetic images, which are generated with the help of a Diffusion model [6, 7], an image-to-image model. The real images capture artificial impacts created on a B737 wing section [2], and various dents caused due to hailstorms on a slat section of an A380. These images are captured under varying light conditions to replicate the diverse illumination found in aircraft visual inspections, including natural light and flashlights as well as photos from different angles. This helps capture the effect of specular light reflections across the surface to highlight dents on reflective materials and help recognize dents more accurately.

Various image acquisition methods are employed to collect the images, namely a smartphone camera, an Intel RealSense camera mounted on an inspection robot, and a digital single-lens reflex (DSLR) camera. To further augment the dataset for training, we generate synthetic images based on 276 out of 614 real images, with two synthetic images being generated for every real image, leading to a total of 552 synthetic images. More details can be found in [7]. The annotated labels on the dataset were “dent” and “no_dent”. The “no_dent” is introduced to label other types of defects such as corrosion or peeling paint to differentiate it from dents. Some sample images of the dataset are showcased in Table 1. The dataset is split into train and test datasets in a ratio of 80:20, with all the synthetic images being assigned to the training subset and only real images being used for the test subset. In total, the training dataset consisted of 933 images and the test dataset contained 233 images. To optimize training, we leveraged pre-trained YOLOv11 and RT-DETR models, which were initially trained on the popular COCO (Common Objects in Context)[2] dataset. The NVIDIA GeForce RTX 4070 SUPER GPU is utilized to finetune these pre-trained models for our specific task. The training process involved 200 epochs with a learning rate of 0.001.

Results and Discussion



After training the models for 200 epochs on the training dataset, they are evaluated on the test dataset in two ways: quantitatively and qualitatively. For the quantitative method, the mean accuracy precision of the model predictions was compared with the ground truth labels to evaluate how accurately the model localized the dents. There are two variations of mAP used to evaluate the results: mAP50 and mAP50-95, which are both valued in the range of 0–1, where a higher value indicates a better model accuracy. The mAP50 is calculated at an intersection over union (IoU) threshold of 0.5. In the mAP50-95 metric, the model’s average performance is taken across IoU thresholds from 0.5 to 0.95 in steps of 0.05. Due to this difference in the calculation, the scores of mAP50 are generally higher than mAP50-95. The quantitative results for the models are summarized in Table 2. The YOLOv11 has a mAP50 score of 0.64 and mAP50-95 of 0.27. After training the RT-DETR with the same learning rate and epochs as the YOLOv11, it achieved a mAP50 score of 0.57 and a corresponding mAP50-95 value of 0.23. Compared to other existing studies [4], where the performance for dent identification was around 0.5, our approach achieved a higher score of 0.64, indicating an improvement in dent detection accuracy.

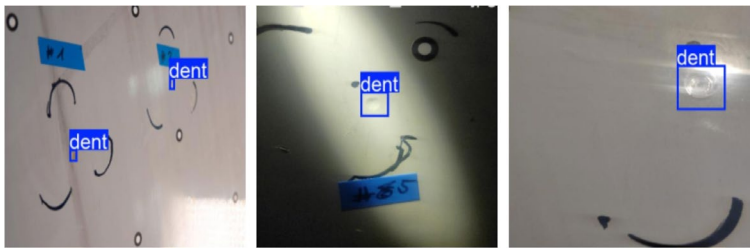
Table 1: Overview of dent dataset showing real and synthetic images under different lighting.

(a) Real Images (left box) vs. Synthetic Images (right box).



(b) Effect of light reflections across dented surface in real images.

Table 2: Quantitative results for the accuracy precision of the models.

Model	mAP50	mAP50-95
YOLOv11	0.64	0.27
RT-DETR	0.57	0.23

The qualitative method involves observing the bounding box predictions of the models, and comparing them against the annotated labels of the test dataset. The models predict bounding boxes along with a prediction label and a corresponding confidence score for each detected dent. The confidence score is in the range of 0–1 to indicate the probability of the classification being correct. A comparison of the ground truth labels against the dent predictions of YOLOv11 and RT-DETR is shown in Fig.1.

(b) Prediction of YOLOv11

(c) Prediction of RT-DETR

Figure. 1: Comparison of (a) ground truth labels against dent detection predictions of (b) YOLOv11 and (c) RT-DETR.

Based on the tests conducted, both YOLOv11 and RT-DETR demonstrated a high degree of accuracy in detecting dents across aircraft surfaces, with the YOLOv11 achieving marginally better results compared to RT-DETR. It was also observed that the introduction of synthetic images for training helped improve the accuracy of both the models as compared to when they were only trained on real images. As real images are used to generate more training images, the damages produced in the synthetic images are very similar to the dents found in a real scenario with pixel-level deviations. This introduces the required variation needed in a training dataset to enable better training of the models. The unique illumination modes employed during image capture enabled the models to comprehend the diverse ways dents can appear under different environmental conditions. This is observed in Table 1(b), where the left image reveals dents due to the gap in the line of light as it deviates around the dent, creating a stark contrast. The right image showcases shadows around the curve and partial illumination of the dent, resulting in a more nuanced representation. This approach helps develop a deeper understanding of how environmental factors influence dent appearance as well as recognize the variations in lighting conditions during inspections.

Conclusion

In this study, two deep-learning models, YOLOv11 and RT-DETR, are trained on a novel dent dataset to develop a dent detection system for aircraft damage assessment. A diverse dataset comprising real and synthetic images was used, captured under varying light conditions to account for the impact of specular light reflections on dent visibility. Comparative evaluation of YOLOv11 and RT-DETR models showed that YOLOv11 outperformed RT-DETR, albeit with a modest margin. The findings contribute to the existing literature on dent detection using deep-learning methods and highlight the effectiveness of synthetic images in datasets for more comprehensive understanding of lighting effects on surface features. Future work can build upon this work by expanding the dataset to include more synthetic images for training deep-learning architectures and exploring the use of light reflections to reveal damages.

Keywords: GNSS Positioning, Multipath Mitigation, Adaptive Weighting, Code-Minus-Carrier

Abstract. This work addresses the challenge of multipath interference in Global Navigation Satellite System (GNSS) positioning. An approach is proposed to improve accuracy through adaptive weighting strategies and multipath isolation techniques. Weighting methods based on elevation and carrier-to-noise ratio (C/N0) are employed, and this strategy is combined with a multipath detection technique using the Code-minus-carrier (CMC) rate of change. The method is tested using a Piksi Multi GNSS Module, with data processed using Standard Point Positioning (SPP) techniques. An 8-state filter based on a Position-Velocity (PV) model is implemented for dynamic state estimation. Experiments in static and dynamic scenarios demonstrate significant improvements in positioning accuracy.

Introduction

GNSS is critical for autonomous guidance, providing accurate positioning and timing. However, multipath remains a challenging error source, occurring when signals reach the receiver via multiple paths, leading to interference and range errors. Robust integrity measures are essential for detecting and identifying outliers and unmodeled errors [1]. Weighting residuals with appropriate variance models can significantly improve positioning accuracy, particularly by accounting for the elevation dependence of pseudorange errors [2]. Proper modeling of measurement variances, using dual-frequency iono-corrected code-minus-carrier combinations and Bayesian analysis, can help characterize multipath effects and develop more accurate error models [3]. In this work, we present a characterization of pseudorange errors based on both satellite elevation and C/N0. Our analysis shows that lower elevation angles generally correspond to increased pseudorange noise. Moreover, we observe that C/N0 is low not only for low-elevation satellites but also in cases of multipath or other disturbances, suggesting that C/N0 may capture a broader range of error sources compared to elevation alone. These observations motivate the use of pseudorange measurement weighting strategies in the position estimation stage. Specifically, we have chosen to test these weighting techniques within an Extended Kalman Filter position-velocity (PV) model [4]. Additionally, we employ CMC analysis to detect multipath effects, as proposed by [5]. By examining the time-differenced CMC (TDCMC), we establish thresholds for multipath detection based on satellite elevation. This allows for the identification and potential exclusion of measurements significantly affected by multipath. Our experimental results compare the performance of C/N0-based and elevation-based weighting schemes for pseudorange measurements within the Extended Kalman

Filter (EKF). The integration of CMC-based multipath detection with these weighting strategies is also evaluated.

Methodology

In this chapter, we present a two-step approach to enhance GNSS positioning accuracy. First, we conduct a characterization of pseudorange errors, analyzing their relationship with both satellite elevation and CN/0. The receiver position has been kept fixed and known during the characterization phase. Subsequently, we implement this error model within an EKF framework. The model is used to differentially weight pseudorange measurements in the EKF, optimizing the integration of satellite observations based on their expected error characteristics.

Pseudo range Characterization. Let us define the code observable:

$$R_i = \rho_i + c(dt_r - dt_i) + Tr_i + I_i + MP_i + \varepsilon_i \quad (1)$$

where the subscript i refers to the i-th satellite, ρ_i is the geometric distance between the satellite and the receiver's position, R_i is the GNSS code observation, cdt_r is the receiver clock offset delay, cdt_i is the satellite clock offset delay, Tr_i stands for the tropospheric effects, I_i gathers the ionospheric effects, ε_i constitutes the remaining errors in the code observations. The following errors: leap seconds, relativistic effects, satellite clock drift, Sagnac effect, Timing Group Delay (TGD) correction and satellite movement have been corrected. The ionospheric correction has been performed using the ionosphere-free combination of f_{L1} and f_{L2}, and the tropospheric correction using the delay model of [6]. We have considered a series of pseudorange errors $\varepsilon_{i,j}$, where i represents the i-th satellite and j represents the j-th observation. These errors are assumed to follow a normal distribution with zero mean and variance $\sigma^2(\theta)$, where θ is the elevation of the i-th satellite corresponding to that pseudorange observation. This can be expressed as $\varepsilon_{i,j} \sim \mathcal{N}(0, \sigma^2(\theta))$. Additionally, we have also considered the distribution $\mathcal{N}(0, C/N0)$, where $C/N0$ is the carrier-to-noise density ratio associated with the pseudorange observation.

For pseudorange weighting, we have considered the following variance models as in [3]:

$$\sigma^2(\theta) = a + \frac{b}{\sin\theta} \qquad \sigma^2(C/N0) = c + d \cdot 10^{-C/N0/10} \quad (2)$$

Estimation of multipath with Code Minus Carrier techniques. In addition to the code observable (Equation 1), let us define the carrier phase observable Φ_i for the i-th satellite:

$$\Phi_i = \rho_i + c(dt_r - dt_i) + Tr_i - I_i + \lambda N_i + mp_i + \zeta_i \quad (3)$$

where λ is the wavelength of the carrier signal, N_i is the integer ambiguity, and ζ_i represents the noise and multipath effects. To estimate multipath effects, first, the CMC observable is computed by subtracting the phase measurements from the code measurements (eq. 4), then, to remove the carrier phase ambiguity term (λN_i), the rate of change of multipath and noise is obtained by differencing consecutive CMC measurements (eq. 5):

$$\mathrm{CMC}_i = R_i - \Phi_i = 2I_i - \lambda N_i + MP_i - mp_i + \varepsilon_i - \zeta_i \quad (4)$$

$$\Delta\mathrm{CMC}_{i,k} = \frac{1}{\Delta t}\left(\mathrm{CMC}_{i,k} - \mathrm{CMC}_{i,k-1}\right) = 2\dot{I}_{i,k} + \dot{MP}_{i,k} + \dot{\varepsilon}_{i,k} \quad (5)$$

Materials Research Proceedings 69 (2026) 42-47 https://doi.org/10.21741/9781644904251-8

where k represents the epoch index. To characterize the behavior of $\sigma_{\Delta CMC}$ in low multipath environments, an analysis has been conducted in an open sky static scenario. Then the standard deviation of ΔCMC has been calculated as a function of the elevation angle of the satellite θ. Based on this characterization, we defined a multipath detection threshold empirically as $T_k = 3\sigma_{\Delta CMC}(\theta)$. When the absolute value of ΔCMC exceeds this threshold, it indicates a high probability of significant multipath effects on the measurement.

Extended Kalman Filter Implementation. The adopted filter is an 8-state filter based on a Position-Velocity (PV) model where the acceleration is assumed to be white noise and the velocity and position are estimated as random-walk processes. The state vector $\mathrm{x_k}$ consists of the receiver's position (x, y, z), velocity $(\dot{x}, \dot{y}, \dot{z})$, clock bias ct_r, and clock drift $c\dot{t_r}$. In the prediction phase, we estimate the state $\hat{\boldsymbol{x}}_{k|k-1}$ and the state covariance matrix $\boldsymbol{P_{k|k-1}}$ as follows:

$$\hat{\boldsymbol{x}}_{k|k-1} = \boldsymbol{A}_k \hat{\boldsymbol{x}}_{k-1|k-1} \qquad \boldsymbol{K_k} = \boldsymbol{P_{k|k-1}} \boldsymbol{H_k^T} \left(\boldsymbol{H_k} \boldsymbol{P_{k|k-1}} \boldsymbol{H_k^T} + \boldsymbol{R_k}\right)^{-1}$$

$$\boldsymbol{P_{k|k-1}} = \boldsymbol{A}_k \boldsymbol{P_{k-1|k-1}} \boldsymbol{A_k^T} + \boldsymbol{Q_k} \qquad \hat{\boldsymbol{x}}_{k|k} = \hat{\boldsymbol{x}}_{k|k-1} + \boldsymbol{K_k} \left(\boldsymbol{z_k} - \boldsymbol{h}\left(\hat{\boldsymbol{x}}_{k|k-1}\right)\right)$$

$$\boldsymbol{P_{k|k}} = (\boldsymbol{I} - \boldsymbol{K_k} \boldsymbol{H_k}) \boldsymbol{P_{k|k-1}} \tag{5}$$

where $\boldsymbol{A}_k$ is the state transition matrix, $\boldsymbol{Q_k}$ is the covariance matrix of the process noise, $\boldsymbol{K_k}$ is the Kalman gain, $\boldsymbol{H_k}$ is the measurement matrix, $\boldsymbol{R_k}$ is the measurement noise covariance matrix, $\boldsymbol{z_k}$ is the measurement vector, and $h(\cdot)$ is the measurement function. The measurement function $\boldsymbol{h}\left(\hat{\boldsymbol{x}}_{k|k-1}\right)$ represents the expected pseudorange measurements $\hat{\rho}_i$ for each satellite i, calculated as the geometric distance between the receiver position $\boldsymbol{r}_r$ and the satellite position $\boldsymbol{r}_i$, plus the receiver clock bias δt_r: $\hat{\rho}_i = \|\boldsymbol{r}_r - \boldsymbol{r}_i\| + c\delta t_r$. The noise covariance measurement matrix $\boldsymbol{R_k}$ has only diagonal elements σ_i^2 that represent the variance of the pseudorange measurement for each satellite i, as determined from the previous characterization. The observations corresponding to signals for which multipath has been identified using the ΔCMC threshold criterion are eliminated from the measurement vector $\boldsymbol{z_k}$ and the corresponding rows and columns are removed from the measurement noise covariance matrix $\boldsymbol{R_k}$.

Results

The experiments were conducted using the Piksi Multi GNSS Module (https://www.swiftnav.com/piksi-multi). Figure 1 presents the pseudorange code error profiles during the acquisition phase, with each line representing a different visible satellite. The data were acquired on July 18, 2025, at a location with latitude 45.411955° and longitude 11.898037°, focusing on GPS L1 and L2 signals. The graph displays the $\varepsilon_{i,j}$ values as calculated in equation (1). Moreover, Figure 1 provides a skyplot representation of the visible satellites, with the color of each marker indicating the C/N0, higher C/N0 values generally correspond to more reliable pseudorange measurements.

Materials Research Proceedings 69 (2026) 42-47 https://doi.org/10.21741/9781644904251-8

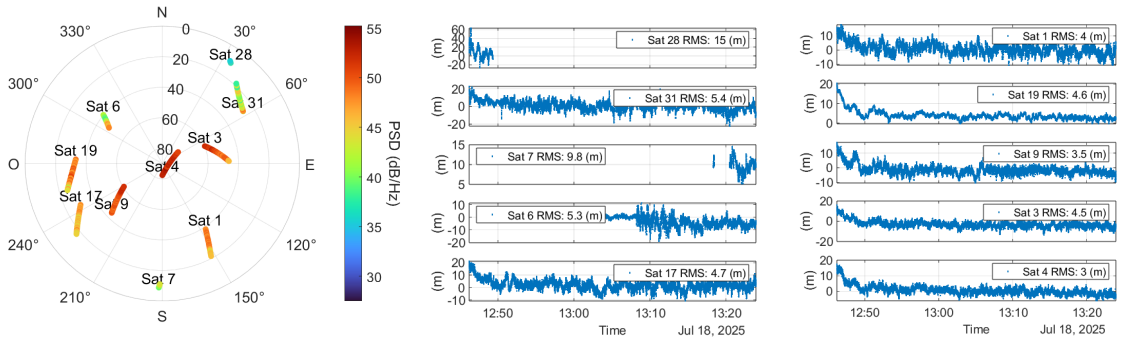

Figure 1 (Left) Skyplot of visible satellites. The C/N0 is visualized for each satellite. (Middle-Right) Pseudorange code error profiles during the acquisition phase for each visible satellite.

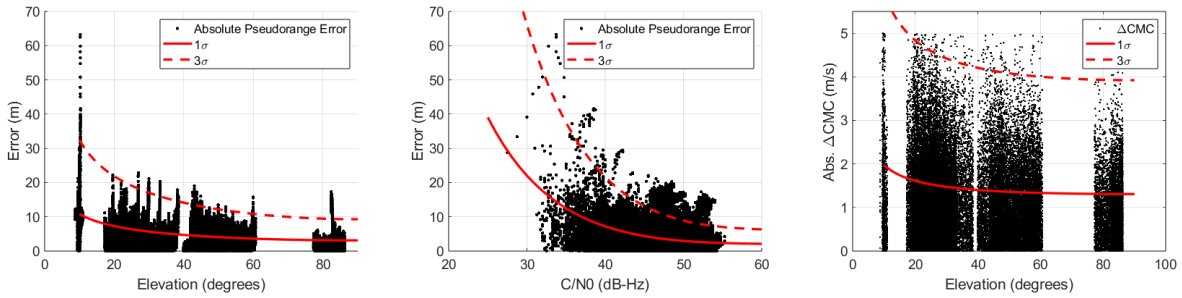

Figure 2 Statistical Characterization of Pseudorange Errors: Standard deviation of pseudorange error as a function of satellite elevation ($\boldsymbol{\theta}$) (left) and as a function of C/N0 (middle). (right) Absolute $\boldsymbol{\Delta CMC}$ as a function of satellite elevation.

Figure 2 presents the characterization of pseudorange errors $\varepsilon_{i,j}$ as a function of θ and the C/N0. It is evident that pseudorange accuracy tends to degrade at lower elevation angles, which is expected due to increased atmospheric path delays and multipath effects. Similarly, Figure 2 shows the standard deviation of the pseudorange error as a function of the C/N0. This plot demonstrates that higher C/N0 values generally correspond to lower pseudorange errors. From fitting the models in Eq. 2 to the variance found for each bin, the following variance models $\sigma^2(\theta) = -13 + 23/\sin\theta$ and $\sigma^2(C/N0) = 4 + (693^2)10^{-C/N0/10}$ have been obtained, these models have been used during the weighting phases.

The performance of the proposed method was evaluated under both static and dynamic conditions to assess its robustness and accuracy across various scenarios. The static test, performed in open sky and low-multipath environment, was conducted on July 18, 2025, from 13:27 to 13:39 UTC. This test used a precisely known reference position with coordinates latitude 45.411733 ° and longitude 11.899049 °, located in Parco Europa, Padova, Italy. Figure 3 presents the normal probability plots of positioning errors for the tested models: constant variance, elevation-weighted variance, C/N0-weighted variance, and C/N0-weighted variance with multipath isolation. The results shows that incorporating variance models significantly enhances the accuracy of localization. The C/N0-weighted variance model exhibits superior performance, yielding a distribution that more closely adheres to the theoretical normal distribution. However, in this scenario, the isolation of multipath effects does not significantly improve the performance of the C/N0-weighted variance model.

Materials Research Proceedings 69 (2026) 42-47 https://doi.org/10.21741/9781644904251-8

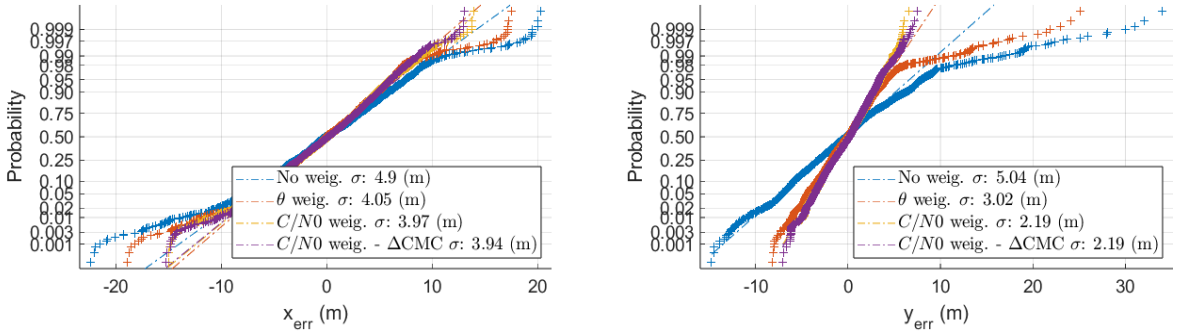

Figure 3 Normal probability plots assessing the distributional characteristics of positioning errors.

Figure 4 (Left) Comparison of trajectories reconstructed using EKF. (Right) Trajectory traveled and sections in which the presence of multipath was identified.

To assess the algorithm's performance under more challenging and realistic conditions, a dynamic test was conducted. This test involved the reconstruction of a trajectory that encompassed both open-sky environments and areas with significant building presence. Figure 4 presents the comparison of the reconstructed trajectories during this test. The blue trajectory represents the path reconstructed using an EKF with constant pseudorange variance. The orange and yellow trajectory respectively shows the results obtained using the elevation-weighted and the C/N0-weighted variance models. The purple trajectory shows the C/N0-weighted variance models combined with the multipath isolation performed with the $\Delta\boldsymbol{CMC}$ analysis. A detailed examination of the trajectories reveals that the C/N0-weighted variance model yields better results, particularly in areas prone to multipath effects. The analysis of the $\Delta\boldsymbol{CMC}$ appears to effectively identify the presence of multipath-affected zones. However, the improvement in the trajectory reconstruction is relatively small, indicating that the C/N0-based weighting scheme already mitigates the undesirable effects of multipath to a significant extent.

Conclusions

This study presents a comprehensive analysis of GNSS pseudorange errors and their impact on positioning accuracy, focused on the effectiveness of different variance models in an EKF framework. The results show the advantage of employing adaptive weighting strategies based on satellite elevation and C/N0 in both static and dynamic scenarios. Pseudorange error characterization revealed strong correlation with elevation and C/N0, providing a basis for developing more accurate variance models. The C/N0-weighted variance model outperformed constant variance and elevation-weighted models, particularly in multipath-prone environments. $\Delta\boldsymbol{CMC}$ seems to successfully identifying areas impacted by multipath. Nonetheless, the enhancement in trajectory reconstruction is minor, suggesting that, for the testes scenario, the C/N0-based weighting scheme reduces the negative effects of multipath on its own.

Keywords: Lunar Landing, Vision-Based Navigation, Moonlight, Deep-Learning

Abstract. The renewed momentum in lunar exploration has driven the development of dedicated lunar communication and navigation infrastructures such as the European Space Agency's Moonlight Lunar Communication and Navigation System (LCNS). In this context, landing operations are key mission phases that enable humans and scientific experiments to reach the Moon surface. However, recent crashes of both public and private missions have highlighted how challenging and complex such operations are. As such, this work investigates the achievable navigation performance of a lunar lander targeting the Moon's South Pole through the integration of One-Way Ranging signals from LCNS and Deep Learning–based Vision-Based Navigation measurements, showcasing the benefits that the fusion of these two distinct type of measures can bring.

Introduction

Planetary landings represent a very challenging scenario for Guidance, Navigation and Control (GNC) systems. Indeed, due to a combination of fast-landing dynamics, communication delays, and restricted coverage of landing areas, real-time ground control is often limited or impractical. Recent attempts to land on the lunar surface have further highlighted the need for an autonomous and reliable GNC module. Thus, to support these missions, the European Space Agency (ESA) is currently developing the Moonlight Lunar Communication and Navigation System (LCNS) that will provide GNSS-like signals enabling One-Way Ranging (OWR) for future lunar users. However, as the constellation will be gradually deployed, an initial key challenge will be the limited availability of such signals with respect to well-established Earth GNSS systems. Within this context, current and future landing missions rely on Vision-Based Navigation (VBN) techniques to estimate the state of the lander while minimizing the overall size, weight and power of the GNC subsystem. As such, this study aims to showcase the performance and robustness improvements that the integration of radiometric OWR signals with AI-based VBN techniques can bring to landing vehicles.

Landing Trajectory

The considered mission scenario consists in the spacecraft descent from the pericenter of an elliptical Low Lunar Orbit (LLO) (100×30 km altitude) to touchdown at a targeted landing site close to the Lunar South Pole. The trajectory reproduces the common scheme of lunar landings and begins with the Main Braking Burn (MBB), where the engines are initiated at full thrust to reduce the orbital velocity. This maneuver lasts until the lander reaches the Pitch-Up Gate (PGA), at an altitude of about 1 km, where thrust is re-oriented towards the vertical direction and the Hazard Detection and Avoidance (HDA) sensors and routines are activated. A final powered

Materials Research Proceedings 69 (2026) 48-53 https://doi.org/10.21741/9781644904251-9

descent is foreseen for the last few hundreds of meters and ends before the final vertical descent at the Vertical Gate (VGA), where the horizontal velocity becomes null.

The trajectory was generated following the expected profile of the Argonaut mission [1], using an indirect optimization technique for the main braking phase, and a semi-analytical guidance for the final approach [2]. The lander is assumed to have an initial mass of 7000 kg, a maximum thrust of 18000 N, and a specific impulse of 330s. The entire descent duration is of 584s. The target landing site has been selected near the Sverdrup crater, in proximity of the South Pole, at approximately 153° W and 88° S.

The dynamical model used to simulate the true lander dynamics includes most of the major perturbations that are relevant in a lunar scenario and that affect the navigation accuracy. Specifically, it accounts for the gravitational point-mass accelerations due to the Earth, Sun and Moon as well as the effects of the irregular lunar gravity field. The latter are modelled using a spherical harmonic expansion up to 120×120 degree and order. On the other hand, control errors are assumed null.

On-board Sensors

The lander is equipped with a monocular camera to acquire navigation images and with two antennas to retrieve the LCNS signals. An Inertial Measurement Unit (IMU) is instead used to retrieve both acceleration and angular velocity readings. Finally, a star tracker enables precise attitude measurements, with an accuracy up to 10 arcseconds. A brief overview of the mathematical modeling of each sensor is provided hereafter.

Inline with previous work [3], the LCNS constellation is comprised of 4 satellites deployed on 4 distinct Elliptical Lunar Frozen Orbits (ELFO). The constellation parameters are based on internal Moonlight studies and are designed to optimize the South Pole visibility. All satellites are deployed on orbits with a 24-hours orbital period and a nominal eccentricity of 0.63.

The Signal-in-Space Error (SISE) is modeled using a realistic Orbit Determination and Time Synchronization (ODTS) simulator [4], which provides the time series of the errors in each satellite's position, velocity, and clock states. The user on-board clock is modelled using a two-state clock model, in which the frequency deviation is originated from two types of noise, a White Frequency Modulation (WFM) and a Random Walk Frequency Modulation (RWFM). The standard deviations of the noises are based upon a space-qualified OCXO, inline with previous studies [3]. The LCNS receiver is designed to track the LunaNet AFS signal specifications using Delay Locked Loop (DLL) and Frequency Locked Loop (PLL) techniques, providing as an output the pseudorange and doppler quantities with respect to each visible LCNS satellite. The standard DLL and FLL equations are used to characterize the pseudorange and measurement noises. The patterns for the transmitting and receiving antennas are also based upon the on-going Moonlight studies [3,4].

A high-fidelity model is used to account for the measurement errors that real IMUs are subject to, including non-orthogonalities, scale factor, bias and noise errors. The parameters are loosely based upon the flight-proven LN-200HPS model from Northrop Grumman.

A monocular camera is installed on the side of the lander, at angle of 22.5° with respect to the face normal, ensuring constant visibility of the Moon surface throughout the spacecraft descent. The camera is based upon the standard pinhole model, with a 640×640 resolution and a Field-of-View (FOV) of 45°. Images of the Moon surface are generated using the in-house rendering software presented in [5]. Two distinct pipelines are used to process the acquired images.

Materials Research Proceedings 69 (2026) 48-53 https://doi.org/10.21741/9781644904251-9

Navigation Filter Architecture

The navigation module consists of an Extended Kalman Filter (EKF) to estimate the absolute inertial position and velocity of the lander together with the LCNS OWR receiver clock bias and drift, and a Multiplicative Extended Kalman Filter (MEKF) to estimate the lander inertial attitude and gyroscope bias. An overview of the entire navigation module is given by Figure 1.

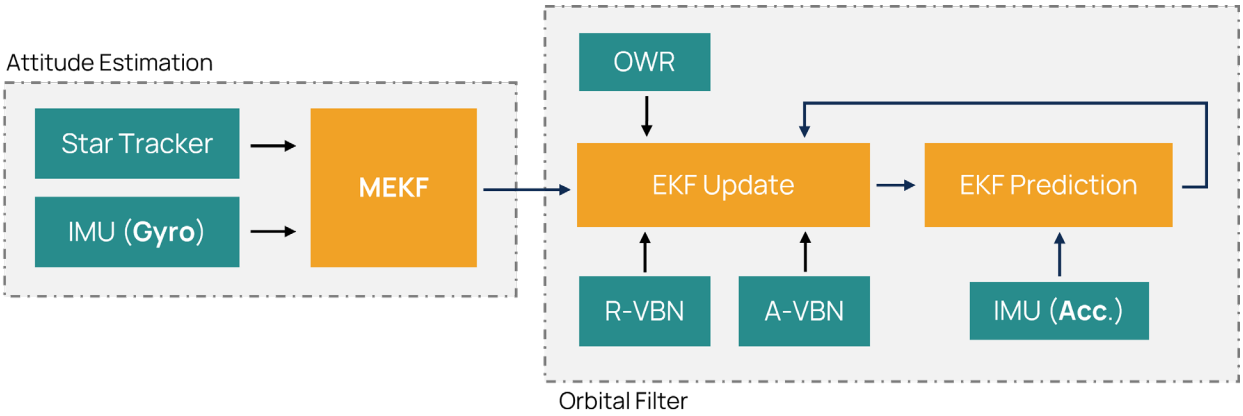

Figure 1: High-level overview of the navigation block interfaces.

The Absolute Vision Based Navigation (A-VBN) module uses Moon impact craters as landmarks, comparing them with a dedicated on-board crater catalogue to retrieve absolute estimates of the lander position. The adopted catalogue is derived from the global Robbins catalogue [6], which has been expanded by manually mapping all the visible craters along the expected spacecraft groundtrack. A Deep Neural Network (DNN) based upon the YOLOv11n architecture is used to identify the bounding box surrounding each crater. Subsequently the crater shape is fitted with an ellipse and matched against the crater database to retrieve its selenographic coordinates. The crater matching algorithm is based upon an iterative direct matching strategy, which leverages the estimated spacecraft position and orientation to project onto the image plane the on-board catalogue. Detected and projected craters are then transformed into bivariate Gaussian Probability Density Functions (PDFs), and their similarity is quantified through the Gaussian Angle distance. A RANSAC-based outlier rejection strategy is then used to identify potential wrong matches. Finally, the resulting pairs of detected and projected craters are used to assemble a Perspective-n-Crater (PnC) problem, which leverages the known spacecraft orientation and the full information from the crater shapes to compute an estimate of the spacecraft position with respect to the Moon-fixed frame [7]. The M-estimator SAmple Consensum (MSAC) algorithm is used to further mitigate the impact of outliers.

On the other hand, the Relative Vision Based Navigation (R-VBN) module integrates multiple-view geometry and deep-learning to estimate the direction of motion of the lander from one image frame to the other. It leverages SuperPoint, a deep-learning based feature extractor [8] to identify 2D features in the images, which are then matched using a brute-force approach. Using the known spacecraft attitude a system of equations enforcing the epipolar constraint is then assembled and solved for the relative camera translation direction [7]. To enhance robustness, MSAC is again adopted to reject potential outliers from the identified 2D features pairs.

Both the EKF and the MEKF filters are executed at 10 Hz, with the IMU measurements sampled at the same frequency. On the other hand, due to the post-processing requirements, the A-VBN position estimate is assumed to be available at a frequency of 0.1 Hz and with a delay of 10s (i.e., the measurement at time k is associated to the pose the spacecraft had 10 seconds before k), while the R-VBN measures are given at a frequency of 0.5 Hz. Finally, the OWR pseudorange and

Materials Research Proceedings 69 (2026) 48-53 https://doi.org/10.21741/9781644904251-9

Doppler signals are ingested at 1 Hz and fused using a tightly-coupled approach. Stochastic Cloning (SC) is used to handle both delayed and relative measurements by making two independent copies of the position states, each synchronized to the associated measurement. A simplified dynamic model is used to predict the inertial position and velocity of the lander, which uses a 40×40 expansion of the Moon gravity field. For the process noise, the global contribution of unmodelled dynamic accelerations and IMU biases is assumed to behave as a First-Order Gauss-Markov (FOGM) processes, following the Dynamic Model Compensation (DMC) algorithm. On the other hand, the process noise of the clock states assumes the clock drift is also driven by a FOGM, while the clock bias is the integral of the drift plus a Gaussian noise term.

Results and Discussion

A Montecarlo simulation with 200 samples has been performed for two distinct scenarios, with 2 and 3 visible LCNS satellites, respectively. The results in terms of 3D position error are reported in Figure 2. In both cases the final navigation error is very small, under 7m (99th) with 2 satellites and smaller than 5m (99th) with 3. A comparison between the two also highlights a faster convergence when 3 satellites are available, as well as the maximum error being smaller than 40m with respect to the 50m achieved when only 2 LCNS signals are tracked.

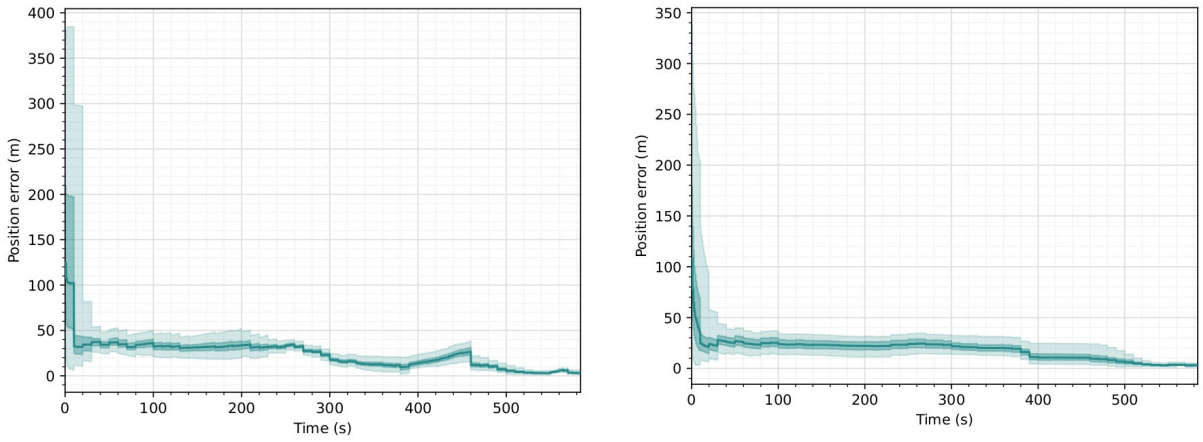

Figure 2: 3D position error throughout the descent with 2 (left) and 3 (right) LCNS satellites in visibility

The benefits of merging VBN and OWR measurements can be further appreciated by comparing the results in Figure 2 with those in Figure 3, which reports the Montecarlo simulations when VBN-only measures are considered. Indeed, despite the VBN-only solution already provides a satisfactory final navigation error below 20m (99th), the addition of OWR measurements further improves this result, reducing the maximum navigation error after the initial convergence from 100m to around 50m. Moreover, these added signals can also prove beneficial when above areas that are either not covered by the on-board crater catalogues or are characterized by unfavorable illumination conditions, scenarios in which the VBN may struggle to provide meaningful measures.

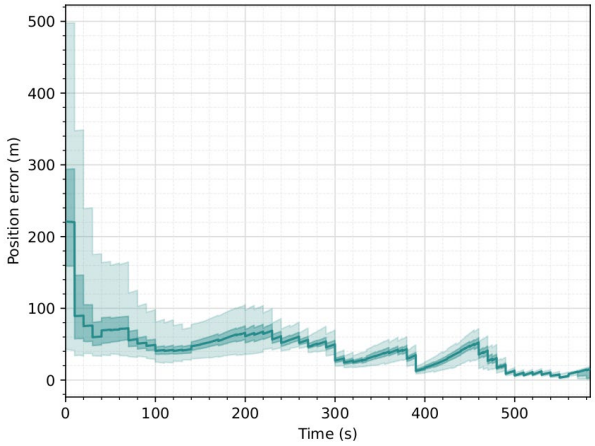

Figure 3: 3D position error throughout the descent trajectory with VBN-only measurements

On the other hand, it is well known that for OWR measures, a minimum of 4 visible satellites is requested to compute a position-fix. In this regard, these simulations highlight that the addition of VBN measurements allows a stable navigation solution to be computed even with limited LCNS availability.

Conclusions

The International Space Exploration Coordination Group (ISECG) has quantified 90m as a threshold for the maximum landing uncertainty with respect to the target location that guarantees the safety of the operations. This contribution shows that the fusion of vision-based and radiometric data from the proposed LCNS constellation is capable of meeting this strict navigation requirement over a candidate landing site at the Lunar South Pole. Moreover, it highlights the robustness of the solution even when only a portion of the LCNS satellites is visible.

Keywords: Metamaterials, Acoustic Metacontinuum, Spacetime, Metasurfaces, Convective Metasurfaces

Abstract. Acoustic metamaterials enable advanced wavefront control, offering compact and lightweight solutions for noise reduction in aeronautical applications. As thin metasurface, they can be integrated onto existing structures, like nacelle intakes or control surfaces, to absorb or redirect acoustic energy. However, performance degrades in the presence of a background flow due to the change in the mechanism of propagation of the acoustic perturbation. To address this, a spacetime-based analytical framework incorporates flow effects in the medium design by introducing spacetime coordinate transformations. The mathematical tools of differential geometry extend the applicability of static designs to convective environments. This study evaluates the performance of a convective phase gradient metasurface based on a space-coiled, 8-unit cell design, optimised for frequency robustness. Numerical solutions obtained in the frequency domain aim to assess the capability of a flow-corrected design in maintaining wave deflection under grazing flow.

Introduction

Metamaterials have revealed themselves to be a powerful technology to achieve the full control of moulding wavefronts, a task hard to accomplish with the existing materials due to the limitations of their material properties. By intending the meta-device as a three-dimensional composite of periodic or non-periodic structure, tailored responses to specific excitations are affordable [1]. Therefore, exotic wave manipulations (*i.e.*, metabehaviours) can be realised, and in the context of aeronautical applications, acoustic metamaterials appear as a promising strategy for noise abatement purposes [2]. The interest in this advanced technology solution is increased by the possibility of generating exotic wave manipulation with light and compact solutions that do not penalise the weight nor the size of the aircraft. In this fashion, the meta-device appears in the form of a metasurface - *i.e.*, a thin distribution of a material – [3] that can be implemented as a superficial treatment of the already existing surfaces of the airfoil, thus representing an acceptable solution that does not require the innovation of the aircraft concept and layout.

Such could be used to generate absorption of the acoustic energy or the steering of the wavefront in a target direction [2, 4]. The solution is mainly implemented in the nacelle intakes [5], but it could also be applied on the flight control surfaces. However, the topic still captures the research efforts' interest since, in aeronautics, it is not possible to neglect the interaction effects between acoustic waves and the complex background field that develops from the fluid-structure interaction. This coupling alters the propagation mechanism of the acoustic perturbation, causing metadevices to lose their effectiveness in manipulating acoustic wavefronts [6,7]. Different research groups tried to overcome such limitations, introducing correction factors in the design parameters [8,9,10]. Nevertheless, it is believed that the solution can be found in the analytical framework proposed in 2020 in Iemma and Palma [11] based on the combination of the acoustic metacontinuum model of Norris [12] and the spacetime reinterpretation of the convective phenomena [13, 14]. Indeed, spacetime curvature is generated whenever the propagating medium

manifests anisotropic acoustic parameter distribution or whenever there is convection. Therefore, it appears reasonable to describe the phenomenon in a (3+1)-dimensional differential manifold, where the equations governing the acoustic perturbation propagation show up in a conservative form. Based on these observations, it is possible to introduce the background flow information into the analytic design of the acoustic metacontinuum by exploiting the formal invariance of the governing equations to spacetime change of coordinates. The approach has already been tested on a cloaking benchmark in a context of high-fidelity models for the hosting fluid and experimentally realisable Gaussian-beam acoustic sources [15], where some correction defect is still present in the convective design. However, it is also proven that the approach is not influenced by the specific acoustic mirage aimed at, but limited solely by the possibility of including general flow conditions through the specific spacetime mapping used [16]. Therefore, in the present work, the performance of convective phase gradient metasurfaces (PGMs) is evaluated.

Analytical Modelling of a Convective PGM

The acoustic metasurface considered is in a space-coiled solution, which guarantees the compactness of the device, and it is based on a unit cell of eight units [17]. The building blocks operate in a 2π phase range, and their performances are optimised in the sense that their dependency on the frequency of the incoming wave is minimised. Therefore, the optimum design proposed in [18] is associated with the constructive parameters of the eight-block unit cell that provides an equispaced phase delay in the scattered field. The acoustic behaviour of this assembly is then associated with the behaviour of an equivalent acoustic metafluid model. Hence, the framework relies on the extended continuum model of Norris in [12] (*acoustic metacontinuum*) whose governing equation for the acoustic fluctuation propagation is in terms of pseudo-pressure, and, in the present test case, it assumes the form

$$\partial_{tt} p + K \nabla \cdot (\boldsymbol{\rho}^{-1} \nabla p) = 0, \tag{1}$$

by having addressed the anisotropic material parameter distribution of the device to the inertia tensor $\boldsymbol{\rho}$, and being K the space-varying function for the bulk modulus. The metafluid cell can mimic the acoustic behaviour of the original cell by properly defining $\boldsymbol{\rho}$ and K through the following coordinate transformation

$$x = X, \quad y - y_0 = \frac{l_{mf}}{l_{eq}}(Y - Y_0), \quad z = Z \qquad \text{with} \quad Y_0 < Y < l_{eq}, \tag{2}$$

with l_{eq} the equivalent length of a straight channel associated with the space-coiled cell, and l_{mf} is the arbitrarily chosen thickness for the equivalent metafluid domain. Therefore, the parameters in Eq. (1) are specified by the deformation gradient tensor $\boldsymbol{F}$ associated with the transformation in Eq. (2), as

$$K = K_0 \det(\boldsymbol{F}), \quad \boldsymbol{\rho} = \rho_0 det(\boldsymbol{F})(\boldsymbol{V}\boldsymbol{V}^T)^{-1}, \tag{3}$$

with K_0 and ρ_0 the referenced values for the metacontinuum to fulfil the impedance matching condition with the external conventional fluid, and avoid any unwanted reflection.

In [18], the consistency of the results obtained concerning the implementation of the whole architecture has already been proven through a cost-efficient optimization framework. Nevertheless, the device maintains its performance if it is set to operate in a quiescent medium. Therefore, the work aims at assessing the performances of an aeroacoustic PGM whose static design is the one obtained in [18] and represented by Eqs. (1) and (2), and where the background

flow features are included through the spacetime framework proposed in [11]. Specifically, by moving in a $(3+1)$-dimensional differential manifold, it is possible to recast Eq. (1) as

$$\partial_\mu (W^{\mu\nu} \partial_\nu p) = 0, \tag{4}$$

where $\boldsymbol{\partial}$ is the fourth-dimensional nabla differential operator, and $\boldsymbol{W}$ is the second-order tensor enclosing the metric information associated with the propagating mechanism of the acoustic perturbation. The adaptation of the static design is thus provided by the introduction of the Prandtl-Glauert transformation that, in a spacetime formalism, assumes the form

$$\xi_0' = \beta \xi_0 + M_\infty \xi_2', \quad \xi_1' = \xi_1, \quad \xi_2' = \frac{\xi_2}{\beta}, \quad \xi_3' = \xi_3, \tag{5}$$

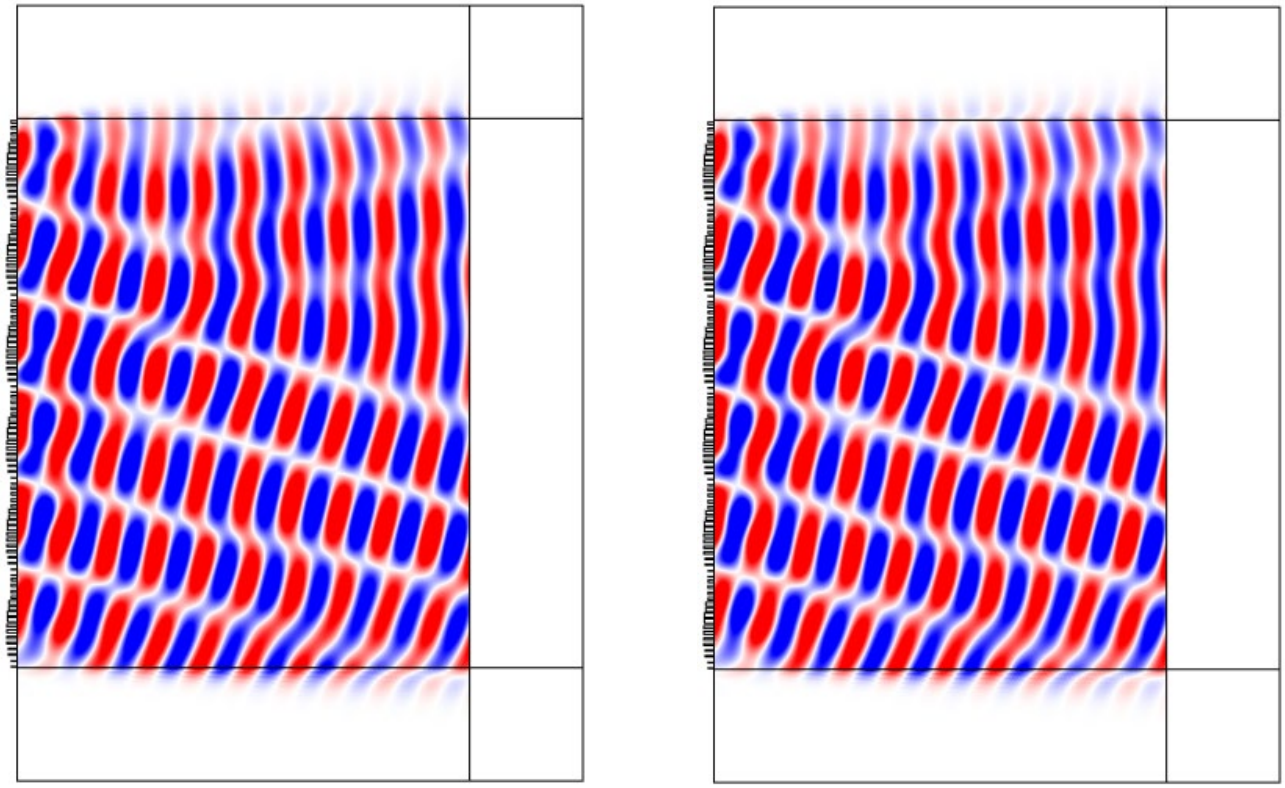
being $\beta = \sqrt{1 - M_\infty^2}$ the Prandtl-Glauert contraction factor along the y direction. Equation (5) associates a propagation uniformly convected by the free stream with an equivalent isotropic pattern field. Therefore, if $\boldsymbol{\Lambda}$ represent the Jacobian matrix for Eq. (5), then its inverse must be implemented to adapt the acoustic metacontinuum design enclosed in $\boldsymbol{W}$ to convective environments

$$\boldsymbol{W}_c = \boldsymbol{\Lambda}^{-1} \boldsymbol{W} \boldsymbol{\Lambda}^{-T}, \tag{6}$$

being $\boldsymbol{W}_c$ the spacetime-corrected tensor enclosing the new metacontinuum design where the background flow characteristics captured by $\boldsymbol{\Lambda}^{-1}$ are accounted for.

Numerical Results

To assess the performance of the resulting convective PGM, numerical simulations are performed in the frequency domain through a commercial FEM solver. The test case chosen sees a rectangular domain addressed to the external conventional fluid, modelled as a linearised potential fluid, and with which the metadevice is in communication. A plane wave is proceeding from right to left and is impinging on the left boundary where the metacontinuum is disposed. A uniform background flow of Mach 0.3 from top to bottom is introduced to include the effect of a grazing flow. The simulations are performed in the frequency domain, with a working frequency of $f = 857.5\ [Hz]$ that corresponds to a wavelength of $\lambda = 0.4\ [m]$, which is one-tenth the distance between the left and right boundaries of the domain. Perfectly Matched Layers (PML) surround the boundaries in communication with conventional fluid. Figure 1 assesses the equivalence of the performances in static conditions ($M_\infty = 0$), with the reflected wave correctly deflected downward for both configurations. However, the introduction of the grazing flow associated with a Mach number of 0.3 and indicated by the red arrows in Fig. 2, causes a substantial reduction ability of the static design to perform the expected extraordinary reflection (see Fig. 2a). On the other hand, the adapted design can maintain the deflection of the wavefronts in the lower part of the domain (see Fig. 2b). Unwanted reflections are observed in the upper part of the computational domain. They are likely related to numerical artefacts, such as imperfect absorption in the PML region or the limited domain extent.



Conclusions

An analytically adapted design for a metasurface performing extraordinary reflection has been numerically evaluated. The spacetime framework used to derive the PGM design is independent of the specific acoustic mirage aimed at. In fact, concerning the state of the art where spacetime transformations are applied on a cloaking benchmark, here the spacetime-corrected

Materials Research Proceedings 69 (2026) 54-59 https://doi.org/10.21741/9781644904251-10

metacontinuum is used to recover the performance decay of a static PGM. The numerical simulations presented in this work corroborate this assumption by displaying a pressure field that maintains the expected deflection towards the lower part of the domain, even in the presence of a grazing flow. Still, the resulting device should be tested in its sensitivity to the frequency emissions, to assess whether the optimised static design maintains its robustness to the frequency of the incoming wave.

Keywords: Turbulent Boundary Layer, Wall-Pressure Fluctuations, Chase Model, Deep Learning, Transformers

Abstract. The structural vibrations and aerodynamic noise induced by the wall-pressure fluctuations due to a turbulent boundary layer have received great attention in recent years. Nowadays, the prediction of the vibroacoustic response of structures subjected to this type of source relies on the use of statistical quantities and semi-empirical spectral models in the frequency-wavenumber domain. This work explores machine learning techniques to reconstruct the complex coherence function from the structural response. The behaviour of a rectangular plate under stochastic loading is simulated using the Chase model for four flow conditions, and the resulting response at grid points is used to train an encoder-only transformer. The results show that the algorithm satisfactorily reproduces the Chase-like coherence trends at all the flow conditions.

Introduction

The interest of all major sectors of transportation engineering in the effects of the turbulent boundary layer (TBL) and resulting wall-pressure fluctuations (WPFs) has grown in recent years, as the generated dynamic loads induce mechanical vibrations and structural noise [1]. Being far from negligible, the structural noise has a detrimental impact on the acoustic comfort of passengers and crew members, whereas structural vibrations may impair the operating life of the system.

The investigation of these issues is still nowadays an intrinsically complex challenge. The stochastic nature of the WPFs can be described only through statistical quantities, such as mean-square pressure or two-points correlation functions, typically modelled via semiempirical formulations based on a combination of theoretical assumptions and experimental observations. Several methods have been proposed in literature ranging from mathematically simple formulations to analytically more complex descriptions, like Chase model [2], which offers great accuracy at the cost of an increased number of empirical constants, to be determined experimentally. The Chase model describes the two-points pressure spectrum, which is the product between the auto-spectrum, conveying the amplitude information, and the coherence function, carrying the spatial information, therefore essential for the accurate estimation of the load distribution over the structural domain.

The objective of this work is to exploit the potential of deep learning techniques to reconstruct the Chase-like coherence function of the two-point spectra of TBL-induced WPFs from the structural response of a plate subjected to TBL loading. The main aim is to assess whether a data-driven algorithm can be trained to learn and reproduce the behavior of this function, therefore enabling the reconstruction of the pressure field over a structure subjected to random loading.

Materials Research Proceedings 69 (2026) 60-65 https://doi.org/10.21741/9781644904251-11

Machine learning has already been applied to reconstruct models of TBL-induced WPFs [1, 3], however its use was limited to the reconstruction of real-valued functions. This work proposes an encoder-only transformer to reconstruct the complex coherence function, treated as a sequence in the machine learning sense [4], starting from response data and flow conditions.

Encoder-only transformer and dataset

The deep learning method chosen for this activity is an encoder-only transformer (EOT) [5, 4], preferred to other methods as the problem at hand requires a direct mapping over a fixed frequency grid, the encoder block has substantially a fixed structure, reducing the hyperparameter tuning to a limited number of global variables, and the multi-head self-attention mechanism allows to model explicitly long-range dependencies, rather than focusing on local patterns. Fig. 1 displays the structure of an encoder-only transformer.

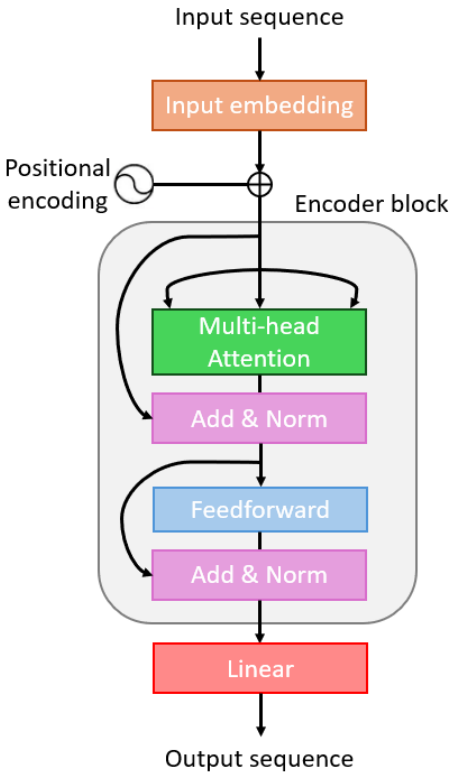

Figure 1 - Structure of the encoder-only transformer.

The test case is a rectangular, plexiglas plate with dimensions 0.58×0.20×0.003 m^3, subjected to a TBL loading at four different flow conditions and clamped boundary conditions. The numerical mesh is made of 29 × 10 grid points. Modal analysis is performed, and the estimated mode shapes are used to calculate the structural response under stochastic load, representative of a TBL excitation described by Chase model, with parameters, flow characteristics and approach reported in Ciappi et al. [6] and Casaburo et al. [1]. These results are used as part of the dataset.

The input to the transformer consists of both scalar and sequential features. The scalar input comprises nine quantities: the nondimensional x and y coordinates of the two points, the nondimensional stream- and cross-wise distances, the flow speed outside the boundary layer, the friction velocity, and the boundary-layer thickness. These are followed by six sequences of length 100, given by the amplitude and phase of the structural response autospectrum at each of the two points. To better exploit the phase information and avoid discontinuities, each phase sequence is split into two sequences defined by its cosine and sine. The output of the transformer consists of two sequences of length 100, representing the real and imaginary parts of the coherence function.

Materials Research Proceedings 69 (2026) 60-65 https://doi.org/10.21741/9781644904251-11

This choice is motivated by the strong instability of the phase sequence and to limit the output prediction to only two sequences, instead of three, which would be required if a sine/cosine transform were applied directly to the coherence phase. The dataset is augmented by considering all possible pairs of grid points, discarding symmetric pairs and all cases in which the response is identically zero due to the boundary conditions. For each flow condition, 39,402 observations are provided, resulting in a full dataset with size 157,608 × 809. The dataset is polluted with 5% magnitude Gaussian noise and is split into a training set, containing the observations from three flow conditions, and a test set, containing an unseen flow condition. This setup is more appropriate to assess the generalization capability of the transformer, since mixing all flow conditions across the training and test sets would lead to information leakage and overestimated performances. For the same reason, standardization is performed using only the statistical estimators computed on the training set.

The optimal transformer for the task at hand has the hyperparameters and training settings summarized in Table 1. While the initial values were chosen according to rules of thumb from the literature [5], the final configuration was determined by analysing the training and test errors.

Table 1 - Hyperparameters and training settings of the encoder-only transformer.

Training settings	Value
Model dimension	160
Scalar embedding dimension	64
Sequence embedding dimension	96
Batch size	128
Dimension feedforward network	768
Dropout ratio	0.1
Number of encoder layers	8
Number of attention heads	4
Weight decay	0.015
Number of epochs	100
Gradient accumulation factor	2
Ratio of used datasets	0.25

Both the real and imaginary parts of the coherence function exhibit a variable-length tail with values close to zero, which biases the training loss. In fact, even an initial and trivial prediction close to zero already yields a low average error, providing a weak learning signal on the non-zero part of the coherence and limiting the model's ability to improve. For this reason, being $\tilde{E}(f)$ the normalized energy of the signal in frequency, every output sequence is modulated with weights $w(f)$ defined as

$$w(f) = 0.1 + 0.9\tilde{E}(f) \tag{1}$$

Huber loss with $\delta = 0.25$ is adopted for training, and AdamW is used as optimizer to obtain a more interpretable and effective weight-decay behaviour [7]. The learning rate is controlled by a scheduler that first applies a warm-up phase, in order to prevent exploding gradients during the initial epochs and to mitigate the sensitivity of transformers to the initial learning rate. After the warm-up, a cosine decay schedule is employed for fine tuning. Optimizer stability is further improved through gradient accumulation. Additional mechanisms introduced to reduce weight noise and overfitting include dropout, exponential moving averaging of the weights, and stochastic weight averaging.

Materials Research Proceedings 69 (2026) 60-65 https://doi.org/10.21741/9781644904251-11

Validation of transformer performances

The training and generalization capabilities of the transformer are assessed through four tasks, each training the model on three flow conditions and testing it on the fourth, which is excluded from the training set. The average training and test errors over three runs for each task are reported in Fig. 2. While the training errors (Fig. 2, left) show similar decreasing trends as the number of epochs increases, the test errors (Fig. 2, right) strongly depend on the specific task. Lower test errors are obtained when the 30 kn and 35 kn flow conditions are used as test cases, whereas for 25 kn and 40 kn the test error tends to increase and then plateau, leading to overall lower performance. This behaviour is expected: generalizing to flow conditions at the extremes of the considered range is more challenging for deep learning models. The numbers in the right plot indicate the best epoch.

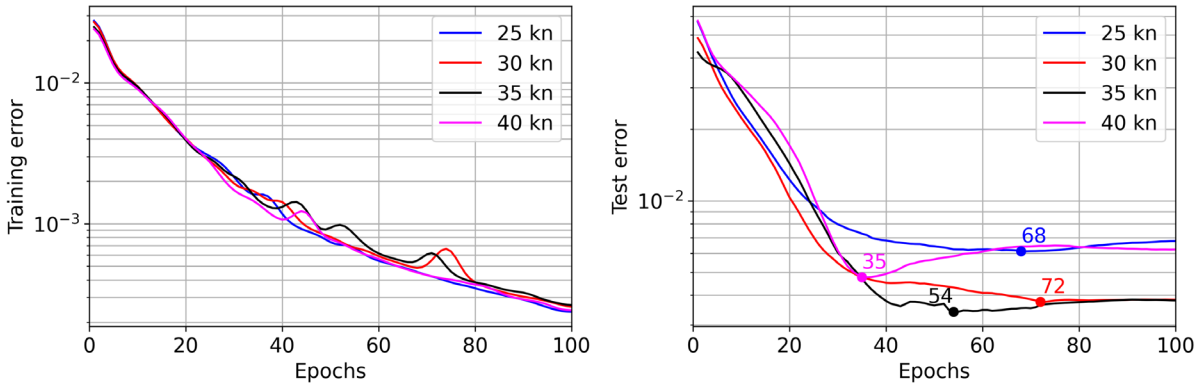

Figure 2 - Average training and test errors for each flow condition. Left: training error. Right: test error.

The reconstruction of the real and imaginary parts for four observations, each corresponding to a pair of points at different distances at 35 kn, is shown in Fig. 3, where the target sequences are compared with those predicted by the transformer at the best epoch. Further confirmation of the transformer's performance is provided in the left part of Fig. 4, which shows the magnitude of the coherence function, a representation closer to those commonly reported in the scientific literature. The target sequence is estimated with the Chase model. The stream- and cross-wise distances (ξ, η) are in meters, and they are indicated, along with the flow stream direction, in the right part of Fig. 4. The predictions shown in Figs. 3-4 are consistent with the test errors reported in Fig. 2 and further confirm the reliability of the encoder-only transformer architecture.

Conclusions

An encoder-only transformer is trained to reconstruct the Chase-like complex coherence function of the TBL-induced WPFs acting on a rectangular plate, starting from structural response and flow conditions data. Four tasks are performed, each one using three flow conditions for training and one condition for testing. The overall performances are satisfactory, as the chosen architecture provides good reconstruction of the output sequences, even for flow conditions at the boundaries of the considered range. These results pave the way for further generalization tests and the introduction of experimental measurements.

Keywords: Convolutional Neural Networks (CNN), U-Net, Computational Fluid Dynamics (CFD), Field Reconstruction, Super-Resolution, Multifidelity

Abstract. In recent years, there has been a growing interest in applying deep learning techniques to Computational Fluid Dynamics (CFD), particularly for accelerating simulations and enhancing data resolution. This work explores the use of Convolutional Neural Networks (CNNs) to reconstruct high-resolution CFD fields from low-resolution inputs. A U-Net architecture was selected due to its proven ability to capture both global context and fine-scale features through its encoder–decoder structure combined with skip connections, facilitating detailed reconstructions. The study focuses on two canonical CFD problems: a bump-in-a-duct configuration and a hydrogen combustion chamber. These cases were chosen to encompass both non-reactive and reactive flow regimes and to test the generalization capability of the model under different physical conditions. The network was trained to predict high-resolution pressure, axial velocity, and heat of reaction fields from their corresponding low-resolution versions, thus performing a super-resolution task. Due to the limited size of the available dataset, several regularization techniques were employed to improve model robustness, including Dropout layers and Batch Normalization. Additionally, different data normalization strategies were tested, such as Z-normalization and Min–Max scaling, to enhance training stability and ensure faster convergence. A multi-network approach was also developed to separately handle the prediction of pressure fields and that of axial velocity and heat release rate, mitigating the risk of feature mixing and allowing each network to specialize in learning specific patterns. The datasets were generated using two solvers: a custom Fortran-based code solving the non-dimensional Euler equations, and the commercial CFD software Ansys Fluent for more complex reactive flow simulations. This combination enabled the creation of a multifidelity database, covering a wide range of fluid dynamic behaviors and ensuring better generalization capabilities during training and validation phases. The training process involved careful hyperparameter optimization, early stopping strategies, and loss function selection to prevent overfitting and maximize prediction quality. Quantitative assessments demonstrated prediction errors on the order of a few percent, while qualitative analyses confirmed the ability of the models to accurately reconstruct the flow structures, even in complex reacting flows. The final phase of the project focused on identifying potential future developments of the proposed framework, particularly exploring the capability of the U-Net architecture to address a broader class of problems. One promising direction involves extending the methodology to correct two-dimensional solutions in order to approximate three-dimensional flow fields. This approach consists of training the network with the 2D planes extracted from the full 3D simulations. Furthermore, techniques such as data augmentation could be implemented to improve the model's generalization and robustness. The main contribution of this work includes the dataset generation, the design and implementation of the U-Net architecture, the training framework, and the

performance evaluation. The results highlight the promising role of CNN-based surrogate models in enhancing CFD simulation capabilities and accelerating future engineering workflows by enabling fast and accurate predictions across different fidelity levels.

Introduction

Deep learning approaches are increasingly used to complement conventional CFD [1] solvers, aiming to accelerate simulations, reduce computational costs, and improve data resolution [2]. Convolutional Neural Networks (CNNs), with their strong capability in pattern recognition and feature extraction, have shown potential in reconstructing high-fidelity flow fields from coarse data. This study applies a U-Net-based CNN architecture to perform a super-resolution task on CFD fields. The goal is to recover high-resolution distributions flow field from their corresponding low-resolution counterparts.

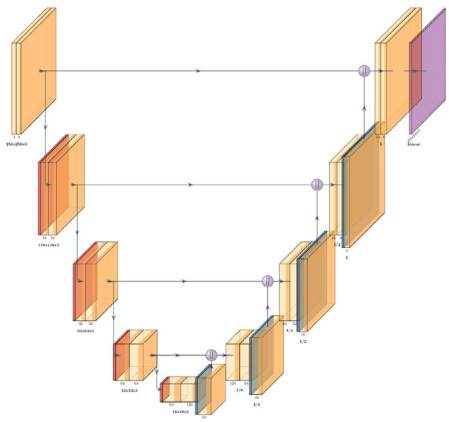

Figure 1 : The U-net structure.

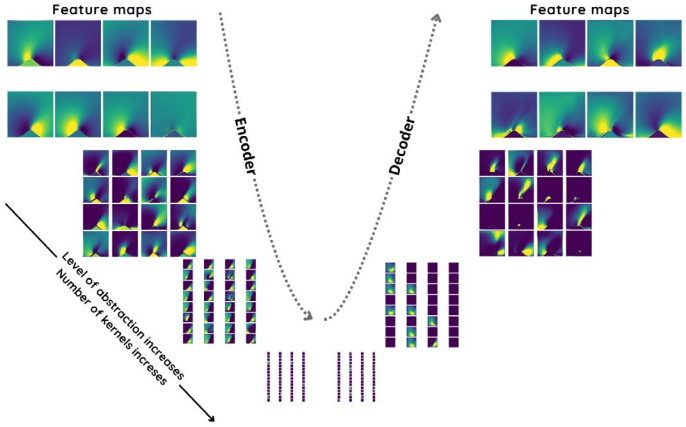

Figure 2: Feature maps extracted during training.

The classic U-Net [3] (Fig. 1) follows a symmetric **encoder-decoder** structure with **skip connections**. It consists of two main parts:

- **Contracting path (encoder)**: this path captures context through successive applications of *convolutions*, each followed by a non-linear *activation function* and a *max-pooling* operation for downsampling. With each downsampling step, the number of feature channels doubles.
- **Expanding path (decoder)**: this path performs *upsampling* of the feature maps using interpolation methods (e.g., nearest-neighbor, or bilinear) followed by convolutional layers. Each step halves the number of channels and concatenates the result with the corresponding feature maps from the contracting path (skip connections). This fusion helps the network localize features accurately.

The network ends with a 1x1 convolution to map the last layer feature vector to the desired number of output classes or regression values. This architecture allows the U-Net to combine coarse contextual information with fine spatial details.

Core Operations in U-Net

The U-Net architecture relies on a sequence of well-established operations in deep learning, we treated many of them in the previous section:

Materials Research Proceedings 69 (2026) 66-71 https://doi.org/10.21741/9781644904251-12

- **Convolution**: each convolutional layer applies learnable filters (typically 3x3) to the input feature maps. At the beginning of training the kernel are randomly weighted. The output of this operation is a set of output channels known as **feature maps**.
- **Max Pooling**: a downsampling operation where a window (commonly 2x2) slides over the input, and only the maximum value within the window is retained.
- **Upsampling**: In the decoder, spatial resolution is restored using learned upsampling, typically with *nearest neighbor* or *bilinear interpolation*, followed by convolutional layers to refine the features.
- **Concatenation (also known as Skip Connections)**: Skip connections link encoder and decoder features at equal resolutions, preserving spatial details and aiding gradient flow. They prevent vanishing gradients, enhance training efficiency, and merge low-level and high-level information, enabling precise segmentation even with few labeled samples.

A python framework (Fig. 3) has been written in order to:

- Import CFD scenes from the solver and interpolate them onto a uniform grid.
- Crop a subregion of interest and apply a mask for out-of-domain points if needed.
- Normalize the dataset using different strategies.
- Train the U-net with two approaches:
  1. Run a single U-net model for all fields.
  2. Run separate U-net models for each field.
- Correct the low-fidelity simulation, denormalize the output, and interpolate back to the original grid.

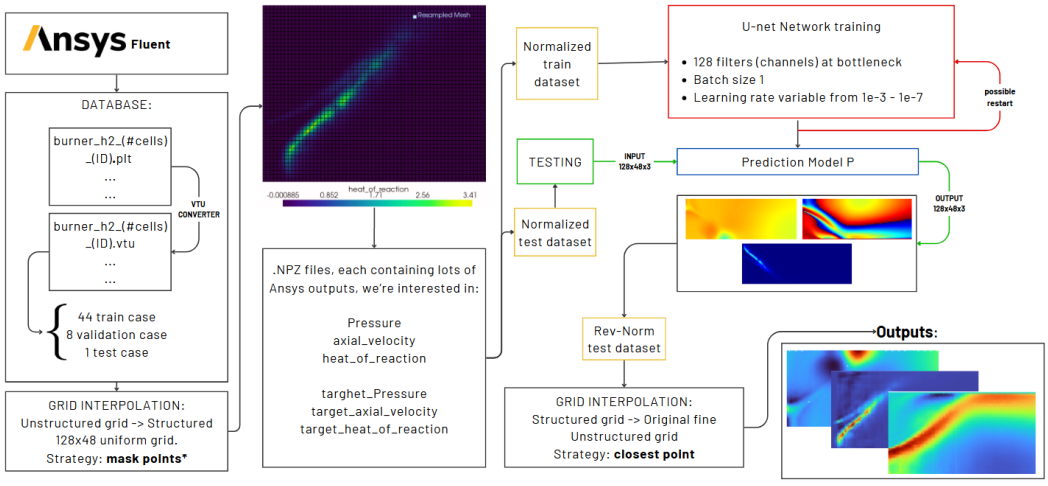

Figure 3 : The workflow of the framework

Two test cases were selected to validate the framework: a non-reactive "bump-in-a-duct" configuration and a reactive hydrogen burner [4], representing a multifidelity scenario that combines Euler or RANS-based simulations.

Materials Research Proceedings 69 (2026) 66-71 https://doi.org/10.21741/9781644904251-12

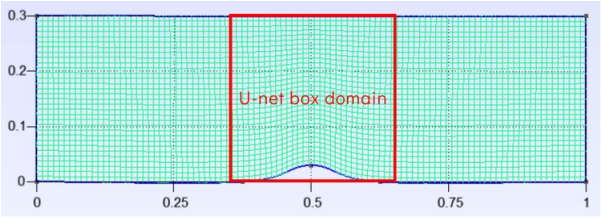

Figure 4 : Bump - low fidelity mesh (3k nodes)

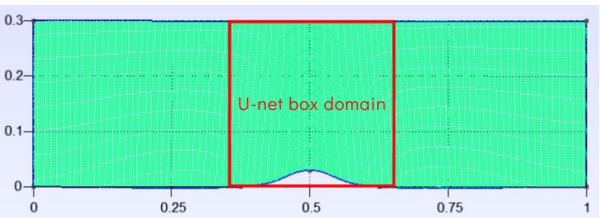

Figure 5 : Bump - high fidelity mesh (30k nodes)

Methodology

The database was generated using two distinct CFD solvers. The non-reactive dataset derives from a Fortran-based Euler code, while the reactive one comes from Ansys Fluent [5] simulations of a lean premixed hydrogen–air burner. The high-resolution fields were downsampled to generate corresponding low-fidelity maps, producing paired inputs and targets for network training. The U-Net architecture employed consists of an encoder–decoder structure with skip connections linking corresponding layers. These connections preserve spatial information that would otherwise be lost during the downsampling process. The encoder extracts global flow patterns, and the decoder reconstructs localized structures, such as shocks or flame fronts. Regularization was introduced via Dropout and Batch Normalization layers to enhance model generalization. A multi-network configuration was adopted to separately predict flow fields, avoiding feature maps interference.

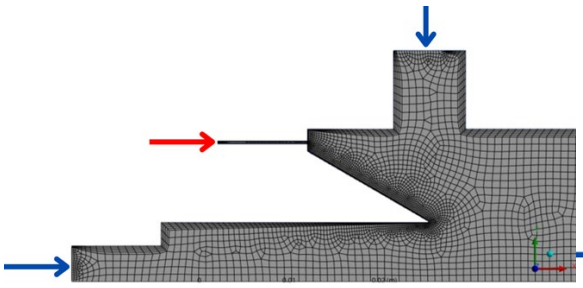

Figure 6: Hyd. burner - Low fidelity mesh (40k nodes)

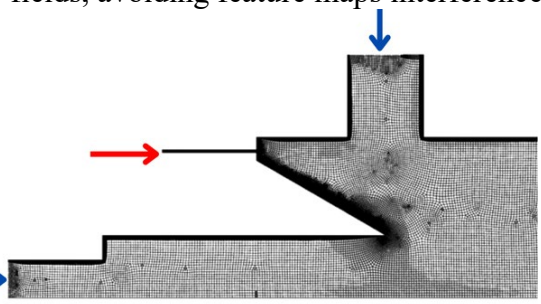

Figure 7 : Hyd. burner - high fidelity mesh (200k nodes)

Results and Discussion

Due to the limited size of the dataset, several combinations of batch size, dropout, and hyperparameters were tested, until good results have been reached. The trained networks achieved accurate reconstructions across both test cases. For the bump-in-a-duct case, the predicted wall-pressure distributions closely matched the high-fidelity results (Fig. 8). In the reactive burner case, the U-Net reproduced consistent with the high-fidelity reference solution (Fig. 9). The proposed framework successfully captured both global and local flow features, proving robust despite the dataset limitations. The analysis also highlighted the advantages of the multi-network configurations, which improved stability and accuracy for the different physical quantities.

Materials Research Proceedings 69 (2026) 66-71 https://doi.org/10.21741/9781644904251-12

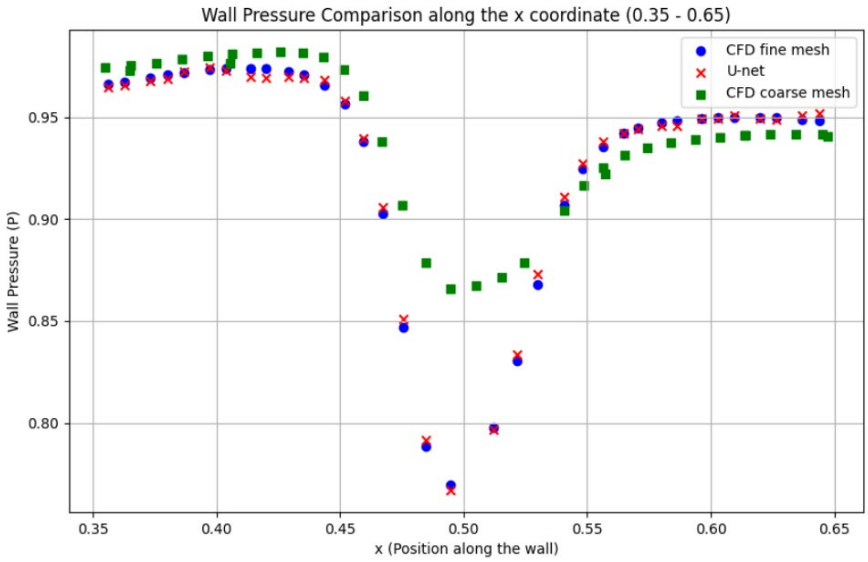

Figure 8 : Reconstruction of the high-fidelity wall pressure in the bump-in-a-duct configuration.

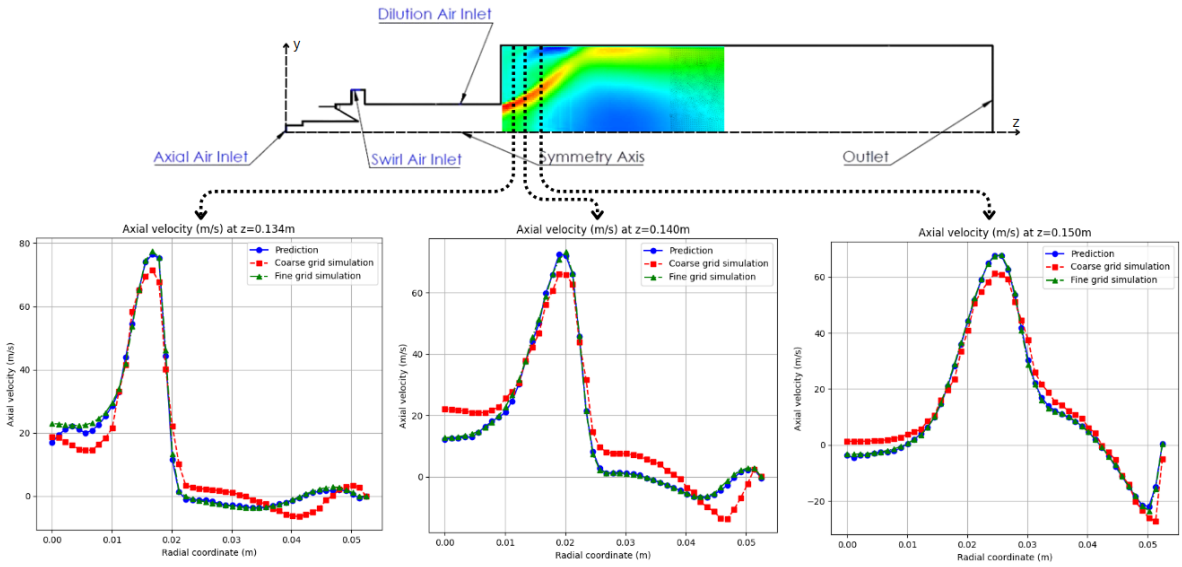

Figure 9 : Reconstruction of the high-fidelity velocity field for the hydrogen burner case. Radial profiles are shown at three different axial positions.

Conclusions

A Convolutional Neural Network based on the U-Net architecture was developed and applied to the reconstruction of high-resolution CFD fields from low-resolution data under multifidelity conditions. The method effectively recovered detailed pressure, velocity, and heat of reaction (for the specific case of the combustor) distributions across different flow regimes. Future work will focus on extending the approach to three-dimensional field correction and on implementing data augmentation strategies to improve generalization.

Keywords: Pose, Computer Vision, YOLO, Synthetic Dataset, Extended-Kalman-Filter, Lab-Testing, Sim2Real

Abstract. This paper presents a scalable framework for real-time, 6-DOF pose estimation of uncooperative space objects using monocular cameras. We address dataset scarcity by generating mission-specific synthetic data augmented with style randomization to mitigate domain shift. A lightweight YOLOv11n-pose model extracts keypoints, which feed into a RANSAC-PnP solver for initial pose estimation, refined through an Extended Kalman Filter leveraging rigid body dynamics. Validation against synthetic sequences and laboratory experiments with a 1:1 replica demonstrates mean orientation errors of 3.9° and translation errors of 1.1%, matching state-of-the-art performance. The pipeline maintains robustness under challenging lighting conditions and domain shift, achieving ~50 fps on GPU and ~5 fps on CPU, enabling deployment on resource-constrained platforms for on-orbit servicing and debris removal missions.

Introduction

In the context of the actual space environment characterized by growing congestion due to the rise of the new space economy, autonomous pose estimation of unprepared/uncooperative space objects represents a critical bottleneck for next-generation space missions, from debris removal to on-orbit servicing. While active sensors offer reliable localization, their power requirements make monocular cameras coupled with deep learning the preferred solution [1]. However, this approach faces the critical challenge of requiring thousands of training images, often not publicly available and hence replaced by synthetically generated datasets which inevitably create a performance gap when deployed in real scenarios. This gap in literature is referred to as the sim-to-real (sim2real) gap [2]. While more mature domains, like maritime, medical or automotive, have developed mitigation strategies to the sim2real gap using domain-specific Generative Adversarial Networks (GAN) [3] or using a limited subset of real data [4] in training the intrinsic complexity of the space domains makes such mitigations challenging to apply. On the space application matter, recent solutions proposed leverages texture randomization [2] and online refinement [5] to adapt the model to the distinctive optical features of real space imagery (e.g. contrast, illumination, saturation etc.). Nevertheless, pose estimation is often not addressed as a whole but rather analysed separately, leaving integration and deployment matters unsolved.

This work utilizes deep learning tools to efficiently tackle this challenge, presenting a scalable, low-cost framework that leverages Commercial-Off-The-Shelf (COTS) solutions to enable real-time pose estimation of unprepared/uncooperative Space Resident Objects (SROs). Deep learning techniques were chosen given that traditional methods rely heavily on hand-crafted features that are easily compromised by texture-less surfaces, lighting variations, and occlusions – conditions inherent to uncooperative/unprepared targets. Our approach addresses the challenge of limited space-domain datasets while maintaining the accuracy and time sensitiveness required for mission-critical applications. Our contributions are threefold: (1) we leverage Blender, a free software, to generate mission-tailored synthetic datasets that are subsequently enhanced using domain-agnostic style transfer as well as physics-driven test sequences; (2) we train a COTS YOLO11n-pose

Materials Research Proceedings 69 (2026) 72-77 https://doi.org/10.21741/9781644904251-13

Convolutional Neural Network (CNN) to locate landmarks in real-time and estimate SRO pose using Perspective-n-Point (PnP) algorithms coupled with a physics-aware Extended Kalman Filter (EKF); and (3) we provide a preliminary validation of the entire framework with representative laboratory imagery, demonstrating practical applicability for space missions.

Methods

Our pipeline starts with developing a CAD model of the mission-specific SRO, in our case a platform with a core and two solar panels – easily modifiable for specific needs. The object's dimensions were kept below 10 cm in order to be easily manufactured in full scale, via 3-D printing, for later real imagery validation [6]. The model is imported in Blender [7] and representative textures are applied to the different surfaces. The camera is modelled with a 5.2×7.1 mm sensor and 3 mm focal length *f* yielding a wide yet undistorted Field-of-View (>100°): this design choice was made to obtain an apparent target size resembling that of the same target but at a longer distance with a longer *f* or of a scaled-up target at a longer distance with the same *f*. Rendering is automated by positioning the camera in spherical coordinates (θ, φ, r) relative to the target object at the origin, with a varying radial distance $r \in [600,\ 3000]$ mm and angular coordinates incrementally varying by $\Delta\theta, \Delta\varphi = 1°$ per frame, to generate labels of target-camera poses and keypoint positions. Images were augmented with imaging artifacts: (i) Gaussian noise with standard deviation $\sigma \sim U(0.0,0.5)$, (ii) lateral chromatic aberration simulated by independently translating red and blue channels by $\Delta x, \Delta y \sim U(-5, +5)$ pixels while maintaining the green channel as reference, and (iii) randomized gamma correction $\gamma \sim U(0.4,1.4)$and exposure $E \sim U(0.4,1.4)$. Additional stochastic effects included glow and color adjustments applied probabilistically to enhance photorealistic diversity. This yields a dataset of 56000 labelled 1920x1080 px images which are additionally randomly sampled (1 out of 5) and augmented with domain-agnostic style transfer [8] by randomizing low-level features while maintaining high-level semantic content to increment robustness of the model to domain shift (Figure 1).

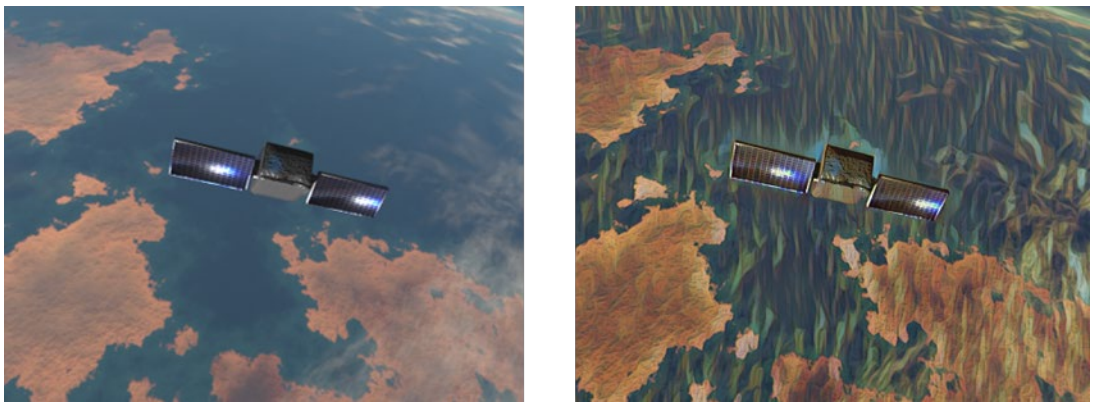

Figure 1 Sample of rendered dataset and its augmented version

The dataset obtained is used to train a YOLO11n-pose model [9]. Among the possible CNN-based architectures (HRnet, R-CNN, Fast R-CNN), YOLO was chosen for its capability to deliver accuracy levels comparable to larger models [10] while retaining real-time latency values. Indeed, as anticipated, this consideration was made relatively to a possible implementation of the pipeline for actual navigation purposes, where inference time, as well as computational power, is a significant factor. The training suite is derived from the state-of-the-art Ultralytics [11] implementation, with a key modification performed related to the Object Keypoint Similarity (OKS) loss function (1)

Materials Research Proceedings 69 (2026) 72-77 https://doi.org/10.21741/9781644904251-13

$$OKS = \sum_i \frac{\exp\left(\frac{d_i^2}{2s^2\sigma_i^2}\right)\delta(v_i>0)}{\sum_i \delta(v_i>0)} \quad (1)$$

where d_i is the Euclidean distance between the predicted and ground truth locations for keypoint i, s is the object scale, σ_i is a per-keypoint sigma value encoding annotation difficult and represents a per-keypoint standard deviation parameter, δ (v_i >0) is 1 if the keypoint is visible and 0 otherwise. In particular σ_i associated to keypoints located in the core structure – less prone to symmetry ambiguity – was decreased with respect to the outer keypoints to prioritize their accurate localization during training, improving overall pose stability. The trained model output a bounding box and the 2D pixel coordinates (and confidence) for all 20 keypoints.

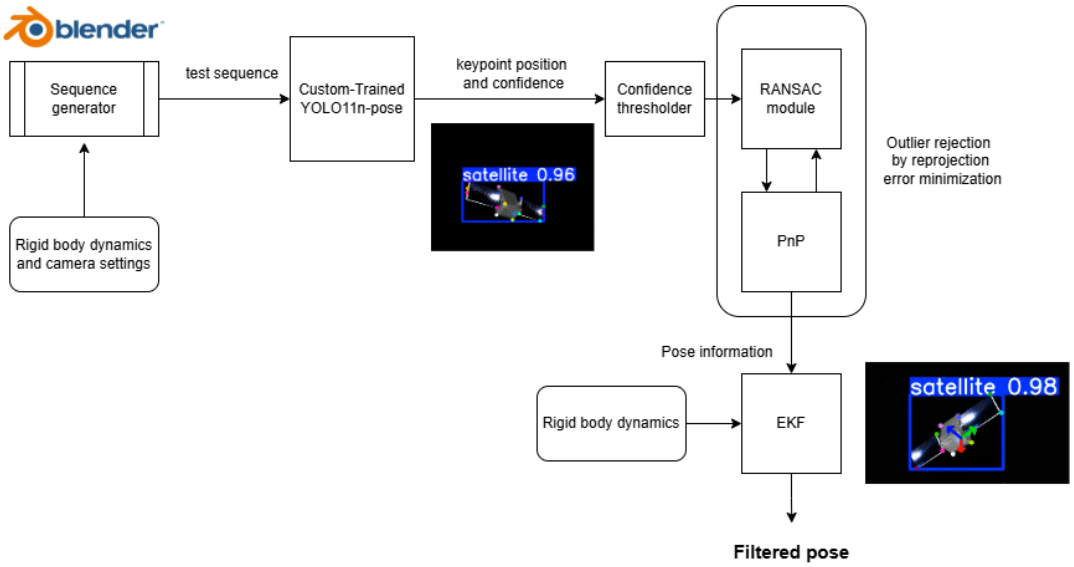

Figure 2 Pose estimation pipeline

As depicted in Figure 2, the high-confidence set of 2-D coordinates obtained from YOLO is fed into a combined RANSAC – Perspective-n-Point (RPnP) block for the first estimate of the pose. The RANSAC module works iteratively as a watchdog for possible outliers. Indeed, the module samples randomly a subset of the 2-D keypoints provided and the PnP module, implementing Efficient-PnP [12], obtain a pose which in turn is used to evaluate the reprojection error e_r. Keypoints with e_r larger than a certain threshold are labelled as outliers and are not used in the subsequent pose estimation steps. The RANSAC process continues until a predetermined level of confidence, calculated as in [13], is reached. The final pose, consisting of a translation vector and a quaternions quartet describing the relative asset of the RSO, is used as measurement input to an EKF which incorporates the rigid body dynamics typical of an uncontrolled tumbling object in space. The EKF's prediction step propagates the satellite's 19 elements state (position, orientation, angular velocity, linear velocity, inertia tensor) using Euler's equations for rigid body dynamics. This filtering step (running at 100Hz, with 10Hz measurements) rejects spurious measurements and provides a stable pose estimate even if the RPnP block temporarily fails ensuring smooth and physically-consistent tracking. The introduction of an EKF in our method make it different from several solutions in literature which are intended for single shot pose estimation [1]. This choice is motivated by a focus on the practical implementation of the estimation pipeline rather solely on its performance.

Results

The proposed pipeline was tested with both synthetic and real imagery. Relatively to synthetic testing, three sequences of 800 frames each were generated using Blender and simulated the

Materials Research Proceedings 69 (2026) 72-77 https://doi.org/10.21741/9781644904251-13

approach of a servicing spacecraft to a tumbling SRO. The dynamics of the SRO, which rotates with angular velocities ω up to 0.5 radians/s along the three axes according to Euler laws for rigid bodies $I\,I\dot{\omega} + \omega \times (I\omega) = \tau$ with inertia tensor when impacted by a debris applying a torque τ, is constant across the three scenarios while the motion of the chaser is defined to expose the pipeline to a wider range of conditions. According to standardized metrics [1], the translation error is calculated as $e_t = \left|t_{est} - t_{gt}\right|_2$ and the normalized translation error as $\overline{e_t} = e_t / \left|t_{gt}\right|_2$ while the orientation error is calculated as the angular distance between the unit quaternions representing the estimated target rotation with respect to the camera frame q_{est}^{bc} and the true rotation with respect to the camera frame q_{true}^{bc} as $e_q = 2 \cdot \arccos\left(\left|\langle q_{est}^{bc}, q_{true}^{bc}\rangle\right|\right)$. The following Table 1 summarizes the conditions as well as the results of the synthetic experiments for both RANSAC-PnP (RPnP) and filtered estimations.

Table 1 Experiments condition and results

Exp.	Range	Closing speed	Tgt. Cond.	Mean $\overline{e_t}$		Mean e_q	
				EKF	RPnP	EKF	RPnP
Nr.1	2.5 – 1.3 m	0.015 m/s	Nominal (f=3 mm)	1.64%	2.4%	3.9°	5.38°
Nr.2	50 – 30 m	0.25 m/s	Nominal (f=60 mm)	1.13%	1.41%	4.41°	4.76°
Nr.3	2.5 – 1.3 m	0.015 m/s	Damaged (f=3 mm)	3.18%	5.45%	7.8°	14.60°

The experiments were conducted on different hardware platforms, in order to evaluate both the portability of the framework and the capability to provide real-time results also on CPUs while retaining the accuracy levels obtained until now. The models were optimized using the OpenVINO™ toolkit for inference on Intel CPUs.

Table 2 Inference time (ms) on different hardware with input dimensions in brackets

Hardware	Pythorch (1920x1080)	OpenVINO™ FP32 (1920x1080)	OpenVINO™ FB32 (1132×640)	OpenVINO™ FB32 (640×640)
Nvidia GPU V100	10.3	/	/	/
Xeon® CPU	158.50	52.09	/	/
Intel® Core® i7 10th gen CPU	945.23	549.21 (453.33 for FP16)	198.32	181.27

Table 2 presents the inference time measured in different hardware conditions. It is worth noting that in all the cases presented aside from that of the last column the errors obtained varied of 0.5% with respect to the benchmark condition (i.e. Pytorch model with input 1920x1080).

For real imagery validation, videos were recorded using a 1:1 replica of the Blender-designed RSO. The mock-up featured a reflective coating simulating spacecraft thermal insulation and PVC-covered solar panels to reflect direct light. Orbital conditions were simulated by suspending the target against a black background to minimize shadows, with motion induced by manual push. The suspension constrained rotation to the local vertical axis only. Background imperfections (reflections, stains) provided additional complexity for testing keypoint extraction robustness. Frames captured with a GoPro Hero 7 White varied in initial target orientation and lighting conditions (diffused or direct).

Quantitative analysis of the two scenarios revealed that frames with diffused light exhibited stable low-luminance conditions (mean=21.73±0.90) with full dynamic range utilization (254.6±0.5). In contrast, direct light frames showed significantly higher temporal variability (mean luminance=19.39±5.47) with largely fluctuating contrast (0.818±0.138) and dynamic range (247.7±33.3). In both set of frames Shannon entropy of the intensity histogram remains low (~4.6

bits), indicating limited tonal gradations. Examples of diffuse and direct light frames are reported in Figure 3.

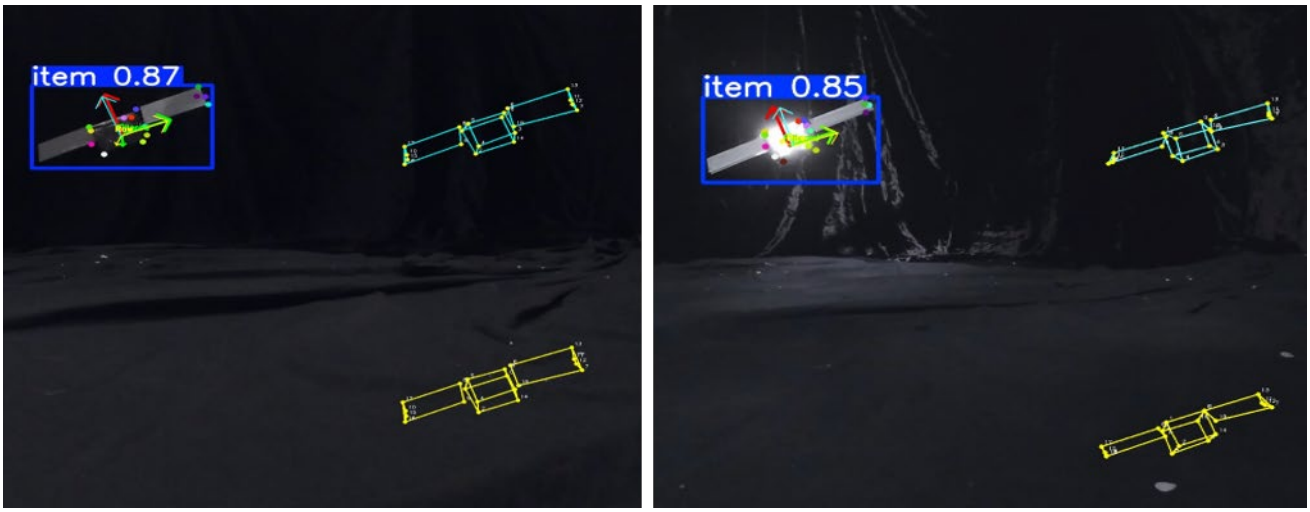

Figure 3 Example of diffused (sx) and direct light (dx) imagery. In cyan the silhouette of the pose from RPnP estimation and in yellow from RPnP-EKF combined estimation

Relatively to the diffused light subset (716 frames), the mean orientation error e_q for RPnP is 21.16° while for EKF is 11.30. The mean normalized translation error $\bar{e_t}$ for RPnP is 6.7% while for EKF is 4.6%. Relatively to the direct light subset (350 frames), the results obtained shows lower adaptability because the model struggles to provide coherent keypoints location across subsequent frames given the extreme variability of lighting conditions. Indeed, mean e_q for RPnP is 77.18° while the mean e_q for EKF is 68.51° given that the filter cannot properly initialize. Relatively to the normalized translation error $\bar{e_t}$, RPnP is 19.5% while for EKF is 4.9%. The experiments showed that the integration of an EKF can dramatically increase the performance of the system specifically in conditions where a slight domain shift can be appreciated. This benefit is strongly marked in the improvement of e_q for the diffused light subset as well as in the synthetic scenario where a damaged target is present. Similarly, an improvement for $\bar{e_t}$ can be seen in the direct light scenario. The direct light scenario was a useful case-study to steer future works, in order to address cases where target features are partially obscured by harsh illumination conditions.

Conclusions

This paper introduced a scalable framework for real-time 6-DOF pose estimation of uncooperative space objects using monocular vision and deep learning. By combining synthetic dataset generation with style randomization, the estimation pipeline composed of a YOLO11n-pose model and a coupled PnP-EKF block achieved state-of-the-art performance with mean orientation errors of 3.9° and translation errors of 1.1% on synthetic sequences. Laboratory validation demonstrated successful sim-to-real transfer under diffused lighting, with the EKF significantly improving robustness. Real-time performance across hardware platforms (~50 fps GPU, ~5 fps CPU) enables deployment on resource-constrained spacecraft for proximity operations and debris removal. While strong and direct illumination revealed limitations requiring further investigation including study on on-line adaptation, the results validate the practical applicability of COTS-based solutions for autonomous space missions.

Abstract. A quadrotor Unmanned Air Vehicle (UAV) consumes considerable energy in its rotors. Due to the limited payload of the UAV, the on-board batteries are small and have limited capacity. Thus, generating minimum-energy trajectories is of great importance to increase quadrotor UAV flight time. This work proposes a novel method for generating optimal energy trajectories for a quadrotor UAV subject to spatial constraints. The objective is to drive the vehicle from an initial hovering condition to a desired final hovering condition, flying within assigned boundaries and avoiding obstacles, while minimizing the energy expended by the rotors. In this work the quadrotor thrusts are expressed as linear combinations of orthonormal basis functions, and the trajectory planning problem is formulated as an optimization problem in which the weights of the basis expansion are the decision variables. The proposed approach is validated by a numerical example in which the optimization problem is solved by using a gradient-based local optimization algorithm with the gradients computed by employing the differentiable programming technique.

Introduction

Many real-world applications of UAVs require operation in environments characterized by boundaries and obstacles, including inspection, transportation, surveillance, and search and rescue activities. Trajectory generation (or motion planning) is critically important in these scenarios [1].

Quadrotors play a primary role among UAVs. Their motion is controlled by varying the rotational speeds of four rotors which modify the thrusts generated by each of the four propellers. A quadrotor UAV consumes considerable energy through its rotors. Due to the limited payload capacity, onboard batteries are small and have limited storage capability. Thus, the generation of energy-minimizing trajectories is of paramount importance for increasing quadrotor UAV flight time.

This work proposes a novel method for generating optimal energy trajectories for a quadrotor UAV subject to spatial constraints. The objective is to drive the vehicle from an initial hovering condition to a desired final hovering condition, flying within assigned boundaries and avoiding obstacles, while minimizing the energy expended by the rotors.

Quadrotor Model

In a quadrotor UAV four identical rotors and propellers are located at the vertices of a square and generate a thrust and torque normal to the plane of the square (see Fig. 1).

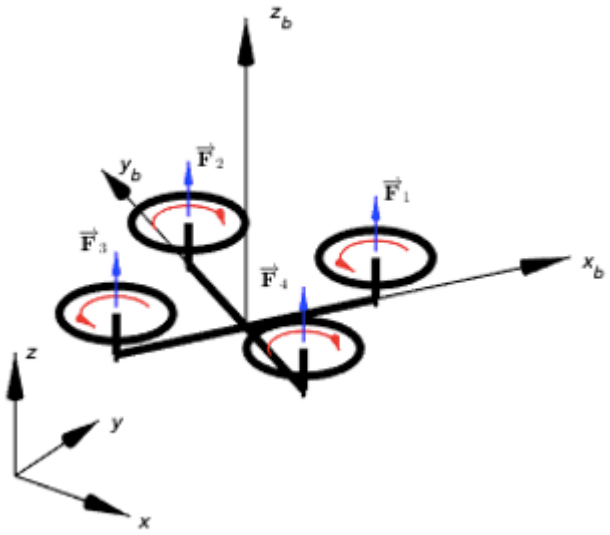

Figure 1: Sketch of a quadrotor

Choose a right-handed inertial reference frame $\{x,y,z\}$ with the z axis pointing upward, and a right-handed body frame $\{x_b,y_b,z_b\}$. The origin of the body frame is located at the center of mass of the vehicle. The first and the second axes $x_b\, y_b$, lie in the plane defined by the centers of the four rotors. The third axis z_b is normal to this plane. The following conventions are assumed for the rotors and propellers, and the thrust and moment that they exert on the quadrotor UAV. Assume that the thrust of each propeller is directly controlled, and the direction of the thrust of each propeller is normal to the quadrotor plane. Let F_j $j = 1,...,4$ be the projection along z_b of the thrust generated by propeller j . Propellers 1 and 3 are assumed to generate positive F_1 and F_3 when rotating counterclockwise. Propellers 2 and 4 do the same when rotating clockwise. The projection of the total thrust along z_b is given by $F_{tot} = \sum_{j=1}^{4} F_j$. Assume that the torque generated by each propeller is directly proportional to its thrust. Since it is assumed that propellers 1 and 3 rotate counterclockwise when they generate positive F_1 and F_3, and propellers 2 and 4 rotate clockwise when they generate a positive F_2 and F_4 , the torque generated by the j-th propeller along z_b can be written as $T_j = (-1)^j cF_j$ where $c > 0$ is a coefficient. Let d denote the distance from the center of mass to the center of each rotor, and let $\mathbf{M}$ denote the body coordinates of the total moment applied to the quadrotor with respect to its center of mass. Thus, obtain

$$\begin{bmatrix} F_{tot} \\ \mathbf{M} \end{bmatrix} = \mathbf{HF} \tag{1}$$

with

$$\mathbf{H} = \begin{bmatrix} 1 & 1 & 1 & 1 \\ 0 & d & 0 & -d \\ -d & 0 & d & 0 \\ -c & c & -c & c \end{bmatrix} \quad \mathbf{F} = \begin{bmatrix} F_1 \\ F_2 \\ F_3 \\ F_4 \end{bmatrix} \tag{2}$$

The equations of motion of the quadrotor UAV can be written as follows

Materials Research Proceedings 69 (2026) 78-83 https://doi.org/10.21741/9781644904251-14

$$\dot{\mathbf{p}} = \mathbf{v}$$

$$\dot{\mathbf{v}} = -g\mathbf{e}_3 + \frac{F_{tot}}{m}\mathbf{R}\mathbf{e}_3 \tag{3}$$

$$\dot{\mathbf{R}} = \mathbf{R}\,\boldsymbol{\omega}^{\times}$$

$$\mathbf{J}\dot{\boldsymbol{\omega}} = -\boldsymbol{\omega}^{\times}\mathbf{J}\boldsymbol{\omega} + \mathbf{M}$$

in which m is the mass, **J** is the inertia matrix, **p** and **v** are the position and velocity of the center of mass resolved in the inertial frame, **R** is the rotation matrix that transforms a column matrix of body coordinates into the corresponding column matrix of inertial coordinates, **ω** is the angular velocity resolved in body frame, $\boldsymbol{\omega}^{\times}$ denotes the matrix associated to **ω** to perform the cross-product operation, g is the gravity acceleration, and $\mathbf{e}_3=[0\ 0\ 1]^T$.

Minimum Energy Trajectory

In the proposed approach for trajectory generation, the flight time t_f is fixed along with the following initial conditions

$$\mathbf{p}(0) = \mathbf{p}_i \quad \mathbf{v}(0) = \mathbf{0} \quad \mathbf{R}(0) = \mathbf{R}_z(\psi_0) \quad \boldsymbol{\omega}(0) = \mathbf{0} \tag{4}$$

where $\mathbf{R}_z(\psi_0)$ represents a rotation ψ_0 about the z axis. The following desired final conditions are given

$$\mathbf{p}(t_f) = \mathbf{p}_f \quad \mathbf{v}(t_f) = \mathbf{0} \quad \mathbf{R}(t_f) = \mathbf{I}_{\mathbf{3}\times\mathbf{3}} \quad \boldsymbol{\omega}(t_f) = \mathbf{0} \tag{5}$$

Obstacles and boundaries are present in the flight space leading to a constraint of the following type

$$\mathbf{c}_{\text{obs}}(\mathbf{p}(t)) \leq \mathbf{0} \quad 0 \leq t \leq t_f \tag{6}$$

The objective is determining a thrust input **F**(t) defined over the interval [0 t_f] such that the corresponding position **p**(t), velocity **v**(t), attitude **R**(t), and angular velocity $\boldsymbol{\omega}$(t) satisfy the final conditions in Eq. (5) and the boundaries and obstacles constraint in Eq. (6).

It is important to select a trajectory that saves the energy spent by the rotors so to increase the autonomy of the UAV. The expression of the actual energy due to rotors is quite complex. Thus, it becomes hard to perform optimization using that cost index. However, intuitively the actual energy is related to the "energy" of the thrust **F** generated by the propellers which is given by

$$\int_0^{\mathrm{t_f}} ||\,\mathbf{F}(\mathrm{t})||^2 \mathrm{dt} \tag{7}$$

which measures the "energy" related to the control action performed by the propellers. However, for the trajectory generation problem studied in this work, it seems more appropriate to consider as cost function the "energy" related to the control action performed by the propellers required to

Materials Research Proceedings 69 (2026) 78-83 https://doi.org/10.21741/9781644904251-14

move the UAV away from a hovering condition since the UAV must be hovering at the initial and final time of its flight. Since in hovering condition $F_j(t) = mg/4$ j = 1,2,3,4 the following cost index is considered

$$\mathcal{E} = \int_0^{t_f} \left\| \mathbf{F}(t) - \frac{mg}{4}\mathbf{e} \right\|^2 dt \tag{8}$$

with $\mathbf{e}=[1\ 1\ 1\ 1]^T$.

Trajectory Generation Using Basis Functions

In this work trajectory generation is performed by first expressing the propellers thrusts as follows

$$F_j(t) = \frac{mg}{4} + \sum_{k=1}^{M} \alpha_{jk} u_k(t) \quad j = 1,2,3,4 \tag{9}$$

for a set of M basis functions $u_k(t)$ $k=1,\ldots,M$ $0 \le t \le t_f$. The basis functions must satisfy the following end-point conditions $u_k(0)= u_k(t_f)=0$. The latter conditions guarantee the fulfilment of the following equations $F_j(0) = F_j(t_f) = mg/4$ j=1,2,3,4 which are required for having the UAV hovering at the initial and final times.

The trajectory generation problem is formulated as a nonlinear programming problem in which the decision variables are the weights α_{jk} in Eq. (9). The cost index is given by Eq. (8). Achieving the desired final position, final velocity, final attitude, and final angular velocity is enforced through the following four scalar equality constraints

$$\left\|\mathbf{p}(t_f) - \mathbf{p}_f\right\|^2 = 0 \quad \left\|\mathbf{v}(t_f)\right\|^2 = 0 \quad 3 - \mathrm{tr}[\mathbf{R}(t_f)] = 0 \quad \left\|\boldsymbol{\omega}(t_f)\right\|^2 = 0 \tag{10}$$

where tr denotes the trace of a matrix. The boundaries and obstacles constraints are expressed as in Eq. (6).

Numerical Example

The proposed method is applied to the following numerical example. The mass of the UAV is m = 0.5 kg, its inertia matrix is equal to $\mathbf{J}$ = diag [0.0622 0.0733 0.0964] kg m^2, $c = 5\cdot10^{-3}$ m, d = 0.2 m (see Eq. (2)). The boundary constraint $z \ge 0$ is introduced since plane z = 0 corresponds to the ground. The initial and desired final positions are given by $\mathbf{p}_i=[0.5\ 0\ 1]^T$ m $\mathbf{p}_f=[0.5\ 1.5\ 4]^T$ m. A box-shaped obstacle is present in between those positions. Four vertices of the obstacle are on the ground and have the following coordinates $\mathbf{w}_1=[0.25\ 0.75\ 0]^T$ $\mathbf{w}_2=[0.75\ 0.75\ 0]^T$ $\mathbf{w}_3=[0.25\ 1.25\ 0]^T$ $\mathbf{w}_4=[0.75\ 1.25\ 0]^T$. The remaining four vertices are at the height of 6 m. The flight time is t_f=3 s.

To generate the trajectory by using the proposed approach, the interval $0 \le t \le t_f$ is discretized into N = 300 equal segments defining $\Delta = t_f/N$ and $t_l = (l-1)\Delta$ $l = 1,\ldots,N+1$. Consequently, the equations of motion in Eq. (3) are discretized and the boundary and obstacle constraints in Eq. (6) are enforced only at discrete times t_l. The basis functions $u_k(t)$ k = 1,...,M are obtained by defining samples $u_k(t_l)$ and applying a zero-order hold interpolation. The samples $u_k(t_l)$ are chosen as the so-called Slepian sequences [2]. These sequences are parameterized by their length N set to 300, and by the half-bandwidth parameter $W \in [0\ 0.5]$. In this numerical study, the first M = 6 Slepian sequences with W = 0.02 are considered.

Materials Research Proceedings 69 (2026) 78-83 https://doi.org/10.21741/9781644904251-14

The resulting nonlinear programming problem is solved numerically by using a local gradient-based optimization. The computation of gradients is carried out by using the differentiable programming technique also known as automatic differentiation. Differentiable programming is neither a symbolic computer algebra system nor a method that relies on finite-difference numerical derivatives. Rather, differentiable programming systems provide numerical expressions of analytic derivatives and a seamless framework for implementing the chain rule from differential calculus.

The time evolutions of the four rotor thrusts F_j $j = 1,...,4$ are showcased in Fig. 2. The corresponding path followed by the center of mass is displayed in Fig. 3.

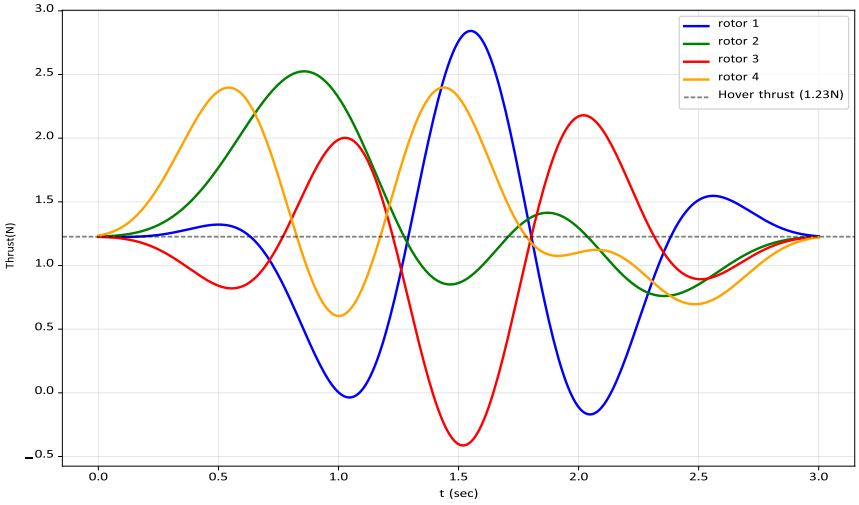

Figure 2: Time evolutions of the thrusts

The final values satisfy the following equalities

$$\| \mathbf{p}(t_f) - \mathbf{p}_f \| = 1.25 \cdot 10^{-6}\,\text{m} \quad \|\mathbf{v}(t_f)\| = 1.22 \cdot 10^{-4}\,\text{m/s}$$
$$3 - \text{tr}(\mathbf{R}(t_f)) = 1.35 \cdot 10^{-10} \quad \|\boldsymbol{\omega}(t_f)\| = 1.46 \cdot 10^{-8}\,\text{deg/s} \tag{11}$$

The distance from the box-shaped obstacle changes with time as indicated in Fig. 4.

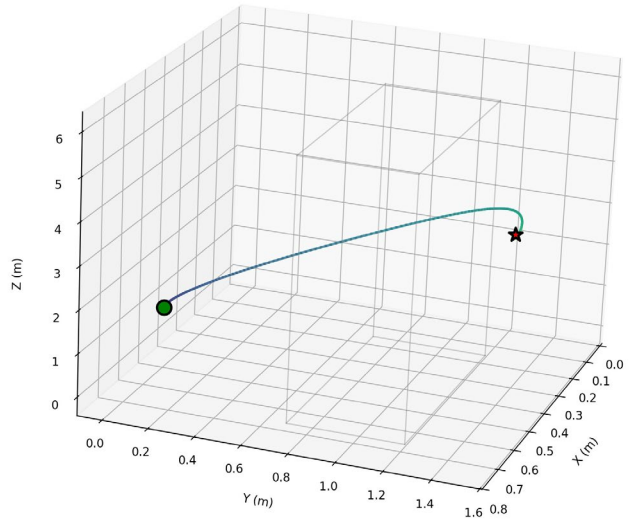

Figure 3: Path followed by the center of mass (green circle = initial position, red star = final position)

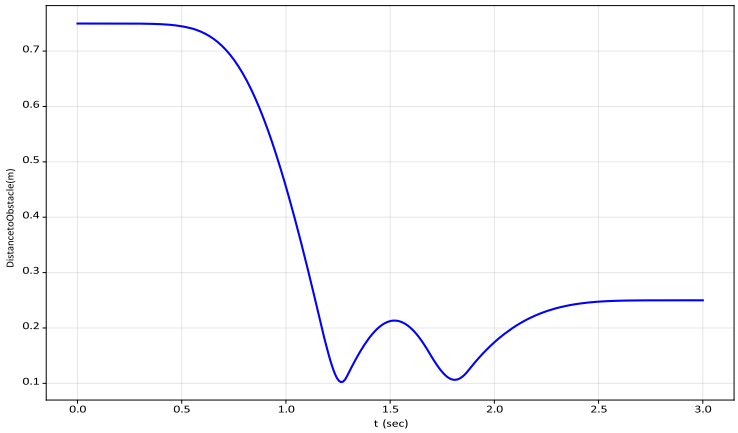

Figure 4: Time evolution of the distance to the box-shaped obstacle

Concluding Remarks

The trajectory generation approach for quadrotor UAVs presented in this work provides a systematic method for determining trajectories from a given hovering condition to a desired hovering condition with fixed flight time including spatial constraints while minimizing the energy spent by the rotors. The method relies on a basis function expansion of the propellers thrust and in solving a nonlinear programming problem using a gradient-based method. A numerical example has shown the effectiveness of the proposed approach.

Keywords: Aerodynamic Prediction, Machine Learning, Random Seed Initialization, Ensemble Modelling, Airfoil Performance, Seed Sensitivity, Model Reproducibility, Pseudo-Random Number Generator

Abstract. Accurate aerodynamic performance prediction remains critical in preliminary design and optimization workflows. This study proposes a hybrid deep learning framework that combines convolutional neural networks (CNNs), operating directly on raw airfoil geometries, with two fully connected branches that process engineered shape descriptors and flow parameters such as angle of attack and Reynolds number. This model is trained on a high-resolution dataset generated via XFOIL simulations, covering 91 NACA 4-digit airfoils across 200 aerodynamic conditions each, spanning Reynolds numbers from 500,000 up to 5,000,000 and angles of attack between -5˚ and 14˚. A key novelty introduced in this work is the investigation of how random seed initialization influences predictive accuracy. In machine learning, a random seed is a fixed numerical input that initializes the pseudo-random number generator responsible for operations such as weight-initialization and data shuffling. While typically treated as a background setting, the *seed plays a critical role in defining the starting conditions of model training* and can directly influence final performance outcomes. Results show that models with identical architecture and data can differ in performance by up to 250% depending solely on the seed used during training. To mitigate this variability, ensemble strategies based on seed diversity were also explored, leading to greater consistency and generalization. The top-performing single-seed model tested (seed 0) achieved a mean absolute percentage error (MAPE) of 1.1% for lift coefficient and 0.57% for drag coefficient, with R^2 values of 0.9998 and 0.9954, respectively. The best ensemble built from three diverse seeds (C2) achieved slightly higher generalization: 1.43% MAPE C_L, 1.19% MAPE C_D, with R^2 values of 0.9999 and 0.9968. All models tested, spanning ten seeds and five ensembles, achieved R^2 scores exceeding 0.97. The results emphasize that treating seed selection as a fixed default can overlook significant variability, and that ensemble calibration can serve as a robust strategy to improve prediction reliability.

Introduction

Machine learning (ML) is increasingly used in aerodynamic prediction as a data-driven framework capable of learning the complex relationships between geometry, flow conditions, and aerodynamic performance. Various ML architectures, including convolutional neural networks [1], multilayer perceptron (MLPs) [2], and ensemble strategies [3], have been explored for

Materials Research Proceedings 69 (2026) 84-87 https://doi.org/10.21741/9781644904251-15

aerodynamic performance estimation. These studies demonstrate the potential of ML to bridge the gap between accuracy and computational efficiency, which represents the primary downside of traditional computational fluid dynamic (CFD) tools [4, 5].

Despite this progress, one important factor has been largely overlooked: *the influence of random seed initialization*. In ML, seeds determine weight initialization, data shuffling, and training dynamics. Although seeds are typically fixed for reproducibility, their role as an active parameter influencing accuracy and stability has not been systematically investigated in aerodynamic applications. This present study investigates the influence of random seed sensitivity on the results obtained from an identical machine learning architecture. The initial scope was to calibrate the model in a fully reproducible manner; however, the process revealed significant variations in performance caused solely by the seed selection. Under identical data and architecture, prediction errors *varied by up to 250% depending only on the random seed selection.* In common ML libraries, *the seed is a 32-bit unsigned integer*, which translated into over four billion possible initialization states, therefore an exhaustive sweep is infeasible. In this study, an intentional but limited sampling of seeds was used to capture representative variability while keeping the analysis computationally practical.

By *recognizing seed selection as a design parameter* rather than a procedural formality, this study reinforces the reliability of machine learning-based aerodynamic prediction and establishes concrete guidelines for their consistent integration into aerodynamic design workflows.

Methodology

Following earlier CFD-based analyses of airfoil aerodynamics [6], the study focuses on adopting a machine learning approach to mitigate the computational cost challenge. Therefore, as presented in detail in [7], the methodology is built on a self-generated database of NACA four-digit airfoils. A total of 112 geometries were considered, of which 91 were used for training and 21 were excluded for independent testing. For each airfoil, aerodynamic data was collected from XFOIL simulations at Reynolds numbers between 0.5 and 5 million (in steps of 0.5 million) and angles of attack from -5˚ up to 14˚, resulting in approximately 18,200 samples. Each sample corresponds to an airfoil evaluated under a specific combination of flow conditions and geometric parameters, including lift and drag coefficients, coordinate distributions, Reynolds number, angle of attack, and engineered features such as maximum thickness and camber.

The proposed model employs a hybrid neural network architecture designed to capture both geometric and aerodynamic relationships. The airfoil geometry is processed through a one-dimensional convolutional branch that extracts local contour features from coordinate points. In parallel, a dense network interprets flow parameters – angle of attack and Reynolds number – while a second dense branch encodes engineered shape descriptors such as maximum thickness and camber. The three latent representations are then merged into a unified feature space, enabling the network to learn coupled geometric-aerodynamic interactions. The fused output is directed toward two dedicated prediction heads for lift and drag coefficients. This setup represents the single-seed configuration, where one model is trained with a specific initialization state. In the ensemble approach, several identical networks with the same architecture are trained independently using different random seeds, and their predictions are averaged to obtain a more stable result. The difference between the single-seed and ensemble configurations is illustrated in Figure 1, where the ensemble approach combines multiple independently trained single-seed models to produce an average prediction.

Materials Research Proceedings 69 (2026) 84-87 https://doi.org/10.21741/9781644904251-15

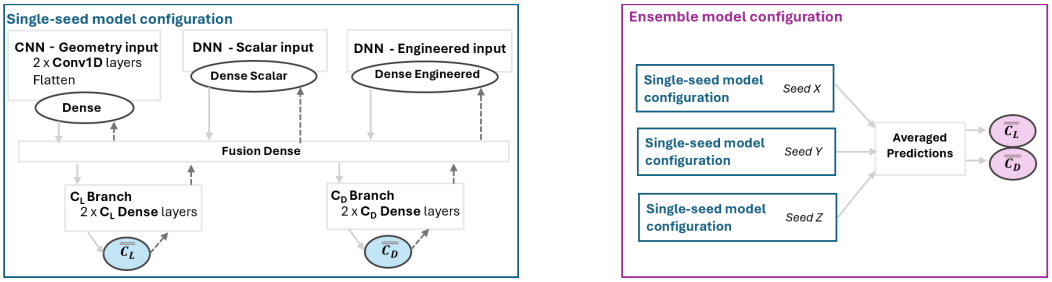

Figure 1. Single-seed and ensemble configurations of the hybrid CNN–DNN model

In order to analyze seed variability, three groups of experiments were defined: *Group A*, using consecutive seeds (42-46) to test local stability; *Group B*, using diverse seeds (0, 1, 123, 777, 999) to explore broader variability; and *Group C*, consisting of ensembles formed from three independently trained models with different seeds to evaluate robustness through averaging.

Results and Discussion

Experiments with individual seeds, as presented in Table 1, show that lift predictions remain generally stable across different initializations, with mean absolute percentage error between 1.1-1.9%. In contrast, drag predictions are highly sensitive, with errors ranging from 0.57% up to 2.02%. From Groups A and B, the best performer was seed 0, with achieved C_L MAPE of 1.1% and C_D MAPE of 0.57%, corresponding to R^2 values above 0.995. The worst performer was seed 45, with C_L MAPE of 1.86% and C_D MAPE of 1.92%, alongside noticeably lower R^2 for drag. This comparison shows that simply *changing the seed can significantly increase the prediction error*, despite using identical data and architecture. Across all tested cases, *error variation reached up to 250%* (e.g. MAPE C_D values varying from 0.57% on Group B, Seed 0 to 2.02% on Group A, Seed 43), confirming that seed initialization is a non-negligible factor in aerodynamic ML prediction.

Table 1. Performance metrics of single-seed models across Groups A and B

Single seeds	MAPE C_L	MAPE C_D	R^2 C_L	R^2 C_D
Group A, Seed 42	1.33%	1.07%	0.9998	0.9933
Group A, Seed 43	1.41%	2.02%	0.9996	0.98
Group A, Seed 44	1.67%	0.84%	0.9998	0.9909
Group A, Seed 45	1.86%	1.92%	0.9998	0.9784
Group A, Seed 46	1.27%	1.19%	0.9998	0.99
Group B, Seed 0	1.10%	0.57%	0.9998	0.9954
Group B, Seed 1	1.97%	0.99%	0.9998	0.9938
Group B, Seed 123	1.08%	1.54%	0.9999	0.9855
Group B, Seed 777	1.78%	1.70%	0.9998	0.9861
Group B, Seed 999	1.65%	0.58%	0.9998	0.9974

From Group C, as presented in Table 2, the most effective ensemble, C2 (610, 987, 75025), achieved C_L MAPE of 1.43% and C_D MAPE of 1.19%, delivering smoother R^2 values across all test airfoils compared to single seeds. By contrast, C1 (17, 89, 257) was the weakest ensemble, with overall errors around 2.2%. In the case of Ensemble C3, the lift coefficient error (MAPE 2.72 %) was approximately 46 % higher than the worst-performing single-seed model, indicating the possible presence of an unfavourable or “black swan” seed within the configuration. The ensemble output represents the mean of predictions from independently trained models. While

mathematically this is a simple average, the resulting predictions could be more accurate because random seed and underestimations cancel each other out.

Table 2. Performance metrics of ensemble models across Group C

Ensembles	**MAPE C_L**	**MAPE C_D**	**R^2 C_L**	**R^2 C_D**
C1 = (17, 89, 257)	1.78%,	2.62%	0.9998	0.9887
C2 = (610, 987, 75025)	1.43%	1.19%	0.9999	0.9968
C3 = (2^8, 2^{16}, $2^{32}-1$)	2.72%	1.08%	0.9998	0.997
C4 = (0, 123, 999)	1.82%	1.46%	0.9999	0.9936
C5 = (43, 45, 777)	1.55%	2.01%	0.9999	0.9893

The simulations confirm that random seed initialization is not a mere implementation detail but a *parameter with a measurable impact on machine learning-based aerodynamic prediction*. Within the tested range, certain seeds yielded better accuracy on the lift branch, while others performed more effectively on the drag branch, showing that initialization can influence each output differently. To mitigate these variations, a *weighted ensemble strategy* could be developed in future work, assigning greater influence to seeds that perform best on specific aerodynamic coefficients. Given that the random seed space spans billions of initialization states, exhaustive exploration is infeasible. This highlights the importance of adopting deliberate sampling and ensemble strategies to balance reproducibility with the computational efficiency expected from machine learning approaches.

Keywords: System-of-Systems, Agent-Based Modelling and Simulation, OODA Loop, Wildfire Suppression, Collaborative AI

Abstract. Agent-Based Modelling and Simulation (ABMS) is widely used in System-of-Systems (SoS) studies to represent constituent systems operating in dynamic environments. However, the absence of standardised agent architectures hinders scalability, behaviour traceability, and comparative evaluation of emergence, coordination, and operational performance. This work introduces a modular agent design based on Observe–Orient–Decide–Act (OODA) loops as a framework for SoS simulations, enabling transparent information flow and Artificial Intelligence (AI) integration at the decision layer. A wildfire suppression scenario is used for the study, modelling firefighting crews, aircraft, helicopters, bulldozers, and an incident commander as OODA-driven agents. Results show that OODA-based agents exhibit coherent and traceable team behaviours, adaptive task switching, and communication-driven coordination, supporting the study of emergence and interoperability in SoS operations. The Decision stage is designed for future improvements in the form of learning-based AI and Large Language Models to enhance autonomy and operational fidelity.

Introduction

The advancements of Artificial Intelligence (AI) are opening new possibilities in the field of product development. A proper understanding of the complexity of a new product and all its subsystems could greatly benefit from the new AI-enabled technologies. Systems Engineering is strongly correlated with the product development process as it provides standardised methods and tools to handle the complexity of the new system in a traceable manner [1].

For the proper generation of requirements, it is important to have a clear idea and understanding of how the new system will operate and interact with other systems.

Background

System of Systems (SoS) analysis is a valuable tool for finding needs and capabilities that will be translated into requirements for new systems [2]. Communication, interoperability and performance are some of the several key aspects analysed for the collection of constituent systems that form the SoS. For these analyses, ABMS is typically used, as the resources needed to evaluate a complete operation with several constituent systems in a complex and dynamic environment can become exorbitant [3]. The focus of ABMS is the evolution and interactions of large-scale complex systems, which is also the main concern of SoS analysis. The agents in the model are a representation of the constituent systems within an SoS. The agents are implemented to mimic the capabilities and behaviours of the systems during the execution of a mission. Their behaviours will be affected by the interactions they have with one another and with the environment. This is a key

Materials Research Proceedings 69 (2026) 88-93 https://doi.org/10.21741/9781644904251-16

part of the SoS simulation and analysis, as the interactions and behavioural changes might lead to emergent behaviours that are very difficult to predict.

Contribution

The present work considers the use of the Observe-Orient-Decide-Act (OODA) loop as the standard method for Agent-Based Modelling oriented towards SoS analysis. The OODA loop was originally proposed for military operations [4], but it provides a flexible structure for implementing agents and their behavioural rules that is easily relatable to operational guidelines. Moreover, the use of OODA loops is considered a step towards more generalised and agnostic frameworks for representing different systems. The OODA loop can be mapped into agent behaviour rules:

1. Observe: agents acquire information using sensors and external inputs.
2. Orient: agents use the observed data and compare it with the situational context.
3. Decide: decision-making logic selects optimal actions in response to the information propagated from the orientation phase.
4. Act: actions are executed, influencing the agents' state, the other agents and the system environment.

This approach is considered as a manner to ease the characterisation of SoS architectures in simulations, increases operational fidelity, and improves the scalability by allowing variable forms of AI to be included in the Decision phase of the loop.

Study Case

A wildfire suppression scenario is used as a case study. In this context, multiple constituent systems will be included: bulldozers, water bomber aircraft, helicopters, ground teams, and an incident commander are modelled as agents. Each of the agents will be implemented from an embedded base OODA and loop extended to their own characteristics. The agents' behaviour will change dynamically depending on the information that they receive through communication. They will decide and act depending on the information, situation and assigned tactics. The proposed implementation structure is expected to help capture emergent effects from coordinated strategies, communication, and allow for different levels of AI sophistication to be used in the agents' decision-making processes. This generalised approach enables the flexible testing of diverse AI models, SoS architectures and their impact on system performance and operational safety. By providing an adaptable and scalable agent modelling structure oriented for SoS, the OODA-loop method helps to improve fidelity of simulations for complex missions, leaving the increment in computational resources dependent only on the sophistication of the AI used.

Implementation

The implementation of the agents attempts to follow OODA loops in such a way that, in the Decision step of the loop, different forms of AI could be used for extending the implementation. The steps of the loop perform were implemented as follows:

- Observe (perception/inputs): Agents gather data from the world current state such fire grid, distance fields, costs, terrain multipliers, fuel state, etc. This is done via the shared memory in terms of the software implementation.
- Orient (context building/interpretation): Agents derive context from observations: compare terrain costs, possible routes, inaccessible-gap flags, live metadata from the quadrants that split the map into a grid, or day/night thresholds for tactics. The special case is the incident commander agent world picture, who depends on the communication and information from

Materials Research Proceedings 69 (2026) 88-93 https://doi.org/10.21741/9781644904251-16

other agents to know who is where, what is left to do, assignment counts, local completed sets, and finish-and-exit targets.

- Decide (select behaviour): The choice of what to do is mainly done by the commander:
  - Assigns targets (quadrants) and tracks completion of tasks.
  - Implemented rule tables for choosing points of interest and suppression strategy.
  - Switches between main and alternative tactics given thresholds and time-of-day.

  All agents can take decisions to some extent, and it is this step of the OODA loop that is open to the inclusion of advanced forms of AI.
- Act (executes task): Movements are done by the agents using path planning (A* search algorithm and direct-path checks) [5], and they perform tasks such as apply suppression over cells (which updates on-fire pixels) or transport other agents (this task is only realizable by helicopters). In the case of low fuel, the perform actions for returning to base and refuel.

The OODA loop shown in Fig. 1 is the most basic form of it, but there are versions where intents have been added between Orient and Decide, with continuous evaluation of knowledge and beliefs, in order to separate desires and orders [6].

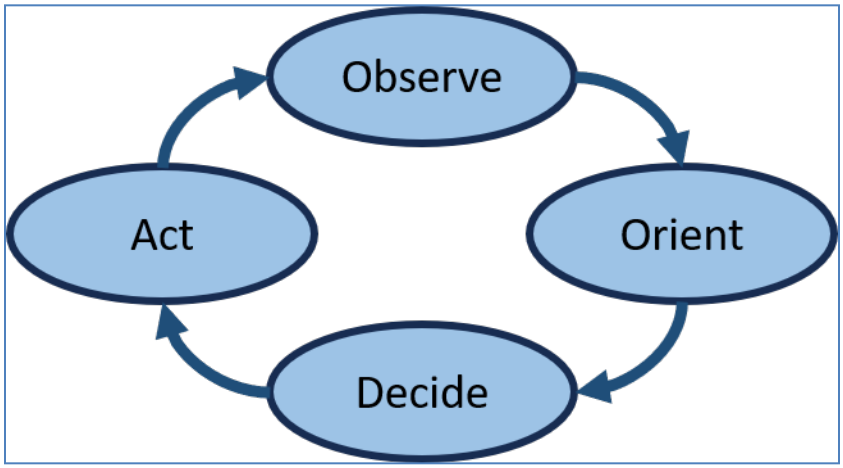

Figure 1: Observe-Orient-Decide-Act loop used by agents.

Discussion

The agent-based model with the agents based on the OODA loop allowed to represent important topics for studying SoS. Collaboration and communication to reach a common goal are particularly difficult, as any form of information exchange for taking decisions based on prior knowledge require to use some form of AI. For the present case, decision trees have been used, which limit the decision capabilities and are considered an AI in narrow form. However, the results were satisfactory since agents performing tasks are aware of their surroundings and react and communicate to events.

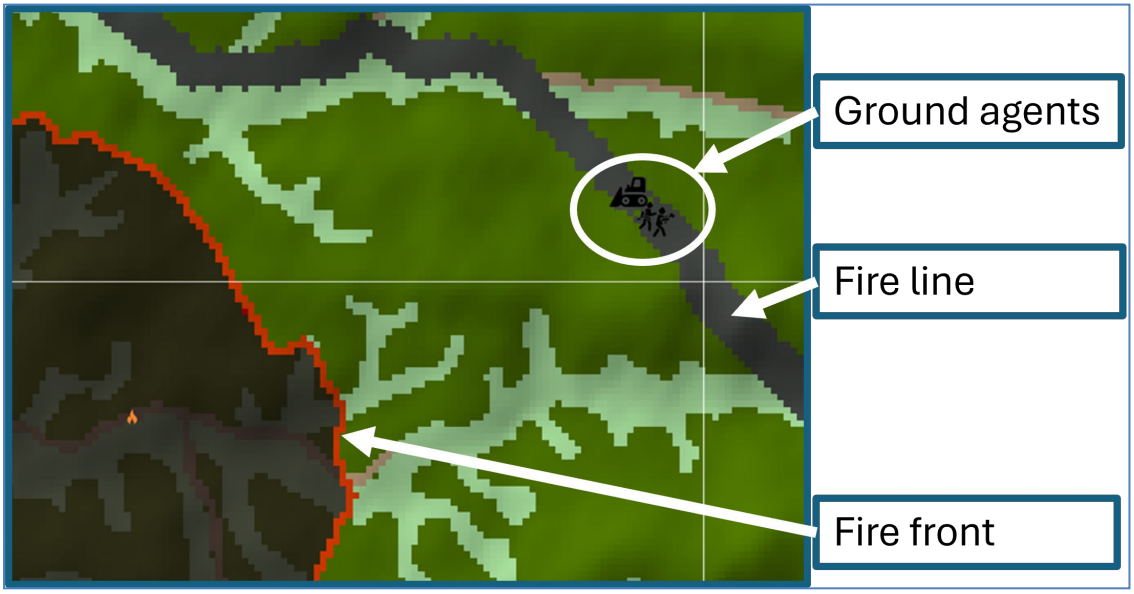

Figure 2: Agents collaborating during a simulation of a wildfire suppression case.

An example of this can be seen in Fig. 2, where ground agents are working for closing a fire line to stop the fire front from spreading. The agents are assigned to a location by the commander agent to create the fire line in a certain direction. The simulation showed that, if they observe another agent working in the line and they close it, they stop the current action, communicate the completion and request another task. In the example of the figure the bulldozer will drive to a different location and the firefighters will request transport to their next location. The implementation, nevertheless, is still the most basic form of OODA loops with a very simple form of intelligence, which in terms of operational credibility can generate situations that would be open to debate with stakeholders and experts. For example, when many firefighters are assigned to work on a line at a certain area, they try to work in parallel, leading to situations where they become less efficient due to a lack of advanced forms of planning.

A further advantage of the OODA-based agent design is that it enables traceability of decisions and actions during the simulation. Each stage of the loop generates information that is exchanged and recorded between agents, forming a continuous flow of observations, decisions, and actions. These communications are automatically stored in a text-based log, creating a chronological record of assignments, acknowledgements, and task completions (see Table 1). This allows reconstruction of how the commander's decisions propagate through the SoS and how agents respond to changing conditions. The sequence also supports post-simulation analysis of coordination efficiency, task timing, and communication reliability, which are essential for validating and improving the models.

Table 1: Agents communication during a simulation of a wildfire suppression case.

Time (hh:mm:ss)	**Sender**	**Receiver**	**Message Summary**
15:03:30	Commander	Hotel-1	Assigned suppress in Q53
15:03:30	Commander	Sierra-1	Assigned suppress in Q53; helper
16:05:43	Hotel-2	Commander	Reported Q53 task complete
16:10:04	Sierra-2	Commander	Reported Q53 task complete

The modular OODA structure also strengthens how communication is modelled across architectural layers of a System of Systems. By explicitly separating Observation, Orientation,

Decision, and Action, it defines clear points where information must be exchanged between agents and higher-level systems. This mirrors real operational architectures, where systems contribute to and depend on shared situational awareness. In this way, OODA provides a unifying logic that links system-level design with software and agent-based implementation. Each message or data exchange can be associated with a stage of the Decision cycle, improving consistency between intent and execution while enhancing interpretability of communication behaviours.

Despite these advantages, some limitations remain. The conceptual OODA framework is flexible and continuous, allowing entities to operate at different speeds, but in the agent-based simulation all loops run synchronously on a shared time step. This simplifies computation yet limits realism, as agents react simultaneously rather than at their own decision rates. In real operations, commanders and field units act asynchronously, and these temporal differences shape coordination and response dynamics. Future work should introduce variable or event-driven update cycles so that agents process information and decide independently while maintaining coordinated communication within the OODA framework.

Conclusion and Future Work

The implemented model has shown that using OODA loops as framework results in agents with behaviours that are closer to those of humans. The different steps in the loop can be implemented separately, making the code easier to maintain and understand. Moreover, the information that is propagated from one step to the next of the loop can be traced, making it possible to understand if the amount of shared is correct, which pieces must be communicated and how this affects the behaviour of an agent representing a constituent system. For an SoS, where there are many interactions that results in its overall behaviour, it is important to understand what the constituent systems need from the group and what they bring to the group value.

The Decision part of the loop is the most relevant part for including different levels of AI as future work. Starting from a narrow form of AI, different methods can be used, such as Machine Learning, for training agents in a certain situation. However, this would be a very challenging task. Following the case of a fire suppression operation, firefighters and pilots are trained in real life both as individuals and as a group, but they also need to follow the orders of a commander. It is then important to be able to include communication into the training, so they learn by using both individual and group knowledge. With the recent advancements in AI, the OODA loops could also include image recognition or forms of Large-Language Models for including outputs similar to human communication, which brings another layer to the research about relevant communication and information in SoS, in order to avoid miscommunication or knowledge gaps that will affect the group performance and the resilience of the SoS.

Acknowledgments

The research presented in this paper has been performed in the framework of the COLOSSUS project (Collaborative System of Systems Exploration of Aviation Products, Services and Business Models) and has received funding from the European Union Horizon Europe programme under grant agreement No. 101097120. The Swiss participation in the Colossus project is supported by the Swiss State Secretariat for Education, Research and Innovation (SERI) under contract number 22.00609. The authors would also like to acknowledge the Swedish Innovation Agency (VINNOVA) and The Swedish Defence Materiel Administration (FMV) for financial support through the grant 2019-05371. Finally, the authors want to acknowledge the insightful discussions about the topic with Kristian Amadori.

Keywords: Advanced Air Mobility (AAM), eVTOL (Electric Vertical Take-Off and Landing), Agent-Based Simulation, Demand Estimation, Transportation Economics

Abstract. We develop an integrated methodology at the UAM fleet level combining multi-agent transport simulation (MATSim) with profit optimization. The approach is applied to three simulation scenarios (Los Angeles, Kyoto, Rhine-Ruhr) with varying network sizes, ticket prices, and eVTOL vehicle characteristics. Demand surrogates are analyzed for large-scale simulation prediction. Results of all scenarios indicate that profitable UAM operations by 2030 require autonomous flight, scenario specific ticket pricing, and efficient eVTOL designs.

Introduction

With ongoing development of electric vertical take-off and landing (eVTOL) vehicles, certifications for U-Space operations, and battery technologies, the feasibility of Urban Air Mobility (UAM) applications is increasing. In passenger transport, this potential is mainly based on travel time savings, but high costs are limiting the future market potential. Consequently, cost optimization approaches are needed at the strategic and operational levels. These include optimized vertiport station placement, configuration and size of the eVTOL fleet, and ticket pricing. In previous studies, several simulations and optimization models have been introduced and applied to individual use cases. Particularly relevant are agent-based transport systems that incorporate both time savings and costs for UAM and ground-based transport modes in a comprehensive modeling environment [1].

A comprehensive analysis of UAM further requires consideration of overlapping research areas: aerodynamic performance of eVTOL vehicles, dispatching within overall demand scenarios, acceptance respectively user preferences, air traffic management, battery technologies and sustainability, vertiport placement and operation, and certification of partially autonomous fleets [2, 3].

In recent research, comprehensive system definitions have been introduced, specifically for UAM and AAM (Advanced Air Mobility – which also includes logistics operations, medical care, and search and rescue applications). These methodological frameworks are called system-of-system approaches or UAM ecosystem analyses, both of which specify the air transportation system [4, 5].

There is a research gap in the comparability of previous UAM studies on air transportation system level, including UAM market potential studies. This work aims to first establish a generally applicable evaluation methodology for UAM and then apply it to various metropolitan regions in a global context.

Methodology

To address both aspects of comprehensive large-scale simulation and specific optimization for profitability, the methodology is divided into three steps: (1) UAM demand simulation, (2) profit maximization, and (3) resulting UAM evaluation. These steps enable modeling between eVTOL

Content from this work may be used under the terms of the Creative Commons Attribution 3.0 license. Any further distribution of this work must maintain attribution to the author(s) and the title of the work, journal citation and DOI. Published under license by Materials Research Forum LLC.

Materials Research Proceedings 69 (2026) 94-98 https://doi.org/10.21741/9781644904251-17

vehicle design and the overall transportation system, including competing modes of transportation within metropolitan areas. Consequently, the existing transportation network and conceptualized eVTOL vehicles are input to the UAM ecosystem. Figure 1 shows the modular structure.

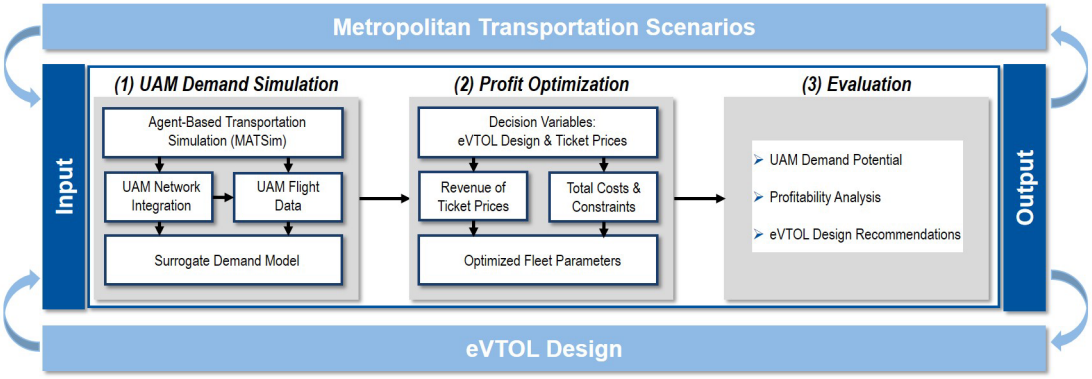

Figure 1. Methodology for modular evaluation of different UAM demand scenarios.

First, existing ground-based demand scenarios from metropolitan regions are considered and evaluated using Multi-Agent Transport Simulation (MATSim) [6]. To create demand-efficient vertiport networks, potential UAM candidate flights are analyzed with k-means clustering. Since UAM only enables travel time savings over medium to long distances, a lower boundary is relevant as input for k-means clustering, which can be set to 15 kilometers based on previous studies. In the next step, the simulation of UAM demand is carried out using MATSim UAM extension. Further modeling includes UAM ticket prices, eVTOL vehicle range limitations, and specific speeds on the UAM network links. Through iterative simulation, in which agents test different modes of transport with temporal and spatial variations, the overall benefit of the agents' daily schedules is optimized. These comparable and reproducible UAM flight data can be extended to demand surrogate models using larger randomized UAM input datasets [7]. Table 1 summarizes default settings and value ranges.

Table 1. Parameter input for surrogate demand models.

parameter	unit	default	value range
fixed price	€	10	[0, 30]
variable price	€/pkm	1.50	[0.80, 2.5]
range	km	200	[20, 200]
cruise speed	m/s	85	[25, 85]

Second, UAM demand data is input to profit optimization, where eVTOL vehicle concepts, battery masses, horizontal flight speed, and ticket prices are decision variables. The revenue is generated by the ticket prices of the UAM flights operated, while the costs are modeled as total costs of ownership from the perspective of a fleet operator, including energy, maintenance, batteries, vehicle acquisition, vertiport operations, air traffic management, charging, and vertiport infrastructure.

Third, the simulated UAM flight data have an optimum point that the operator aims to achieve. Sensitivities of the technology assumptions are added for further profit analyses. eVTOL design recommendations are derived from vehicle-specific decision variables. These in turn represent input for vehicle design as a further loop in the overall methodology.

Study

Simulation. The open-source population data from the following simulation scenarios is used for the UAM demand analysis: Los Angeles [8], Kyoto [9], and Rhine-Ruhr [10, 11]. The latter is

Materials Research Proceedings 69 (2026) 94-98 https://doi.org/10.21741/9781644904251-17

considered a comparison scenario together with analyses that have been carried out recently [12, 13]. Accordingly, the same default settings are used.

Network analysis. K-means clustering of 1% population data for mobility routes over 15 km is used as the initial UAM network to exclude short-distance biases. For the Los Angeles simulation scenario, this results in around 124,000 trips, with an average distance of 9.5 km and a median of 5.6 km. For the Kyoto simulation scenario, this results in around 11,000 trips, with an average distance of 11 km and a median of 3.9 km, which is due to the reduced network size. The Rhine-Ruhr simulation scenario is medium-sized with around 24,000 UAM candidate trips.

UAM network analysis. Figure 2 shows (a) an efficient and high density UAM station network, (b) the coverage of all simulated flight distances, and (c) flight counts. This results in regression functions, with polynomial and exponential approaches having a coefficient of determination (R^2) of 0.99. Estimated power-law scaling for vertiports $n \in [0,100]$ result:

$$(1)\ \text{distance}(n) = 2.32\ n^{0.823}$$
$$(2)\ \text{count}(n) = 1.84\ n^{0.871}$$

The sublinear elasticities (0.823 and 0.871) are consistent with network scaling effects. The reference network of 55 vertiports accounts for 70% of total demand. For the smaller simulation scenario Kyoto, the coefficients of determination are around 0.82 with an indicated target network size of 15 to 25 vertiports.

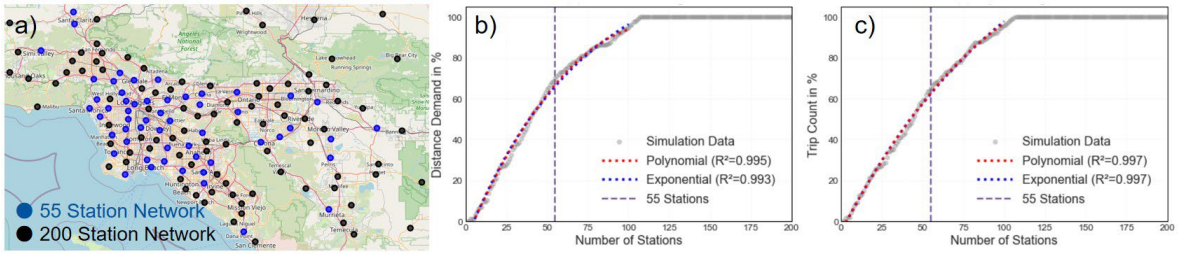

Figure 2. UAM network size effects for simulation scenario Los Angeles.

UAM demand analysis. The surrogate demand models for count and distance are derived from 40 randomized simulations and 150 iterations per scenario, considering Table 1. Comparing these simulation scenarios, it can be shown that the average coefficients of determination are around 0.8, with flight count, larger scenarios, and polynomial models of higher accuracy. The demand surrogate models are linearized and passed on to the profit optimizer.

Profitability analysis. For technology assumptions for the year 2030, this results in feasible business cases. Table 2 shows the resulting key fleet level characteristics. A comparison of the current eVTOL designs indicates that the Joby S4 is the best performing vehicle. The vehicle's study ranges vary less between simulation scenarios than ticket prices.

Table 2. Results of fleet level profit analyses.

parameter	Rhine-Ruhr	Los Angeles	Kyoto
network size	55	100	15
fixed ticket price	12 €	17 €	10 €
variable ticket price	1 €/pkm	1.70 €/pkm	1.15 €/pkm
eVTOL design	Joby S4	Joby S4	Joby S4
study range	95 km	125 km	90 km
2025 profit potential	no	no	no
2030 profit potential	yes	yes	yes*

2025 (2030) assumptions are piloted (autonomous) operation and 250 (400) Wh/kg.
*Kyoto profitability depends on reduced network size (15 stations), extended network analysis indicates marginal viability.

Discussion

UAM demand modeling. The introduced methodology enables consistent and reproducible simulation of demand data using MATSim UAM. Although simple linear regression modeling is possible as an interface for profit optimization, polynomial regression modeling is more accurate. A more detailed analysis with larger data sets and more feature parameter variations is relevant. The simulation studies show a relevant difference between UAM candidate stations and demand-efficient UAM networks, which highlights UAM fleet simulation as key aspect in the methodology.

UAM profitability. It can be stated that autonomous flight operations are necessary and ticket prices comprising fixed and variable prices are profit-enhancing. This enables greater demand over longer distances in all scenarios. The highest ticket prices in the simulation scenario Los Angeles result from (i) the generally higher price structure in California, (ii) greater UAM distances, and (iii) less competition from public transport. The latter is more relevant in both the Kyoto and Rhine-Ruhr scenarios.

eVTOL designs. Cost-efficient vehicles at the UAM fleet level require low energy consumption for longer distances, efficient hovering, and the possibility of passenger pooling to reduce fleet size and maintenance costs. These requirements are best met by the Joby S4, which also offers the advantage of a high cruise speed.

Summary

We develop a modular evaluation framework that enables a consistent comparison of UAM business cases across metropolitan regions. We combine surrogate modeling of agent-based demand simulations to account for system complexity. The study demonstrates that autonomous operations and scenario specific ticket pricing are critical success factors, with the Joby S4 emerging as the most cost-efficient vehicle design across all analyzed scenarios. Regional differences in optimal ticket pricing reflect variations in travel distances and public transport competition, highlighting the need for region-specific UAM business models.

Abstract. The article reports the experimental findings of a 3D-printed modular airframe with interchangeable stabilizers tested in a wind tunnel. In particular, it describes how variations in the stabilizer geometry affect the aerodynamic performance of the airframe. Parameters of measurement (airflow velocity, air density, slope angle, and sideslip) were put into the Sting program for accurate data acquisition during the test campaigns. The Sting software, realised in Gdynia (Poland) in 2018, is useful to run calibration sequences and keep measurement biases under a minimum value as well as to enable real-time model simulations and data analyses. The wind tunnel used was a closed-circuit modular tunnel with a 2400 mm fan, which is capable of generating air velocities up to 60 m/s, with a modular chamber design enabling a variety of test objects. The chosen setup allowed for measurements at an airflow velocity of 27–29 m/s, which is typical of small-scale aerodynamic testing, while allowing accurate force and moment readings. The model was studied in a wind tunnel where test campaigns were carried out to see how stabilizer configurations affect aerodynamic performance metrics like lift, drag, and side forces. As a result, the test data have been processed and analysed to find key aerodynamic results, which were then compared across different stabilizer setups to check their performance and compare several stabilisers' configurations, highlighting those ones that improve aerodynamic stability and efficiency.

Introduction

This article is a comprehensive overview of the analysis and tests made on a PLA modular model of a 1:10 scaled gyroplane inspired by the Gyroplane I-28 ILOT [1], the Carter Copter Gyrocopter [2], and the T6 Aduster gyroplane [3] with the aim of increasing the amount of data relating to the aerodynamic behaviour of the model to speed up design optimization processes. The model construction and numerical analyses were presented in a previous article [4] where is carefully described the design and the construction of a 3D-printed modular airframe with interchangeable vertical stabilizers. Particular attention was on the post-processing in order to create a solid piece ready to be used in wind tunnel tests. The modular construction applied is an innovation that enables systematic aerodynamic performance investigation of vertical stabilizer effects.

The wind tunnel

The wind tunnel is horizontally-oriented and equipped with two interchangeable measurement chambers. The high-speed test section, with an internal dimension of 1275 × 1415 mm, allows flow velocities up to 60 m/s, while the larger environment test section, the one used in this research with dimension of 1800 × 2000 mm, has a maximum velocity of 30 m/s. In Figure 1 a wind tunnel overview is given.

Materials Research Proceedings 69 (2026) 100-105 https://doi.org/10.21741/9781644904251-18

Fig. 1 View of the wind tunnel

Both test sections are particularly suited to measure accurately aerodynamic forces and pressures on whole aircraft models, as well as to:

• Optimize object shapes for aerodynamic drag reduction and flight characteristics improvement.

• Analyze the influence of airflow on structural stability, critical for aircraft, race cars, bridges, and skyscrapers.

• Study aerodynamic properties like lift, drag, and aerodynamic moments varying the slope angle and airflow speeds.

The tunnel circuit consists of four 90° bends, each of which has flow-guide palisades fitted to provide even flow and minimal pressure losses. The drive system is an axial fan with a diameter of 2.4 m located within a streamlined casing to reduce aerodynamic disturbances, with the heat dissipation being directed out of the tunnel. There is an air cooler ducted in position between the third diffuser and the first low-velocity bend in effort to control the air temperature during prolonged operation. To ensure good quality flow in the test section, a honeycomb straightener and a velocity-stabilizing screen set are positioned upstream of the contraction and ground-layer formation duct. The tunnel body is composed of a modular framework. The overall size of the tunnel is 18.7 m long, 7.4 m wide, and 3.3 m high (3.7 m with support pillars). The structure offers excellent flow quality, such as a core velocity uniformity of more than 0.6 m/s, a turbulence intensity of less than 0.3%, and a maximum angularity of the flow of less than 0.3° in vertical and horizontal directions. At maximum airspeed, the Reynolds number based on a reference length of 1 m is below 2×10^5, and this offers uniform test conditions for both fundamental research on boundary-layer development and applied, involving aerodynamic loads, flutter behaviour, and flow-structure dynamics. These conditions are at the base of precise aerodynamic measurements.

Model assembly

The model assembly included several accurate procedures. It begins with the mounting of the tail part of the airframe, along with the first set of tested vertical stabilizers with a wedging angle of 0°. Place the prepared part of the model on the strain gauge transducer of the wind tunnel requires high precision due to the sensitivity of the measuring device [5]. When the tail section is placed, it is screwed in place with a hex socket screw as reported in Figure 2 (a-b-c). In order to eliminate possible air turbulence, which may appear due to the gaps in the connected elements, insulating tape is used. During the assembly of individual sets of vertical stabilizers, the method of their protection was modified. The original idea was to use cotter pins or pins made of wire with a diameter of 2 mm to prevent the stabilizers from falling out during measurements. However, due to the difficulty of pulling out these cotter pins, they were replaced with wood screws. Thanks to this modification, the strain gauges of the measuring scale are exposed to much less vibrations.

Materials Research Proceedings 69 (2026) 100-105 https://doi.org/10.21741/9781644904251-18

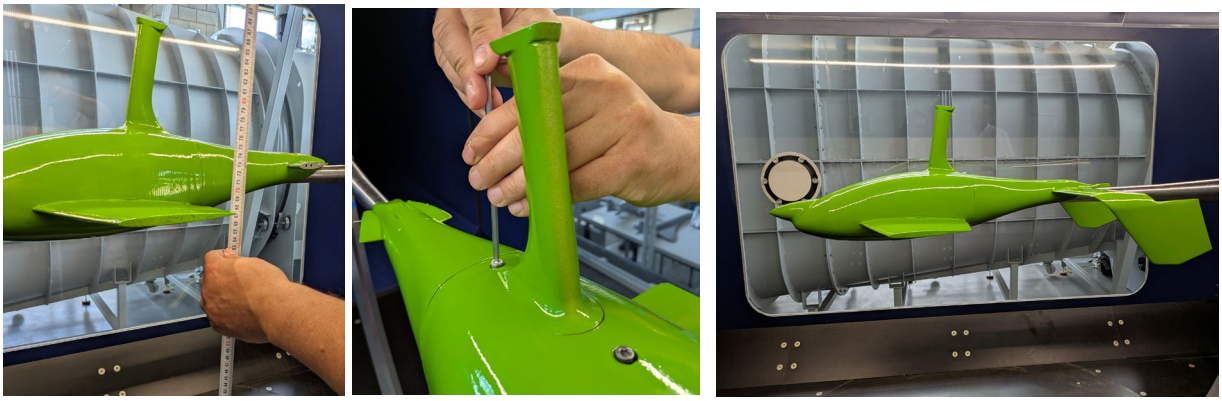

Fig. 2a,2b,2c Assembly and placement on the wind tunnel stand

To prevent the screws from causing unnecessary resistance and air turbulence, the holes were chamfered on the surface of the ballasts so that the screw head could be flush with the surface of the element.

Measurement procedure

Measurements were taken at a constant airflow speed, varying the angle of attack (α) and sideslip angle (β) systematically to cover a wide range of flight conditions.

The aerodynamic forces and moments recorded during testing were processed to calculate standard coefficients (Cx, Cy, Cz) and performance ratios (like Cz/Cx), creating a detailed aerodynamic profile for each configuration.

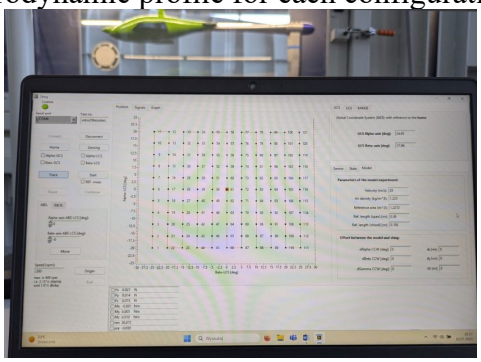

Fig. 3 View of the STING software during measurements

Fig. 4 View of the wind tunnel control panel

The STING software [6, 7] a data acquisition and calibration environment, has been developed to support six-component force balances in wind tunnel testing. It allows for a direct comparison between experimental data and predictions based on aerodynamic models, reducing post-processing time and improving the repeatability of measurements. The Sting software was used to handle measurement control and data collection, including automatic calibration (tare) for each stabilizer configuration, from -15° to +15° in 5° increments, including a baseline with no stabilizers, and for data acquisition (air flow velocity, air density, slope angle and slide, etc.).

The measurements were carried out using: Air velocity: 29 m/s; Slope angle α in the range of ±20° with increments of 2.5°; Glide angle β in the range of ±25°with increments of 5°.

Therefore, according to the abovementioned parameters, 121 measurement conditions were acquired by the STING program (Figure 3).

Later, is the tare calibration was carried out. It consists in going through all measurement points without the tunnel fan running eliminating the effect of the model's weight on the measurements.

Materials Research Proceedings 69 (2026) 100-105 https://doi.org/10.21741/9781644904251-18

Taring was done individually for each set of stabilizers. Once taring was completed [8], the side panel of the test stand was sealed, and the measurement series began. On the tunnel control panel, the predefined value of the airflow speed was set (Figure 4).

The results were collected as data file easy to be processed into tables and graphs. Forces and moments acting on the model were analyzed. The reference system applied is shown in Figure 5.

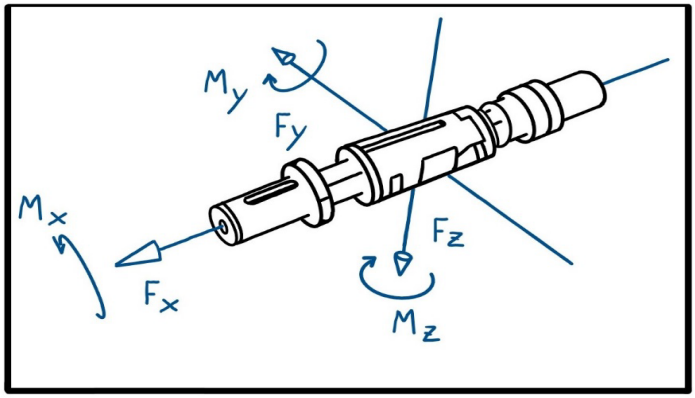

Fig. 5 Diagram of aerodynamic moments and forces in relation to the measuring element of the aerodynamic of the wind tunnel

Measurements results and analysis

During this research, several relevant values were achieved. In particular drag coefficient C_x, lift coefficient Cz, side force coefficient Cy and force ratio Cz/Cx [9] in addition to axis forces and moments were calculated for each slope angle using the equations reported below. [10, 11]. The tests did not take into account the influence of propellers or rotor windage.

1. Drag coefficient equation (C_x)

$$\mathbf{C_x = \frac{2F_x}{\rho V^2 S}} \tag{1}$$

Where $\mathbf{F_x}$ is the aerodynamic drag force, **ρ** the air density, **V** the air flow velocity and **S** the reference area of the model.

2. Lift coefficient equation (C_z)

$$C_z = \frac{F_z}{\frac{1}{2}\rho V^2 S} \tag{2}$$

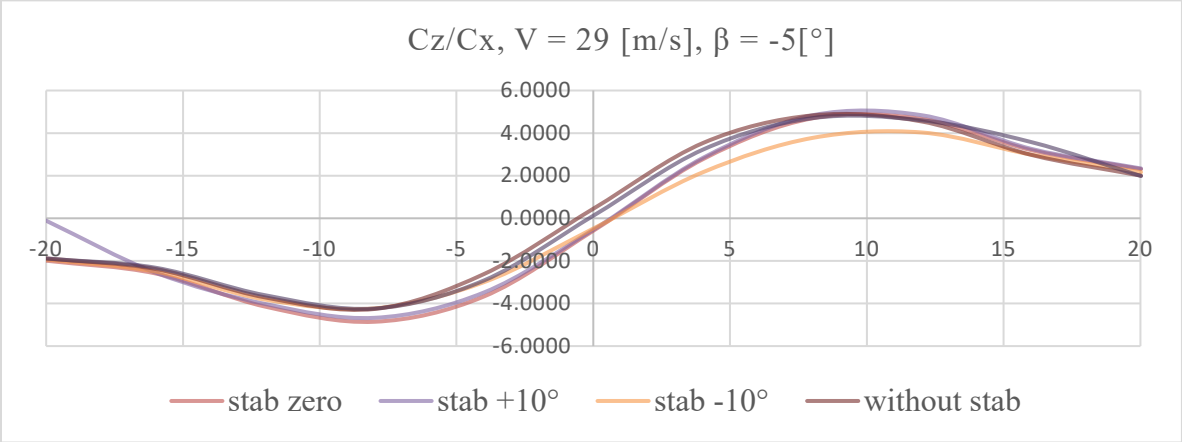
Being F_z the aerodynamic lift, ρ the air density, V the air flow speed, and S the reference model surface, respectively.

3. Side force coefficient equation (C_y)

$$C_y = \frac{F_y}{\frac{1}{2}\rho V^2 S} \tag{3}$$

Where F_y is the aerodynamic side force, **ρ** the air density, **V** the air flow velocity and **S** the reference area of the model.

4. Force ratio equation (E)



$$E = \frac{C_z}{C_x} \tag{4}$$

Being C_z the lift coefficient and C_x the drag coefficient.

Materials Research Proceedings 69 (2026) 100-105 https://doi.org/10.21741/9781644904251-18

The calculations were made using the results for the sliding angles β from -20° to +20° and the air flow velocity equal to V = 29 m/s, with the stabilizer settings shown in Table 1 and connected with the following stabilizer angles: Stabilizer angle = 0°; Stabilizer angle = +15°; Stabilizer angle = -15°; Without stabilizer.

Table 1 Example of graph obtained analysing force ratio at a sliding angle of -5° and at a velocity of 29 [m/s]

Conclusions

Based on the tests carried out in the wind tunnel, it was possible to analyze the different effects connected with the modifications of the basic configuration.

The more the wedge angle increases, the higher the stability and aerodynamic efficiency are. Such an effect can be observed in the lift/drag ratio, despite this involves a reduction in the optimal slope angle.

Asymmetric flow tests, i.e. with $\beta \neq 0$, show a small yaw moment coefficient. However, it can be noticed that as the drift angle increases, a strong roll moment is generated, which is accentuated as the slope angle increases, highlighting a strong lateral instability. Furthermore, the drift angle leads to an increase in drag, lateral force, and lift, with a consequent reduction in pitch moment.
With the use of smaller stabilizers, a reduced stability can be observed. Increasing the drift angle partially improves stability, which confirms the need for larger tail surfaces.

In symmetrical flights, increasing the surface area of the horizontal tailplane improves longitudinal stability. In addition, there is an increase of approximately 10% in the lift coefficient and its drift, while the angle of lift remains unchanged.

In asymmetric flows, the tailplane area has minimal effects on the aerodynamic coefficients in conditions of drift and zero slope angle. What would make a difference, increasing both horizontal stability and lateral force, is the possibility of adding a ventral fin below the fuselage.
In conclusion, it can be observed that the optimal configuration requires sufficiently large tail planes [12] and a positive wedge angle to ensure stability and efficiency.

Overall, the wind tunnel tests provided a quality dataset for the evaluation of vertical stabilizers' contribution to the control of aerodynamic performance.

The systematic method ensured comparability among configurations, and experimental setup precision minimized measurement uncertainty. The findings offer application in the optimization of stabilizer design for model aircraft and as a validation reference for numerical models.

To sum up, this research provides insights for the researcher in the aerodynamic domain of aircraft stabilizers by detailing the latest techniques in aerodynamic flow analysis. These results aim to deepen the understanding of stabilizer-induced aerodynamic behavior in small-scale aircraft. By measuring how changes in wedging angles affect key aerodynamic parameters, this research offers useful data for improving tail design in both academic and industrial settings.

Additionally, the methodology used, which involved models and systematic wind tunnel testing, can serve as a guide for future aerodynamic studies.

Abstract. The optimization of aircraft stability and aerodynamic performance is a key aspect of modern aerospace engineering, especially concerning vertical stabilizers, which are essential for maintaining yaw stability and controlling sideslip during flight. To enable adequate analysis regarding performance, stability, and control, a validated aerodynamic model of the aircraft has been created. The main goal of the study is to evaluate how stabilizer shape affects the aerodynamic traits of the airframe. In this paper it is examined a detailed view of the modular aircraft model, which was created, to ensure accurate and repeatable results, using computer-aided design (CAD) software and manufactured with fused deposition modelling (FDM) 3D printing using polylactic acid (PLA) material. This method provided a balance between strength and flexibility, allowing for precise reproduction of complex parts while reducing material waste. The modular design of the airframe enabled quick swapping of stabilizer components, making systematic and comparative analysis across different setups easier and ensuring consistent measurements under the same conditions. This research discusses the aerodynamic features of an aircraft model with modular, interchangeable vertical stabilizers set at different wedging angles. In total, there are seven pairs of easily replaceable elements. The model has been obtained in order to be used to perform tests in the wind tunnel. To sum up this research provides an airframe model construction and design traded off additive manufacturing effectiveness with attention to post-processing in order to create a solid experimental piece. Modular construction is an applied innovation that enables systematic aerodynamic performance investigation of vertical stabilizer effects.

Introduction

Airplanes and helicopters have been studied exhaustively, to the point of becoming a standard and well-established area of modern aviation. Nevertheless, ultralight aircraft such as the gyroplane, which offer significantly lower operational and maintenance costs, have always been quite underrated.

Despite their remarkable characteristics such as a rotor, similar to that of a helicopter, which generates lift through autorotation, and as an engine-driven propeller, similar to an airplane's, which provides thrust, the gyroplane has spent nearly a century in the shadow of both airplanes and helicopters [1].

In recent years, instead, there has been a renewed interest in gyroplanes, due to their safety, simplicity of use and price as well as their ability to take off and land short distances, which makes them best for recreational, training and potential urban mobility applications.

Materials Research Proceedings 69 (2026) 106-111 https://doi.org/10.21741/9781644904251-19

The model design

In this paper, the design and the manufacture of a modular scaled model of a gyroplane is presented in order to analyze how different stabilizers influence the aerodynamics of the aircraft.

The initial gyroplane used as reference was the I-28 (Fig.1), designed by Sieć Badawcza Łukasiewicz – the Polish Institute of Aviation known as iLOT- in 2010 as part of the project named "Technology for implement a new type of rotorcraft into commercial practice" [2] and, lately, manufactured in 2012 through a collaboration with the Aviation Arthur Trendak [3].

The I-28 is a two-seat gyroplane featuring a 6-meter-long fuselage. It is equipped with a two-blade, ground-driven prerotational rotor, with the drive shaft divided by universal joints and guided within the rotor pylon. Propulsion is provided by a 110 kW diesel engine driving a propeller with a diameter of 1.73 m.

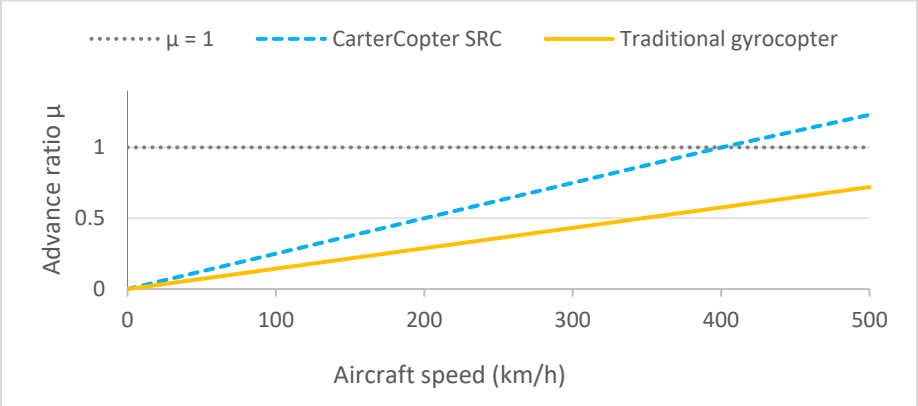
The I-28 was later modified through the addition of wings by Carter Aviation Technologies, and this configuration, known as CarterCopter (fig.2), was used as the starting point for the analysis in this work.

The CarterCopter prototype was developed to prove the slow rotor compound technology, which consists of slowing the rotor during the cruise and letting the wings supply the majority of lift as speed increases.

Fig.1 Gyrocopter I-28

Fig.2 CarterCopter gyrocopter

The practical result was visible in the value of the advance ratio μ – the relationship between the aircraft's forward speed and the tip speed of its rotor blades.



In conventional helicopters, μ was typically around 0.3-0.4. Trying to push a helicopter faster would run into serious problems as the retreating blade stalls - no more lift contribute - and the advancing blade approaches supersonic speed - huge drag and instability.

The CarterCopter, instead, became the first rotorcraft in history capable of obtaining = 1, its airspeed was equal to the rotor tip speed (table 1).

This innovation showed that with a slowed rotor and fixed wings, it is possible to fly much faster than with a helicopter while still having short or vertical takeoff and landing [4].

This research was focused on creating a model to perform systematic tests on its aerodynamic properties. The prototype was designed trying to maintain scaled geometric similarity, consider the Reynolds number consistently within the limits of the wind tunnel, and preserve the relative proportions of key aerodynamic surfaces.

Table 1. Comparison of Advance ratio μ

Computational geometry

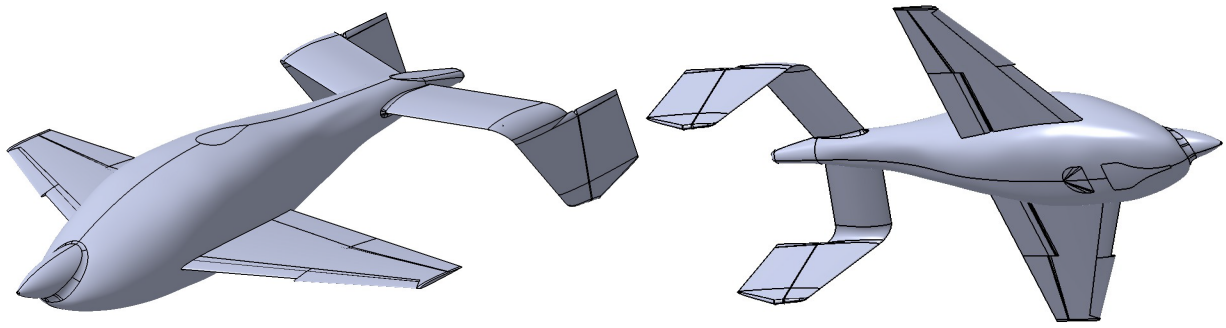


Fig 4-5 Different views of the model in the CAD software

The solid geometry was then imported to Design Modeler in ANSYS Workbench, where further simplifications were performed for the mesh quality enhancement. These included reducing fragmented surfaces, healing irregularities, eliminating sharp angles, and smoothing edges. Tools such as Repair, Merge, Hard Edges, Holes, Spikes, and Faces were used to improve geometric consistency.

Then, the model was discretized based on tetrahedral elements, whose size, number, and quality were checked as influential parameters on simulation accuracy.

A mesh sensitivity analysis was conducted to access the effect of the element density on aerodynamic predictions. On the half-height geometry, a mesh of 0.98 million elements under-predicted drag by 39% and lift by 52% in comparison with a refined mesh of 1.67 million elements. Further refining the mesh to 2.46 million elements reduced differences to approximately 1% in drag and 7% in lift and was considered appropriate for the objectives of the present study.

In the initial design phase, it was recommended the fuselage to be redesigned for improved aerodynamics. More precisely, provisions for enhancing fuselage airflow, especially aft of the nacelles and wing–fuselage junctions, were included. These were intended to eliminate adverse force gradients on the horizontal stabilizer, so that the overall performance was improved.

Construction

Particular relevance was given to the model creation phase, essential for reliable prototype's tests and evaluate its effectiveness.

A modular design approach was adopted instead of constructing a single, fixed-geometry model to allow the analysis of different stabilizer deflection angles (± 15, 10 and 5 degrees [6]).

Materials Research Proceedings 69 (2026) 106-111 https://doi.org/10.21741/9781644904251-19

The modularity of the prototype facilitates an easy replacement and adjustment of stabilizers and an identical testing across configurations. This offered not just improved efficiency of experimentation but also comparability of results.

Before testing, the model was printed using Fused Deposition Modelling (FDM) technology. The process consists in heating Polylactic Acid (PLA) filaments, extruding them through a nozzle and depositing layer by layer on a worktable.

The resulting 3D draft model made up of several elements is reported in Figure 6.

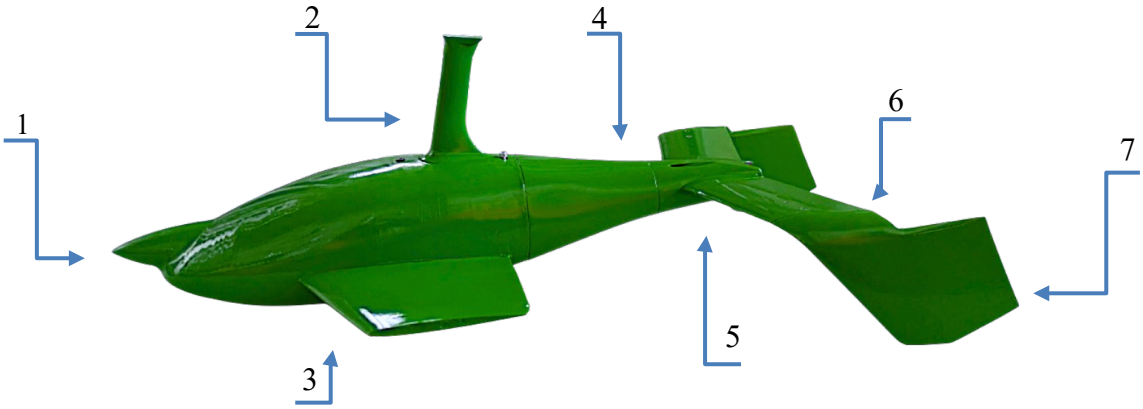

Fig. 6 Division of the gyroplane into individual components: 1- nose, 2- mast ,3- left wing, 4- first half of the tail, 5-second half of the tail, 6- horizontal stabilizers, 7- vertical stabilizers

The model went through a rigorous process of refinement to prevent interference during testing and to ensure precise alignment and smooth connections.

All the elements were refined [7], removing support structures, sanding in multiple stages, filling surfaces, and applying primers and varnishes.

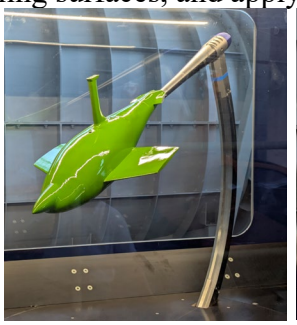

Fig.7-8 Different views of the printed model on the wind tunnel stand first without and then with stabilizer

Fig. 9 Cuboid-shape core on the wind tunnel stand

Finally, the main structural element of the tail was connected to the core, located at the front of the model as reported in Figures 7 and 8.

A special profiled socket for a metal sleeve was provided into the cuboid-shaped core. Such a sleeve is an adapter to connect the model to the wind tunnel balance system as shown in Figure 9. The upper part of the tail consists of two halves, allowing the connection of the main element of the tail with the horizontal stabilizers.

The vertical stabilizers, which are the main subject of the study, were arranged in interchangeable pairs with deflection angles ranging from ±15 degrees (every 5 degrees).

There are seven pairs of easily replaceable elements, which are placed directly on the horizontal stabilizers via an insertion element and secured using metal cotter pins.

Materials Research Proceedings 69 (2026) 106-111 https://doi.org/10.21741/9781644904251-19

Although considerable attention was paid to manufacturing accuracy, minor surface irregularities were detected. Consequently, further steps as rough machining, surface finishing, and painting were carried out to ensure aerodynamic smoothness and dimensional precision.

Turbulence Modelling and Numerical Approach

Preliminary numerical studies were carried out using Ansys Fluent. The applied turbulence model was the SST (Shear Stress Transport) [8] one, to reduce the computing effort. The numerical model capable of obtaining results such as drag coefficient, pressure distribution, and vortices extremely close to what would realistically occur in flight.

The study considers the results of numerical tests of aerodynamic loads on a 1:10 scale model of the gyroplane fuselage and for actual geometry. The tests carried out on the fuselage do not take into account the influence of operating propellers and the aerodynamic drag of the rotor. The aerodynamic characteristics necessary for analyzing the longitudinal and directional stability of the gyroplane have been obtained. All forces and moments are calculated in the velocity system. During the calculations, the following parameters were considered: speed of 29 m/s, air density of 1,225 kg/m³, reference span length of 0.36 m, and reference chord length of 0.193 m.

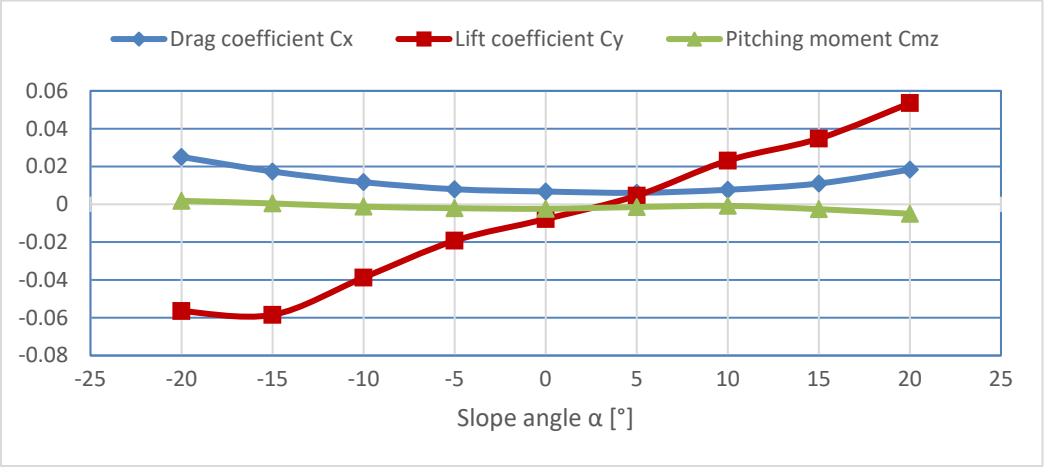

Fig.10 Drag, lift and pitching moment varying the slope angle

Figure 10 shows the main results. In particular, the coefficients of drag, lift, and the pitching moment are reported as a function of the slope angle (α) from -20° to +20° for the tail-pinned gyro [9].

The measurement area of the object under examination is of 1,2272 m², to which a velocity condition (velocity input) has been assigned at the inlet and a pressure condition (pressure output) at the outlet. The remaining walls are recorded as walls, including the surfaces of the gyroplane fuselage.

The analyses were conducted as a pressure-based model, variable in time and at steady state. Air was the fluid flowing through the test object, but an incompressible flow was assumed, and the material definition assumed an ideal incompressible gas. This simplification is acceptable if the flow velocity is less than 0.3 Mach. In the case under consideration, for the assumed temperature of T-288 K, the limit value is 367.4 km/h (the speed of sound for these conditions is 340 m/s, or 1,224.6 km/h).

Conclusions

In this overview paper, the historical background was presented that led to the design and construction of an innovative gyroplane model equipped with different stabilizers to be tested into a wind tunnel. Particular attention was paid to the model modularity, which was strictly connected to the research needs. Moreover, preliminary 3D numerical analyses were carried out, applying

the commercial tool Ansys Fluent, to estimate drug, lift and pitching moment of the gyroplane under several slope angles. On the basis of the promising numerical results, the study will be carried on testing the gyroplane into a wind tunnel, comparing the effect of several stabilizers.

Acknowledgments
The present study was carried out under the Erasmus+ Program. In particular, the Authors want to thank the Lublin University of Technology, and the University of Roma Tre for their kind support.

Abstract. New noise regulations are issued to respond to the expected impact of a massive exploitation of drones in the urban environment. The small size and low flight speed of drones is related to flight regimes characterised by low Reynolds numbers with ignorable compressibility effects. This has recently raised interest in the study of noise generated by transitional airfoils at moderate angles of attack. Where distinct narrow-band frequency peaks, which are perceived as a pitching sound over the broadband noise, are known to arise. Therefore, raising concerns in the design of quieter drones. The current research studies the effects of the airfoil trailing edge thickness on the generation of secondary tones. The flow around a NACA 0012 airfoil and the associated acoustic signature are studied with 2D DNS for six different values of the airfoil trailing edge thickness at $\mathrm{Re}=2.0\times10^5$, $\mathrm{Ma}=0.1$, $\mathrm{AoA}=2.0°$. The role played by the trailing edge thickness in establishing a reattachment region downstream of the laminar separation bubble on the airfoil pressure side is shown. For the first time it is demonstrated that the presence of such reattachment region just upstream of the airfoil trailing edge leads to non-negligible differences in the airfoil acoustic signature. Furthermore, an existing acoustic sharpness criterion is revised considering the presence of the reattachment region. Finally, the fluid dynamics behind the generation of the side tones is described.

Introduction

Airfoil self-noise typically shows a broadband character [1]. But varying the airfoil trailing edge thickness, mechanisms related to the flow dynamics behind the generation of tones are promoted differently. Therefore, airfoils with a sharper trailing edge emit more tonal noise because of the vortex shedding becoming more predominant, while airfoils with a sharper trailing edge are more broadband. Blake conducted an experimental campaign [2] to derive an empirical parameter [3] to determine when an airfoil can be considered acoustically sharp, given different free-stream flow conditions and airfoil trailing edge geometries. But the difficulty in describing the airfoil acoustic signature emerges at moderate Reynolds numbers [4] and at low angles of attack [5, 6], when distinct narrow-band frequency peaks between 20 and 30 dB above the background level [5] arise. The existence of such discrete frequency tones was firstly identified in the early 1970s in [7, 8, 9]. In the pioneering research by Paterson et al. [10] a characteristic *ladder-type* structure in the tonal frequencies with tones undergoing jumps as the free-stream velocity changes was identified. The main aerodynamic source of tones was addressed by Tam [11] to be found in disturbances of the Tollmien-Schlichting instability waves. Lowson et al. [12] concluded for the first time that the appearance of tones is related to the presence of a laminar separation bubble on the airfoil pressure side. With Nash et al. [4] remarking that it is the close proximity of the separation bubble to the airfoil trailing edge the sufficient condition, and not the presence of separation alone. The role of

the angle of attack on the generation of tones was studied by Plogmann et al. [6]. And the role of the Mach number on the laminar separation bubble was recently studied by Pröbsting et al [13].

Numerical solver

High-fidelity 2D compressible Direct Numerical Simulations (DNS) are run in *HiPSTAR*, a *High-Performance Solver for Turbulence and Aeroacoustics Research*. The numerical solver uses an explicit 4th-order central standard-difference scheme with a five-point stencil for spatial discretisation furtherly implemented with a Carpenter boundary scheme, and a 4th-order-accurate five-stage Runge-Kutta integration scheme.

The free-stream conditions are defined by Prandtl number $Pr = 0.70$, Sutherland's dimensionless temperature $S/T_\infty = 0.3686$, Reynolds number $Re = 2.0 \times 10^5$, Mach number $Ma = 0.1$, angle of attack $AoA = 2.0°$. All variables are dimensionless, with the airfoil chord as the reference length.

Grid and boundary conditions

The computational domain is made of three independent structured meshes coupled using a stable overset technique. Specifically, an outer background cartesian mesh discretising the far-field, an O-grid discretising the region around the airfoil, a fish-tail mesh discretising the airfoil wake-region.

In total, the overall grid points are about 10.5 million.

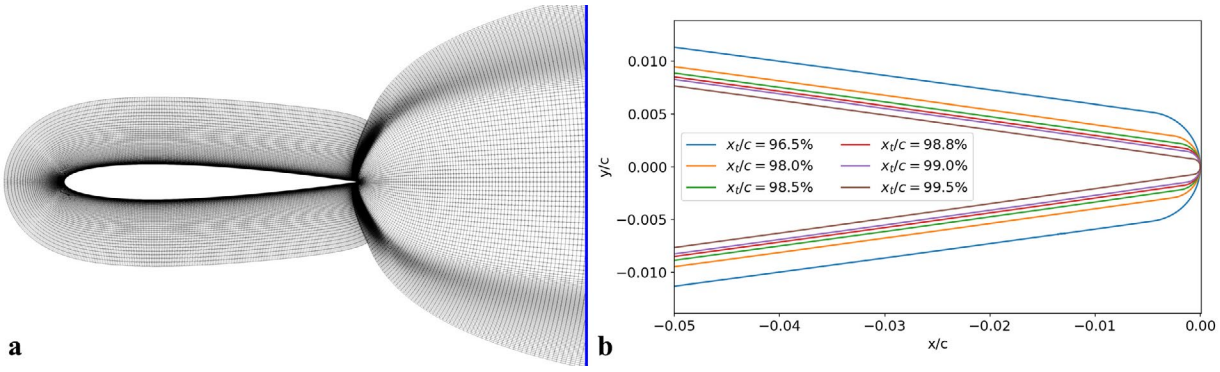

Figure 1 (a) O-grid and part of the fish-tail mesh, (b) comparison of the airfoil trailing edge for different cases.

The free-stream flow is enforced on the outer boundaries by Dirichlet boundary conditions. Reflections from the airfoil's wake are dampened out by zonal characteristic boundary condition on the right outer boundary. Reflections from the acoustic waves are dampened out by integral characteristic boundary conditions (*sponges*) on the remaining outer borders.

The trailing edge of the airfoil is rounded off with a tangential circle to the local surface at a distance x_t/c from the airfoil leading edge, as reported in *table 1* for the six cases. The airfoil is then rescaled to a unitary chord length. The resulting airfoil trailing edges are shown in *figure 1(b)*.

Table 1 Location of the airfoil trailing edge round-off [1st row]and related airfoil trailing edge thickness [2nd row].

x_t/c	0.965	0.980	0.985	0.988	0.990	0.995
$h/c\ [\times 10^{-3}]$	9.9174	5.7239	4.3012	3.4544	2.8737	1.4457

The hydrodynamic and acoustic fields are recorded in a time interval long 30 flow-through-time units after convergence is reached.

Materials Research Proceedings 69 (2026) 112-118 https://doi.org/10.21741/9781644904251-20

Results

A laminar separation bubble (LSB) is present on both airfoil sides.

In general, the separation point moves toward the leading edge with a bigger displacement than the one of the reattachment point. The remarkable phenomenon shown in *figure 2* is that a reattachment region is present on the airfoil pressure side in close proximity of the airfoil trailing edge for the cases $x_t/c \geq 0.988$.

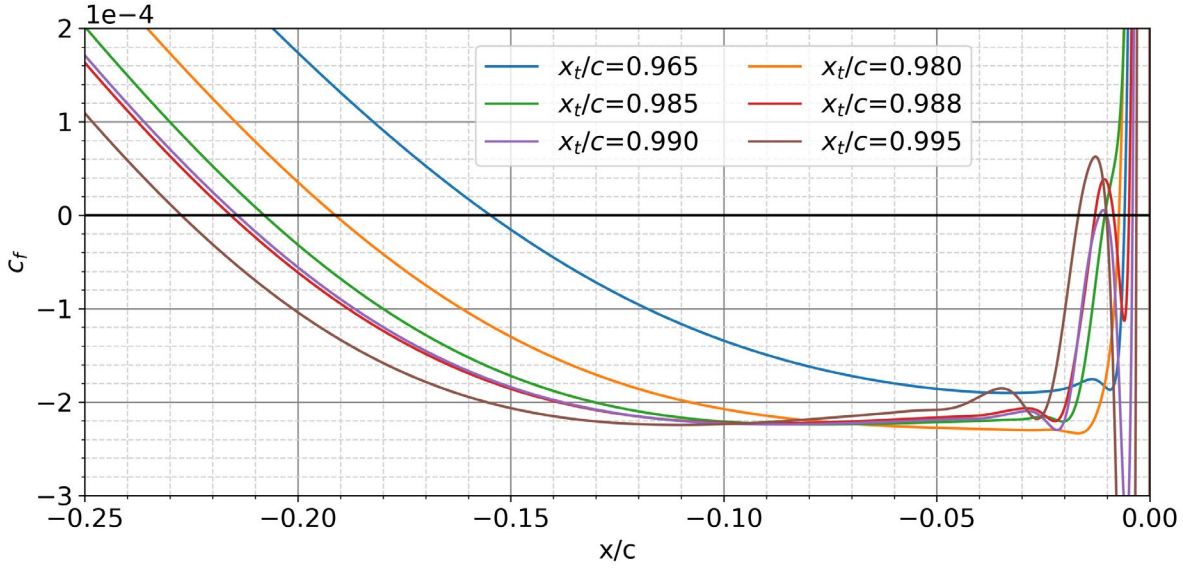

Figure 2 Local chord-wise distribution of the skin-friction coefficient on the airfoil pressure side.

Blake's acoustic sharpness criterion $(h/c)/\delta^*_{tot}$ is given by the ratio of the trailing edge thickness and the displacement thickness measured on both airfoil sides at the trailing edge [3]. A criterion is missing for *laminar* airfoils with a blunt trailing edge described by a local circular arc.

Table 2 Blake's acoustic sharpness parameter [3] calculated for the DNS cases.

x_t/c	0.965	0.980	0.985	0.988	0.990	0.995
$(h/c)\ /\delta^*_{suc}\ [\times 10^{-1}]$	7.633	4.058	2.998	2.377	1.935	0.957
$(h/c)\ /\delta^*_{pres}\ [\times 10^{-1}]$	6.047	2.877	1.968	1.522	1.291	0.609
$(h/c)\ /\delta^*_{tot}$	1.3680	0.6935	0.4966	0.3899	0.3226	0.1565

Therefore, the parameter is calculated for the six DNS cases (*table 2*). The local-reconstruction method proposed in [14] was used to calculate the boundary layer thickness. Given the difference in magnitude and the accountability of different phenomena happening on the two airfoil sides, it is here proposed that the parameter should be calculated separately for the two airfoil sides. For the flow conditions at hand, transition between cases without and with reattachment happens at $(h/c)\ /\delta^*_{pres} \approx 0.197$. With side tones radiated often for cases with a smaller value. The ratio of the same parameter calculated at the trailing edge and at the separation point for the transitional case is 1.946. With cases radiating side tones having a bigger ratio.

The different hydrodynamic fields on the airfoil pressure side are associated with different acoustic fields. With the directivity curves, shown in *figure 3(a)*, that do not simply scale, given a different airfoil trailing edge thickness. The main directivity angle does not change notably. But it is observed that the blunter the airfoil trailing edge, the more directional the overall acoustic signature is. A second lobe is more evident for airfoils without a reattachment region on the pressure side because of the absence of interference by additional side tones. Indeed, the missing lobe becomes evident for all the cases when the directivity plot is filtered in a band-pass interval

centred at the unstable frequency of the suction-sided laminar separation bubble, as shown in *figure 3(b)*.

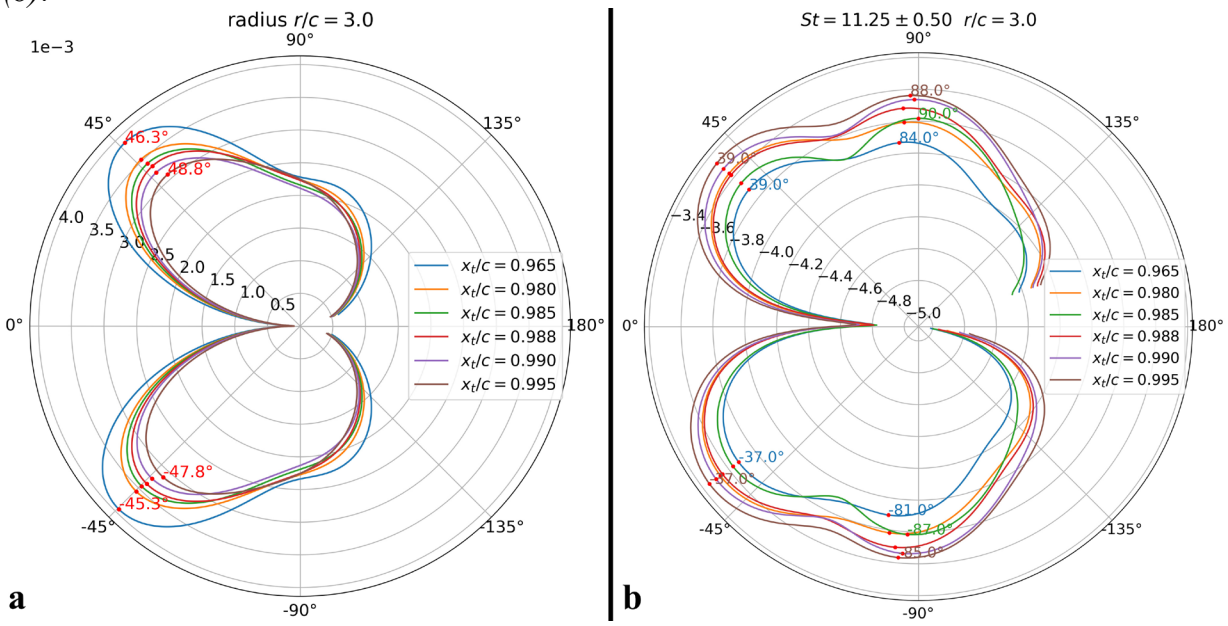

Figure 3 Directivity plot of the root-mean-squared pressure fluctuations recorded at a distance $r/c = 3.0$ from the airfoil trailing edge: (a) non-filtered, (b) filtered around the Tollmien-Schlichting frequency.

High frequency second tones are observed to be radiated *often* only for the cases with a reattachment region on the airfoil pressure side. This is visible in the instantaneous dilatation field, as shown in *figure 4(a)*. And since the time derivative of density balances the divergence of the velocity field, which can be used to visualise the acoustic field, the high-frequency second tones become visible in the power spectral density of the time-derived pressure fluctuations as well, as shown in *figure 4(b)*. With some peaks at higher frequencies and an evident lower decay rate for airfoils exhibiting a pressure-sided reattachment region.

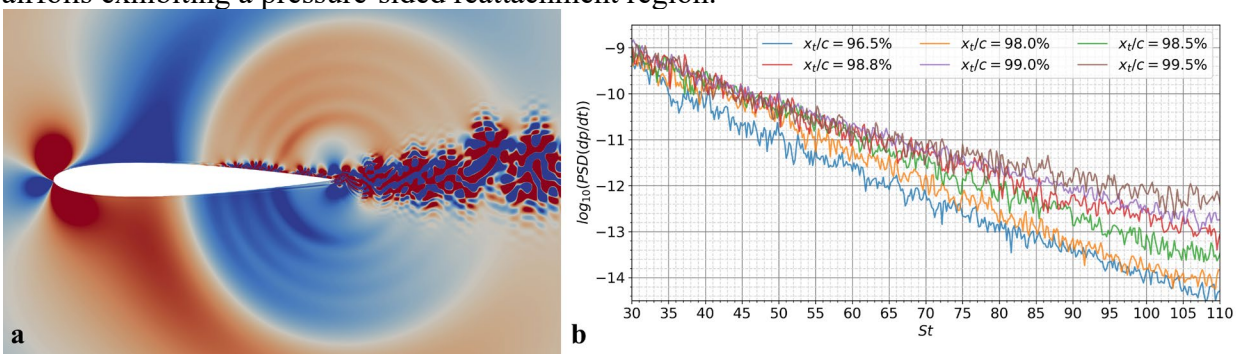

Figure 4 (a) Side tones visible in the instantaneous dilatation field. Range is chosen to highlight the second tones, with the side effect of the wake and laminar separation bubble on the airfoil suction side that look noisier than they are. (b) Power spectral density of the time-derived pressure recorded at $(x/c, y/c)=(0.0;1.0)$, calculated applying the Welch method with a Hann window long 5 flow-through-time units and 50% overlap.

High frequency *consecutive* secondary tones are seen to arise from the interaction of one or two eddies in close proximity of the airfoil trailing edge, with the latter acting as a scattering source. This is visible in *figure 5*. Here a vortex is growing in the recirculation region downstream of the trailing edge, thanks to the locally re-attached flow downstream of the laminar separation bubble

Materials Research Proceedings 69 (2026) 112-118 https://doi.org/10.21741/9781644904251-20

on the airfoil pressure side. When a local region of opposite sign of vorticity, which follows the vortex just shedded from the suction-side, slips over the mentioned small vortex. The pressure fluctuations related to the interaction of these two local concentrations of vorticity of opposite sign is scattered by the trailing edge in high-frequency side tones.

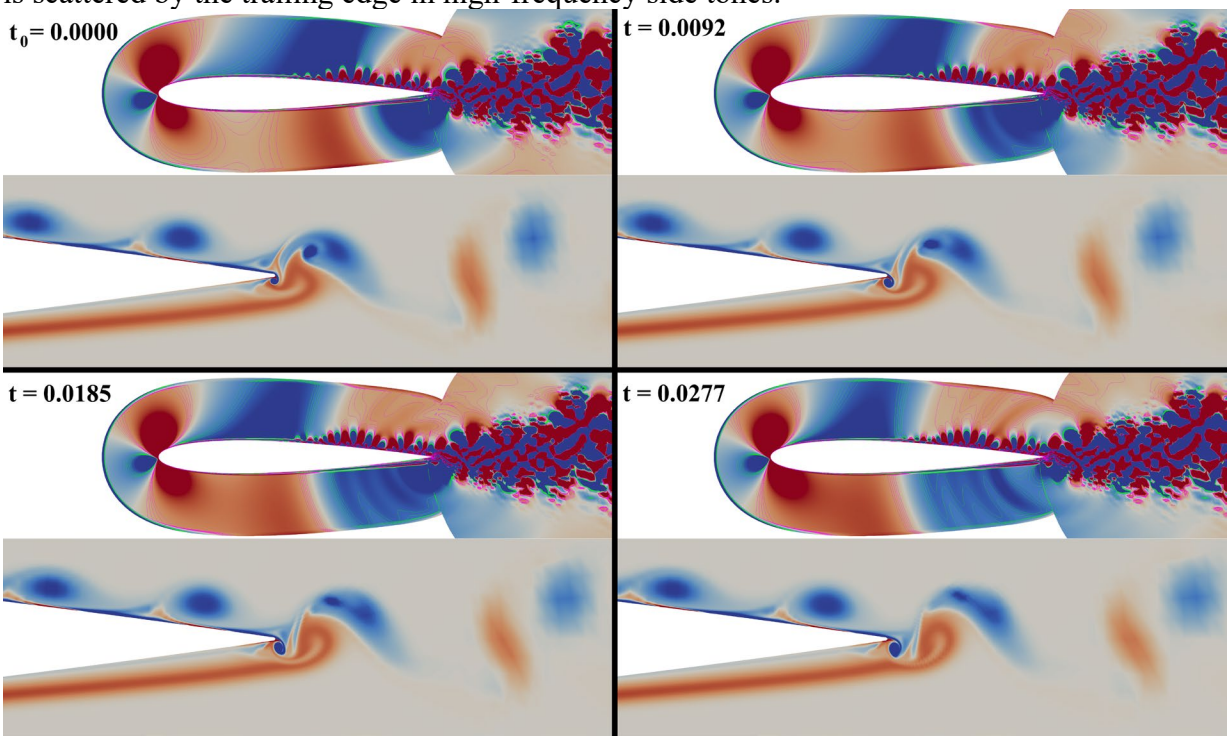

Figure 5 Interaction of vortices behind the generation of high-frequency side tones for the sharpest airfoil trailing edge case. Spatial distribution of the divergence of the velocity vector [upper row] and of its vorticity [bottom row].

A *single* secondary tone is observed to be emitted *rarely* in the cases without a reattachment region for the laminar boundary layer developing on the airfoil pressure side. In this case (*figure 6*), the tone is generated by the spinning of a vortex at the trailing edge. This vortex sheds in phase opposition with respect to the incoming vortex convected from the suction side. Therefore, the incoming vortex does not scatter energetically at the trailing edge and the associated tone is quieter.

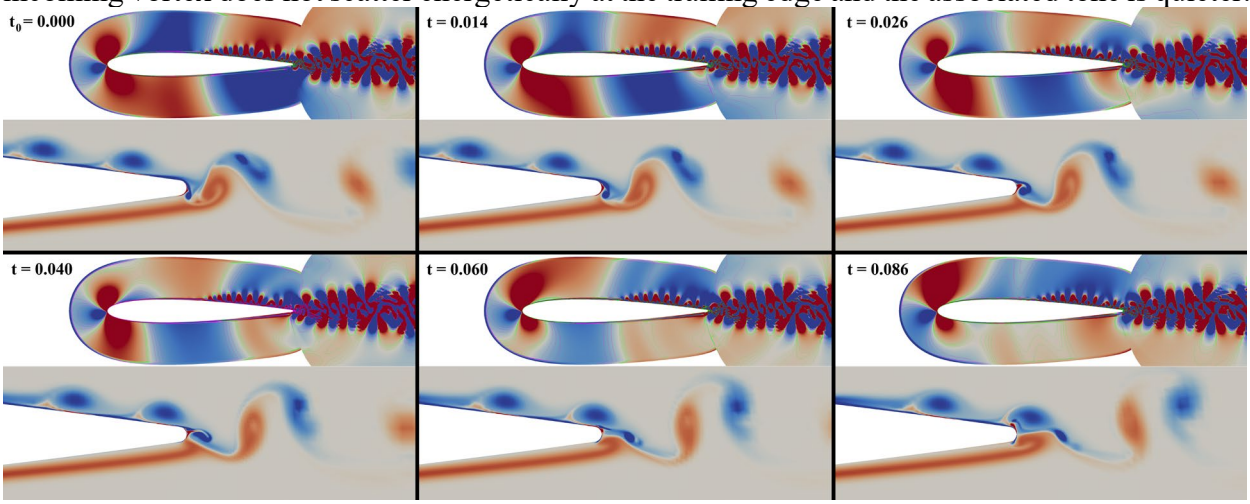

Figure 6 Interaction of vortices behind the generation of high-frequency side tones for the bluntest airfoil trailing edge case. Spatial distribution of the divergence of the velocity vector [upper row] and of its vorticity [bottom row].

Conclusions

At a moderate Reynolds number and for a nearly incompressible flow, varying the airfoil trailing edge thickness while keeping unitary chord length allows the laminar flow to reattach on the airfoil pressure side. The present paper shows for the first time how the presence of a reattached laminar flow is associated with a different acoustic field. Therefore, existing empirical parameters aimed at determining when an airfoil can be considered acoustically sharp or not do not consider such phenomenon. Specifically, the acoustic field changes because of the presence of additional secondary tones. Sharper cases with a reattachment region promote different interactions between vortices rolled up from the laminar separation bubbles on the two airfoil sides and convected past the airfoil trailing edge. These eddy-with-eddy self-sustained interactions generate high-frequency secondary consecutive tones. On the contrary, the absence of such interactions in cases without a reattachment, make secondary single tones possible only rarely and due to a non-self-sustained offset in the main shedding frequency.

Abstract. Supersonic commercial aircraft have the potential to greatly reduce global travel times, but key challenges, such as high fuel consumption due to increased drag at supersonic speed, remain a barrier to commercial feasibility. In this study, a Concorde-like delta wing aircraft was modelled and analysed using ANSYS Fluent at different Mach numbers, such as Mach 0.8, 1.02,1.5 and 2. During supersonic flight, significant aerodynamic drag is generated primarily due to wave drag. A multi-stage nose spike was designed and tested to reduce the drag. Results indicate that a stage 4 spike reduced the total drag by 4.23% at Mach 1.5, and the Lift to Drag ratio has increased by 3.9%. The simulation results were compared and validated against results from a previous research paper It is recommended that at subsonic speed, the spike be retracted in position 1, position 2 is optimal for transonic speeds, and position 4 performs best at supersonic speeds.

Introduction

Commercial supersonic flight ended with the Concorde retirement in 2003 after nearly three decades of operation with British Airways and Air France. Despite its technological success, Concorde faced two major challenges the sonic boom, which restricted supersonic flight over land and high operating costs due to poor fuel efficiency. Both issues arise from the physics of supersonic flight, as an aircraft approaches and exceeds Mach 1, which is the speed of sound, the air in front of the aircraft begins to compress, resulting in the formation of shock waves. These shock waves not only produce a sonic boom but also introduce a component of drag known as wave drag, which can increase the total drag by more than 50% [1]. This significant increase in drag is responsible for the poor fuel efficiency of supersonic flight. There is renewed interest in the commercial supersonic market, with companies such as Boom Supersonic actively working to bring back supersonic commercial flight. The market is projected to be valued at USD 70 billion by 2034 [2]. However, aviation currently contributes approximately 2.5% of global carbon emissions, highlighting the need for a solution to make commercial supersonic travel environmentally viable [3].

Improving fuel efficiency and reducing drag in supersonic flight was greatly advanced by the development of the area rule in the 1950s[4]. This rule demonstrates that the significant increase in drag at transonic and supersonic speeds is heavily influenced by the longitudinal distribution of the cross-sectional area. A smooth and gradual change in cross-sectional area will minimise the increase in drag. [5]Supersonic fuselage designs often include a bottleneck section near the wings to reduce the change in cross-sectional area distribution. While it is effective at reducing drag,

Materials Research Proceedings 69 (2026) 119-124 https://doi.org/10.21741/9781644904251-21

such a design compromises the cabin layout and limits the number of passenger seats [6] creating challenges for commercial aviation. [7]Variable sweep wings allow an aircraft to optimise performance at low and high Mach numbers. The wings sweep back to reduce the cross-sectional area change as the Mach number increases. However, the mechanisms are heavy, complex and difficult to maintain. [8]Extended nose designs, such as the NASA X-59, reduce the strength of the initial shock by distributing it along the length of the nose. Such a design does, however, limit pilot visibility, which is essential for certification in commercial applications. An alternative approach is the use of a slender retractable nose spike, [9] Gulfstream Aerospace has previously experimented with an extendable nose boom concept that extends in front of the fuselage at high speeds to break up the strong initial shock into subsequent smaller shocks, and the spike would be retracted at lower speeds, such as for take-off and landing. Gulfstream developed this concept to avoid impacting the internal cabin and cargo space. The concept was tested in an F15 platform, but its application for commercial supersonic aircraft has not been analysed. This study will examine the aerodynamic benefits of a multi-stage spike in reducing drag for supersonic transport aircraft. A simplified Concorde-type model will be analysed using computational fluid dynamics with baseline lift and drag values evaluated at Mach 0.8,1.02,1.5 and 2. Testing done by Gulfstream showed that while a single stage spike reduced the initial overpressure, multistage spikes effectively split the primary shock, lowering peak overpressure [10] .

Design

The baseline configuration was derived from a Concorde-type design from a previous analysis [11]. The long and slender fuselage, along with the ogive delta, was designed on Fusion 360 with the NACA 64A210 aerofoil being utilised. The Fuselage section was generated from longitudinal and cross-sectional sketches, which were mirrored about the centreline. The final base model measured 62 m in length. The wing geometry was produced by lofting the aerofoil section with the leading and trailing edge curves. The final wingspan measures 25.46 m Finally, the vertical stabiliser and the engine inlets were modelled. For computational fluid dynamics (CFD), all components were unified into a single body and uniformly scaled down by a factor of 1:10. The scaled-down dimension measures 6.2 m in length and a span of 2.54 m. This was done to reduce the computational time and allow for a denser mesh. A multistage nose spike consisting of four different stages was designed with the modification beginning from the approximate location of the bulkhead in front of the cockpit. The retracted stage measures 0.69 m in length with a radius of 224mm, while the fully extended stage measures 2.59 m in length. The spike proportions were based on a ratio derived from Gulfstream Aerospace. Figure 1 show the base and the multistage spike configurations and figure 2 shows the four different spike stages.

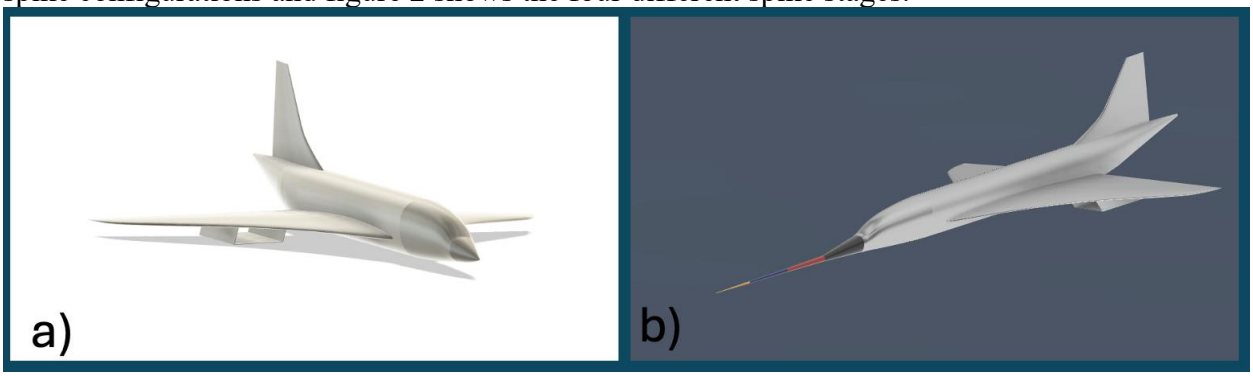

Figure 1 a) Base configuration b) Multi-Stage spike configuration

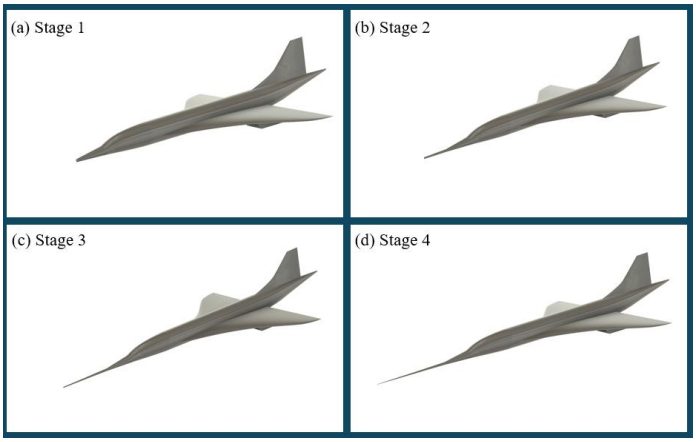

Figure 2 Four different Spike Stages

Computational Analysis

ANSYS Fluent was used to conduct the CFD simulation. The aircraft model geometry was imported into Design Modeller, and a C-Type domain was generated 40 m upstream and 60 m downstream. The aircraft model was subtracted from the domain using a Boolean command. The mesh generation was carried out using Fluent's watertight meshing. A poly hexacore mesh was used, and an inflation layer with 20 layers and a target wall y+ of 5 was applied to accurately resolve the boundary layer. The final mesh contained approximately 800,000 cells with an average orthogonal quality and skewness of 0.97 and 0.0024, respectively. A mesh-independent study was performed to ensure the accuracy of the results. The simulations were performed using a steady-state density-based solver. The K -ω SST turbulence model was employed as it is good at capturing the boundary layer Curvature correction and compressibility effect were enabled to improve accuracy[12]. The ideal gas model and Sutherland viscosity model were used to model the air properties. The Boundary conditions include a pressure far field and a pressure outlet based on the simulation setting from a base reference paper. The aircraft surface was defined as a no-slip wall. The operating conditions were based on standard atmospheric data at four Mach numbers 0.8,1.02,1.5 and 2. All cases were analysed at a 5-degree angle of attack. The implicit solver was used along with Solution steering to improve convergence and stability. The lift and drag coefficient was analysed and compared against the base reference paper to validate the results, following which the multi-stage spike was implemented and analysed under the simulation conditions from table 1 .

Table 1 Simulation conditions

Mach number	Angle of attack (degrees)	Altitude (m)	Temperature (K)	Pressure (Pa)	Density ($Kg.m^{-3}$)
0.8	5	5090	255.09	53402	0.7359
1.02	5	7940	236.60	35961	0.5248
1.5	5	18288	216.65	7231.20	0.1206
2	5	18288	216.65	7231.20	0.1206

Results

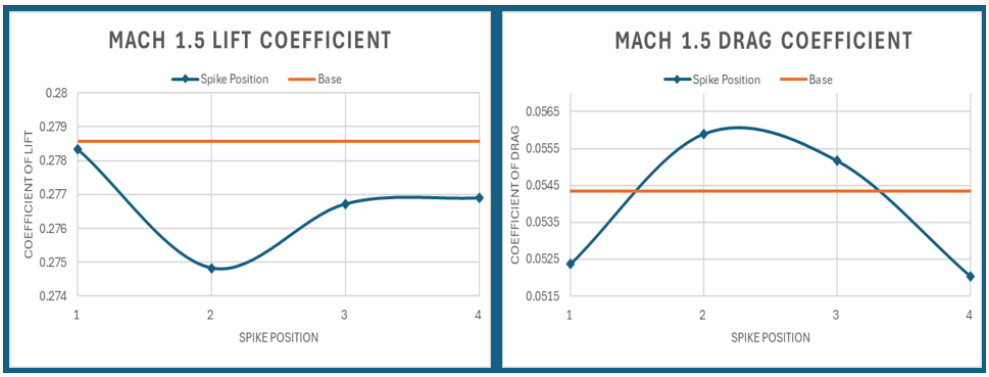

Figure 3 Lift and Drag Coefficient

At Mach 1.5, the baseline configuration produced a lift coefficient of 0.2786. With spike position 1, lift decreased marginally to 0.2783, a 10% decrease. The lowest lift was observed at position 2, while positions 3 and 4 had only a 0.6% decrease in lift relative to the baseline
In terms of drag, the baseline coefficient was 0.0543. Spike 1 reduced drag to 0.524, representing a 3,6% improvement. Position 4 achieved the greatest drag reduction with a 4.2% decrease in the drag coefficient. Considering both lift and drag, position 4 produced the most favourable lift-to-drag ratio. Thus, spike position 4 was identified as the most aerodynamically effective configuration at Mach 1.5

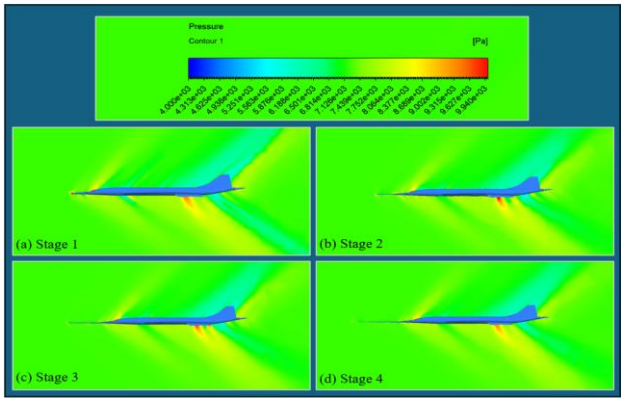

Figure 4 Spike stages pressure contours

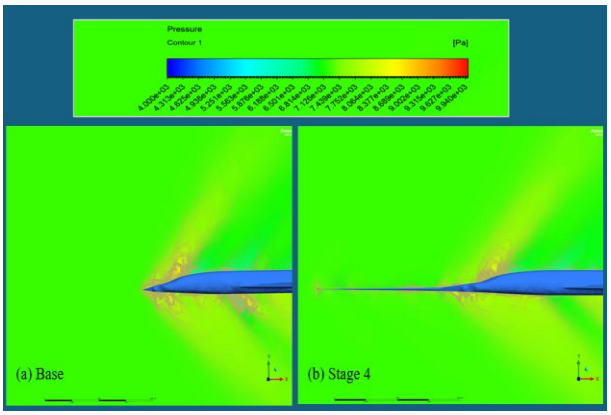

Figure 5 Nose Close-up Pressure Contours

The pressure contours in figure 4 further support these results. Across all supersonic cases, shock waves originated at the nose of the aircraft, with the shock deflection angle increasing as the Mach number increased. However, their intensity diminished progressively with the extension of the spike. The stage 4 configuration displayed notably weaker and more diffuse shocks, indicating improved shock mitigation at higher Mach numbers. Pressure distribution ranged between 4000 Pa and 9000 Pa. Overall, the analysis demonstrates that a multistage spike can efficiently reduce drag and improve aerodynamic efficiency at supersonic speeds.

A more detailed comparison in figure 5 of the baseline configuration with the stage 4 spike configuration clearly shows the representation of the shockwaves. The colour scale ranges from 4000 Pa in blue to 9000 Pa in red, with the green corresponding to approximately 7000 Pa, the atmospheric pressure at an altitude of 18000 m. In the base configuration, a strong singular shock was observed at the nose of the aircraft. The pressure contour in this region reaches close to 8800 Pa, significantly above the standard atmospheric pressure. This concentrated rise in pressure is a characteristic of wave drag due to the formation of a strong supersonic shock. By contrast, in the stage 4 spike configuration, instead of a single strong shock, there are multiple weaker shocks

distributed along the length of the spike. These shocks appear to not coalesce, resulting in a lower intensity. This diffusion of the shock strength indicates improvements in reducing the wave drag and the overall total drag on the aircraft. Analysing the Lift to drag ratio across 4 different Mach numbers and spike positions, at Mach 0.8, the baseline achieves the highest L/D However, using a spike reduces the efficiency in subsonic Mach numbers. In the transonic regime, Mach 1.02 spike position 2 provides a 1.5% increase in the L/D. At supersonic Mach numbers, spike position 4 increases the L/D by 3.9% at Mach 1.5 and 0.38% at Mach 2. Based on these results, the spike should remain retracted at subsonic speeds, partially extended to position 2 at transonic speeds and fully extended at position 4 in supersonic flight to maximise aerodynamic efficiency and reduce drag, which will contribute to lower fuel consumption and emissions.

The results were validated against values from a previous study. Comparing the values at Mach 1.5, the coefficient values from the analysis deviated by only 3.77% and 5.54 % for the lift and drag coefficient values, respectively, from the reference study. Additionally, a mesh-independent study was conducted to ensure that the mesh quality did not affect the results, as can be seen in figure 6

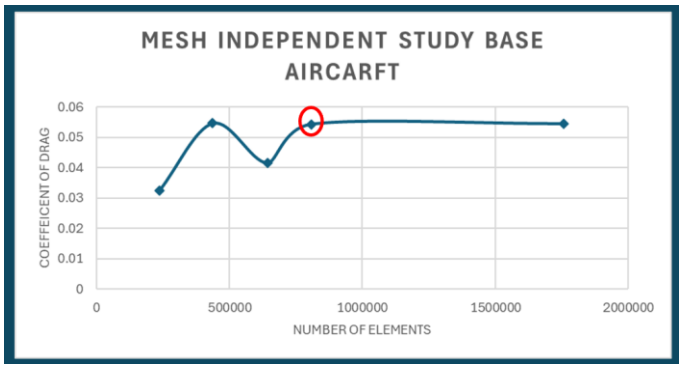

Figure 6 Mesh Independent Study

Conclusion

This study investigated the aerodynamic performance of a supersonic transport aircraft using a multi-stage nose spike to reduce total drag. Using CFD simulation in Ansys Fluent at Mach numbers 0.8,10.2,1.5 and 2, the lift and drag coefficients were analysed along with pressure contours. Results indicate that while the spike reduces efficiency in subsonic conditions. At Mach 1.5, the stage 4 position reduces drag by 4.23% and improves the lift to drag ratio by 3.9%. Pressure contours indicate that the spike diffuses the strong nose shock into multiple weaker shocks, reducing the drag. These results highlight the potential of a multistage nose spike for enhancing the aerodynamic performance and reducing drag and fuel consumption for future supersonic passenger aircraft.

Keywords: Computational Analysis, Viscous Drag, Raw-Riblets, Surface Pattern

Abstract. Emission reduction is of global importance and a big challenge in the aviation industry. In this research project, the emission issue was addressed aerodynamically by improving the performance of wings in transonic flow. This improvement was achieved by implementing a Raw-riblet pattern at different locations on the top surface of the wing as this showed higher values of viscous drag. Viscous drag is a large composition of total drag and reducing them will help to reduce the fuel consumption of aircraft and effectively reduce the carbon emissions. Two types of designs named Low-depth (0.305) and Low-depth (0.455) patterns were developed based on the 'Raw Riblet'. Computational analyses were carried out in the commercial code FLUENT with the help of the Spalart-Allmaras turbulence model to capture the viscous drag issues on the normal NACA 0012 wing at different angles of attack and solved them using the biomimetic patterns implemented. It was evidenced in this research work that the Low-depth (0.455) Raw Riblet pattern could reduce a significant amount of viscous drag on the NACA wing when compared to the Low-depth (0.305) pattern. Compatibility tests were done to check the suitability and stability of the model and mesh, respectively, and compared them to the experimental results. This research demonstrated the potential of surface texture-based solutions for aerodynamic design improvement and emission reduction.

Introduction

Commercial aviation has grown every year. Airbus has forecasted 43420 new aircraft deliveries between 2025 and 2044 [1]. This will increase aviation emissions in near future. Xueli et al., mentioned in their work that carbon emissions are a concern in the aviation industry [2]. Carbon emission from commercial aviation is expected to contribute 25% of overall emissions by 2050 [3]. It is essential that this issue needs to be addressed. Feuvre [4] stated that the aviation industry is committed to reducing carbon emissions by 50% in the year 2050. To mitigate this issue, a number of research are still carried out in the areas of propulsion, aerodynamics, structures, aircraft design and beyond. Capoccitti et al., [5] discussed about three important areas for researchers to look at in order to reduce the use of fossil fuels. They are structural (weight), propulsion (engine) and aerodynamic improvements. Out of these three elements, aerodynamic improvement was selected in this research project and it can be achieved by reducing drag on aircraft [6]. The longest phase of a commercial aircraft is the cruise and in that flight phase, the amount of skin-friction drag generation would be as high as 50% of total drag [7]. Skin friction drag, which is also known as viscous drag, is generated because of the contact (sliding motion, especially) between the aerodynamic body and air particles. Kumar et al., [8] reviewed five types of viscous drag reduction

Materials Research Proceedings 69 (2026) 125-129 https://doi.org/10.21741/9781644904251-22

methods and concluded that surface morphology is the most reliable method because it has been verified both computationally and experimentally. Liu et al., [9] proved in their research work that the surface structures could reduce the disturbances in the fluid flow. Lloyd et al., [10] mentioned in their research that shark-skin mimicked structures have evolved as a mechanism to reduce skin friction. The most common method used to develop a surface structure is biomimetics. In this method, the solutions are observed and mimicked from nature to solve the issues in engineering sciences. Our previous research works on shark skin inspired surface patterns had proved that a significant amount of drag reduction could be achieved in airflow [11-14]. Hence, in this research, the same 'Raw Riblet' pattern was implemented on the chosen wing surface (especially, where the issues identified) in different ways to reduce the skin friction drag, which is the main aim of this research.

Computational Design

Using the coordinates from airfoiltools.com [15], the NACA 0012 aerofoil was generated in the SolidWorks software and it was then extruded into a three-dimensional model, as shown in Fig. 1(a). In previous research work [11], the Raw Riblet (RR) pattern, which is shown in Fig. 1(b), was developed using the scanning microscopic image of a Requiem shark. This RR pattern was then implemented on the NACA 0012 wing surface in two different positions based on the issues observed. Fig. 1(c) depicts the implemented hollow RR pattern near the leading edge with a cut-depth of 0.455 metres from the top to mid-surface and hence, called a one low depth RR (1-LRR, 0.455) model. Similarly, another design was made by reducing the cut-depth from 0.455 to 0.305 metres for analysing the influence of depth in the performance of the RR pattern and hence, called the one lower depth RR (1-LRR, 0.305) model, which is shown in Fig. 1(d). All these designs were then exported to IGES format and imported into ANSYS.

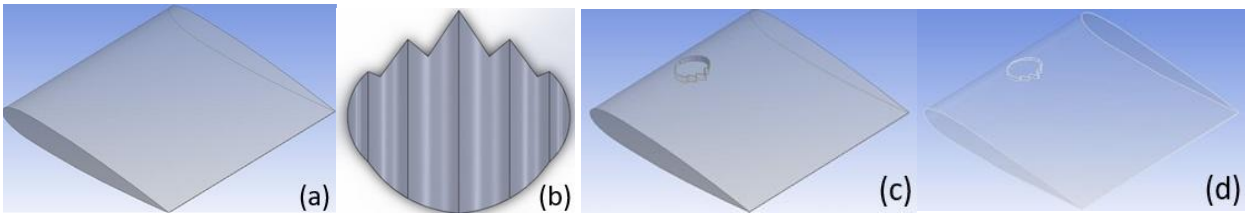

Figure 1. (a) NACA 0012, (b) Top view of RR[11], (c) 1-LRR (.455), (d) 1-LRR (0.305)

Computational Analysis

The three-dimensional NACA 0012 wing was imported into ANSYS Design Modeler and a computational domain was created. With the use of the Boolean tool, the solid boundary and wing were defined. This was then read into Mesh, where all the solid surfaces of the wing were named as top, bottom, trailing edge and riblets. The outer computational domain was considered the control volume, through which the air flows. Higher order elements and program-controlled automatic inflation were opted to minimise the errors and not inflate the selected boundaries, respectively. Most of the settings were set to default and the mesh was generated with 1.9 million nodes and 1.3 million elements. Quality check was carried out and the meshed design was brought into Fluent and the polyhedral mesh was selected, which helped reduce the element size, nodes and computational time. The Spalart-Allmaras viscous model was chosen as it involves the solution of the kinematic turbulent viscosity transport equation only, and it agrees well with experimental results [16]. Hence, less effort is required to solve when compared to other models. As the Eulerian approach was selected, the angle of flow was modified. A coupled solution method was chosen and discretization variables were defined as second order to reduce the time in solving the equations and then the iterations were done. These simulations were repeated for different angles of attack (0^0, 3^0, 6^0, 9^0, 12^0), in the 0.8 Mach number flow, which matched the cruise speed

Materials Research Proceedings 69 (2026) 125-129 https://doi.org/10.21741/9781644904251-22

of commercial flights in general. The same computational simulation procedure was repeated for 1-LRR (0.455) and 1-LRR(0.305) models.

Results and Discussion

Outputs such as lift coefficient and viscous drag values were noted at the end of analyses. Based on the comparison between the lift coefficient results, which is shown in Fig. 2(a), it was observed that both 1-LRR(0.455) and 1-LRR(0.305) had generated the same levels of lift at 3^0, 6^0, 9^0 and slightly lesser levels of lift at 0^0 and 12^0, when compared to the NACA 0012. These are acceptable levels and thus demonstrate potential in biomimetic designs. Similarly, comparing the viscous drag results against angle of attack, as shown in Fig. 2(b), it was identified that both biomimetic designs performed very well in reducing the drag when compared to the original wing at all of angles of attack. When the angle of attack was increased, the rate of viscous drag reduction was observed largely in both biomimetic designs.

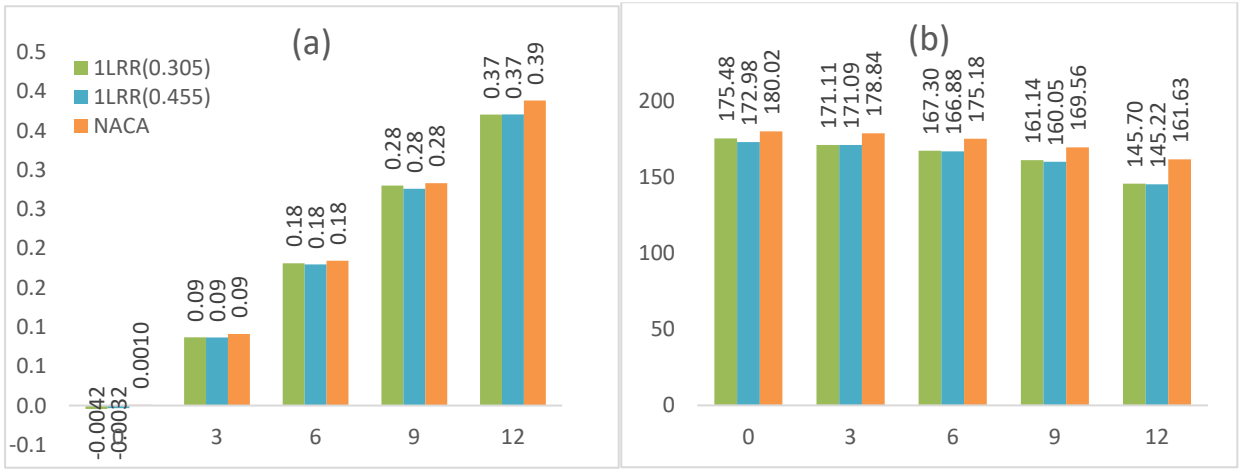

Figure 2. (a) Lift Coefficient Vs Angle of Attack, (b) Viscous Drag Vs Angle of Attack

1-LRR (0.455) reduced the viscous drag between the range 3.91 and 10.15 % from 0^0 to 12^0 angles of attack. Although 1-LRR(0.305) model has reduced the drag in the range of 2.52 to 9.85%, it is still a bit less than the deeper 1-LRR (0.455) model. For example, at 12^0 angle of attack, NACA 0012's top surface has medium and low values of skin friction drag as shown in Fig. 3(a). This is higher when compared to both biomimetic designs. Fig. 3(b) and (c) illustrate the skin friction contours of 1-LRR(0.455) and 1-LRR(0.305), respectively. From these figures, it can be noted that the skin friction distribution values on 1-LRR(0.455) were much lower compared to those on 1-LRR(0.305). This is due to the differences in the depths of the hollow raw riblet patterns applied on the models. The hollow pattern enabled the reversed flow at high angles of attack to circulate, lift, re-reverse/straighten and join the mainstream flow. This reduced the disturbance in the flow, which led to a reduction in the skin-friction coefficient.

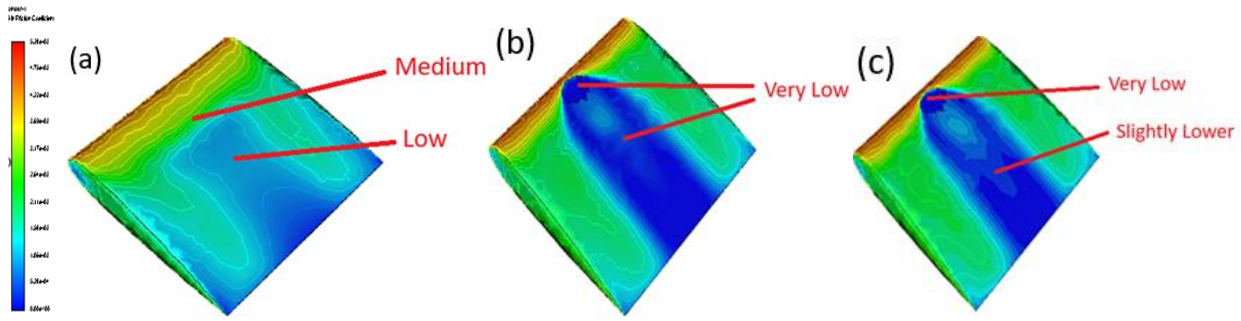

Figure 3. Skin Friction Contour at 12^0: (a) NACA 0012, (b) 1-LRR (0.455), (c) 1-LRR (0.305)

Validation

Validation tests were carried out to verify the accuracy of the procedure and results. In the model compatibility test, many viscous models such as K-epsilon, K-omega, Transition K-Kl-omega and Spalart Allmaras were used to analyse the NACA 0012, separately, to find a suitable turbulence model for this research. Eventually, the Spalart Allmaras was selected as it resulted in closer agreement with experimental values. In order to find a suitable mesh, a grid compatibility test was conducted. This was done by meshing the NACA 0012 model with their control volume at different mesh element sizes, such as 0.3, 0.4, 0.5, 0.6, 0.7, 0.8, 0.9, 1, 1.5 and 2 and solving them in Fluent. Additionally, a grid independence test was carried out to ensure the stability of the results. Based on these tests, a 0.5 mesh element size was chosen as it agreed well with the experimental values and had used them the mesh procedure.

Conclusion

As aimed, the viscous drag reduction was achieved in both models using the biomimetic pattern. Especially, the 1-LRR(0.455) model achieved a maximum of 10.15% viscous drag reduction at 120 angle of attack in the transonic flow regime. This aerodynamic improvement would help reduce the fuel consumption requirements and hence, emissions. Overall, this research has proved the potential in the hollow biomimetic raw riblet pattern in reducing the viscous drag and improving the wing aerodynamics. Technical elements such as structural strength of the wing, experimental modelling and tests are to be explored in the future for further enhancement of this work and bringing this idea into reality.

Keywords: Gardon Gauge, Calibration, Heat Flux, Sensor, Laser

Abstract. Sensor calibration is important for validity of data acquired during experimental testing. Heat flux sensors, used in the SCIROCCO experimental facility at CIRA, are critical to ensure that thermodynamic conditions comparable to those typical of re-entry maneuvers are achieved. This work aims to develop a numerical model for sensor simulation. A preliminary analysis has shown good response of the model to variation of flux diameter. The model will be used to investigate the implications and limits of using a continuous laser as a reference thermal source for sensor calibration to create an experimental setup for future activities.

Introduction

Extreme thermodynamic conditions achieved during re-entry from space require careful design and testing of vehicle components. Among them, structural safety of Thermal Protection Systems is fundamental to ensure safety of crew and payloads. Their experimental characterization is performed through testing in Plasma Wind Tunnels, like the SCIROCCO facility at the Italian Aerospace Research Centre (CIRA) [1], in which high-enthalpy levels are achieved to reproduce re-entry conditions using plasma flows [2].

During such tests, thermal heat flux must be measured with high accuracy to increase the reliability of test data and hence components. Gargon Gauges (GGs) are considered as the most reliable and accurate sensors, and they can operate over a wide range of heat flux intensities, reaching up to 3000 kW/m^2 [3]. A standard calibration procedure is still missing, and those existing fail in achieving heat flux intensities comparable to those generated during re-entry maneuvers. Most of them are based on blackbody radiation as a thermal source under vacuum conditions to minimize convective heat, while other procedures have been developed or are under investigation [4]-[6]. The main limits to be faced are the high energy consumption, the low accuracy deriving from poorly known energy of the thermal source and the lack of repeatability.

The aim of this work is to develop an advanced numerical model of a complete GG that can be used to investigate an innovative calibration procedure currently being developed at CIRA. The calibration procedure employs a laser as a well-defined thermal source to calibrate GGs in a repeatable, accurate, sustainable and safe manner. The emitted power can be accurately measured using a thermal sensor for low power lasers and the laser is subsequently used for GG calibration, as schematically shown in Fig. 1.

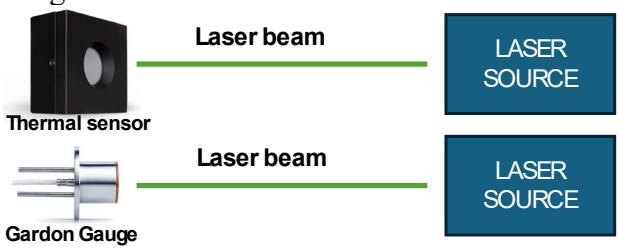

Fig. 1 – Schematization of laser power characterization for GG calibration.

Materials Research Proceedings 69 (2026) 130-135 https://doi.org/10.21741/9781644904251-23

Theoretical background

GG sensors consist of a thin electrical insulating disk in which a thermopile, composed of constantan and copper, is arranged along a circular path, forming the sensitive element (SE) of the sensor. The disk is coated with a high-emissivity black paint that maximizes absorptivity, improving sensor sensitivity. The SE is mounted in a brass body that serves as both a mechanical support and a heat sink, thanks to its integrated water-cooling circuit, which maintains a fixed perimeter temperature of the SE. The structure of the sensor is schematized in Fig. 2. The incident flux is absorbed by the SE and the heat is distributed through conduction creating a radial temperature distribution. The perimeter of the SE is kept at fixed temperature by the brass body. The heat flux measurement is realized by sensing the electric voltage generated by the thermopile based on the Seebeck effect [7].

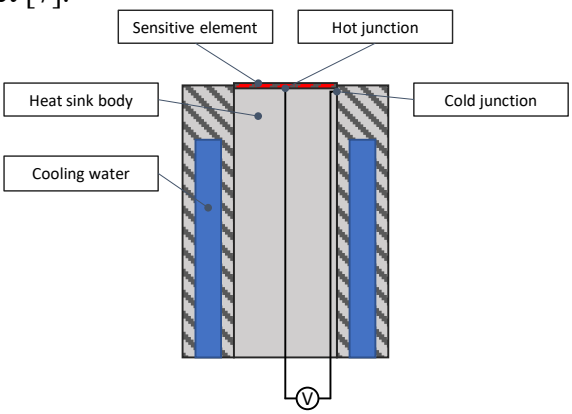

Fig. 2 – GG operational scheme.

Numerical methodology

The sensor was modelled to simulate its thermoelectric behavior under steady-state heat flux conditions representing the laser input energy. The model was created by leveraging the Mechanical module in Ansys Workbench, employing Finite Element Analysis (FEA) to solve the governing equations of heat transfer and thermoelectric phenomena. To create a highly detailed model, a real sensor was sectioned and its geometry was reproduced in the model allowing detailed representation of the SE, the brass body and the cooling system, as reported in Fig. 3.

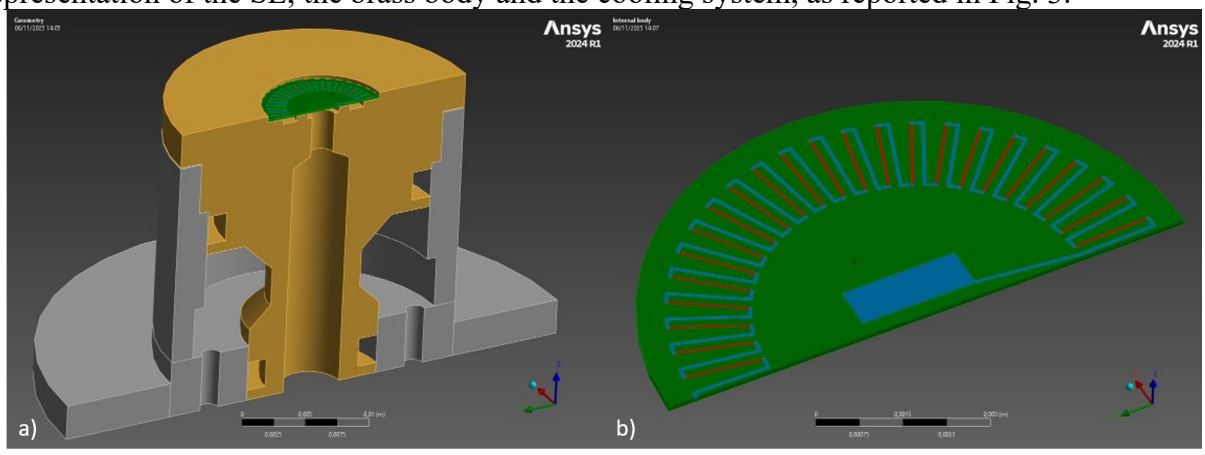

Fig. 3 - Model geometry: a) entire model; b) SE detail showing thermopile layout (copper in blue and constantan in red).

Material properties were included in the model in temperature dependent tables, using data from scientific literature [8]-[16]. Boundary conditions include convective heat transfer from the water-cooling circuit, with the heat transfer coefficient estimated using the Dittus-Boelter correlation for pipes and the flat plate correlation for the cavity, averaged over the heat exchange surface; radiative

Materials Research Proceedings 69 (2026) 130-135 https://doi.org/10.21741/9781644904251-23

heat flux is calculated providing emissivity of material and setting a fixed ambient temperature; the heat flux modeling the laser was imposed on the upper surface of the SE with varying diameter (spanning from 7 to 10 mm) for fixed power intensity equal to 0.4 W. The main parameters of the model are resumed in Table 1. The model considers half sensor with proper boundary conditions (e.g. adiabatic surfaces for heat exchange), as perfect symmetry can be exploited to reduce simulation time without affecting the results. The lower surface of the SE is also considered adiabatic, as the real sensor has insulating material to minimize the heat flux across SE thickness.

Table 1: Geometric dimensions and material properties used in the model.

Parameter	Value	Unit
SE diameter	10	[mm]
Body diameter	25.4	[mm]
Body total height	22.4	[mm]
Flange diameter	43.9	[mm]
Flange height	3	[mm]
Internal diameter, larger	11.6	[mm]
Internal diameter, smaller	2	[mm]
Convective heat exchange surface	129.21	[mm^2]
Sensor volume	6317.7	[mm^3]
Convective heat coefficient	1535	[$W/(m^{2*}K)$]
Body emissivity	0.07	[-]

Model Results

The model facilitates a better understanding of physics within the sensor about temperature and voltage behavior. In Fig. 4 is reported the temperature distribution of the sensor when the heat flux diameter is equal to the SE's diameter. The simulation confirms that the body and the SE's perimeter are almost at 20 °C. The slight increase in SE's perimeter temperature should be accounted for during sensor calibration to accurately estimate the calibration uncertainty.

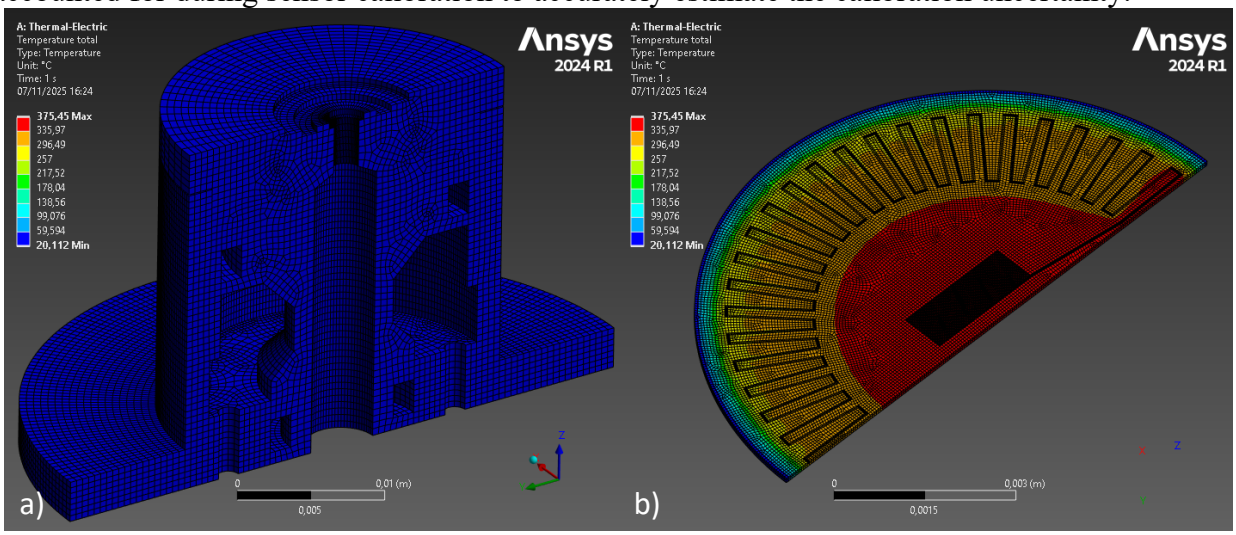

Fig. 4 – Temperature field of the sensor: a) body; b) SE.

By modifying the flux diameter with constant power, the thermopile shows an increase in maximum temperature at the center and a decrease of the temperature closer to the border (Fig. 5). Even if the temperature is higher for a diameter of 7 mm and equal to 491.43 °C, the maximum value is below the maximum temperature allowed by the manufacturer, which is equal to 600 °C [17]. That is reflected in the output voltage, plotted in Fig. 6 as the difference between the voltage

Materials Research Proceedings 69 (2026) 130-135 https://doi.org/10.21741/9781644904251-23

of the central region and that of the transversal surface of the copper wire cut from the plane of symmetry. Initially, a reduction of flux diameter leads to an increase of voltage. That is ascribable to the increase of temperature of the central region and the reduction of temperature of the border region that is no longer directly hit by the flux. When the diameter reaches 7 mm, the voltage starts to decrease, due to the radiative loss deriving from the elevated temperature achieved in this case, which reduces the overall flux flowing in the sensor.

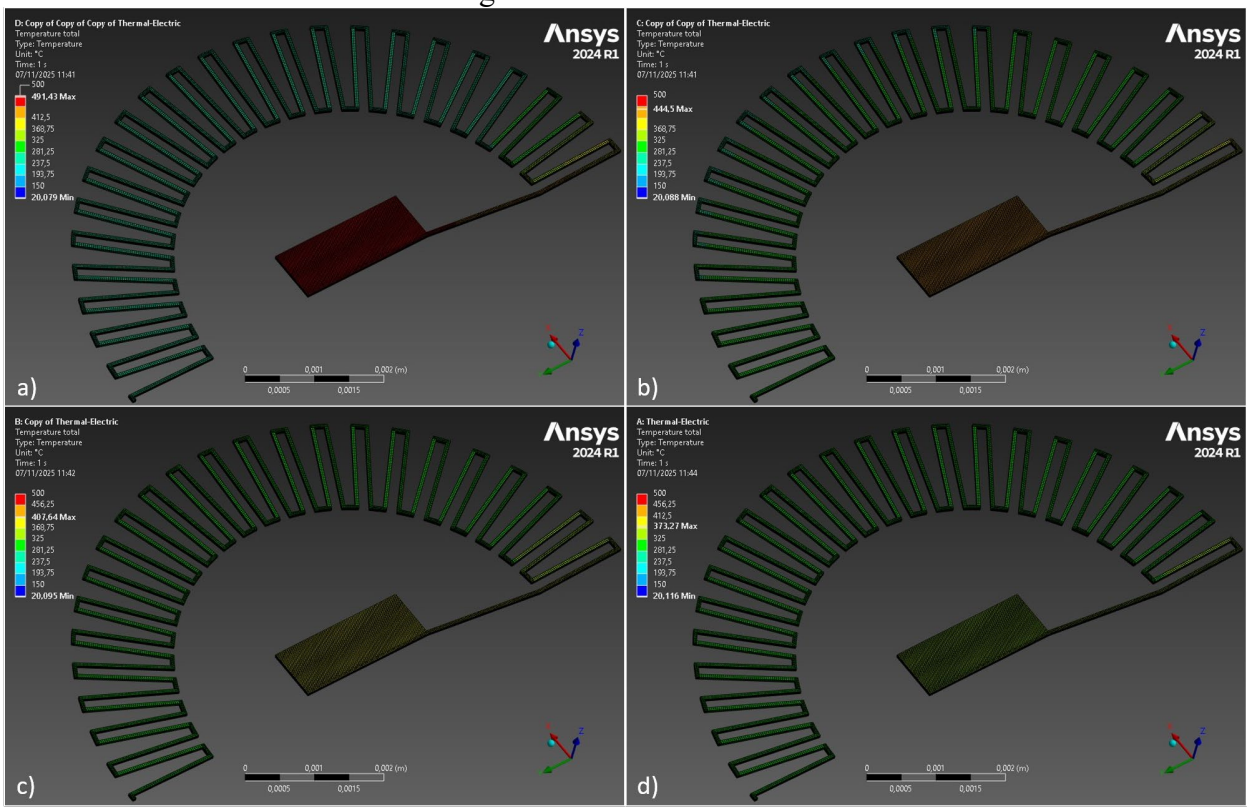

Fig. 5 – Temperature distribution of the thermopile for varying flux diameter at fixed power: a) 7 mm; b) 8 mm; c) 9 mm; d) 10 mm.

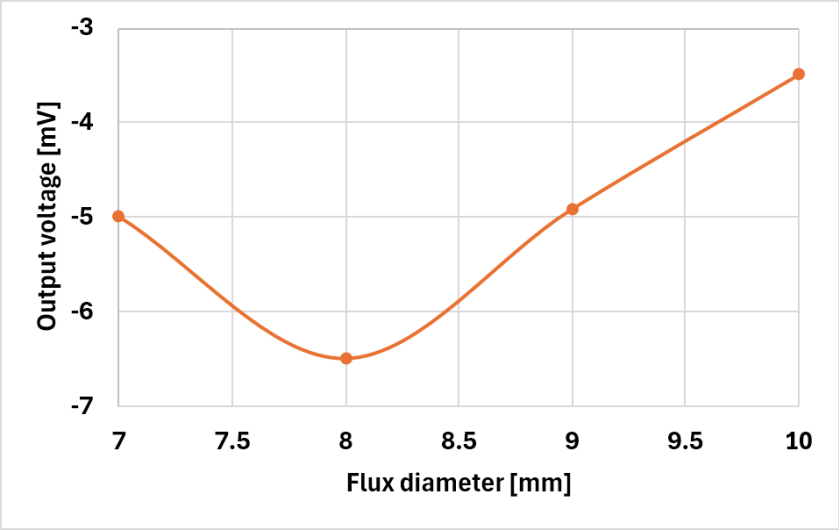

Fig. 6 – Output voltage against flux diameter at fixed power.

Conclusions

An advanced numerical model of a GG sensor has been developed using a real sensor to obtain all the fundamental information regarding its geometry. Material properties and boundary conditions

have been obtained from scientific literature or estimated based on typical experimental setups. The model provides data and information regarding the thermoelectrical phenomena within the sensor, such as the temperature distribution and the output voltage.

Future activities will investigate the influence and implications of using a laser as a thermal source for calibration of these sensors, guiding in the preparation of an experimental test bench for calibration activities.

Keywords: Off-Design, Variable Camber, Differential Flap Setting

Abstract. The present investigations analyze the influence of Variable Camber by Differential Flap Setting (DFS) on the aerodynamic performance of the DLR-F25 configuration in off-design flight conditions. Therefore, trailing edge (TE) flap deflections at the design point (h = 35000 ft) and off-design point (h = 29000 ft) are studied. The aim of the research at hand is to identify the optimal flap deflection angle for the corresponding flight conditions and thus to distinguish the difference in the aerodynamics due to DFS.

Introduction

Air traffic is responsible for approximately 3.5% of the global climate effect, consisting of CO_2-based and non-CO_2-based emissions, such as contrails and contrail-cirrus [1]. In combination with the annual growth in air traffic of approx. 2% [2], the necessity of the reduction of climate impacting emissions is increased. Furthermore, the growth in air traffic increases the importance of vertical leveling of aircraft. Subsequently, the investigation of the aerodynamic performance on multiple flight levels, should be considered in the aircraft design. Currently, the design process of an aircraft focuses on the cruise design point and only a performance driven altitude step to compensate aircraft weight variation due to fuel burn. Further analysis of the flight conditions in reduced flight levels, described as off-design conditions, is still necessary.

As part of the LuFo project AirTiMe, the aim of the present work is to analyze the aerodynamics of the DLR-F25 configuration (Figure 1) in off-design conditions. To improve the aerodynamic performance of the aircraft while operating in off-design conditions, DFS can be applied, which applies differential position of the TE devices. Due to DFS, the shock impact positions as well as the circulation distribution over the wing is influenced so that the aircraft flight performance (L/D over Mach or Lift Coefficient C_L) can be improved.

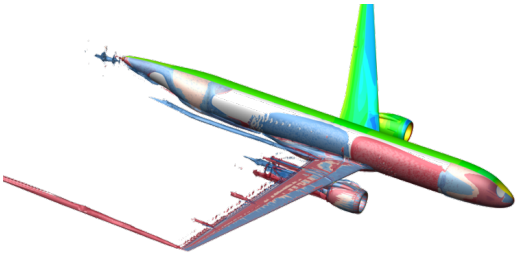

Fig. 1: Flow topology of DLR-F25.

To fulfill the aim of the present work, the aerodynamic performance of the configuration in the cruise design point, 35000 ft, serves as a reference (Mission Scenario 1 (MS1)). Three additional MS considering different off-design parameters evaluate the influence of Mach number, True Airspeed (TAS) and C_L on the aerodynamic performance of the configuration, when the flight level is reduced to 29000 ft. In MS2, the Mach number of MS1 is kept constant. In MS3, the TAS is kept constant, which leads to a reduced Mach number. In MS4, the Mach number is reduced to

Lift Coefficient	C_L [-]	0.592	0.449	0.473	0.592

Configuration DLR-F25

The short-medium range transport aircraft configuration DLR-F25 is used in the study at hand. The configuration includes multiple moveable devices [3]. In Figure 2, the moveable layout of the DLR-F25 is visualized. It includes the two different types of moveables: three segmented Adaptive Dropped Hinge Flap (Inboard flap (IB), Flaperon 1 (F1), Outboard flap (OB)) and two segmented Plain Flap (Flaperon 2 (F2), Flaperon 3 (F3)), which are collectively used. The configuration considered here contains neither a horizontal nor a vertical tail plane.

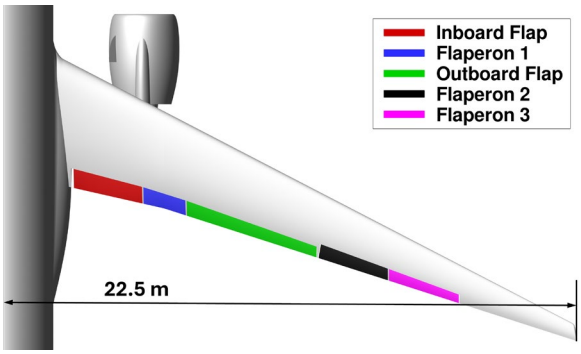

Fig. 2: Moveable layout of DLR-F25.

Methodology

The design space is explored by a Design of Experiment (DoE) sampling. Within this design space, the TE devices are deflected in a range of δ = -3° to 3° in the present investigations. To create the DoE, a Sobol's sequence [4] algorithm is used. In the end, a combination of 109 different TE deflection combinations are included within the DoE.

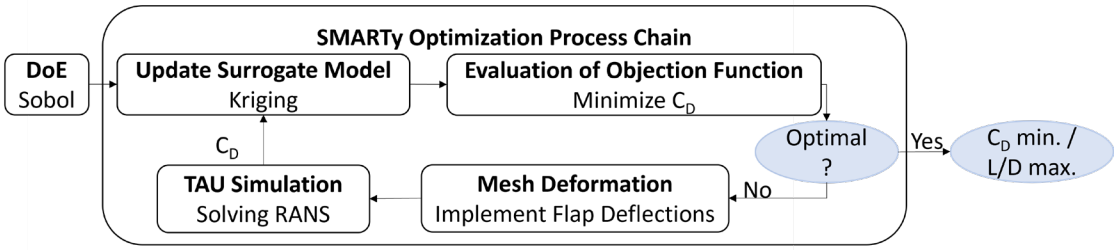

Fig. 3: SMARTy optimization process chain.

The computational grid is generated with the use of ANSA [5] and the TE flap deflections are implemented by the use of mesh deformation technique.

For aerodynamic analysis the DLR TAU code that solves the steady compressible RANS equations [6] has been applied to the different configurations. Within the CFD simulations, the Spalart-Allmaras turbulence model in its negative formulation is used.

The TAU simulations are set up to reach the constant target lift coefficient C_L. The Surrogate Modeling for AeRo Data Toolbox (SMARTy) is a modular python package and forecasts aerodynamic data based on high-fidelity CFD simulations [7]. The Toolbox is used for the implementation of Surrogate Based Optimization (SBO) processes. Based on the DoE the in Figure 3 illustrated optimization process chain is implemented to find the optimal DFS. The DFS is defined as optimal if the configuration achieves a minimum drag coefficient C_D or maximum lift-to-drag ratio L/D, which is equivalent because of the constant C_L in the TAU simulations.

Materials Research Proceedings 69 (2026) 136-141 https://doi.org/10.21741/9781644904251-24

Computational Results

In this section, the influence of Variable Camber by DFS on the aerodynamic performance in off-design flight conditions is discussed. For the off-design analysis, the flight level (FL) is reduced by 6000 ft. The reduced FL, leads to a reduced air density and temperature which influences the Mach number, the TAS, and C_L as it is the case for MS2 to MS4. With a reduced C_L, the Angle of Attack (AoA) is reduced as well in the off-design (MS2, MS3). When C_L remains unchanged, the Mach number is reduced (MS4), due to which the AoA is increased to reach the targeted C_L. The implementation of TE deflections further influences the circulation distribution and AoA. Due to a positive flap deflection, the camber of the wing is increased and thus locally increases the lift. A reduced local lift is implemented by negative flap deflection angles. The optimal DFS depends on the flight conditions and varies between the MS. The simulations show, that for each MS, the inboard flaps (IB, F1, OB) are deflected negatively and the outboard flaps F2 and F3 are deflected positively to improve the aerodynamic performance. The increased L/D indicates the improvement of the aerodynamic performance. The optimal configuration contains the optimal DFS which were found either from an optimization of the surrogate model based on the initial DoE or from the simulation results of the initial DoE. For MS2 a full SBO cycle with refinement of the surrogate model was performed to assess the predictive quality of the surrogate model. The comparison of the result of the SBO and the direct evaluation of the sample points in the DoE resulted in a difference of less than 1 drag count (10^{-4}). Because of this, the optimal configuration of MS3 and MS4 was found by a direct analysis of the DoE. The TE deflection angles of each moveable as well as the resulting flight parameters are listed in Table 2.

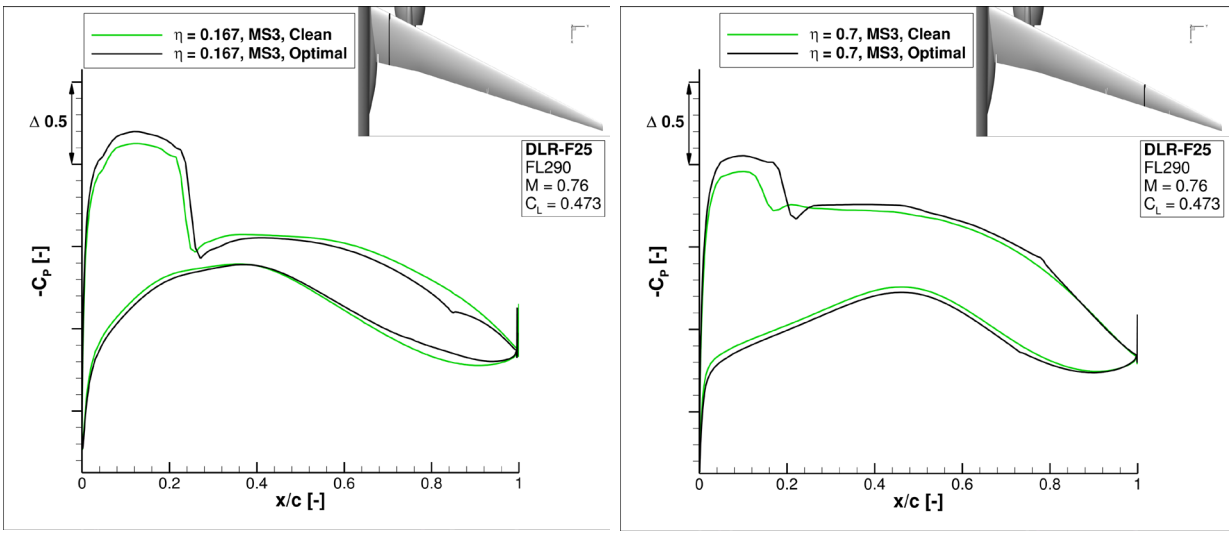

Table 2: Flight parameters of each MS - clean config. vs. config. with optimal DFS.

	Config.	δ_{IB} [°]	δ_{F1} [°]	δ_{OB} [°]	$\delta_{F2,3}$ [°]	α [°]	C_L $[\cdot 10^{-2}]$	C_D $[\cdot 10^{-4}]$	L/D [-]
MS1	Clean	0	0	0	0	1.59	59.2	283	20.87
	Optimal	-0.3	-0.8	-0.5	1.6	1.62	59.2	282	20.96 (+Δ0.43%)
MS2	Clean	0	0	0	0	0.64	44.9	235	19.09
	Optimal	-2.6	-2.8	-1.7	0	1.32	44.9	231	19.42(+Δ1.62%)
MS3	Clean	0	0	0	0	0.94	47.3	239	19.83
	Optimal	-1.7	-1.7	-2.2	0.9	1.45	47.3	236	20.04(+Δ1.11%)
MS4	Clean	0	0	0	0	2.28	59.2	269	21.94
	Optimal	-2.1	-2.1	0.2	2.1	2.48	59.2	268	22.07(+Δ0.59%)

The influence of the DFS on the aerodynamics is similar for each MS, regardless of the optimal TE deflection angles. Because of this, the change due to DFS is highlighted in the following paragraphs using MS3.

Materials Research Proceedings 69 (2026) 136-141 https://doi.org/10.21741/9781644904251-24

In Figure 4 the pressure distributions at two different spanwise positions of the optimal configuration are compared to the clean configuration, that does not include TE deflections. The pressure distribution at η = 0.4 is illustrated in Figure 4a and at η = 0.7 in Figure 4b. The AoA of MS3 is increased by implementing DFS. Due to this, the suction peek is more pronounced at both wing segments. Furthermore, the shock wave system is influenced. In- (η = 0.167) and outboard (η = 0.7), the shock wave is intensified and shifted downstream compared to the clean configuration. In combination with the increased pressure on the bottom of the wing near the leading edge, the pressure difference is locally increased. In the rear part of the wing sections, the pressure difference between upper and lower side of the wing is reduced for x/c > 0.5 at the inboard segment and remains higher or unchanged at the outboard segment. At the inboard segment η = 0.167, the slice cuts through the negative deflected inboard flap of the DLR-F25 as well. The negative flap deflection leads to a deceleration of the flow in front of the flap bend (x/c ≈ 0.85), due to which the pressure is increased locally on the upper side of the wing. However, on the lower side of the wing, the pressure is slightly reduced. At the outboard segment η = 0.7, the positive deflection of F2 and F3 further reduce the pressure on the upper side and increase the pressure on the lower side. Overall, the center of pressure is shifted upstream, which reduces the rear loading of the wing.

(a) η = 0.176 *(b) η = 0.7*

Fig. 4: Pressure distributions.

Materials Research Proceedings 69 (2026) 136-141 https://doi.org/10.21741/9781644904251-24

The circulation distributions of the optimal configuration are compared to the clean configuration in Figure 5. The circulation Γ of the flaps (dashed lines) depends on the flap deflection angle. As it was shown in the pressure distributions, a negative flap deflection leads to a reduction of Γ and a positive flap deflection, as it is necessary for the optimal configuration for F2 and F3, increases Γ. The changes in the spanwise load distribution are also reflected in the overall load distribution for wing and flaps (solid lines). The inboard load reduction and outboard load augmentation shifts the center of pressure to the wing tip. Due to this, the load distribution is shifted closer to an elliptical load distribution, which is resulting in a reduced induced drag.

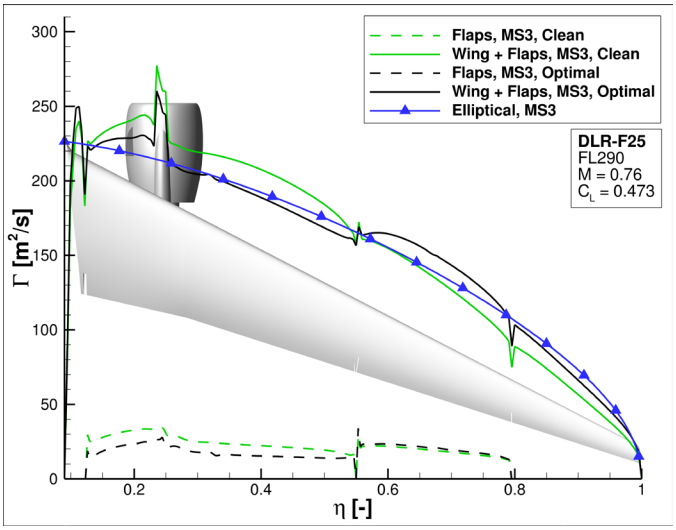

Fig. 5: Circulation distribution, MS3.

In Figure 6 the lift-to-drag ratio of the clean configuration in each MS and the possible improvement by DFS implementation is illustrated. In the design point (MS1), DFS can slightly improve the aerodynamic performance. In the off-design (MS2, 3, 4) the improvement reached by DFS is higher:

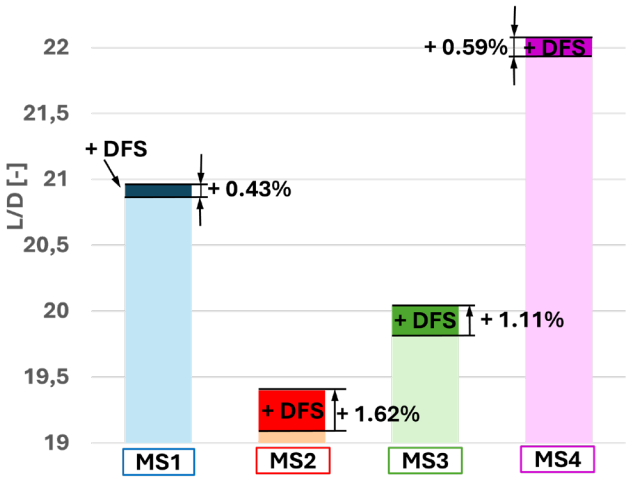

Fig. 6: DFS improvements.

MS2, the scenario at same Mach number shows the lowest aerodynamic performance, but the highest potential of DFS. This can be attributed that due to the higher dynamic pressure, the AoA is reduced by approximately 1° and the wing is operated away from the optimal design point.

MS4, the scenario at the same lift coefficient, shows an increased aerodynamic performance even without DFS. The improvement may be attributed to reduced wave drag at lower Mach number.

Summing up, the DFS is more beneficial at low AoA. This may be that the circulation distribution adaptation is more sensitive at low AoA or, conversely, as soon as C_L is high the load redistribution due to DFS is less sensitive.

Summary

In the current work the influence of DFS on the aerodynamic performance in off-design flight conditions were investigated. The off-design was defined as a flight level reduction by 6000 ft. For the investigations the transport aircraft configuration DLR-F25 was used.

The aerodynamic performance was evaluated based on the lift-to-drag ratio of each configuration. Implementing DFS during cruise, is able to improve the aerodynamic performance. Regardless of the flight conditions, it has been shown that a negative flap deflection in the inboard area and a positive flap deflection in the outboard area of the wing produce optimum aerodynamic

performance. A positive deflection increases the camber of the wing locally, due to which the local contribution of lift is increased. A negative deflection reduces the lift generation locally by implementing a negative camber line. In general, the ideal DFS leads to a shift of the spanwise circulation distribution towards an elliptical distribution, which is resulting in a reduced induced drag.

The results of the present study provide a basis for further studies on flight route adaptation with the motivation to reduce non-CO_2-based emissions.

Acknowledgment

The presented work is partially funded by the Federal Ministry for Economic Affairs and Climate Action (BMWK) as part of the LuFo VI-3 project AirTiMe, funding reference: 20A2201A. The results shown here were achieved as part of a master's thesis at the Institute of Jet Propulsion and Turbomachinery of the TU Braunschweig. The authors gratefully acknowledge the scientific support and HPC resources provided by the German Aerospace Center (DLR). The HPC systems CARA and CARO are partially funded by the Saxon State Ministry for Economic Affairs, Labour and Transport, the Ministry of Science and Culture of Lower Saxony, and the BMWK. The DLR-F25 is a conceptual design of an advanced short-to-medium-range airliner provided by DLR. It features an initial shape of a very high-aspect-ratio wing and was developed as a challenge for high-fidelity disciplinary and multi-disciplinary preliminary design. The development was funded by the BMWK as part of the LuFo project VIRENFREI.

Keywords: Unsteady Aerodynamics, Rotor Aerodynamics, Rotary Wing, Küssner-Schwarz, Free-Wake, Generalized Lifting Line Theory

Abstract. This study presents a time-marching lifting-line algorithm to predict the unsteady aerodynamics of rotors. Validation studies employing purely harmonic and damped oscillatory wing and blade motions have demonstrated the solver's ability to accurately and stably predict unsteady loads. Augmenting the free and prescribed wake solvers recently developed, this method extends their time-marching framework to rotary wing applications in forward flight. In the present formulation, wake-induced velocities are evaluated via a free-wake model, while sectional forces are computed via Küssner-Schwarz unsteady theory. The bound circulation is derived by an unsteady Kutta-Joukowski relation. From there, both load and circulation equations are cast into state-space form. A vital modification for rotating blades is the careful definition of the reduced frequency, dealing with the accuracy of the prediction of dynamic loads and circulation.

Introduction

Lifting-line models remain widely used in industrial rotorcraft applications [1] because they offer a favorable cost–accuracy trade-off and allow seamless integration with structural and inertial models. At the same time, their computational efficiency makes them a natural choice for optimization studies, which are essential during the early phases of aircraft design.

The model presented here extends analytical aerodynamic methods to modern free-wake lifting-line solvers, thereby combining computational efficiency with numerical corrections that enhances robustness and load-prediction accuracy.

The application to forward flight represents the most recent challenge addressed by the model, which has already been validated on finite wings [2] and proprotors in axial flight [3]. The flexible formulation adopted granted the possibility to investigate a range of different reduced frequencies in both studies, always providing accurate predictions when compared to fully three-dimensional boundary element method simulations. The enhancements are especially evident when compared to the application of a canonical lifting-line model in which the unsteady prediction is recovered solely through the action of the numerical wake.

In doing so, the proposed approach bridges, in a novel fashion, the gap between simplified formulations and fully three-dimensional computational methods, enabling accurate predictions of unsteady loads without the prohibitive cost of high-fidelity CFD simulations. The resulting framework provides a versatile foundation for future aeroelastic and aeroacoustic analyses of rotorcraft operating in complex flight conditions.

Theoretical Formulation

The proposed *Unsteady Lifting Line Theory* (ULLT) introduces several novel elements to produce a comprehensive and self-consistent framework for predicting unsteady loads on lifting bodies across arbitrary flight conditions.

Küssner-Schwarz Model. The aerodynamic forces on each section of a lifting body can be determined accurately for arbitrary body motions and inflow conditions using the Küssner–Schwarz solution [4] [5]. By contrast, alternative formulations impose assumptions on the downwash distribution—for example, constant or linear profiles [6] – or prescribe specific gust shapes acting on the airfoil [7] [8] [9].

Here, the time reformulated Küssner–Schwarz model developed in [2] is considered, where, using a rational approximation of the lift deficiency function and performing an inverse Fourier transform of both circulatory and noncirculatory generalized aerodynamic loads, a time-domain, state-space formulation of aerodynamic loads of the following type is obtained

$$\begin{cases} \boldsymbol{f}(\tau) = 2b\rho V^2[\boldsymbol{CB}\ddot{\boldsymbol{q}} + (\boldsymbol{CA}+\boldsymbol{DB})\dot{\boldsymbol{q}} + \boldsymbol{DAq} + \boldsymbol{C}\dot{\boldsymbol{t}} + \boldsymbol{Dt} + \boldsymbol{g}(\ddot{r} - (z_1+z_2)\dot{r} + z_1 z_2 r)] \\ \ddot{r} - (\sigma_1+\sigma_2)\dot{r} + \sigma_1\sigma_2 r = \boldsymbol{l}^T\dot{\boldsymbol{q}} + \boldsymbol{h}^T\boldsymbol{q} + \gamma \end{cases} \quad (1)$$

where τ is the non-dimensional time variable, defined as $\tau = V/b$, with V the body velocity and b the airfoil semichord, $\boldsymbol{t}$ is a N-component vector and γ is a scalar whose expressions are given by:

$$\begin{cases} t_n(y,t) = -\frac{1}{\pi V}\int_{-1}^{1}\frac{\cos n\theta(\xi)}{\sqrt{1-\xi^2}}v_i(x(\xi),y,t)d\xi \\ \gamma(y,t) = -\frac{1}{\pi V}\int_{-1}^{1}\frac{\sqrt{1-\xi^2}}{1-\xi}v_i(x(\xi),y,t)d\xi \\ \text{for } n = 0,1,\dots,N \end{cases} \quad (2)$$

For the definition of the other symbols in Eq. 1, the reader is referred to [2].

With respect to the canonical formulation for the sectional loads of Küssner-Schwarz model, we include three-dimensional effects into the sectional solution accounting for the effects of the wake-induced velocity.

This is achieved by numerically evaluating the chordwise distribution caused by the trailing vortices, since the effects of the shed vortices are already accounted for in Küssner-Schwarz theory. The contributions of the shed vorticity can be reintroduced when the wake differs from the thin and straight vortex sheet assumed by the analytical model; in our case, the best effects are found reintroducing it after 1/4 of the revolution.

The suitable integration of sectional loads given in Eq. 1 along the span gives the total loads acting over the body.

Extension to Rotary-Wing Aerodynamics. To extend the application of the presented unsteady aerodynamic formulation to rotors in hovering or axial flight, we have to assess the spanwise variation of the sectional reduced frequency. That is due to the radial variation of the undisturbed flow velocity (for instance, $V = \Omega r$ in hovering flight, with Ω and r denoting, respectively, rotor angular speed and radial position of the section). Therefore, a global reduced frequency is introduced, along with local rescaling of the reduced frequency, of zeroes and poles of the rational approximations of the lift deficiency function and Kutta-Joukowski transfer function (closely to what is done for tapered wings [10]) is performed. The particular case of rotors in forward flight can be approached in two different ways. The first approach is to keep the scaling of poles and zeroes constant, thus using an average scaling over the entire rotor revolution. The second approach involves considering the scaling to vary at each timestep. The scaling ratio is computed

Materials Research Proceedings 69 (2026) 142-147 https://doi.org/10.21741/9781644904251-25

by comparing the local velocity experienced by each airfoil with the reference hovering tip speed, thereby allowing the poles and zeros to evolve harmonically over the revolution.

This second approach, even if not mathematically exact, is the one that provided the best results, and therefore the one adopted in this study.

Numerical Results

References are The numerical investigation aims to assess the proposed ULLT formulation in terms of its aerodynamic and aeroacoustic results against a widely validated Boundary Element Formulation suited to analyzing thick bodies in unsteady motion in potential flows [11].

The reference rotor is a scaled version of the BO105 helicopter main rotor, exactly like the one used in HELINOISE test campaign [12]. The setup is summarized in Table 1. The forward flight case selected for this study is the #508, characterized by effective tip-path-plane angle $\alpha_{TPP} = -14.63°$ and advance ratio $\mu = 0.148$.

Table 1: Rotor Data

Radius	2.0 [m]
Chord	0.121 [m]
Twist Ratio	-4.0 [deg/m]
Null Twist	@0.70R
Root Cutout	0.22R
Airfoil	NACA23012
Pre-cone	2.5 [°]
RPM	1040

The shape and spatial development of Figure 1 is guaranteed by the free wake algorithm that enhances the velocity distribution required for the proper modeling even in this ULLT method. A solution computed via the Boundary Element Method solver (described in [13]), trimmed around the experimental values of integral forces and moments, is used as benchmark. From its results are derived the commands and the inputs of the aerodynamic simulation performed with the ULLT model.

Materials Research Proceedings 69 (2026) 142-147 https://doi.org/10.21741/9781644904251-25

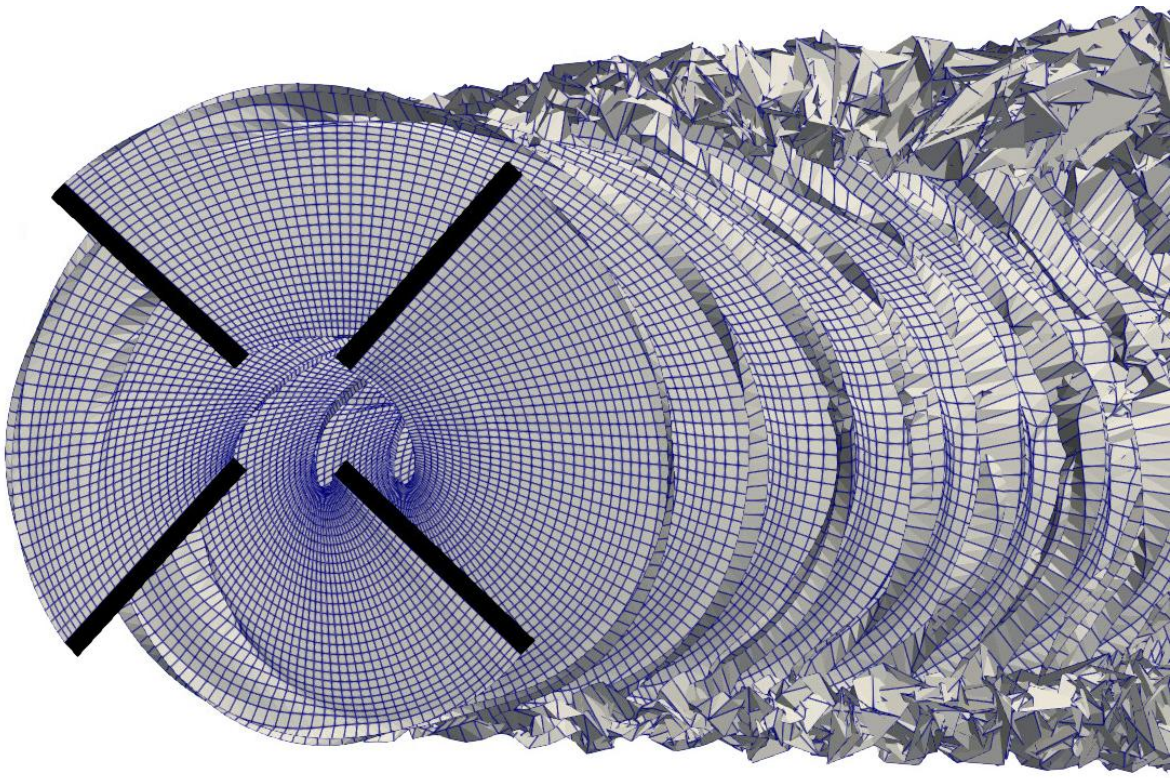

Figure 1: Free Wake Shape for ULLT Rotor Simulation

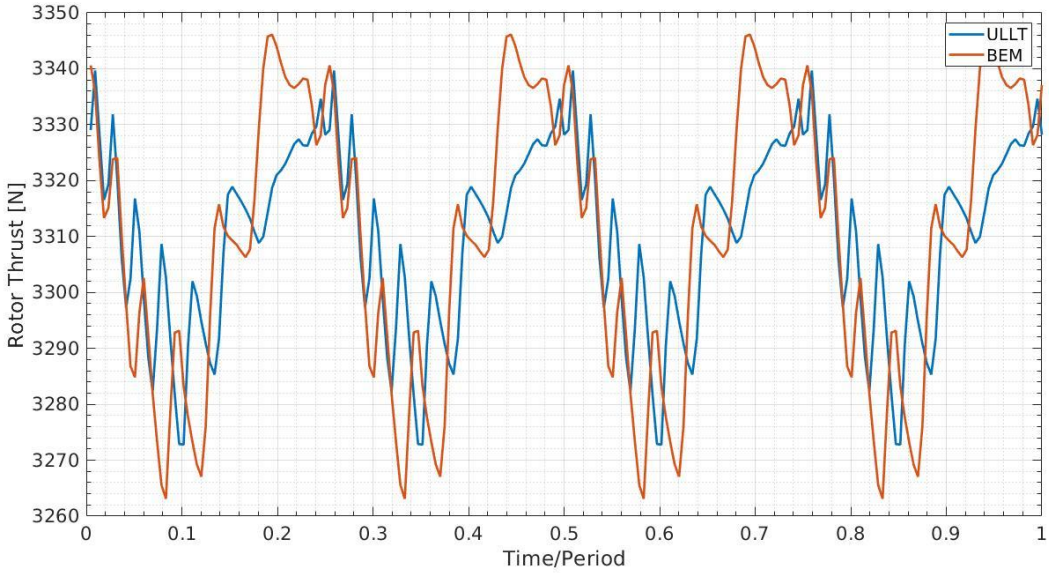

Figure 2: Rotor Thrust Time History Comparison

The single-revolution thrust time history shows a strong correlation between the ULLT and BEM solutions: both free-wake implementations reproduce similar higher-order oscillations while the dominant low-frequency 4/rev blade harmonic is clearly present; the principal discrepancy is that the BEM solution attains the upper envelope of the main harmonic earlier and at a higher magnitude than ULLT, a difference possibly attributable to thickness contributions in the BEM formulation and three-dimensional phenomena unmodeled by the lifting-line approach.

Materials Research Proceedings 69 (2026) 142-147 https://doi.org/10.21741/9781644904251-25

The plotted single-revolution thrust trend demonstrates that both models capture the low-frequency envelope and the dominant forcing, with the 4/rev blade contribution appearing as the principal harmonic in both traces. Higher-order oscillatory content produced by the free-wake algorithms is similar in phase and frequency, which indicates that wake-induced unsteady loading is consistently represented across the two solvers.

Finally, the aeroacoustic analysis is performed using the compact-source version of the Farassat 1A formulation, which enables the radiated noise to be evaluated from the knowledge of the spanwise distribution of the section aerodynamic loads [14]. This implies that this aeroacoustic formulation is well-suited to be coupled with the aforementioned aerodynamic solver. Specifically, for the microphone of the HELINOISE database located at -3.99 [m], -2.70 [m], and -2.30 [m] with respect to the rotor hub (considering an upward z axis and a forward x axis), the time history of the rotor radiated noise, evaluated using the spanwise load distribution from the present ULLT solver, is compared with the BEM results, validated in [15].

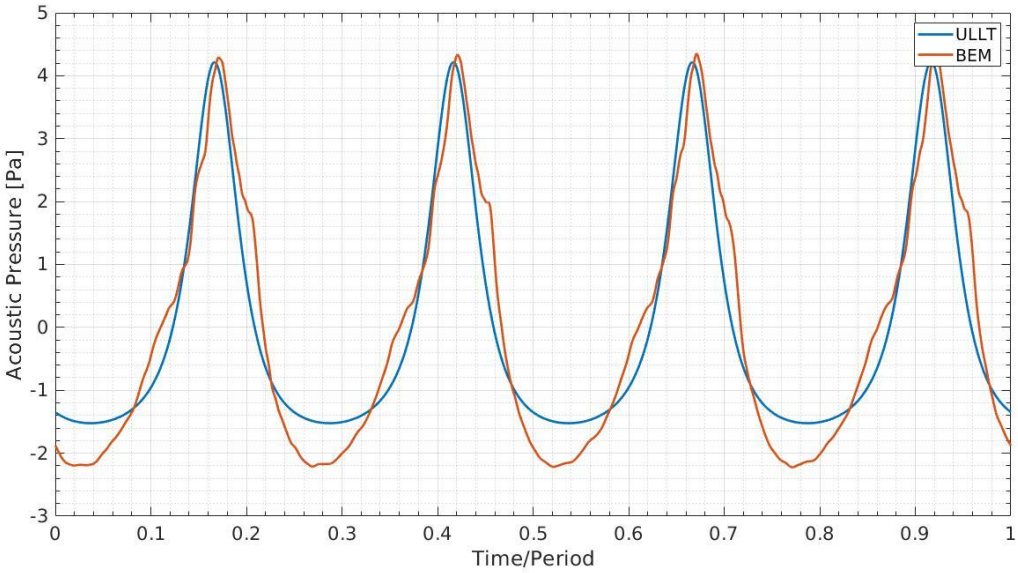

Figure 3: Loading-Noise Acoustic Footprint at Chosen Microphone

As can be seen from figure Figure 3, the ULLT solver accurately captures the loading contribution to noise, producing acoustic traces whose time history and dominant harmonic content closely match those of the validated BEM solution. Given the nature of the ULLT solver, for a proper assessment of accuracy, the contribution of thickness noise was disregarded in this evaluation.

The ULLT predictions accurately reproduce the phase and amplitude of the main low-frequency harmonics (particularly the 4/rev component), yielding a waveform over a single rotor revolution that closely matches the reference data. This confirms that the ULLT approach reliably maps spanwise load distributions into acoustic output, thus once again validating the methodology for predicting the aerodynamic loads on rotor blades.

Conclusions

The methodology presented in this study allows for a novel kind of simulation for unsteady aerodynamics of rotors. The forward flight validation test case shows the potentiality of this application and the validity of the model extension to forward flight cases, where most elements, namely the Küssner-Schwarz model in time and the reduced frequency scaling, are stretched at the edge of their applicability. Nonetheless, the results in terms of load prediction and noise estimation

confirm a very good accuracy, using a full three-dimensional boundary element method solver as benchmark.

Abstract. Internal fluid rotation and slosh in spacecraft tanks produce time-varying torques and changes in effective inertia that directly affect a satellite's rotational dynamics. For small tanks or low fluid mass fractions, these effects can be treated as perturbations, approximated by simple slosh modes, or even considered negligible noise. However, when tanks are large relative to the vehicle's structural mass, the fluid's inertia and unsteady torques can alter the rotational equilibrium and its stability. This work examines how rotating internal fluid motion affects spacecraft attitude stability, with particular attention to the minimal axis instability phenomenon, in which a body containing a cavity filled with a two-phase fluid shift from rotating about its axis of minimum inertia to rotating about its axis of maximum inertia as the fluid dissipates energy, and the consequences of that behaviour for rotation-sensitive missions. The objective is to establish a connection between viscous boundary-layer dissipation mechanisms, the minimal axis instability phenomenon, and the relative time scale, which also depends on the fill level.

Introduction

Modern satellite missions have become increasingly complex and ambitious, often requiring spacecraft to carry significantly more fuel than during the early stages of the space era [7]. Liquid propellants are widely used in many space applications, particularly for high altitude and long duration missions [2]. In such satellites, the propellant can account for a substantial portion of the total mass, often around 40% of the initial launch mass [6]. This large amount of onboard fuel, which remains in a partially filled state for most of the mission duration, gives rise to complex fluid-structure interactions. For rotating spacecraft, this can be seen in changes to the effective inertia tensor as the fluid redistributes and in a moment opposite to the rotation, if it is not rotating about the greatest principal axis of inertia. These unsteady hydrodynamic loads may adversely affect the stability and controllability of the spacecraft. Flight experiments and flight-scale tests have long shown that internal fluid motion can couple strongly to spacecraft attitude: for example, the Wet Satellite Model (WSM) flight experiment produced a measurable minimal axis instability [9]. One criterion to characterize the effect of the fluid is an equivalent timescale, obtained by comparing the angular momentum of the rigid-body with the torque exerted by the fluid on the rigid-body. A convenient estimate is

$$\tau \approx \frac{rigid-body\ angular\ momentum}{characteristic\ fluid\ torque} = \frac{m_b \mathrm{L}^2 \Omega}{M_G^E}$$

where ME denotes the characteristic viscous torque. In practice, the most at-risk satellites satisfy two conditions: a large fluid-structure momentum ratio and a short τ. The characteristic time scale τ is interpreted as the duration over which dissipative fluid torques redistribute angular momentum between the fluid and the rigid body sufficiently to shift the stable rotation of the composite body from the minimum to the maximum inertia axis. This differs from the classical Ekman spin-down time [10], which quantifies only the timescale for transient fluid motion to relax to a quasi-steady internal flow state. To estimate the viscous wall torque, let where M_G^E denotes the characteristic viscous torque. In practice, the most at-risk satellites satisfy two conditions: a large fluid-structure momentum ratio and a short τ. The characteristic time scale τ is interpreted as the duration over which dissipative fluid torques redistribute angular momentum between the fluid and the rigid body sufficiently to shift the stable rotation of the composite body from the minimum to the maximum inertia axis. This differs from the classical Ekman spin-down time [10], which quantifies only the timescale for transient fluid motion to relax to a quasi-steady internal flow state. To estimate the viscous wall torque, let

$$\Omega = \max\{\omega_x(t_0), \omega_y(t_0), \omega_z(t_0)\}.$$

Classical Ekman-layer theory, for Geophysical Fluid Dynamics, requires a small Rossby number $Ro \ll 1$, where $Ro = U/(L\,\Omega)$, so that nonlinear advection is negligible and the Coriolis-driven boundary layer controls the viscous torque [1]. In low-gravity spacecraft tanks, centrifugal effects are largely absorbed into the hydrostatic pressure and the static free-surface shape, but centrifugal and gyroscopic effects can be non-negligible. For the small-rotation regime considered here, a typical Rossby number may be $Ro \sim 1$. Therefore, the near-wall velocity is treated as a small perturbation to the background rotation. In a coupled rigid-body–fluid problem, the perturbation amplitude is defined from the instantaneous slip between the solid body and the fluid. It is expressed as

$$\alpha(t) = \left|\Omega_b(t) - \Omega_f(t)\right|, \quad U(t) \sim \alpha(t) L\Omega \sim L\left|\Omega_b(t) - \Omega_f(t)\right|$$

where $\Omega_b(t)$ is the instantaneous angular velocity of the rigid body and $\Omega_f(t)$ is the mean angular velocity of the fluid bulk. Using the Ekman thickness

$$\delta_E \sim \frac{r\nu}{\Omega}$$

and estimating the wall shear as $\tau_w \sim C_\tau \mu U/\delta_E$, and taking the torque as shear area lever arm, one obtains

$$M_G^E \sim C_\tau \alpha(t) \rho \nu^{1/2} L^4 \Omega^{3/2}$$

with $\mu = \rho\nu$. For two-phase flows, an interfacial torque must be added, which depends on the level of fill, the mobility of the interface, and the surface tension.

Methodology

The numerical simulations for the fluid were performed in the inertial frame using the Arbitrary Lagrangian-Eulerian (ALE) formulation of the Navier-Stokes equations with the VOF method for the two-phase interface. Within this framework, mesh motion was accounted for through the relative convective flux $(\boldsymbol{V} - \boldsymbol{V}_m)$, where $\boldsymbol{V}_m$ denotes the local mesh velocity. The rigid-body motion library was modified to prescribe cavity rotation, ensuring that the mesh boundaries followed the imposed motion in a kinematically consistent manner. It is important to note that no additional Coriolis or centrifugal source terms were introduced in this approach, as the frame is inertial. Nevertheless, the effects of rotation were still captured. The methodology follows the established ALE framework [4, 5, 1, 8].

Materials Research Proceedings 69 (2026) 148-153 https://doi.org/10.21741/9781644904251-26

$$\left.\frac{\partial(\rho \boldsymbol{V})}{\partial t}\right|_{\chi} + \nabla \cdot \rho \boldsymbol{V} \otimes (\boldsymbol{V} - \boldsymbol{V}_m) = -\nabla p + \mu \Delta \boldsymbol{V}, \qquad in\ \Omega, \qquad (1)$$

$$\nabla \cdot (\boldsymbol{V} - \boldsymbol{V}_m) = 0, \qquad in\ \Omega, \qquad (2)$$

where χ is the fixed reference coordinate system. The boundary condition on the moving walls is the no-slip

$$\boldsymbol{V} = \boldsymbol{V}_{wall} = \boldsymbol{V}_m, \qquad in\ \partial\Omega_{wall}$$

The dynamic equations of motion of the tank, are the following [3]

$$m_b \dot{\boldsymbol{V}}_{\boldsymbol{G}} = \boldsymbol{F}^{\boldsymbol{E}} = \boldsymbol{R}_{I\to B} \int_{\partial\Omega_{wall}} (p\,\mathbf{I} - \mu\,(\nabla \boldsymbol{V} + (\nabla \boldsymbol{V})^T) \cdot \mathbf{n}\, dS, \qquad (3)$$

$$\boldsymbol{J}_G \dot{\boldsymbol{\omega}} + \boldsymbol{\omega} \times \boldsymbol{J}_G \boldsymbol{\omega} = \boldsymbol{M}_G^E = \boldsymbol{R}_{I\to B} \int_{\partial\Omega_{wall}} \boldsymbol{r}_G \times (p\,\mathbf{I} - \mu\,(\nabla \boldsymbol{V} + (\nabla \boldsymbol{V})^T) \cdot \mathbf{n}\, dS, \qquad (4)$$

Where m_b and $\boldsymbol{J}_G$ are the tank mass and inertia tensor, $\boldsymbol{V}_G$ is the center of mass velocity, and $\boldsymbol{r}_G$ is the vector pointing to the tank internal surface points from the center of mass. The incompressible two-phase Navier-Stokes equations are solved using OpenFOAM, while the rigid-body equations of motion are integrated through a custom Python script. The iteration scheme for the fluid rigid-body interaction has been implemented in a strong coupling, in which the rigid-body motion exchanges information with the fluid multiple times until a convergence criterion is reached for the wall forces.

Results and Discussion

To investigate the influence of two-phase fluid dissipation on rotational stability, a rectangular tank with dimensions $L \times W \times H = 1.2 \times 0.8 \times 0.2$ m was considered. The liquid phase was modeled as water ($\rho_l = 1000$ kg m^{-3}, $\mu_l = 1 \times 10^{-3}$ Pa s) and the gas phase as air. All cases were initialized with the body rotating about the minimum-inertia axis, J_x. The rigid-body angular momentum about the initial spin axis was $H_b = J_x\,\Omega = 10$ kg m$^2 \times \Omega$ rad/s $= 10\,\Omega$ kg m^2/s The torque prefactor (without $C_\tau\alpha$) was estimated as $\sqrt{\nu} = \sqrt{(1 \times 10^{-6})} = 0.001$ m^2/s$^{1/2}$, $L^4 = 1.2^4 = 2.0736$, and $\rho\sqrt{\nu} = 1000 \times 0.001 = 1$, giving $M_G^E \sim C_\tau \rho \sqrt{\nu} L^4 \Omega^{3/4} \approx \left(C_\tau \alpha \Omega^{3/4}\right) \times 2.0736$ N m, and the corresponding timescale:

$$\tau = \frac{H_b}{M_G^E} \approx \frac{10\Omega}{(C_\tau \alpha \Omega^{3/2}) 2.0736} \approx \frac{4.8225}{C_\tau \alpha \Omega^{1/2}}\ \text{s}$$

In the simulation, the Rossby number was estimated as $\text{Ro} \sim 0.05 - 0.1$. The slip ratio was approximated as$\alpha \sim \text{Ro}$, and assuming $C_\tau \sim O(1)$, the viscous coupling was $C_\tau\alpha \sim \text{Ro}$. Therefore, for $\text{Ro} \sim 0.05$, $C_\tau\alpha \sim 0.05$, and for $\text{Ro} \sim 0.1$, $C_\tau\alpha \sim 0.1$. Two sets of numerical experiments were performed. In the first series, the fill level was fixed at 50% while the initial angular velocity about the minimum-inertia axis was varied. This sweep showed that higher initial rotation rates converged more rapidly to rotation about the maximum-inertia axis (i.e., the axis switch occurred sooner) due to increased fluid torque, as shown in Fig. 1. In the second series, the initial angular velocity was held constant while the fill ratio was varied. Changing the fill modified the free-surface geometry and the gas– liquid interaction, which affected the effective viscous coupling (apparent viscous timescale) and, consequently, the dissipation-driven dynamics, as illustrated in Fig. 2. The timescale, τ , was similar to that observed in the simulation of a tank full of water with a Rossby number of

Materials Research Proceedings 69 (2026) 148-153 https://doi.org/10.21741/9781644904251-26

Ro ~ 0.01. The dimensional analysis was performed without accounting for the interface, which could modify the dissipation by increasing the effective area of the fluid over which the torque was applied.

Table 1 Dissipation-driven timescale τ for different spin rates Ω and coupling strengths $C = C_\tau \alpha$.

Ω [rad/s]	τ (C= 1.0) [s]	τ (C= 0.1) [s]	τ (C = 0.01) [s]
0.50	6.82	68.20	682.00
1.00	4.82	48.23	482.25
2.50	3.05	30.50	305.00
5.00	2.16	21.57	215.67
10.00	1.53	15.25	152.50

Summary

The results confirmed that two-phase fluid dissipation plays a role in determining spacecraft rotational stability. Higher initial spin rates or stronger viscous coupling led to faster axis switching, while reduced fill levels or weaker coupling increased the timescale for dissipation-driven reorientation. Overall, the timescale τ provides a practical metric for assessing susceptibility to the minimal axis instability phenomenon in a variety of spacecraft designs.

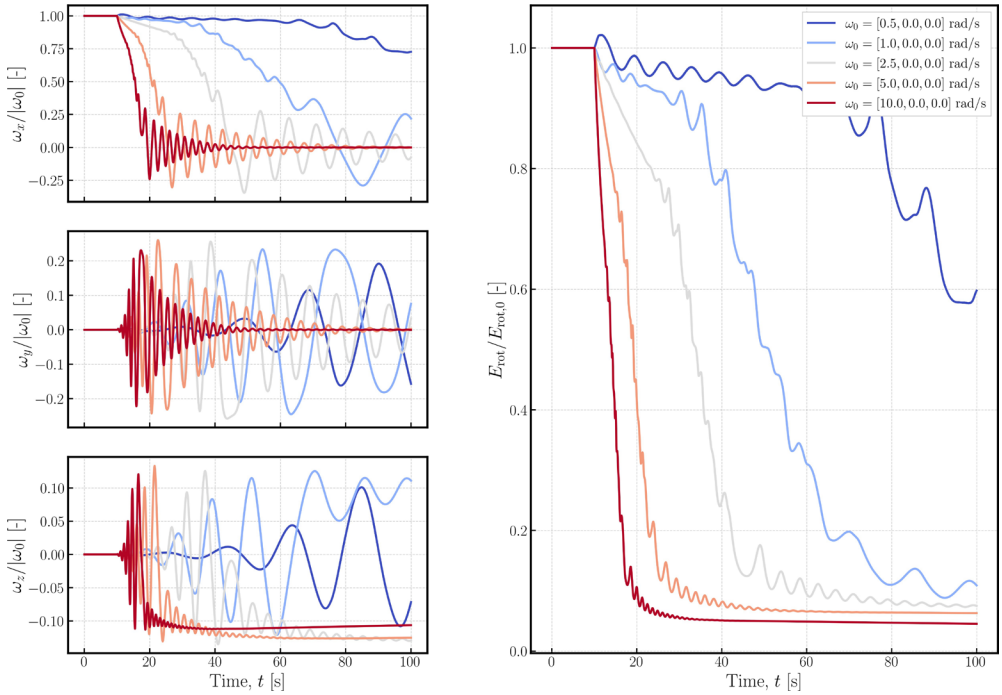

Figure 1: Time evolution of the angular velocity for different initial rotation rates at a fill level of 50%. The principal moments of inertia satisfy $J_z < J_y < J_x$.

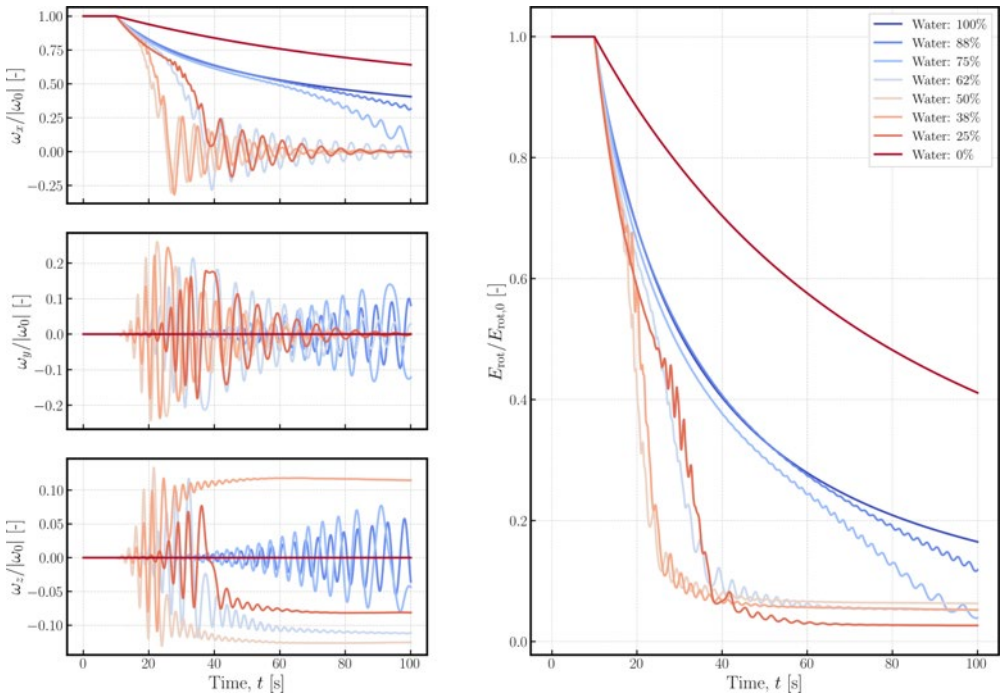

Figure 2: Time evolution of the angular velocity for different fill levels, with an initial angular velocity of 5 rad/s. The principal moments of inertia satisfy y $J_z < J_y < J_x$.

Improving Post-Stall Airfoil Performance Using Synthetic Jet-Based Flow Control

Baris GUNGORDU[1,a *]

[a]gbaris@metu.edu.tr

Keywords: Aerodynamics, Active Flow Control, Computational Fluid Dynamics

Abstract. This study numerically investigates the aerodynamic performance of a NACA0012 airfoil equipped with a leading-edge synthetic jet actuator at a Reynolds number of $1.35x10^5$. The analysis was conducted at a fixed angle of attack of 16° to represent post-stall flow conditions. Two-dimensional unsteady, incompressible Reynolds-Averaged Navier-Stokes equations were solved using a commercial finite-element solver, and the baseline results were validated against available experimental data. The effects of actuation frequency and jet velocity ratio on aerodynamic characteristics were examined. Results indicate that actuation frequency plays a dominant role in flow control effectiveness. At twice the natural wake frequency ($2f_c$), the synthetic jet substantially improved aerodynamic efficiency, increasing the lift-to-drag ratio by up to 34.1% compared to the baseline case. These findings demonstrate the strong potential of synthetic jet actuators for mitigating flow separation and enhancing post-stall performance in future low-energy aerodynamic applications.

Introduction

The global aviation industry, while facilitating rapid transportation and economic development, has also become a notable source of anthropogenic climate change. Recent analyses indicate that commercial aviation contributes about 2.4% of total global CO_2 emissions [1]. A considerable share of this impact originates from aerodynamic inefficiencies, particularly drag-induced fuel consumption during cruise flight [2]. Consequently, many studies have focused on improving aerodynamic performance by reducing drag and increasing the lift-to-drag ratio as part of a broader effort toward sustainable aviation.

Flow separation is among the key causes of aerodynamic inefficiency. It occurs when the boundary layer loses momentum and detaches from the surface under adverse pressure gradients, leading to a marked increase in pressure drag and loss of lift, especially at high angles of attack or during unsteady manoeuvres. Traditional passive flow control methods—such as vortex generators, winglets, and riblets—have been widely applied to alleviate flow separation; however, they lack adaptability to varying flow conditions and flight regimes [3]. In contrast, active flow control (AFC) techniques provide real-time control over the flow field. Among these, synthetic jet actuators (SJAs) have drawn significant attention as a compact, energy-efficient, and geometry-preserving solution [1,9]. By producing zero-net-mass-flux oscillatory jets, SJAs can re-energize the boundary layer and delay separation without requiring an external air supply [4]. These features make them highly suitable for sustainable aircraft applications, enabling performance enhancement with minimal design compromise [5,6]. The jet produced by an SJA is typically described by a sinusoidal velocity profile characterized by its peak jet velocity (U_{jet}) and actuation frequency (f_a).

This study presents a numerical investigation of an NACA0012 airfoil equipped with a single synthetic jet actuator using a commercial finite-element-based solver. The objective is to evaluate aerodynamic improvements, particularly the lift-to-drag ratio, under post-stall conditions. Although the broader motivation relates to the development of energy-efficient flow control

strategies for emission reduction, the current work focuses on the aerodynamic effects at a single angle of attack of 16°.

Model, Computational Methods and Validation

The airfoil has a chord length (c) of 0.15 m and a free-stream flow Reynolds number of parallel to the experimental validation study by Lee and Gerontakos [7]. For the NACA0012 airfoil, incompressible Reynolds-Averaged Navier-Stokes (RANS) was solved over time numerically as the Mach number of the free-stream flow, $M_\infty < 0.3$. The numerical study utilized a 2-D geometry for the airfoil, and $k-\omega$ SST turbulence model was employed. A C-type grid was used with a size of 20c x 20c. The time step of the simulation is $\Delta t = 1\text{x}10^{-4}$, and the total time is set to t = 10 seconds. The solver is using a 2nd order accurate discretization for space and time. The lift and drag coefficients are the time-average values, disregarding the first second. A mesh grid independence test was conducted to ensure that the mesh grid does not affect the results.

Figure 1a illustrates the NACA0012 airfoil with mesh, and Figure 1b presents the illustration of the synthetic jet actuator, which is located near the leading edge of the upper surface, where the orifice mid-point is located at x/c = 5.33%. The synthetic jet actuator is modelled as a velocity boundary condition to mimic the piezoelectric diaphragm and has the same dimensions as reported in the work of Gungordu et al. [4,9].

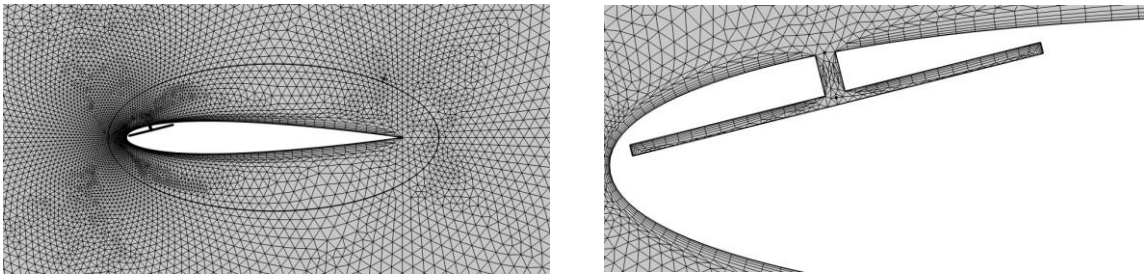

Figure 1: (a) NACA0012 Airfoil with mesh (left) (b) Magnified view of the synthetic jet actuator in the airfoil (right)

The base-flow (i.e., no flow control) lift coefficient results of the airfoil for various angles of attack at a Reynolds number of 1.35×10^5 were taken from the experimental study of Lee and Gerontakos [8]. The results revealed that the accuracy of the numerical study exceeds 95% across the entire angle-of-attack sweep when compared with the experimental data. For the present investigation, the angle of attack of the NACA0012 airfoil was fixed at α = 16°, at which a strong wake formation accompanied by vortex shedding is observed. By performing a power spectral density analysis of the wake using a virtual pressure probe, the characteristic vortex shedding frequency (f_c) was identified as 34.2 Hz. Accordingly, the oscillation frequency of the synthetic jet actuator was selected within this range. The synthetic jet actuation frequency (f_a) was varied as 0.5 f_c, f_c, and 2 f_c.

Results and Discussion

Table 1 summarizes the principal numerical results for the simulated flow-control cases at a fixed angle of attack of 16°. The reported parameters include the velocity ratio (V.R.; defined as the ratio of peak orifice-exit jet velocity to free-stream velocity), synthetic jet actuation frequency, lift-to-drag ratio, the corresponding baseline lift-to-drag ratio without flow control, and the relative percentage difference.

The aerodynamic performance of the airfoil exhibits a clear dependence on both the velocity ratio (V.R.) and the actuation frequency (f_a). At V.R. = 1.0, increasing the actuation frequency leads to a progressive improvement in the lift-to-drag ratio, with C_l/C_d increasing from 3.76 to

4.30, corresponding to a maximum enhancement of 7.1% relative to the baseline. As the velocity ratio increases to V.R. = 1.8, the influence of actuation frequency becomes more pronounced, with the maximum C_l/C_d reaching 5.28 at $2f_c$, representing a 34.1% improvement.

For both velocity ratio cases, actuation frequency of $0.5f_c$ provides only minor or negligible improvements, whereas the intermediate frequency (f_c) results in moderate gains. Overall, the results demonstrate that higher velocity ratios and higher actuation frequencies consistently produce stronger flow-control authority, leading to substantial improvements in aerodynamic efficiency, particularly at $f_a = 2f_c$.

Table 1: *Aerodynamic performance for different velocity ratios and actuation frequencies*

Case	V.R.	Actuation Frequency (f_a)	C_l/C_d	Baseline C_l/C_d	Difference (%)
1	1.0	0.5 f_c	3.76	3.94	−4.5
2	1.0	f_c	4.11	3.94	4.4
3	1.0	2 f_c	4.30	3.94	7.1
4	1.8	0.5 f_c	3.94	3.94	0
5	1.8	f_c	4.84	3.94	23.1
6	1.8	2 f_c	5.28	3.94	34.1

Conclusions

This numerical study investigated the aerodynamic effects of a synthetic jet actuator located at the leading edge of a NACA 0012 airfoil under post-stall flow conditions. The results demonstrate that the actuation frequency is the dominant parameter governing aerodynamic performance. At half of the characteristic wake frequency ($0.5\ f_c$), the actuator provided limited benefits and, in some cases, reduced the lift-to-drag ratio due to intensified vortex shedding. Near the characteristic frequency (f_c), moderate improvements of approximately 4–7% were observed. The most significant performance gains occurred when the actuation frequency was twice the wake frequency ($2\ f_c$), where the lift-to-drag ratio increased by up to 34.1% compared with the baseline case.

In the present study, the synthetic jet actuator was modelled using a prescribed velocity boundary condition at the orifice to emulate the oscillatory jet generated by a piezoelectric diaphragm. While this approach captures the primary aerodynamic effects of synthetic jet actuation, it does not fully represent the coupled structural–fluid–acoustic behaviour of a real piezoelectric actuator. Future work should therefore incorporate a fully coupled physical model of the piezoelectric diaphragm and cavity dynamics to provide a more realistic representation of actuator performance. In addition, extending the numerical framework to three-dimensional simulations would enable the investigation of spanwise effects, three-dimensional vortex structures, and their influence on flow-control effectiveness under realistic operating conditions.

Abstract. Fluid–Structure Interaction plays a critical role in many engineering applications, particularly in the aerospace and aeronautics sectors. In this context, the interaction between fluid flow and bluff bodies is often used to model key aircraft components. While extensive research has been conducted on simple geometries such as circular and square cylinders, polygonal bodies remain comparatively understudied. To address this gap, the Lattice Boltzmann Method with a Multiple-Relaxation-Time collision operator is employed in combination with a Large Eddy Simulation approach based on the Smagorinsky model. This setup is used to simulate the flow past circular and hexagonal cross-section cylinders under two different orientations and in various flow conditions. The Immersed Boundary Method is applied here to represent efficiently the boundary. The study moves investigating the vortex-induced vibrations problem at a Reynolds number of 200, considering a low density ratio between the solid and the fluid density. Results show that the orientation of the hexagonal cylinder strongly affects the wake formation in both stationary and vibrating cases.

Introduction

Understanding the flow behavior around bluff bodies is critically important, particularly in the context of Fluid–Structure Interaction (FSI) problems. In aeronautical applications, components such as engine mounts or landing gear assemblies often act as bluff bodies, causing airflow separation and the formation of vortices. Gaining a detailed understanding of these flow patterns is therefore essential for optimizing designs and reducing the fatigue loads induced by the unsteady flow. Similarly, in the energy sector, understanding the flow pattern is essential to improve the energy efficiency; for instance, in wind farms, downstream turbines are significantly influenced by the wakes generated by the upstream turbines.

To investigate these phenomena, bluff bodies are frequently modeled using simple geometries, such as cylinders with circular or polygonal cross-sections, cubes, spheres, or thin flat plates inclined at specific angles. These idealized shapes provide a practical way to study the fundamental flow behavior around non-streamlined objects while capturing the key mechanisms of separation and vortex formation. Several authors systematically investigated these geometries both experimentally and numerically, with particular emphasis on the influence of cross-sectional shape and incidence angle on the flow characteristics [1, 2, 3]. Specifically, polygonal cross-section

cylinders introduce geometric asymmetries compared to classical circular cylinders, arising from the number of edges and the incidence angle with respect to the free-stream direction [4, 5].

In this work, the Lattice Boltzmann Method (LBM) is adopted with the Multiple Relaxation Time (MRT) collision operator, chosen for its superior numerical stability and accuracy, particularly at high Reynolds numbers, compared to the classical Single Relaxation Time (SRT) approach. Specifically, the present study employs a Large Eddy Simulation (LES) approach based on the Smagorinsky Subgrid-Scale model [6] to investigate both the flow past circular and hexagonal cross-section cylinders. The near-wall eddy viscosity is modeled using the Van Driest function [7].

The Immersed Boundary Method (IBM) is then employed in a three-dimensional LBM framework to efficiently represent complex and moving geometries.

In Section 2, the numerical model is presented which includes a brief description of the employed LBM scheme, followed by an outline of the LES approach, and concluding with the formulation of the IBM. In Section 3 results obtained with the present algorithm are then presented.

Numerical modeling

The LBM is a numerical approach for simulating fluid flows based on the evolution of particle distributions on a discrete lattice. The discrete form of the governing equation can be written as:

$$f_i(\boldsymbol{x}_f + \boldsymbol{c}_i\Delta t, t + \Delta t) = f_i(\boldsymbol{x}_f, t) + \Omega_i(\boldsymbol{x}_f, t)\Delta t + F_i(\boldsymbol{x}_f, t)\Delta t \quad (1)$$

where $f_i(\boldsymbol{x}_f, t)$ represents the distribution functions associated to pre-determined lattice directions $\boldsymbol{c}_i$, $\Omega_i(\boldsymbol{x}_f, t)$ and $F_i(\boldsymbol{x}_f, t)$ are the MRT collision operator and the source term respectively [8].

In Eq. (1), the source term $F_i(\boldsymbol{x}_f, t)$ accounts for internal or external forces acting on the fluid. Among the various forcing schemes available in the literature the present approach adopts Guo's forcing scheme [9].

To handle high Reynolds number flows, rather than employing an excessively fine mesh to resolve all the small turbulent scales, a LES approach based on the Smagorinsky subgrid scale model has been integrated in the present algorithm. This approach allows to model small scale structures while large energy containing turbulent structures, strongly influenced by the geometrical shape of the obstacle, are directly resolved [10, 11, 12]. To account for near-wall effects, Van Driest damping function is then used to let the turbulent viscosity exponentially damp to zero close to the wall.

Finally, to deal with stationary and moving complex geometries within the fluid domain, the IBM, a non-body conformal grid methodology, is adopted. Two different grid systems are used, the Eulerian grid for the fluid which is stationary and the Lagrangian mesh used for the immersed object. The presence of the obstacle in the flow field is then modeled through a force density added in the fluid governing equations in order to satisfy the no-slip condition on the boundary [13, 14, 15]. In this work the Direct-force IB formulation proposed by Kang and Hassan in [13] is used; the diffuse interface scheme is then adopted to represent the boundary.

Furthermore, the D3Q19 lattice stencil is employed, with periodic boundary conditions applied in the spanwise direction to simulate an infinitely long cylinder, while Neumann boundary conditions are imposed on the top and bottom boundaries.

Results

The three-dimensional algorithm has been validated against literature data for flow past a circular cylinder at various Reynolds numbers, using drag and lift coefficients C_d and C_l, and Strouhal number St as benchmark quantities, as summarized in Table 1.

Contour maps of the wakes for the three stationary geometries at Re = 200 are shown in Fig. 1 where the Q-criterion is used to identify vortical structures, which are colored by the magnitude of the lattice velocity.

A distinct secondary vortex with higher energy content characterizes the face oriented hexagonal cylinder compared to the other configurations, likely as a result of a different flow separation induced by the geometry's orientation. In contrast, the edge oriented hexagonal cylinder behaves similarly to the circular cylinder, probably due to its lower azimuthal separation point.

(a)

(b) (c)

Figure 1 Wake visualization using Q-criterion: stationary case, (a) circular cylinder, (b) edge oriented hexagonal cylinder, (c) face oriented hexagonal cylinder

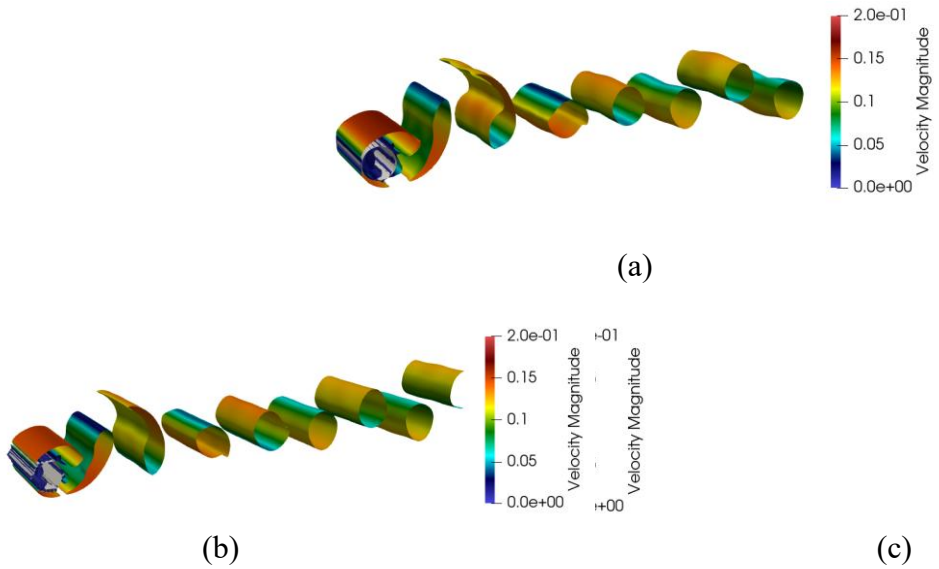

Figure 2 Wake visualization using Q-criterion: VIV case, (a) circular cylinder, (b) edge oriented hexagonal cylinder, (c) face oriented hexagonal cylinder

The wakes of the vibrating geometries at Re = 200 are visualized using the Q-criterion in Fig. 2. Compared to the stationary cases, the circular cylinder and the edge oriented hexagonal cylinder shed vortices that are strongly distorted by the vibration, after which the two single vortices formed during one shedding cycle develop along the centerline without the significant deformation observed in the stationary configuration. The face oriented hexagonal cylinder, on the other hand, exhibits a different pattern, with two pair of primary coherent structures formed in same shedding cycle no longer aligned with the wake centerline and secondary vortices displaying a more elongated shape Fig. 2c.

Conclusions

In this paper, we propose a 3D algorithm based on the coupling between the IBM and the LBM-MRT to investigate Fluid-Structure Interaction problems. The IBM allows for accurate evaluation of the forces exerted on the solid structure. Validation against the benchmark case of flow past a circular cylinder over a range of Reynolds numbers shows a very good agreement.

The analysis is further extended to hexagonal cross-sectional cylinders with different orientations. Comparison of the wake structures reveals that the edge oriented hexagonal cylinder and the circular cylinder exhibit similar wake characteristics, featuring deformed coherent vortices convected along the streamwise direction. In contrast, the face oriented hexagonal cylinder undergoes an earlier transition to three-dimensional vortex formation, characterized by the appearance of secondary vortices superimposed on strongly deformed primary coherent structures.

The investigation is subsequently extended to vibrating configurations. While the circular cylinder and the edge oriented hexagonal cylinder generate comparable wakes with stretched vortices, the face oriented hexagonal cylinder produces elongated vortices that propagate along the streamwise direction, with two pair of primary coherent structures no longer aligned with the centerline.

Keywords: Turbulent Jet; UAV; Flow Measurements

Abstract. Understanding the development of turbulent jets in subsonic nozzles is essential for improving jet noise prediction models and for validating high-fidelity numerical simulations in aerospace applications. Within the framework of the NATO STO AVT-415 activity, a dedicated experimental campaign was carried out at the Italian Aerospace Research Center (CIRA) to investigate the velocity field and turbulence characteristics at the inlet and exit of a novel subsonic nozzle configuration using hot-wire anemometry (HWA). The results offer a comprehensive description of the flow evolution downstream of the nozzle exit and a detailed characterization of the turbulence properties upstream of the nozzle. These measurements are of significant importance for establishing accurate boundary conditions in numerical simulations.

Introduction

The need for optimizing performances of Unmanned Air Vehicles (UAV) in military and civil applications requires the use of advanced computational studies providing both the aerodynamic and the aeroacoustic behavior in particular in the region close to the exhaust of the propulsion system.

The main objective of the *NATO STO AVT-415* group is to investigate intake and exhaust sound radiation of a UCAV-type military vehicle and to evaluate low-noise nozzle concepts by means of dedicated experiments and numerical simulations. The configuration under investigation is the so called DLR-F24 MULDICON that has been thoroughly described in [1, 2, 3, 4]. This specific wind tunnel model is designed around the concurrent agile (unmanned) NATO air vehicle design, the MULDICON UCAV configuration (MULti-Disciplinary CONfiguration)[1]. The original MULDICON UCAV planform design, which originates from NATO AVT-251 [1], was adopted. AVT-251 was not about designing a competitive UCAV but rather aimed at improving earlier designs while moving towards a realistic flyable vehicle. The configuration was slightly modified to allow the integration of an intake and an exhaust channel necessary for the conduction of the experiments [4]. For experimental purposes, the original MULDICON platform remained untouched while the centre body design by FOI (Swedish Defence Research Agency) was selected [5]. This design has a thicker centre-body, leaving more room for the intake and exhaust channels. The system is equipped with a non-axisymmetric nozzle that features an elliptical cross-section at

Materials Research Proceedings 69 (2026) 164-171 https://doi.org/10.21741/9781644904251-29

its interface with the settling chamber and a gradual transition into a high-aspect-ratio rectangular exit section.

While acoustic tests and numerical simulations on this configuration have been carried out in the past, a comprehensive aerodynamic characterisation has never been performed so far. Due to the complexity of the settling chamber and of the nozzle geometry, detailed measurements of velocity and turbulence statistics are essential for the understanding of the flow physics and for the assessment of the boundary conditions used in the numerical approaches.

The main scope of the present activity is to provide an extensive aerodynamic description of the flow in the intake and in the region downstream of the nozzle exit. To this purpose, an extensive measurement campaign has been carried out at the Italian Aerospace Research Centre (CIRA) by means of hot-wire anemometry. In parallel, the nozzle surface pressure distribution has been investigated in order to ensure the repeatability of the test conducted at DLR. The experimental tests provided mean velocity profiles along with higher-order statistics for different positions at the inlet and outlet regions and different Mach numbers.

Experimental set-up

The DLR-F24 Muldicon model was originally designed for use in the anechoic test section of the DNW-NWB (see ref. 4), and a proper setup has been arranged at CIRA to provide the air supply and mass flow control. A picture illustrating the pressure supply arrangement is presented in *Figure 1*. The pneumatic flow system is equipped with a pressure valve regulator, temperature, pressure and mass flow sensors. The operative inlet pressure is maintained by an active closed-loop control. Temperature, mass flow and pressure are measured during the full test.

A cross-cut view through the model centre is shown in *Figure 2*, making visible the arrangement of all components and the detailed contours of the intake duct and nozzle. The section area distribution of the nozzle duct is given in *Figure 3*. The nozzle is equipped with 36 static pressure taps distributed on streamwise-aligned lines on the upper and lower walls of its duct, at the nozzle symmetry plane. Seven pressure taps are spread out streamwise, three taps on each side of the centre line at the 200 mm position (see *Figure 4*). The pressure taps at positions 300 mm, 320 mm and 340 mm are located beneath the exchangeable lower wall plate. Pressure measurements. were carried out by a PSI8400 system. Two differential EPS modules with full-scale values of ± 5 psid and ± 15 psid, respectively, were used.

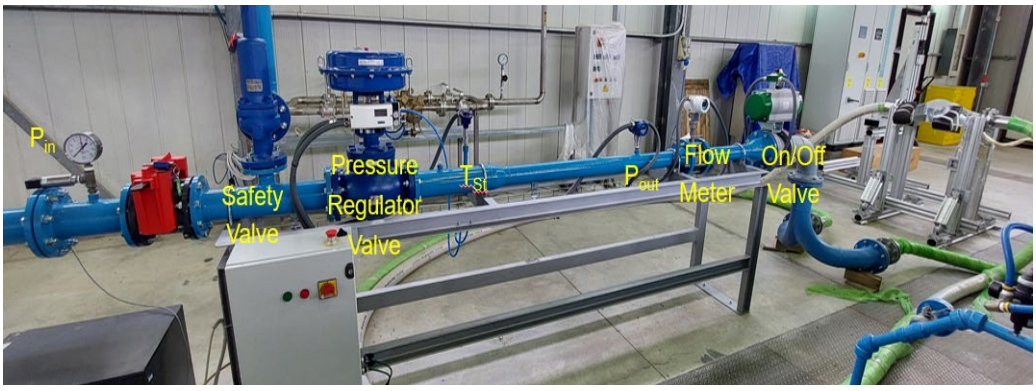

Figure 1 – Picture of the pressure supply system

At the 30 mm position on the upper wall, a 4 mm circular opening is foreseen for the insertion of a hot-wire probe. The probe is tightly held in place using a tight screw-on fitting. The probe mounted at the nozzle entrance is visible in *Figure 5*.

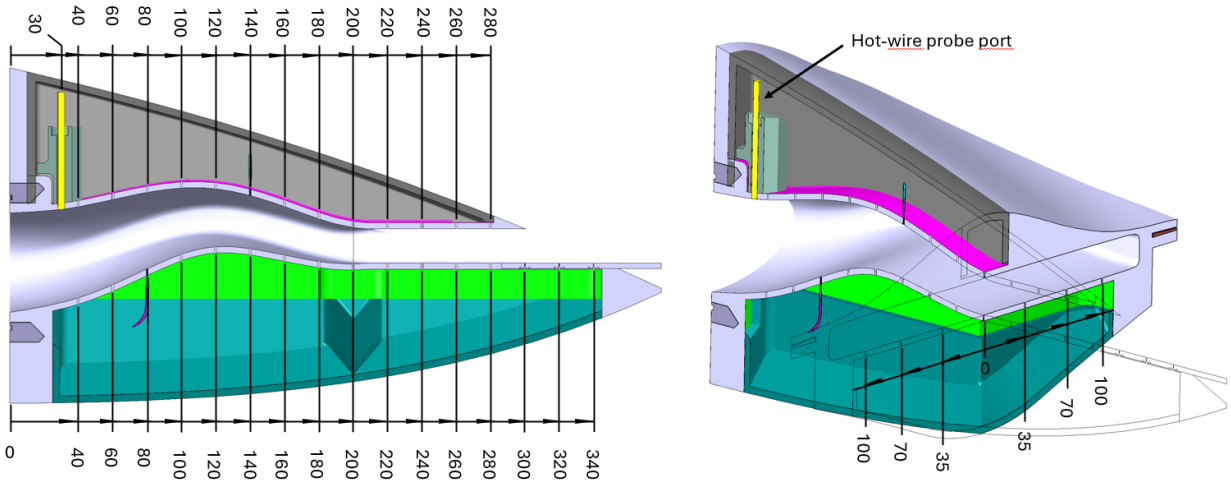

Figure 4. Centre line section (left) and cross-section (right) showing the static pressure taps positions and hot-wire probe port position

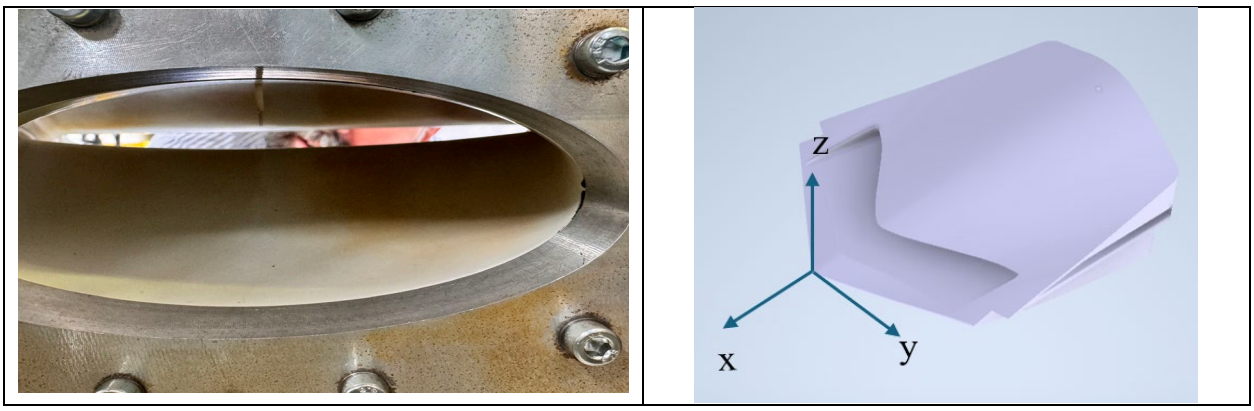

Figure 5: Set-up of the Hot-Wire probe mounted at the nozzle inlet and the reference system adopted for the hot wire positioning in the outer region

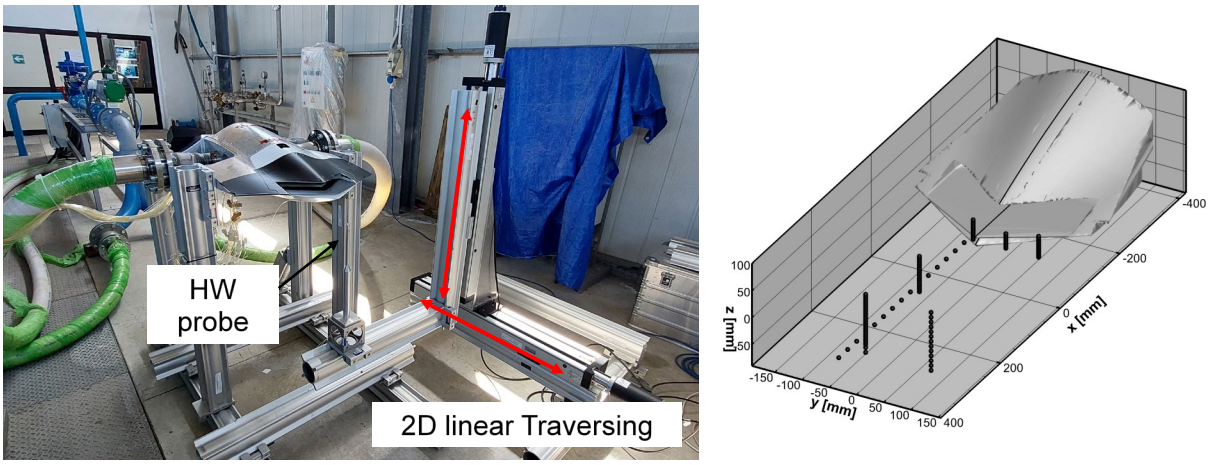

Figure 6 - Sketch of the setup and measured points

The pneumatic pressure system has been designed and installed in CIRA for the purposes of reproducing the same conditions tested in [4]. Preliminary tests have been carried out to verify the response of the pneumatic system and the similarity of the results against data achieved at DNw-NWB.

The nozzle geometry is described in detail in [4], and it features an elliptical cross-section at its interface with the settling chamber, which gradually transitions into a high-aspect-ratio rectangular exit section (266 mm × 20 mm, AR = 13.3).

Measurements have been carried out for subsonic Mach numbers of 0.5 and 0.66. To this end, a Dantec 5-channel Constant Temperature Anemometry (CTA) system was employed with single-component plated tungsten wire probes (5 µm diameter, 1.25 mm length), mounted on a two-dimensional traversing system (*Figure 6*). The setup allowed precise spatial scanning of the jet flow field at specific downstream locations; more than 220 spatial positions were investigated at different coordinates. An overview of the measurement spatial distribution is shown in *Figure 6*. The origin of the reference system was located at the lower tip of the nozzle outlet, with the x-axis directed toward the flow direction, the z-axis upward and vertically directed, and the y-axis oriented as the rule of the right-hand rule.

The probes featured a frequency response of up to 400 kHz in CTA mode. Calibration was conducted in controlled conditions to ensure accurate measurements up to 300 m/s. Velocity signals were acquired over 1.5 seconds at a 30 kHz sampling rate, enabling detailed analysis of both mean flow and turbulence fluctuations.

Materials Research Proceedings 69 (2026) 164-171 https://doi.org/10.21741/9781644904251-29

Results

Three axial positions downstream of the nozzle (x = 0 mm, x = 180 mm, and x = 360 mm) were investigated, with velocity profiles acquired along the z-axis to characterize the jet development. The resulting axial velocity distributions are presented in Figure 7 for the two Mach numbers. At each position, maximum velocity values, Uc, are found near the jet centerline, decreasing with distance from the nozzle exit due to jet spreading. The profiles at x=0 are sharp and narrow, reflecting a thin shear layer, while downstream locations show broader, lower peaks, consistent with turbulent jet decay. By measuring Uc/2 it is possible to assess the jet spreading. The figures show that the jet spreads more rapidly in the case of M=0.66, indicating stronger initial momentum and increased entrainment.

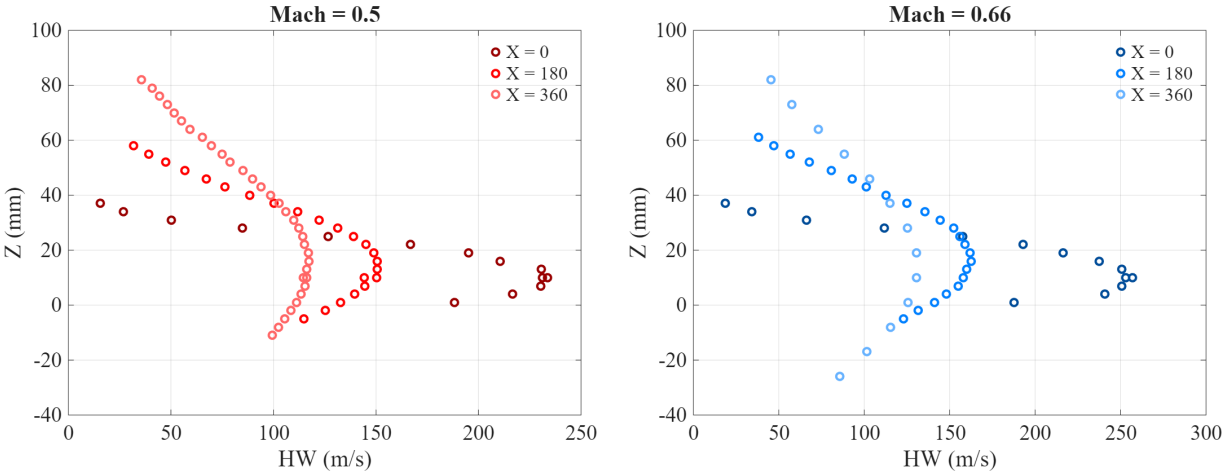

Figure 7 – Axial velocity profiles

Figure 88 shows the standard deviation of the velocity fluctuations along the z-axis. In all cases, the fluctuations exhibit minima at the jet centerline and maxima near to the center of the shear layer, where turbulence intensity is highest due to the strong velocity gradients between the jet core and the ambient flow [5, 6, 7]. The centerline velocity decay, represented as inverse velocity versus axial distance, confirms a monotonic decrease and hints at a slight jet deflection.

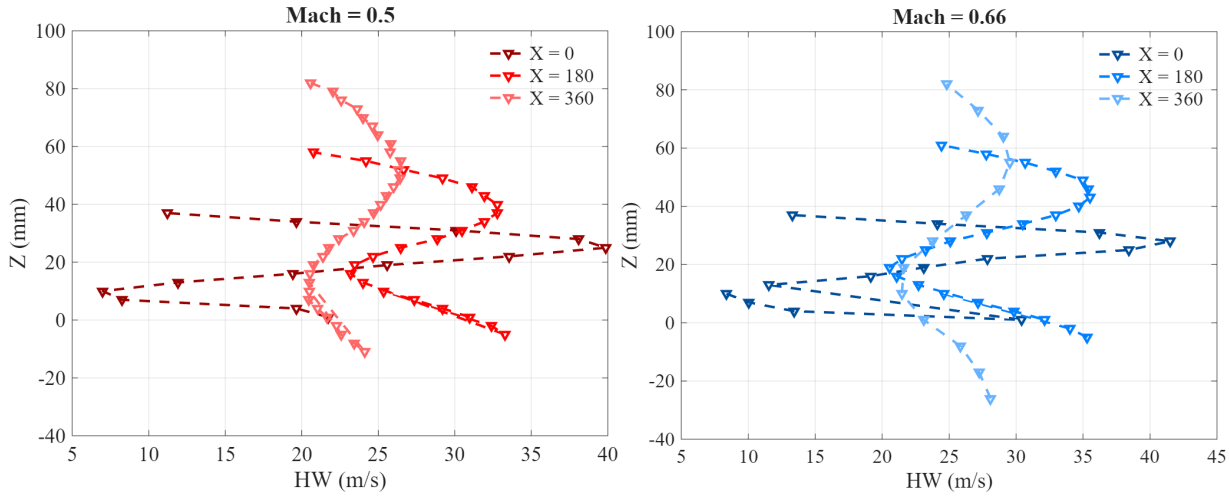

Figure 8 – Standard deviation of the axial velocity

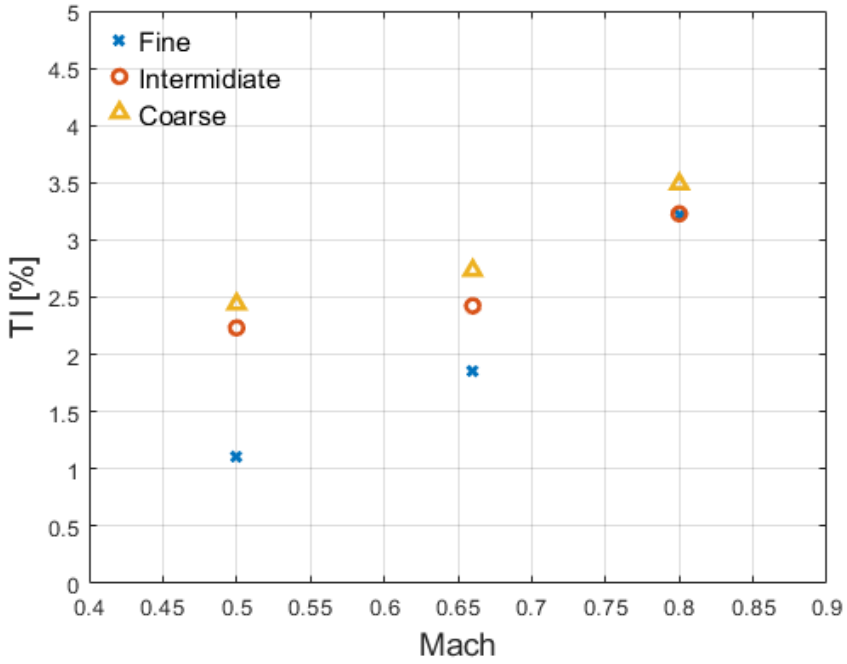
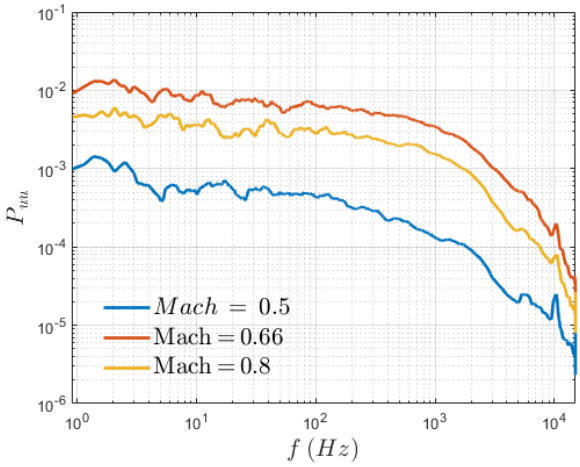
Materials Research Proceedings 69 (2026) 164-171 https://doi.org/10.21741/9781644904251-29

In addition to the downstream measurements, the inlet turbulence conditions were assessed by installing three turbulence-generating grids upstream of the nozzle: fine (0.035 mm × 0.1 mm), intermediate (1 mm × 1 mm), and coarse (2 mm × 2 mm). Hot-wire measurements were performed inside the settling chamber for Mach numbers 0.5, 0.66, and 0.74. These measurements aimed to quantify the turbulence levels introduced by each grid before entering the nozzle.

The turbulence intensity was found to be highest for the coarse grid, decreasing with the intermediate and fine grids, as depicted in Figure 9.





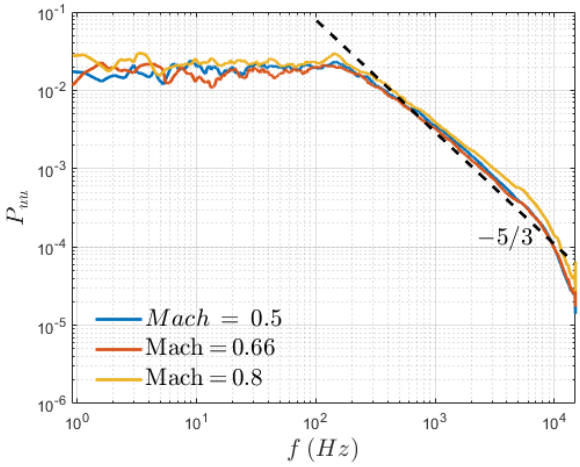


Figure 9 - Turbulence intensity comparison for the three grids

This effect seems to decrease when increasing the Mach number increases and further investigations are needed to clarify this behaviour. As illustrated in Figure 10, power spectral density (PSD) analysis further corroborates these trends: the coarse grid shows a significant shift of energy toward lower frequencies, indicating the presence of large-scale, energetic turbulent structures. These differences in inflow turbulence are expected to impact the downstream jet development and provide valuable reference data for numerical validation.

Conclusions

An extensive hot-wire test campaign was successfully completed, confirming expected behaviors in jet development and offering a robust dataset for future comparisons with CFD and Large-Eddy Simulations (LES). Upcoming work will include Particle Image Velocimetry (PIV) measurements and expanded numerical analyses using the experimental database as validation.

Keywords: Fluid-Structure Interaction, Lattice Boltzmann, Immersed Boundary, Large Eddy Simulation, Vortex Induced Vibration

Abstract. In this work, the Lattice Boltzmann Method based on the Multiple Relaxation Time collision operator is employed to solve the governing fluid flow equations. The method is coupled with the Immersed Boundary Method , a robust meshless approach that represents the geometry of interest on a grid distinct from that used for solving the fluid equations. The interaction between the fluid and the solid boundary is modeled through a body force term, which is transferred between the two grid systems via a Dirac delta function. This coupling enables accurate simulation of fluid–structure interactions involving complex geometries. Within this framework, a Large Eddy Simulation approach is implemented using the Smagorinsky subgrid-scale model, allowing the study of high Reynolds number flow regimes without the need for excessive grid refinement. The study then examines the interaction between a circular cylinder and a lamina at a fixed Reynolds number of 10^4.

Introduction

In modern civil aircraft, landing gears are still critical components for designers, with the main goals to resist the heaviest loads, be the lightest, occupy the smallest volume possible, and meet the safety requirements. Moreover, they are non-redundant, unlike almost the entirety of the other aircraft components, which are designed to ensure the vehicle's correct functionality even after a break.

Retractable landing gears are particularly susceptible to fluid-induced vibrations, not only when deployed but also when retracted, especially in cases of improper closure of the front landing gear hatch. In such scenarios, the flow released by the landing gear generates fluid structures across a range of scales, whose interactions play a critical role in shaping the unsteady aerodynamic loading on nearby surfaces, such as the landing gear door. While large-scale vortices cause global pressure fluctuations, smaller-scale structures contribute to high-frequency vibrations. A thorough understanding of these multi-scale interactions is essential for accurately predicting structural response and assessing the risk of fatigue damage.

Within this context, different Computational Fluid Dynamics (CFD) approaches involving Finite Volume (FV) discretization are employed in the literature [1, 2, 3, 4].

In the present study, the Lattice Boltzmann Method (LBM) with a Multiple Relaxation Time (MRT) collision operator is employed to solve the fluid dynamics equations and coupled with the Immersed Boundary Method (IBM), a meshless approach using distinct grids for the fluid and solid domains. The body–fluid interaction is modeled through a body force term exchanged

Materials Research Proceedings 69 (2026) 172-176 https://doi.org/10.21741/9781644904251-30

between the grids via a Dirac delta function, allowing accurate simulation of complex geometries [5]. A Large Eddy Simulation (LES) framework based on the Smagorinsky subgrid-scale model is incorporated to capture high Reynolds number regimes without excessive grid refinement. Model validation is conducted on the benchmark case of flow past a circular cylinder.

The study then examines the interaction between a cylinder and a rigid lamina fixing the Reynolds number at 1×10^4. The cylinder-lamina configuration may represent a simplified model of the aerodynamic interaction between the landing gear and the adjacent door. The lamina, modeled as a rigid wall-like surface, captures the essential flow mechanisms (i.e. vortex shedding, wake interaction, and unsteady pressure loads) that occur when the landing gear flow impinges on the nearby structures in real aircraft configurations. The high temporal and spatial resolution of the LBM–IBM framework enables detailed analysis of multiscale flow structures and their coupling with the lamina. Finally, the lamina is allowed to vibrate freely, and its distance from the cylinder is varied to investigate fluid–structure interactions and vortex-induced effects.

The paper is structured as follows: Section 2 details the numerical modeling, Section 3 discusses the obtained results, and Section 4 provides the concluding remarks.

Numerical modeling

In the present work, the LBM is used to model fluid flows. The Lattice Boltzmann Equation can be written in its discrete form as:

$$f_i(\boldsymbol{x}_f + \boldsymbol{c}_i\Delta t, t + \Delta t) = f_i(\boldsymbol{x}_f, t) + \Omega_i(\boldsymbol{x}_f, t)\Delta t + F_i(\boldsymbol{x}_f, t)\Delta t \quad (1)$$

where $f_i(\boldsymbol{x}_f, t)$ represents the distribution functions associated to pre-determined lattice directions $\boldsymbol{c}_i$, $\Omega_i(\boldsymbol{x}_f, t)$ and $F_i(\boldsymbol{x}_f, t)$ are the MRT collision operator and the source term respectively. The latter term represents the internal or external forces acting on the fluid and it is modeled using Guo's forcing approach [6, 7].

The LBM is further improved to handle high Reynolds number flows using a LES approach based on the Smagorinsky subgrid scale model. This model is then coupled with the Van Driest damping function to let the turbulent viscosity exponentially damp to zero close to the wall. This approach allows using a coarser mesh reducing computational cost directly resolving large energy containing structures while small scale structures are only modeled [8, 9, 10].

Finally, the IBM is adopted to deal with stationary and moving complex geometries within the fluid domain. Two different grid systems are used, a Lagrangian mesh free to move within the fluid domain used to model the geometry and a stationary cartesian grid for the fluid domain. A force density added in the fluid governing equations is used to model the presence of the obstacle [11, 12, 5]. In this work the diffuse interface scheme based on the IB formulation proposed by Kang and Hassan in [13] is adopted to represent the boundary.

Furthermore, the D3Q19 lattice stencil is employed, with periodic boundary conditions to simulate a lamina and cylinder infinitely long in the spanwise direction, while Neumann boundary conditions are imposed on the top and bottom boundaries.

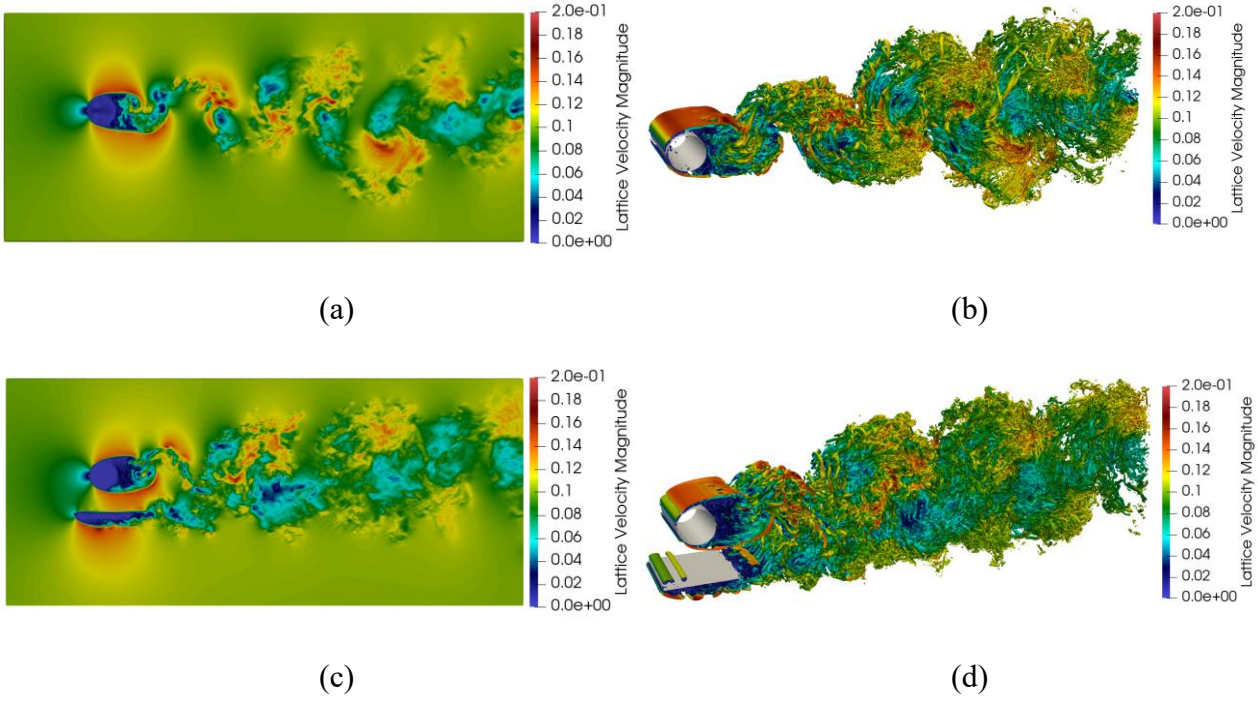
Results

The first part of the results focuses on the validation of the three-dimensional algorithm against reference data from the literature, using the canonical test case of flow past a circular cylinder at a Reynolds number of 1×10^4. The two-dimensional velocity field is shown Fig. 1a, while Fig. 1b presents the wake visualization using the Q-criterion colored by the lattice velocity magnitude. As expected, a distinct Kármán vortex street develops downstream, with coherent vortices convecting in the freestream direction.

Subsequently, the configuration involving a cylinder with a side-mounted lamina is investigated at the same Reynolds number of 1×10^4. The lamina is characterized by an aspect ratio of L/H = 15, where L denotes its streamwise length and H its height. The upper surface of the lamina is

Materials Research Proceedings 69 (2026) 172-176 https://doi.org/10.21741/9781644904251-30

positioned one cylinder diameter below the lower surface of the cylinder. This arrangement enables the analysis of the interaction between the cylinder wake and the nearby laminar structure, providing further insight into the algorithm's ability to reproduce complex three-dimensional flow features.



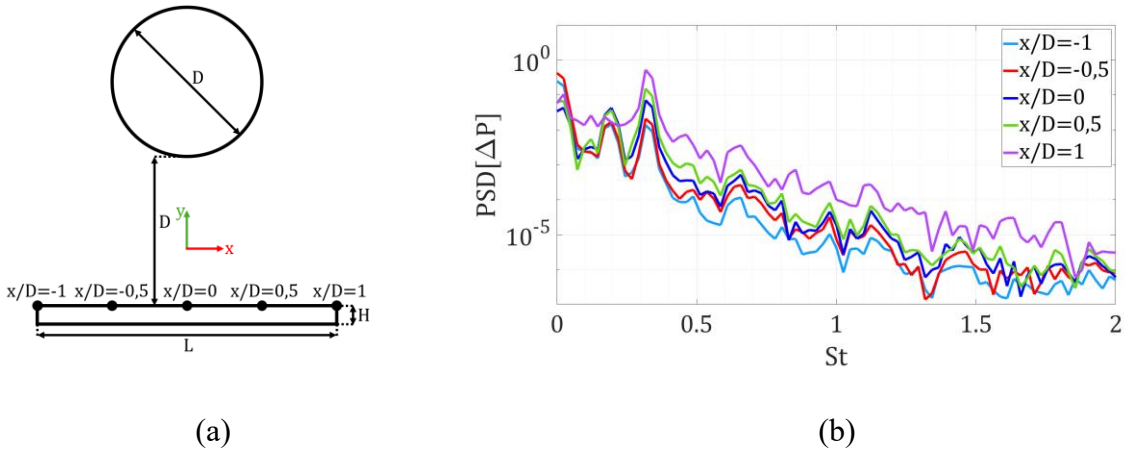


Figure 1 Isolated Cylinder wake: (a) 2D lattice velocity map, (b) Q-criterion; Cylinder with lamina wake (c) 2D lattice velocity map, (d) Q-criterion

The corresponding two-dimensional velocity map, expressed in lattice units, is presented in Fig. 1c. It can be observed that the flow initially separates at the leading edge but rapidly reattaches to the lamina surface due to the influence of the cylinder, which appears to delay flow separation. Further downstream, the wake development is clearly affected by the presence of the lamina, which constrains the wake when compared to the isolated cylinder case. This effect is even more evident in Fig. 1d where the Q-criterion colored by the lattice velocity magnitude reveals the vortical structures. The thin lamina generates additional small-scale vortices that strongly interact with those shed by the cylinder, thereby disturbing their development downstream.

The analysis was further extended to investigate the unsteady wall-pressure load on the lamina by monitoring five discrete points, as schematically illustrated in Fig. 2a. The corresponding unsteady pressure spectra, computed using Welch's method [14], are shown in Fig. 2b. As expected, moving from the leading edge to the trailing edge of the lamina, the broadband power spectral density (PSD) level increases as a consequence of the flow development over the surface. Two distinct peaks are visible in the spectra at different Strouhal numbers: a first peak at $St = 0.19$ corresponding to the vortex-shedding frequency of the circular cylinder, in good agreement with previous studies investigating the effect of the gap between a cylinder and a plane boundary [15, 16].

(a) (b)

Figure 2 (a) Schematic view of the virtual probe positions, (b) Unsteady pressure spectra

Furthermore, the peak intensity progressively diminishes from the leading to the trailing edge, where it becomes indistinguishable, possibly as a consequence of the enhanced broadband energy content induced by the flow grazing along the plate surface. A secondary peak at $St = 0.3$ is consistently detected across all virtual probes, becoming the dominant frequency contribution at $x/D = 1$ This secondary frequency is presumably related to the finite length and aspect ratio of the lamina. However, further analysis is required to confirm this hypothesis.

Conclusions

In this study, the flow around a cylinder with a side-mounted lamina was investigated at a Reynolds number of 1×10^4 using a three-dimensional numerical algorithm that couples the IBM with the LBM-MRT. The computational approach was first validated through the classical benchmark case of flow past a circular cylinder at the same Reynolds number. Subsequent analysis focused on the unsteady pressure loads acting on a thin lamina positioned one diameter away from the cylinder surface, aligned with the freestream flow (zero incidence angle). Comparison of the wake structures for the two configurations clearly highlights the influence of the lamina on wake development. Specifically, the presence of the lamina restricts the motion of vortices that the cylinder sheds, thereby altering the dynamics of the downstream flow. Spectral analysis of the unsteady pressure loads over the lamina surface reveals two distinct frequency components. The first, at $St = 0.19$ corresponds to the characteristic vortex shedding frequency of the cylinder. The second, at $St = 0.3$ becomes increasingly dominant near the trailing edge of the lamina and is likely associated with the finite length and aspect ratio of the lamina itself. These findings highlight the strong coupling between wake dynamics and wall-induced flow confinement. Future work will extend the analysis to configurations with a freely vibrating lamina, to further assess the role of fluid–structure interaction in the onset of flow-induced vibrations.

Abstract. Leading edges of rocket fins made from glass fibre composites were tested in the arc-heated wind tunnel L2K at the German Aerospace Center (DLR) under continuous high-enthalpy flow conditions. Under these aerothermal loads, the leading edge undergoes significant shape deformation, and pyrolysis-induced melt products accumulate on the sides of the fin. Video recordings of the experiments were captured and analysed to track the deformation of the leading edge and the formation of melt products at the sides of the fin. Computer vision algorithms for image segmentation are applied to this data to detect for each frame the region of the image that corresponds to the leading edge and the melt products, respectively. Ultimately, the goal of this analysis is to quantify the deformation of the leading edge and the formation of melt products over the duration of the experiment. The task of image segmentation is performed with a convolutional neural network, based on the U-Net architecture and the neural network approach is compared to a simple threshold procedure. Both methods are able to separate the images into the relevant regions, but the approach using thresholds struggles with the high variation in illumination along the fin and underestimates the amount of melt. Furthermore, the separation between melt and leading edge is difficult to achieve correctly with a threshold. In contrast, the U-Net approach agrees better with manual labels in both regards on unseen test frames. This improved fidelity in the detection of the leading edge and the melt products aids in the automatic analysis of these wind tunnel experiments.

Introduction

Wind tunnel experiments are an important intermediate step between simulation and flight experiments because they provide real experimental data under realistic conditions without the associated costs of a full flight experiment, enabling the validation of simulation results and the preparation of flight missions. These experiments generate a wealth of data which creates opportunities for applying modern data science methods to extract additional insights. For example, computer vision algorithms developed over the past decade can aid significantly in analysing image data that would otherwise require manual inspection. One such application is the automatic segmentation of video data from experiments with leading edges of rocket fins in an arc-heated wind tunnel at DLR Cologne. The goal in this task is, separating each frame of a video into distinct image regions, to enable further downstream analysis such as tracking the deformation of the leading edge. In this paper, a neural network-based approach for this problem is presented, which compares favourably with simpler threshold-based methods.

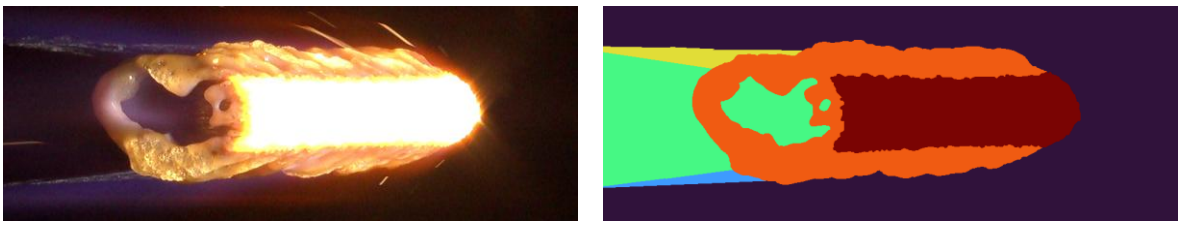
Materials Research Proceedings 69 (2026) 177-182 https://doi.org/10.21741/9781644904251-31

The paper is organized as follows: First the methods are explained, which includes the experimental setup and the use of neural networks for image segmentation. Then, the results of this method are presented, including a quantitative and qualitative evaluation, as well as a comparison to an optimal threshold-based approach. Finally, some conclusions and an outlook for future work is given.

Methods

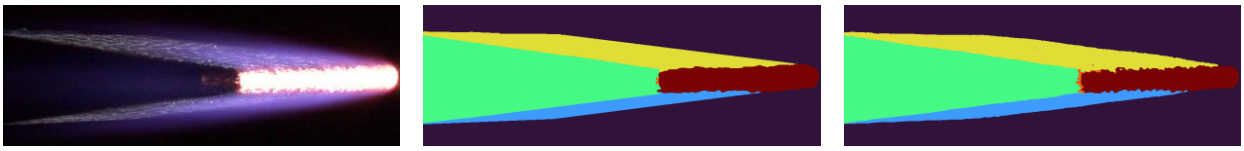


Experimental Setup. The video data, analysed in this study, were recorded during experiments in the arc-heated wind tunnel L2K at DLR Cologne with rocket fin leading edges made from glass fibre composites. These tests are intended to evaluate the suitability of different materials for hypersonic flight conditions by exposing the test specimen to thermal loads comparable to those observed in real flight experiments. Detailed descriptions of the test facilities can be found in [3,4,5]. The experimental conditions are summarized in Table 1, which mirror those of an analogues test campaign with wood fibre materials [1]. The leading edge undergoes significant deformation during these experiments and a total mass loss of 15.8% was recorded. Furthermore, melt products accumulate on the sides of the fin. During the experiment the leading edge is recorded with a video camera, Fig. 1 (a) shows one frame from this video recording. The topic of the present work is the algorithmic analysis of this video data.

Table 1: Experimental conditions

Flow Parameter	Value
Total gas mass flow [g/s]	50
Air mass flow [g/s]	2
Nitrogen mass flow [g/s]	48
Total enthalpy h_0[MJ/kg]	6.85
Stagnation pressure p_s[hPa]	89
$h_0 \cdot \sqrt{p_s}$	64.6
Nozzle configuration (throat/exit diameter) [mm]	29/100
Distance from nozzle exit [mm]	120
Test duration [s]	120

Image Segmentation. A commonly used step in the algorithmic analysis of image data is separating the image into distinct regions, so called classes, with some specific application defined meaning. The result of this step is called a segmentation or mask, which contains for each pixel in the input image the index identifying the class this pixel belongs to. In this work, the input images are the video frames from the wind tunnel experiments described in the previous subsection. The six image regions that are to be distinguished are: background, the three visible sides of the fin (downward, frontward, upward), melt products and leading edge. For the sake of brevity, the classes will be referred to as background, down, front, up, melt and edge, respectively, in the remainder of the paper.



Materials Research Proceedings 69 (2026) 177-182 https://doi.org/10.21741/9781644904251-31

(a) Video frame *(b) Manual segmentation*

Fig. 1: Manually created segmentation. The classes are: background (dark blue), downward side (light blue), frontward side (green), upward side (yellow), melt products (orange) and leading edge (red).

Intersection over Union. To assess the accuracy of an image segmentation algorithm, manual segmentations of some of the images are created first. These can then be used to compute the Intersection over Union (IoU) metric for algorithmically created segmentations. The IoU is computed for each class separately, by counting the number of pixels in the intersection of manual and algorithmic segmentation and dividing by the number of pixels in the union of both segmentations for this class. This fraction is 1 if both algorithm and human labels agree perfectly and it is 0 if the two segmentations are completely disjoint for this class. The background class will be excluded, when computing the IoU, because the IoU for the background heavily depends on how the images are cropped around the object of interest.

(a) Video frame *(b) Manual segmentation* *(c) Neural network prediction*

Fig. 2: Earliest manually labelled frame.

Neural Networks for Image Segmentation. Neural networks have been successfully applied for image segmentation in several domains, such as medical images [2] and high-speed combustion videos [6]. Typically, this is treated as a supervised machine learning problem, which means that a set of training examples of images with corresponding segmentations has to be created first. For example, Fig. 2 shows one such training example, where the different regions of the leading edge were manually annotated. Furthermore, a neural network architecture must be defined to compute the probabilities that each pixel belongs to each of the different classes for a given input image, depending on a set of parameters. In this study, a U-Net architecture is used, which was first proposed for the analysis of medical images [2]. Ultimately, the goal is then, to find a setting for the parameters of the neural network such that the resulting probabilities match the provided segmentations on the training set as closely as possible. This is achieved by applying stochastic gradient descent, or variants thereof, to a minimization problem based on the training data, the network architecture and a loss function, which quantifies the discrepancy between the computed class probabilities and the manual annotations. Finally, after computing a setting for the parameters, which minimizes the total loss on the training set, the neural network with these specific parameter values can be applied to images outside of the training set to obtain for each pixel in the image an estimate of how likely this pixel belongs to each of the different classes. A segmentation can then be obtained by determining the most likely class for each pixel. Fig. 2 shows a comparison of the manual and the neural network-computed segmentation for one of the video frames.

Data augmentation. Machine learning methods that use neural networks are often limited by the quantity and quality of the available training data. Since each image in the training dataset must

be annotated manually, it can be very time-consuming to create a sufficiently large dataset for applying a neural network based method. A common approach to reduce the number of necessary training examples is to apply data augmentation during training. This involves applying random transformations to the input data during training that either preserve the correctness of the corresponding labels, or transform the labels as well. For image segmentation, for example, small changes in brightness usually do not affect the accuracy of the segmentation. On the other hand, if the images are rotated by a small angle, then the segmentations can be rotated in the same way to preserve their correctness. Adding small perturbations like this, while preserving the correctness of the labels, can significantly improve the robustness and accuracy of the resulting prediction model.

Results

Cross Validation. To evaluate the performance of this neural network approach, a 4-fold cross validation is performed on a dataset of 20 manually labelled images. This involves randomly splitting the dataset into four folds, training four U-Net models and leaving one fold out each time. This process was repeated for five different random seeds, resulting in a total of 20 trained models. The 15 images used for training each model are processed 1000 times each with a new randomly sampled data augmentation applied to the image every time. The models are then evaluated on the fold that was left out during their training. Finally, the average Intersection over Union (IoU), as described in the previous section, is computed for each random seed across all 20 images and Table 2 shows the minimum, maximum and mean of the average IoU across the 5 different random seeds. The performance across the different random seeds, and thus different ways of splitting the data, is relatively stable for all the classes. The largest variation can be observed in the segmentation quality of the melt products which varies from 0.7844 to 0.8160 and this is also the class, for which the model performs the worst in general. Examining the accuracies for each frame, cf. Fig. 3, reveals that the main reason for the lower average IoU in the melt class is that this class is segmented poorly in the initial frames.

As can be seen in Fig. 2, there is basically no melt product visible yet at the beginning of the video and because the IoU is a relative error measure, even small absolute errors can lead to a very low IoU.

Table 2: IoU of neural network predictions across 5 different random seeds.

	Down	Front	Up	Melt	Edge
Minimum	0.8258	0.9074	0.8649	0.7844	0.9610
Maximum	0.8516	0.9179	0.8932	0.8160	0.9667
Mean	0.8350	0.9145	0.8811	0.8062	0.9649

Comparison with Optimal Thresholds. The performance of the neural network approach is further evaluated by comparing it to a simple threshold method. To this end, a segmentation pipeline consisting of three stages, pre-processing (optional Gaussian blur and selection of colour channel or greyscale), threshold (global or adaptive) and post-processing (optional morphological transformation) is used. These stages are first applied to determine the leading edge segmentation and are then repeated in a second step for the melt region. The other classes are omitted for this comparison because in practice the edge and melt are the most relevant. The stages each contain several free parameters that have to be chosen, e.g. the value of the threshold or the radius of several sliding-window type filters. To provide an upper bound for the accuracy of this method, an exhaustive brute-force search to determine the optimal value for all free parameter is performed. This search is done once for each annotated image, separately, and once for all images simultaneously. The accuracy of the resulting methods is shown in Table 3 and compared to the average accuracy of the neural network approach. This comparison shows that computing the

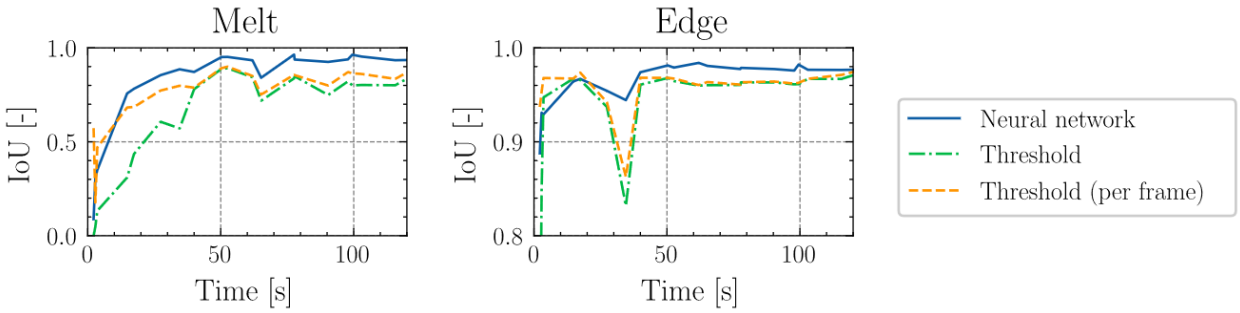
Materials Research Proceedings 69 (2026) 177-182 https://doi.org/10.21741/9781644904251-31

parameters once for all images leads to a significant drop in segmentation quality compared to computing them for each image separately, in particular for the melt products. Furthermore, the neural network approach outperforms even the optimal threshold for each image on average.

Table 3: Intersection over Union (IoU) for different methods.

	Threshold	Threshold (per frame)	Neural network (Mean)
Melt	0.6374	0.7589	0.8062
Edge	0.9326	0.9580	0.9649

Additionally, Fig. 3 shows how the methods compare for each frame by plotting the IoU over the experiment duration. Only in the very beginning do the threshold methods perform better than the neural network, though all methods see a significant drop in accuracy for the earliest frames. For most of the experiment duration, the neural network approach outperforms both threshold-based methods.



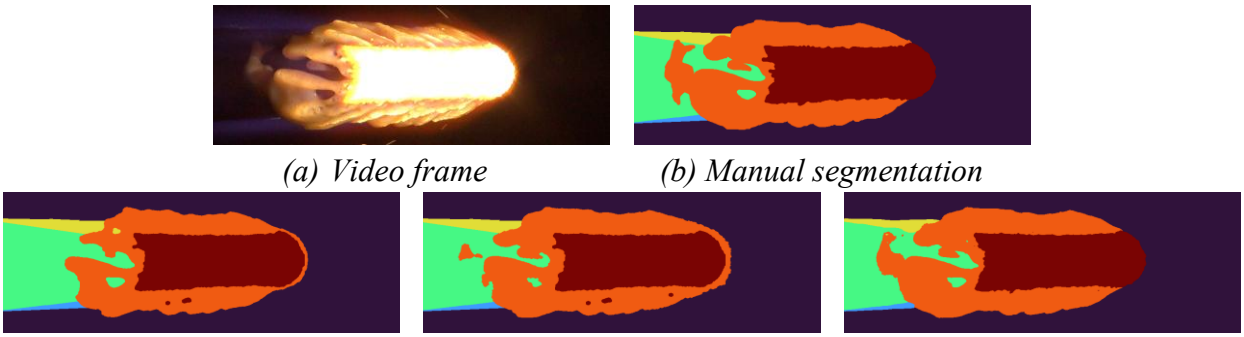


Fig. 3: IoU over time for different segmentation methods.

Fig. 4 depicts the segmentations produced by each method for one frame of the video. One can see, that the threshold method struggles with separating the leading edge from the melt products. Furthermore, parts of the melt products can not be properly detected by a threshold due to the high variation in illumination in the image.

(a) Video frame *(b) Manual segmentation*

(c) Threshold *(d) Threshold (per frame)* *(e) Neural network prediction*

Fig. 4: Comparison of different segmentation methods.

It should be highlighted that to compute the optimal threshold a manual segmentation of that specific frame is needed, rendering this approach useless in practice. Therefore, it is only a theoretical upper bound of what can be achieved with a simple threshold. Conversely, the neural network is evaluated only on frames that were not part of its training set, which means that these segmentations can be computed for other frames without manual segmentation.

Conclusion

A neural network-based approach for image segmentation of videos frames from experiments with a rocket fin leading edge in an arc-heated wind tunnel is presented. This approach is compared

with a simple threshold method, where the parameters, such as the threshold value, are chosen optimally. This serves as a theoretical upper bound on the performance of a simple threshold, as computing the optimal parameters requires the ground truth. Nonetheless, the neural network approach consistently outperforms the simpler threshold method across several random seeds.

In future work, this improved segmentation accuracy will be combined with 3D information about the camera position/rotation to enable downstream tasks, such as quantifying the volume of melt products at the side of the fin or tracking the deformation of the leading edge.

Keywords: ZND Detonation, Reacting Flows, Shock-Combustion Interaction

Abstract. This work assesses the capabilities of an innovative fluid dynamics solver, originally developed to deal with high-enthalpy flows in the context of hypersonic planetary entry, and now applied to simulate problems involving complex interactions between strong shock waves and combustion processes. With a view toward future simulations of rotating detonation combustors, the solver accuracy is assessed by considering 1D and 2D detonation fronts.

Introduction

Over the years, Rotating Detonation Engines (RDEs) have become very attractive in the field of aerospace propulsion due to their high efficiency and mechanical simplicity [1,2]. Moreover, Rotating Detonation Combustors (RDCs), the core component of RDEs, have aroused a growing interest in the field of energy generation as a promising solution to the rising energy demand, climate change, and increasing pollution, all of which threaten human well-being and health.

The main characteristic of such devices is the detonation-based combustion, which, on one hand, is the key feature enabling higher efficiency, and on the other hand, introduces several challenges.

In the aerospace field, RDEs represent an evolution of Pulse Detonation Engines (PDEs) which in turn evolved from pulsejets. These systems can achieve higher efficiency with respect to turbojets, since the pressure gain during the combustion process leads to the Fickett-Jacobs thermodynamic cycle [3]. RDEs retain the advantages of PDEs while employing a continuous combustion process that eliminates the drawbacks associated with intermitted operation. However, the apparent simplicity of these systems hides several issues related to the intrinsic complexity of the supersonic combustion process [4]. Thus, to ensure proper engine operation, a multidimensional numerical solver capable of handling highly compressible flows in chemical non-equilibrium, and capturing complex shock and expansion waves structures, is required.

In this context, the aim of the present work is to extend the capabilities of the Damiso solver [5,6] to deal with detonative combustion. This solver has been developed to simulate high enthalpy flows in thermochemical non-equilibrium, leveraging GPU computational power.

In the present study, the solver has been verified by comparing the results of a 1D detonation with the Zel'dovich–von Neumann–Döring (ZND) solution obtained using CANTERA [7].

Subsequently, 2D simulations of a detonation front have been performed in order to highlight the code's capability to capture multidimensional detonation structures [2,3].

Governing Equations and Numerical Method

The flow field is simulated by solving the Navier–Stokes equations for a multicomponent reacting mixture in chemical non-equilibrium. The system of equations is discretized using a cell-centered finite-volume approach. To deal with the stiffness associated with chemical reactions, an operator-splitting strategy is adopted, separating fluid dynamics from chemistry. The homogeneous system of fluid-dynamic equations is solved first.

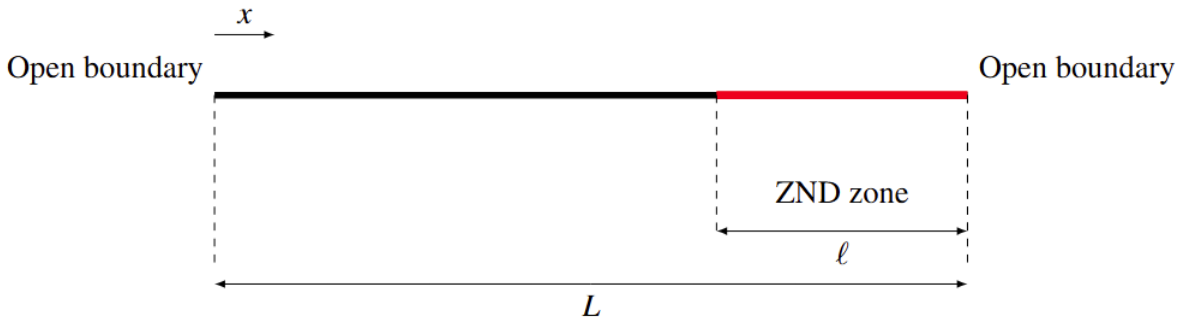

Fig. 1 1D domain for the simulation of the detonation in the lab frame with Damiso.

For this step, the method of lines is employed to separate time and space discretization. First, surface fluxes are computed by employing the Steger and Warming flux vector splitting in combination with a MUSCL (Monotonic Upstream-centered Scheme for Conservation Laws) reconstruction of primitive variables, in order to achieve second-order accuracy. Subsequently, time integration is performed using a third-order Runge–Kutta scheme. Finally, the solution of species partial densities is updated by solving a system of ODEs accounting for the chemical source terms, where an implicit iterative Gauss–Seidel scheme is employed to handle stiffness. Further details can be found in [5,6].

Results

Following the work of Strempfl et al. [2,8], the capabilities of Damiso have been verified by performing a 1D detonation test case, whose results have been compared with those obtained with the well-know and reliable toolbox CANTERA using the Shepherd ToolBox [9].

A hydrogen-air mixture with initial conditions of T_{init} = 300 K, P_{init} = 101325 Pa and an equivalence ratio of ϕ=0.9 was considered [8]. To reduce the computational cost, the 1-step chemical scheme developed by Strempfl et al. [2,8] was employed.

$$H_2 + 0.5O_2 \rightleftharpoons H_2O. \quad (1)$$

Specifically, in Refs. [2,8], the H_2O formation enthalpy at 0 K (-226.8 *kJ/mol*), the Arrhenius pre-exponential factor ($5.3 \cdot 10^{10}$ $1/\left(\sqrt{mol\ cm^{-3}}s\right)$) and the activation energy (18000.0 *cal/mol*) were tuned and optimized in order to match the Chapman–Jouguet detonation speed (D_{CJ}) and the half-reaction thickness obtained with detailed mechanisms.

The CANTERA toolbox was employed to obtain a 1D ZND solution in the detonation-wave reference frame. This solution was then employed as the initial condition for the 1D Damiso simulation in the laboratory frame.

Figure 1 shows the 1D computational domain adopted in Damiso. The total length is $L = 2 \cdot 10^{-3}$ m, whereas the ZND initial solution (in red) extends over $\ell = 7 \cdot 10^{-4}$ m. The CANTERA solution was imposed after transforming the velocity from the detonation to the laboratory frame as:

$$u_{lab}(x) = D_{CJ} - u_{det\text{-}frame}(x), \quad (2)$$

where D_{CJ} = 1920.02 m/s.

The left portion of the domain (in black) represents the region of the fresh, unreacted mixture, which is initially at rest. A uniform mesh with a 6000 cells has been employed.

In order to verify the accuracy of the Damiso solver, the ZND detonation structure was allowed to evolve in time. Therefore, the steady detonation-frame solution provided by CANTERA was compared with the unsteady laboratory-frame solution computed by Damiso.

Materials Research Proceedings 69 (2026) 183-186 https://doi.org/10.21741/9781644904251-32

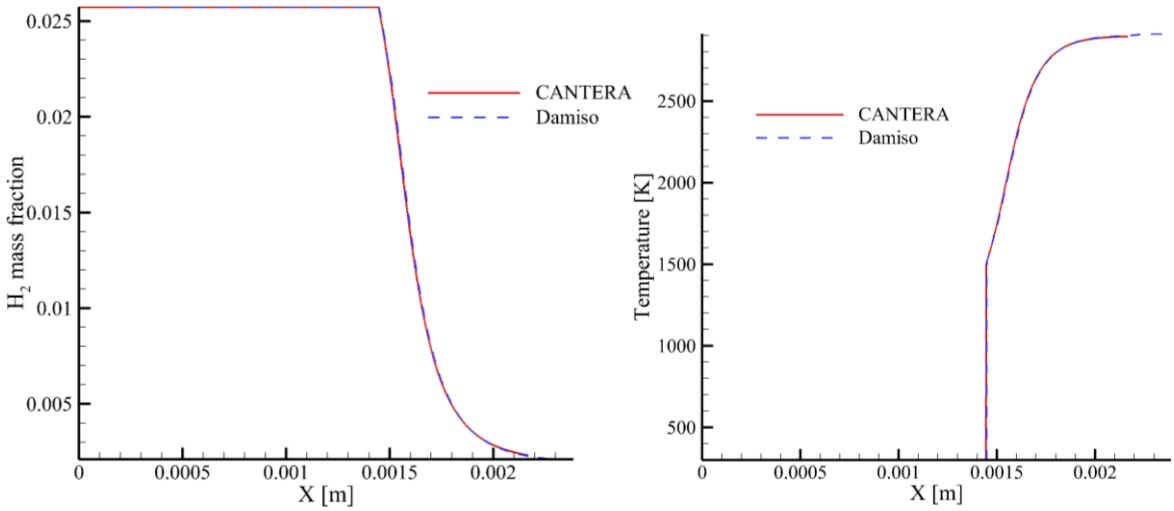

Fig. 2 1D ZND comparison: H_2 mass fraction (left) and temperature (right) profiles.

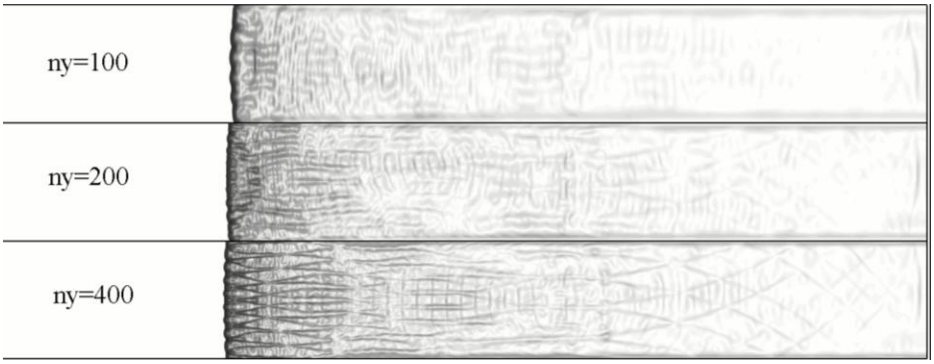

Fig. 3 2D ZND solution for different grid size resolutions along the transverse direction: magnitude of the density gradient.

The comparison is provided in Figs. 2 (left) and (right), showing the H_2 mass-fraction and temperature profiles, respectively. The Damiso solution, taken at a generic time instant, shows excellent agreement with the CANTERA reference solution.

Once the Damiso accuracy had been verified, a 2D detonation tube test case was simulated. The initial conditions are the same of the 1D case, but the computational domain now has L=0.5 m, $\ell=1\cdot10^{-2}$ m, and it extends in the transverse direction for an height of $H=3\cdot10^{-2}$ m. In order to investigate the influence of grid resolution, three uniform meshes with different resolutions were considered. The number of cells along the x-direction is 6000, while three different discretizations have been used along the y-direction, with 100, 200, and 400 cells, respectively. These configurations allow an evaluation of how the numerical resolution affects the morphology of the detonation cells and their spatial periodicity. As in the 1D case, the steady solution obtained with CANTERA was interpolated and imposed on the right side of the domain to initialize the thermochemical profile of the ZND region. In this configuration, however, the detonation front was not initialized as planar, but as a sinusoidal wave with a wavelength equal to one-quarter of the domain height. This choice, promotes the development of transverse instabilities from the very beginning, favoring the rapid formation of the cellular structure of the detonation and reducing the transition from a planar wave to an unstable front.

Figure 3 shows the contour plot of the density-gradient magnitude. The simulations demonstrate that, as the number of cells increases along the transverse direction, the cellular pattern becomes progressively more defined and detailed. The higher resolution enables a more accurate

representation of local instabilities and of the transverse waves that characterize the detonation front.

Summary

In this work, the Damiso solver, originally devised for hypersonic flow simulations, has been assessed for detonation processes. The solver has been verified by comparing the results of a 1D ZND detonation with those obtained using the CANTERA toolbox. Finally, a simulation of a 2D ZND detonation has been performed, demonstrating the capability of the solver to identify the characteristic detonation structures.

Abstract. Low Reynolds number (Re) flows in the range of 1000-10000 are common in applications such as Micro Aerial Vehicles (MAVs), Martian flight, and high-altitude terrestrial flight. The flow around conventional airfoils in this regime exhibits periodic vortex shedding with spanwise coherence at low angles of attack (AoA). These simple cases are very useful for testing and implementing unsteady far-field force decomposition methods within commercial CFD software. In this work, a conventional NACA 0012 airfoil at Re = 5000 and an AoA of 6° was analyzed using time-accurate Navier-Stokes simulations in the commercial CFD code STAR-CCM+. The resulting flow fields were subjected to different far-field analyses based on unsteady thermodynamic approaches and extended mechanical energy balances to include unsteady terms and exergy additions. Near-field drag was compared with various far-field drag predictions, and several decompositions are proposed to isolate the energy, exergy, and thermodynamic contributions to the overall far-field drag. This constitutes the first study of its kind comparing unsteady thermodynamic, mechanical-energy-based, and exergy-based decomposition approaches.

Introduction

Initially conceptualized by Desterac and Van der Vooren [1], far-field methods enable the non-intrusive analysis of bodies in motion, providing information that cannot necessarily be obtained through near-field methods. These advantages, together with the growing emphasis on integrated airframe-propulsion configurations, have led to the continued development of various far-field drag analysis approaches. Many of these methodologies have undergone extensive validation in the steady domain. Drela [2] first derived the mechanical-energy-based power balance decomposition method, which was later extended by Sanders and Laskaridis [3] to employ an absolute reference frame. Arntz et al. [4] further expanded this formulation to include additional exergy terms. Similarly, Toubin [5] developed the momentum-based thermodynamic methods to their current unsteady form. However, these far-field approaches have so far been tested only to a limited extent in the unsteady domain. The Reynolds number range of 1000 - 10000 is commonly used for unsteady cases because the flow around wings in this regime exhibits spanwise-coherent vortex shedding at low to moderate angles of attack. Such flow conditions resemble those encountered by Micro Aerial Vehicles (MAVs), biological insects, and vehicles in Martian flight. Unsteady cases involving fixed- angle-of-attack wings offer suitable testing conditions for far-field methods, as they allow transient flow behavior with unsteady vortex shedding features to be analyzed on fixed grids. This configuration provides relative simplicity, low computational cost,

Materials Research Proceedings 69 (2026) 187-192 https://doi.org/10.21741/9781644904251-33

and clearly defined downstream coherent structures that facilitate the assessment and comparison of unsteady far-field decomposition methodologies.

Methodology

A NACA 0012 airfoil at an angle of attack (AoA) of 6° was analysed using Star CCM+ using an unstructured C-type domain grid at a Reynolds number of 5000 and a Mach number of 0.2, with velocity inlet and pressure outlet boundary conditions. Mesh, domain, and time- independence studies indicated near-field convergence at a mesh size of 1.4 million cells, a domain radius of 100 chord lengths, and a time-step size of 0.0025 c/V_∞, ensuring a convective CFL number below 1 throughout the computational domain. To ensure accurate far-field resolution, the mesh was further refined to 2,097,000 cells. A second-order coupled laminar solver with second-order implicit dual time-stepping was employed, with five inner iterations per time step being sufficient to reduce residuals by two to three orders of magnitude. The wall y^+ value was kept below 0.1 for all simulations. A series of control volumes (CVs) were subsequently defined to analyze and compare far-field methods, as shown in Figure 1, where the CV sizes are non-dimensionalised by the airfoil chord length.

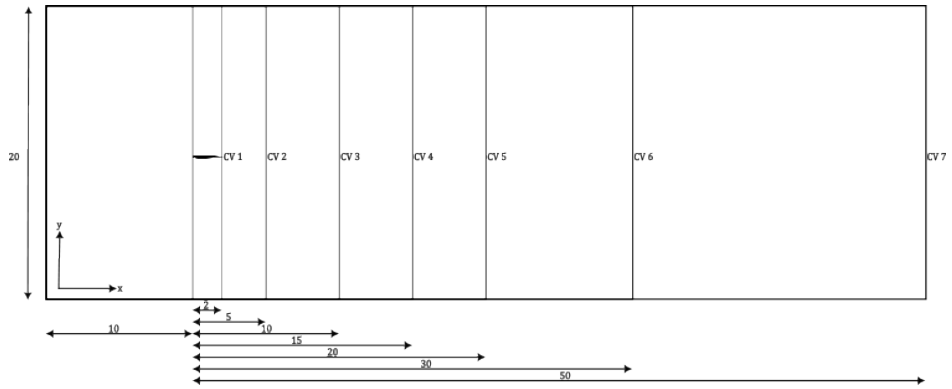

Figure 1: Control Volumes used in Far-Field Analysis of Airfoil

Far-Field energy decompositions were based on the Absolute Reference Frame (ARF) derivation introduced by Sanders and Laskaridis [3], extended here with an additional time-dependent term to account for the inherent unsteadiness of transient flows. This leads to Eq. (1), where the near-field encompasses all propulsive and drag-related elements, while the far-field balances the near-field through a series of energy-based components. As the present test case does not include any propulsive elements, only the near-field body-force term, $F_B \cdot U$, is considered. The far-field terms consist of the volumetric integrals of the rate of change of kinetic energy, $\frac{dE_k}{dt}$, viscous dissipation, Φ, and compression work, Θ, together with the mechanical energy flux across the control volume (CV) surfaces, $\boldsymbol{\mathcal{E}_{WP}}$. The latter can be further decomposed into streamwise (E_a), transverse (E_v), pressure (E_p), and viscous (E_τ) energy components.

$$\overbrace{-\underbrace{\iint \left[p_G \boldsymbol{V'_{cs}} + \bar{\bar{\tau}} \cdot \boldsymbol{V'_{cs}}\right] \cdot dS_B}_{\mathcal{P}_S} + \underbrace{\iiint p\boldsymbol{f} \cdot \boldsymbol{V'} d\mathcal{V}}_{\mathcal{P}_f} + \underbrace{\iint \left[p_G \boldsymbol{V}_\infty + \bar{\bar{\tau}} \cdot \boldsymbol{V}_\infty\right] \cdot \boldsymbol{dS}_B}_{\mathbf{F}_B \cdot U} + \underbrace{\iiint p\boldsymbol{f} \cdot \boldsymbol{V}_\infty d\mathcal{V}}_{\mathbf{F}_f \cdot U}}^{Near\ Field} +$$

$$= \overbrace{\underbrace{\frac{d}{dt}\iiint \frac{\boldsymbol{V}^2}{2}\rho d\mathcal{V}}_{\frac{d\dot{E}_k}{dt}} + \underbrace{\iint \left[\left(\frac{\boldsymbol{V}^2}{2}\rho \boldsymbol{V'}\right) + p_G \boldsymbol{V} - \bar{\bar{\tau}} \cdot \boldsymbol{V}\right] \cdot \boldsymbol{dS_{TP}}}_{\boldsymbol{\mathcal{E}_{WP}}} + \underbrace{\iiint -\boldsymbol{p_G} \nabla \cdot \boldsymbol{V} d\mathcal{V}}_{\Theta} + \underbrace{\iiint \bar{\bar{\tau}} : \nabla \boldsymbol{V} d\mathcal{V}}_{\Phi}}^{Far\ Field} \qquad (1)$$

Far-field exergy decompositions extend the unsteady energy-based formulations by in-corporating the second law of thermodynamics and introducing the concepts of exergy and anergy

Materials Research Proceedings 69 (2026) 187-192 https://doi.org/10.21741/9781644904251-33

into the energy-based framework. First conceptualized by Arntz [4], the derivation shown in Eq.(2) follows a slightly modified approach, using Eq.(1) in the Absolute Reference Frame (ARF) as its starting point.

$$\overbrace{\mathcal{P}_S + \mathcal{P}_f + \underbrace{\iint [p_G \boldsymbol{V}_\infty + \bar{\bar{\tau}} \cdot \boldsymbol{V}_\infty] \cdot \boldsymbol{dS}_B}_{\mathbf{F}_B \cdot U} - \underbrace{\iint \left(1 - \frac{T_\infty}{T}\right) \boldsymbol{q} \cdot \boldsymbol{dS_B}}_{\dot{\chi}_{\boldsymbol{q}}} - \underbrace{\iiint \left(1 - \frac{T_\infty}{T}\right) \rho \dot{q}\, d\mathcal{V}}_{\dot{\chi}_{\dot{q}}}}^{Near\ Field}$$
$$= \overbrace{\underbrace{\frac{d\dot{\mathrm{E}}_k}{dt} + \frac{d}{dt}\iiint \rho \dot{\chi}_s d\mathcal{V}}_{\dot{\chi}_v} + \underbrace{\iint \rho \dot{\chi}_s \boldsymbol{V}' \cdot \boldsymbol{dS_{TP}}}_{\dot{\chi}_{th}} + \underbrace{\boldsymbol{\mathcal{E}_{WP}}}_{\dot{\chi}_m} + \underbrace{\iiint \frac{T_\infty}{T} \bar{\bar{\tau}} : \nabla \boldsymbol{V} d\mathcal{V}}_{\dot{\mathrm{A}}_\Phi} + \underbrace{\iiint T_\infty \mathcal{K} \left(\frac{\nabla \mathrm{T}}{T}\right)^2 d\mathcal{V}}_{\dot{\mathrm{A}}_{\nabla T}}}^{Far\ Field} \quad (2)$$

An alternative family of far-field approaches is based on momentum decompositions. In particular, we present a variation of the unsteady thermodynamic method proposed by Toubin [5], itself derived from the original formulation of Destarac and Van der Vooren [1]. In this approach, a thermodynamic definition of velocity is introduced to define an irreversible velocity component, shown in Eq.(3), which enables the separation of the convective part of the momentum flux. Equation (4) presents a two-component decomposition that divides the far-field drag into unsteady induced drag and viscous drag, the two components expected in a subsonic case without body motion. In the present work, a single integration volume is used; consequently, the unsteady term is fully included in the viscous drag. This differs from the approach of Toubin [5], in which multiple volumes are defined to isolate the various phenomenological drag components.

$$u_{irr} = u_\infty \sqrt{1 + \frac{2\Delta H}{u_\infty^2} + \frac{2}{(\gamma - 1) M_\infty^2} \left(e^{\frac{\gamma - 1 \Delta s}{\gamma \ r}} - 1\right)} \quad (3)$$
$$\text{Near Field Drag}$$

$$\overbrace{\underbrace{\iint (p - p_\infty)(i \cdot n) dS_a}_{Pressure\ Drag} - \underbrace{\iint (\tau_x \cdot n) dS_a}_{Shear\ Drag}}^{Far\ Field\ Drag}$$
$$= \underbrace{\iint -\rho(u - u_{irr}) q - (p - p_\infty) i) \cdot n) dS_e}_{Unsteady\ Induced\ Drag\ (C_{D_{ui}})} + \underbrace{\iint -\rho(u_{irr} - u_\infty) q + \tau_x \cdot n) dS_e - \iiint \frac{\partial \rho(-u_\infty)}{\partial t} d\mathcal{V}}_{Viscous\ Drag\ (C_{D_v})} \quad (4)$$

Results

Figure 2 shows the energy-based decomposition results with downstream wake planes located 10 and 30 chord lengths from the airfoil leading edge, while Fig. 3 presents the corresponding exergy-based decomposition results. Figure 4 then illustrates the momentum-based decom- position results. Here, *t* denotes the fraction of time within a drag-wave cycle, *T*. The average near-field drag coefficient was 0.078454, differing by only 0.32*,* % from the results of Carren˜o Ruiz and D'Ambrosio [6]. All sets of results were found to be in close agreement with the near-field drag and provided complementary data, offering additional insight into the flow field around the airfoil. Table 1 summarizes the average far-field drag results and their relative errors with respect to the near-field drag coefficient, confirming that the overall unsteady far-field methods effectively reproduce near-field values.

Decomposing the energy- and exergy-based results provides valuable insight into the energy and exergy released into the flow field by the asymmetric vortex shedding process, with the mechanical energy flux in particular highlighting the downstream evolution of vortices. The fluctuations in mechanical energy represent recoverable energy carried by vortices crossing the downstream wake plane. As the mechanical energy components dissipate further down- stream, they are replaced by the viscous/anergy dissipation, while the volumetric change in kinetic energy acts as an unsteady correction term that maintains phase synchronization with the near-field drag.

Materials Research Proceedings 69 (2026) 187-192 https://doi.org/10.21741/9781644904251-33

It is important to note that the decline in the amplitude of the mechanical energy flux fluctuations from CV 3 to CV 6 reflects the progressive breakdown of vortices downstream of the airfoil. At the wake plane of CV 6, almost no coherent vor- tex structures are observed, as indicated by the minimal fluctuations in mechanical energy crossing the surface boundaries.

Table 1: Time Averaged Far-Field Drag Coefficients and Relative Error of the Near-Field Drag Coefficient

CV Name	Energy c_d	% error	Exergy c_d	% error	Momentum c_d	% error
CV 3	0.078281	-0.22	0.078157	-0.38	0.078624	+0.22
CV 6	0.079224	+0.98	0.079112	+0.84	0.078614	+0.21

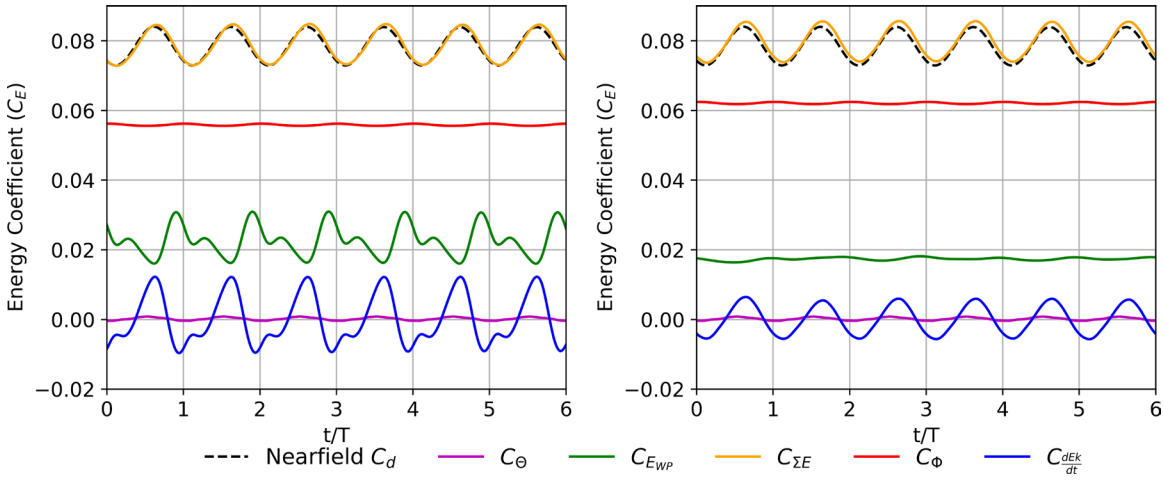

Figure 2: Energy Decompositions, with CV 3 on the left and CV 6 on the right

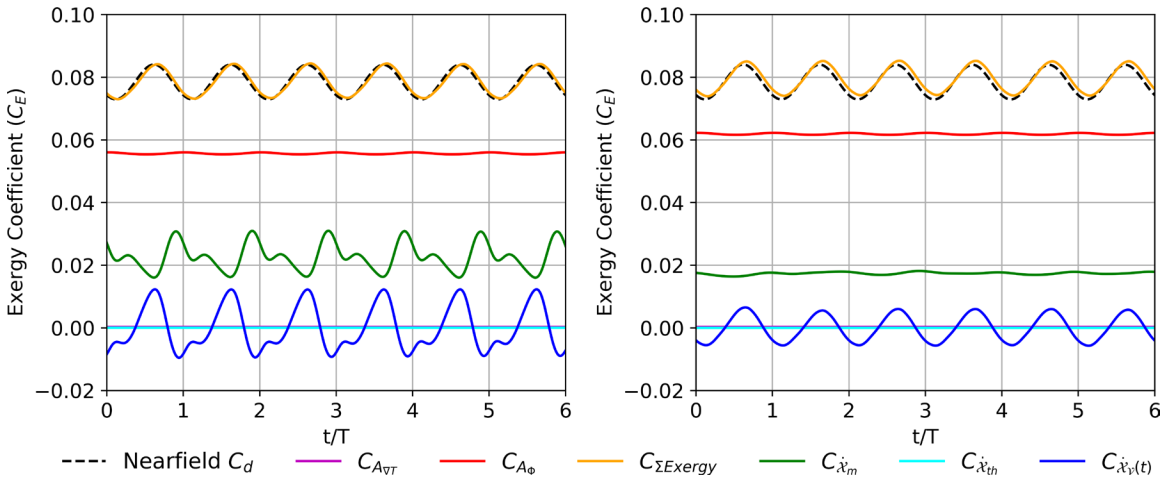

Figure 3: Exergy Decompositions, with CV 3 on the left and CV 6 on the right

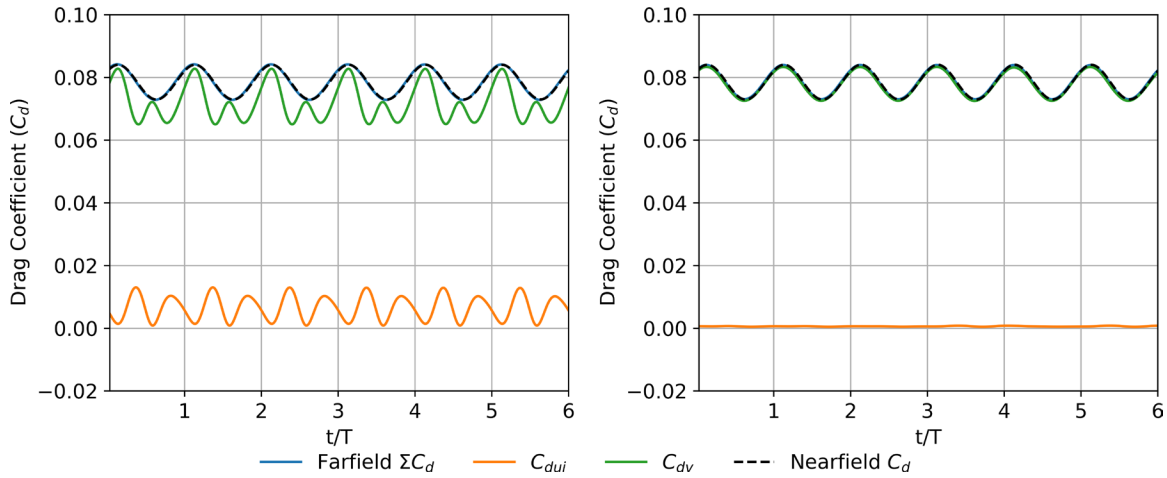

Figure 4: Momentum Decompositions, with CV 3 on the left and CV 6 on the right

The momentum balance provides a reasonable overall estimate of far-field drag in both probed control volumes. Decomposing this total value reveals significant differences in the viscous and unsteady induced components of drag between the two control volumes. CV 3, located closer to the airfoil, still captures the contribution of vortex shedding to the unsteady induced drag. In contrast, CV 6 extends 30 chord lengths downstream of the trailing edge, where the vortices have been subjected to numerical and, to a lesser extent, physical dissipation. It is noteworthy that this vortex decay does not affect the accuracy with which far-field approaches reproduce the near-field drag. Instead, it results in a redistribution of unsteady induced drag into viscous drag, in a manner similar to that observed for the energy- and exergy-based balances.

Conclusions

A NACA 0012 airfoil flying at a Reynolds number of 5000 under Martian atmospheric conditions was analysed using energy-, exergy-, and momentum-based far-field drag decomposition methods. All three far-field approaches yielded overall drag values within 0.25, % of the near-field results, while also providing complementary insights into the drag breakdown. This initial study offers a useful validation of the capabilities of different far-field formulations to analyze naturally unsteady vortex-shedding scenarios of lifting airfoils using the commercial CFD solver STAR-CCM+. The main challenge and primary source of discrepancies in implementing this methodology within a commercial solver lies in the computation of surface integrals in wake planes, where steep gradients can lead to interpolation errors.

This test case enables unsteady far-field formulations in the absolute reference frame to be assessed without the added complexity of mesh motion or turbulence modeling. Unlike traditional postprocessing methods, the far-field equations have been implemented directly within STAR-CCM+, removing the need to export data from the CFD solver for exter- nal processing. This significantly reduces data-storage requirements, as the data can be processed on the fly rather than saved and exported at each timestep for postprocessing. Future work will focus on a detailed comparison of the decompositions and on identifying the interconnections, strengths, and limitations of the proposed approaches.

Keywords: Implicit-Mesh Discontinuous Galerkin Method, High-Order Accuracy, Lid-Driven Cavity Problem, Incompressible Navier-Stokes Equations

Abstract. In this contribution, a novel computational framework for incompressible flow with multi-physics coupling in lid-driven cavities is presented. The framework is based on the implicit-mesh discontinuous Galerkin method, a computational approach that combines an implicit representation of the fluid domain and the variable-order accurate discontinuous Galerkin formulation. The framework falls within the class of embedded-boundary approaches, which are based on the use of an easy-to-generate background grid that is intersected with the domain of analysis to generate the mesh. This allows a simpler mesh generation phase with respect to body-fitted mesh strategies. The use of a discontinuous Galerkin formulation ensures a high-order accurate solution of the problem, even in proximity of generally shaped mesh elements that stem from the mesh generation procedure. A lid-driven cavity benchmark problem is considered to assess the capability and confirm the accuracy of the proposed framework.

Introduction

The interaction between a flow and a cavity is characteristic of many engineering applications, ranging from high-speed flows in combustors [1] and over fuselage bays [2,3] to low-speed flows in the thermal management systems of electronic devices [4]. For these problems, numerical methods are often employed to investigate how the cavity geometry influences flow behavior and key quantities of interest, such as acoustic emissions or heat flux. However, exploring the full range of design parameters requires analyzing multiple meshes for the fluid domain, a process that can be more time-consuming than the analysis itself.

In general, numerical methods for solving partial differential equations in complex domains can be categorized into two main approaches: those based on body-fitted meshes and those using background structured meshes combined with embedded boundaries. Most commercial computational fluid dynamics software libraries adopt the former approach, which, while highly flexible in handling irregular geometrical features, requires significant effort and expertise to generate high-quality mesh elements. In contrast, embedded-boundary (EB) methods construct the mesh by intersecting the domain with an easy-to-generate background grid. This approach simplifies the domain discretization process and is particularly efficient for dynamic adaptive mesh refinement strategies [5]. However, EB methods have traditionally been implemented within finite volume schemes [6,7], which typically achieve only up to second-order accuracy with very few exceptions. For example, very recently, Overton-Katz et al. [8] presented a fourth-order accurate embedded-boundary finite volume scheme for the Stokes flow equations, employing an extended-stencil least-squares reconstruction technique.

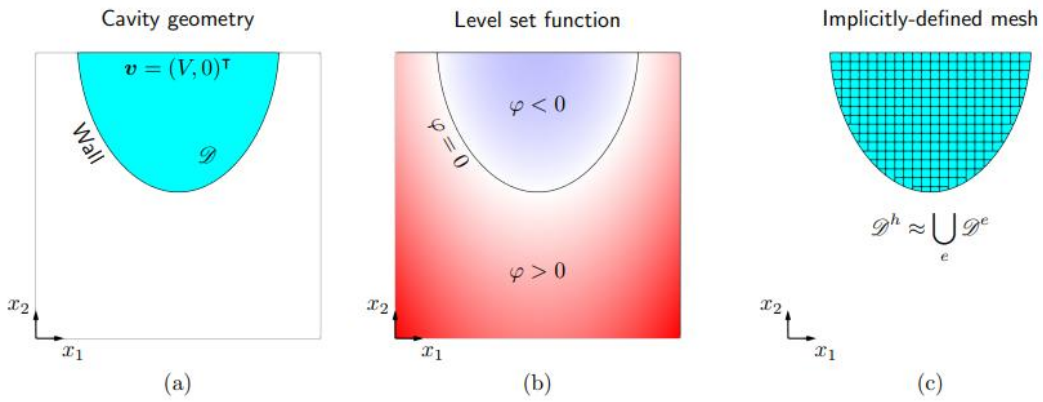

Fig. 1 (a) Geometry and boundary conditions of a lid-driven cavity problem. (b) Implicit geometry representation via a level set function φ. (c) Implicitly-defined mesh of the cavity of Fig. (a).

Discontinuous Galerkin (DG) methods are a viable alternative to finite volume methods as they offer high-order accuracy, local conservation properties, *hp*-adaptivity, and blockstructured mass matrices regardless of the choice of discretization. In fact, DG methods enable high-order accuracy when employed in combination with EB representations as demonstrated in problems related to elastic wave propagation [10], incompressible flow [9] and compressible flow [5].

In this contribution, DG methods are employed in combination with an EB approach to study incompressible flow with multi-physics coupling in lid-driven cavities. The proposed methodology is referred to as implicit-mesh DG method because the considered cavities are represented implicitly by suitably defined level set functions. The lid-driven cavity problem is considered as it represents a classic benchmark in fluid dynamics for code validation, offering a simple setup able to reproduce flow phenomena such as recirculating vortexes, shear layers, corner singularities, and instabilities [11].

Problem statement

Let us consider a lid-driven cavity problem, as shown in Fig. 1(a) , which generally involves of a fluid domain whose top boundary is a lid with a prescribed tangential motion and remaining boundaries are walls featuring a no-slip boundary condition.

The fluid within the cavity is assumed to be governed by the steady Navier-Stokes equation in the laminar regime, which consist of the continuity equation

$$\frac{\partial v_k}{\partial x_k} = 0 \tag{1}$$

and the momentum equation

$$\rho v_k \frac{\partial v_i}{\partial x_k} + \frac{\partial p}{\partial x_i} = \frac{\partial \tau_{ki}}{\partial x_k} + s_i. \tag{2}$$

In Eq. 1 and Eq. 2, x_k is the k -th component of the space location vector, $v_k$is the k -th component of the velocity vector, ρdenotes the fluid density,$p$is the pressure, andτ_{ki}denotes the ki -th component of the viscous stress tensor given by

Materials Research Proceedings 69 (2026) 193-198 https://doi.org/10.21741/9781644904251-34

$$\tau_{ki} = \mu\left(\frac{\partial v_i}{\partial x_k} + \frac{\partial v_k}{\partial x_i}\right) \tag{3}$$

being μ the fluid viscosity. On the other hand, in Eq. 2, s_i denotes i -th component of a generic source vector. For example, considering the Boussinesq approximation for natural convection, the term $s_i$may be written as $s_i = \rho g_i \beta_\vartheta \vartheta$, where $g_i$is the i -th component of gravity acceleration vector, $\beta_\vartheta$is coefficient of volumetric thermal expansion, and $\vartheta \equiv T - T_{ref}$denotes the temperature fluctuation with respect to a reference temperature T_{ref}. In such a case, the pressure $p$appearing in Eq. 2 must be considered as a modified pressure accounting for the gravitational potential, and an additional equation must be included to model the temperature fluctuation field ϑ. Considering the energy equation within the Boussinesq approximation, the following equation is coupled to Eq. 1 to Eq. 2 to account for the transport of ϑ

$$v_k \frac{\partial \vartheta}{\partial x_k} = \alpha \frac{\partial^2 \vartheta}{\partial x_k \partial x_k} \tag{4}$$

where $\alpha$is the thermal diffusivity.

Similar source terms can be added to Eq. 2 and similar transport equations can be considered to account for additional species, such as the presence of humidity.

Implicit-mesh discontinuous Galerkin formulation

The implicit-mesh discontinuous Galerkin formulation for solving Eq. 1 to Eq. 4 is presented in this section. First, it is noted that the equations can be written in compact notation via the following expression

$$-\frac{\partial \Sigma_k}{\partial x_k} + \Psi = 0 \tag{5}$$

where

$$\Sigma_k \equiv \begin{pmatrix} 0 \\ \tau_{k1} - p\delta_{k1} \\ \tau_{k2} - p\delta_{k2} \\ \alpha \frac{\partial \vartheta}{\partial x_k} \end{pmatrix} \quad \text{and} \quad \Psi \equiv \begin{pmatrix} \frac{\partial v_k}{\partial x_k} \\ \rho v_k \frac{\partial v_1}{\partial x_k} + \rho g_1 \beta_\vartheta \theta \\ \rho v_k \frac{\partial v_2}{\partial x_k} + \rho g_2 \beta_\vartheta \theta \\ v_k \frac{\partial \vartheta}{\partial x_k} \end{pmatrix} \tag{6}$$

Here Σ_k and Ψ are functions of the unknown field vector $U$and its gradients, where $U \equiv (v_1, v_2, p, \vartheta)^T$. The system of equations given in Eq. 5 is closed by providing suitable boundary conditions. In case of the lid-driven cavity problem, Dirichlet boundary conditions are provided for the velocity, whereas either prescribed-temperature (i.e.Dirichlet) or prescribed-flux (i.e.Neumann) boundary conditions can be provided for the temperature fluctuation field.

It is then possible to show that the DG weak form associated with Eq. 5 reads as follows: find U^hsuch that $B(V, U^h) = L(V, \bar{U}, \bar{T}) \forall V \in \mathcal{V}^{hp}$,being $\mathcal{V}^{hp}$the space of discontinuous polynomial vector fields, where

$$\begin{aligned} B(V, U^h) \equiv & \int_{\mathcal{D}^h} \left(\frac{\partial V^T}{\partial x_k} \Sigma_k + V^T \Psi\right) dV + \\ & - \int_{\mathscr{J}^h} \left([\![V^T]\!]_k \{\Sigma_k\} + \{\Pi_k^T\} [\![U^h]\!]_k \right) dS + \int_{\mathscr{J}^h} [\![V^T]\!]_k \mu [\![U^h]\!]_k dS + \\ & - \int_{\mathscr{B}_D^h} \left(n_k V^T \Sigma_k + \Pi_k^T U^h n_k\right) dS + \int_{\mathscr{B}_D^h} V^T \mu U^h dS \end{aligned} \tag{7}$$

Materials Research Proceedings 69 (2026) 193-198 https://doi.org/10.21741/9781644904251-34

and

$$L(V,\overline{U},\overline{T}) \equiv \int_{\mathscr{B}_N^h} V^T\,\overline{T}\,dS - \int_{\mathscr{B}_D^h} \Pi_k^T\,\overline{U} n_k dS + \int_{\mathscr{B}_D^h} V^T\,\mu\overline{U}\,dS. \quad (8)$$

In Eq. 7 and Eq. 8, the terms $[\![\bullet]\!]_k$ and $\{\bullet\}$denote the jump and average operators, respectively, whereas the integrals over $\mathcal{D}^h$,$\mathscr{I}^h$,$\mathscr{B}_D^h$and $\mathscr{B}_N^h$are usually referred to as broken integrals and must be intended as the sum over the mesh elements of the integrals computed over each element domain and boundary; for instance, $\int_{\mathcal{D}^h} \bullet\, dV \equiv \sum_e \int_{\mathcal{D}^e} \bullet^e\, dV$, where $\mathcal{D}^e$is the domain of the generic mesh element. Additionally, n_k is the k -th component of the unit normal of the fluid boundary, while Π_k is a symmetrization vector and μ is a penalization matrix that are typical of DG formulations. Further detail on the employed notation can be found in Ref. [12].

The DG formulation introduced above is valid regardless of the type of mesh elements that are chosen to discretize the fluid domain. In this work, the implicitly-defined mesh technique developed in Ref. [5,10] is employed. In particular, the cavity domain is implicitly-defined by a level set function φ such that the domain cavity is identified by the region where φ is negative and its walls are identified by $\varphi = 0$. The level set function is defined in a background rectangle and the intersection between the rectangle and the region $\varphi < 0$identifies the lid of the cavity. As an example, the level set function employed to define the cavity in Fig. 1(a) is shown in Fig. 1(b). Then, to generate the mesh, a background grid is generated using the background rectangle and is intersected with the level set function to generate the implicitly-defined mesh. Fig. 1(c) shows the implicitly-defined mesh of the the cavity of Fig. 1(a).

Results

An example of the capability of the proposed methodology is shown in Fig. 2, where the solution associated with a lid-driven triangular cavity problem is reported. Fig. 2(a) shows the considered geometry, which is represented implicitly by the level set function $\varphi(x) = \frac{2H|x_1|}{L} - x_2$, where H and L are the height and the width, respectively, of the cavity. The associated implicitly-defined mesh is displayed in Fig. 2(b), where it is possible to notice the shape of the elements in proximity of the wall boundaries, obtained as a result of a cell-merging procedure implemented to avoid overly small cut cells. Fig. 2(c) and Fig. 2(d) report the contour plot of the velocity magnitude and the streamlines obtained with the present framework for two values of the Reynolds number $Re \equiv VH/(3\nu)$, namely

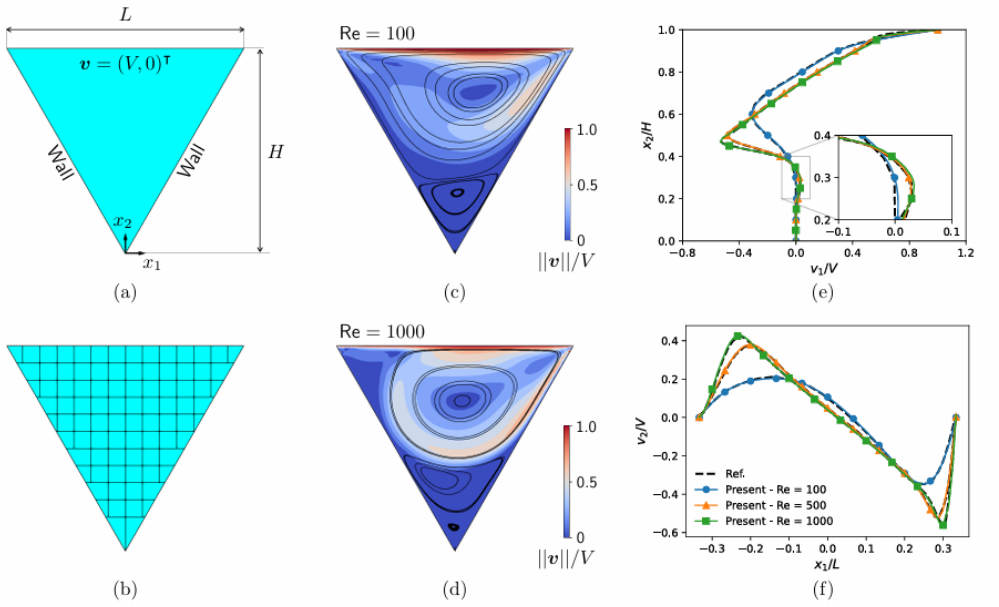

Fig. 2: Implicit-mesh DG solution of the lid-driven triangular cavity problem. (a) Geometry. (b) Implicitly-defined mesh. (c) Contour plot of the velocity magnitude and streamlines for $Re = 100$. *(d) Contour plot of the velocity magnitude and streamlines for* $Re = 1000$. *(e) Profile of the velocity component* v_1 *along the height of the cavity at* $x_1 = 0$. *(f) Profile of the velocity component* v_2 *along the width of the cavity at* $\frac{x_2}{H=\frac{2}{3}}$. *Reference results are taken from Ref. [13].*

$Re = 100$ and $Re = 1000$, respectively, being ν the kinematic viscosity of the fluid. Eventually, Fig. 2(e) and Fig. 2(f) show the profile of the velocity component v_1 along the height of the cavity at $x_1 = 0$ and profile of the velocity component v_2 along the width of the cavity at $\frac{x_2}{H=\frac{2}{3}}$, respectively, along with reference results (the thick dashed lines) taken from Ref. [13]. The comparison confirms the accuracy and the potential of the proposed formulation.

Conclusions

A novel computational framework for the incompressible flow in lid-driven cavity has been presented. The framework is based on combined use of the the implicitly-defined mesh technique to generate the fluid domain partition and the discontinuous Galerkin method to solve the governing equations with high-order accuracy. Numerical results have been presented for the lid-driven flow in a triangular cavity, confirming the accuracy of the proposed formulation. Currently, the method is being extended to account for the multi-physics coupling between temperature, humidity and mass transfer in cavities with general shapes.

Analysis of the Wake Vortex Encounter Risk Under Reduced Vertical Separation Enabled by Geometric Altimetry

Keywords: Wake Turbulence, Wake Vortex, Wake Vortex Encounter, Aircraft Separation Minima

Abstract. As the current requirements of at least 1000 ft vertical separation between aircraft in en-route airspace are mainly determined by the limited accuracy of barometric altimetry, a study has been performed whether these separation minima might be reduced to 500 ft with usage of geometric altimetry. Thus, allowing smaller nominal vertical distances between flight paths, it is to be expected that the risk (in frequency of occurrence and severity) of wake vortex encounters increases. The present study, using a comparative fast-time simulation of traffic at European level for two full-day scenarios, indeed confirms a relative encounter risk increase by a factor of 3 to 4 across all severities (as expressed by the magnitude of the circulation encountered), with this factor being largely independent of the wind situation. Consequently, the exploration of mitigation means such as conditional application of reduced vertical separation or tactical wake conflict prediction tools should be undertaken as part of further development of the concept.

Motivation

In order to increase capacity in en-route airspace and therefore reduce the need for detours, thus contributing to a more environmentally friendly aviation, a reduction of the vertical separation minima has been considered as a part of the research project *Green-GEAR* (Green Operations with Geometric Altitude, Advanced Separation & Route Charging Solutions). Currently, within the so-called RVSM (Reduced Vertical Separation Minima) airspace between flight levels (FLs) 290 to 410 inclusive, a minimum vertical separation of 1000 ft between aircraft is applied. The new RVSM 2 concept [1] aims to reduce this separation minimum to 500 ft while at the same time increasing the upper applicability limit to FL 600, enabled by the usage of geometric altimetry, i.e. usage of GNSS vertical positions, instead of barometric altimetry. In view of the fact that the main contributor to the current value for the minimum vertical separation is the comparatively large allowance for the barometric altimetry system error (ASE), its decrease should be feasible when geometric altimetry is employed.

Geometric altitude reference in cruise implies no longer following the isobaric altitudes that are consistent with aircraft performance, resulting on average in penalties in fuel use as expectable [2,3]. On the other hand, besides the capacity increase reducing the need for detours, the finer granularity of available flight levels could allow flights to operate closer to their optimum altitudes than today, counteracting and possibly outweighing the penalties [4].

A reduction of aircraft separation minima would obviously impact flight safety so that a safety case including consideration of the risks of aircraft collisions under nominal and non-nominal conditions and of wake turbulence encounters is required. The Green-GEAR project has conducted a preliminary safety study for the RVSM 2 concept [5,6]; the results of the wake turbulence risk assessment are presented in this paper. While out of scope here, we note that the aircraft collision risk for RVSM 2 is acceptable under certain conditions [5].

Materials Research Proceedings 69 (2026) 199-204 https://doi.org/10.21741/9781644904251-35

Background and Prior Work

A wake turbulence encounter is a possibly hazardous situation for an aircraft, but such encounters cannot be completely avoided by procedural means alone if any airspace capacity is to be maintained. Existing (procedural) separation minima have been initially defined at ICAO level using expert judgement more than 50 years ago [7], and the only modifications for en-route airspace implemented so far have been the increased horizontal separation from the Boeing B757-300 and the new SUPER wake vortex class (currently only populated by the Airbus A380) and the introduction of RVSM between FLs 290 and 410. Studies for wake vortex risk in the en-route flight phase are scarce (e.g. [8-10] for North American airspace, [11,12] for European airspace) and with the exception of [10] concern the status quo. Due to limited monitoring and reporting of wake vortex encounters, it is difficult to quantify whether the studies correctly estimate their frequency and severity. Especially concerning the latter, it can be observed that the crossing of a wake where forces or moments beyond the aircraft's control capabilities could be generated needs to be regarded as hazardous from a safety point of view *in the absence of further information*, but these effects may only persist for a fraction of a second and need not lead to relevant consequences on practical operations [6].

Method

The analysis is based on a fast-time simulation using a software toolbox [13,14] that had been previously developed and now has been improved. The fast-time simulation uses trajectory data generated from submitted flight plans and meteorological data, in this case from the German COSMO-EU numerical weather prediction model, as input. As there is no (planned) traffic yet adhering to the new flight levels, a corresponding modification of altitudes has been employed for the RVSM 2 scenario, cf. Fig.°1, that also serves to concentrate the traffic around the most popular flight levels, effectively locally increasing traffic density. ASE, different for barometric and geometric altimetry, and flight technical error (FTE) are modelled to obtain actual flight altitudes from nominal ones [6]. The simulation calculates probabilistic corridors with an elliptical shape that contain the wake vortices with a high probability using the well-established P2P model [15,16] that also models the evolution of these wake corridors over time. A semi-deterministic approach (the initial conditions for aircraft trajectories and meteorological parameters are assumed as known in the simulation, while uncertainties in atmospheric effects and consequently wake evolution are modelled) ensures realistic corridor sizes with the proper probability distribution of parameters. The traffic scenario is then evaluated with respect to crossings of the aircraft trajectories with these wake corridors. The final step is a hazard assessment based on the SHAPe model [17-19], which uses the roll control ratio (RCR) as the most relevant parameter and has been integrated into the simulation as part of this work.

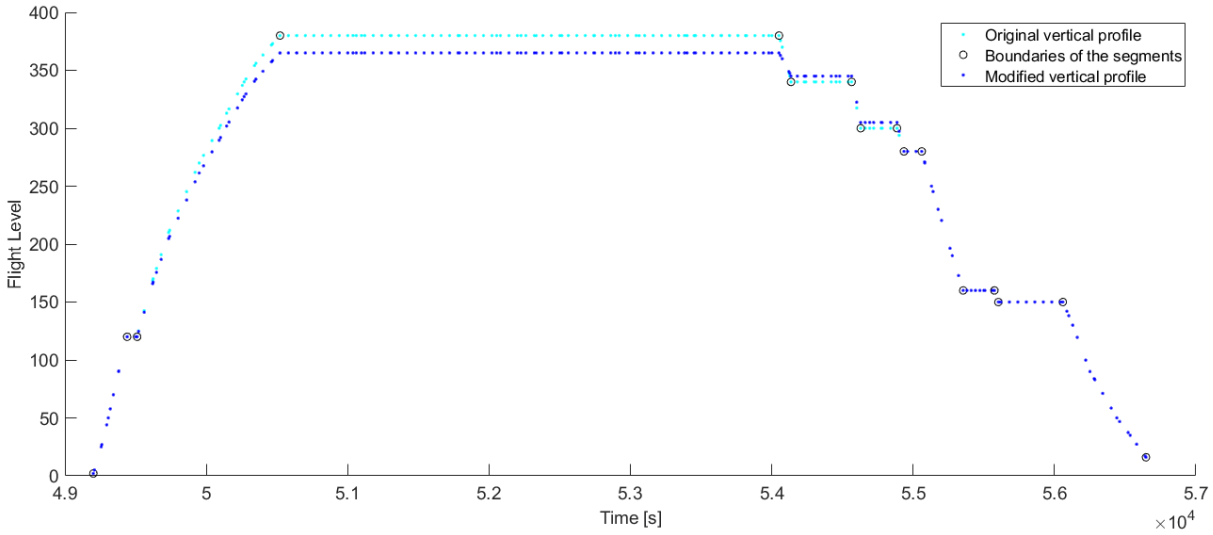

Fig.°1: sample of adapted fight profile, moving horizontal segments to new flight levels

Two full-day scenarios with traffic samples for the whole European airspace (more than 20000 trajectories each) have been analysed in this study: one day with relatively low wind speeds and one day with relatively high wind speeds at the relevant altitudes, as the wind situation strongly influences the horizontal movement of wake vortices and therefore the probability of wake encounters. Both scenarios have been analysed in a baseline version using barometric altimetry and 1000 ft minimum vertical separation in the RVSM airspace as it is used today and in a modified version using geometric altimetry and 500 ft minimum vertical separation as it might be used in the RVSM 2 airspace in the (far) future. Due to limitations of the meteorological data input driver, scenarios from 2014 (14th Feb and 3rd June) were used. The observed increase of traffic densities since then, or even until a possible introduction of RVSM 2, is not modelled, which is believed acceptable as the relevant question is the relative change of encounter risk.

Results

The results show that a reduction of the vertical separation to 500 ft leads to an increase of the number of wake encounters approximately by a factor of 3 to 4 over the full range of encountered circulation values, as shown in Fig.°2 for both scenarios. The figure only contains encounters where the magnitude of the encountered circulation in relation to the respective aircraft's capability to deal with it (as assessed by the SHAPe method) is high enough that the situation cannot be *guaranteed* to be safe. The high-wind-speed scenarios show a smaller overall number of encounters, which can be explained with the higher wind speeds moving the wake vortices away from the generator aircraft's trajectories in many situations so that other aircraft on the same trajectory do not encounter them. Aircraft on adjacent trajectories can encounter wake vortices as a result of strong crosswinds, but overall, the reduction of the number of wake encounters on same trajectory outweighs this effect. Despite the overall number of encounters being very different in the two wind scenarios, the relative increase between baseline and modified separations is approximately the same.

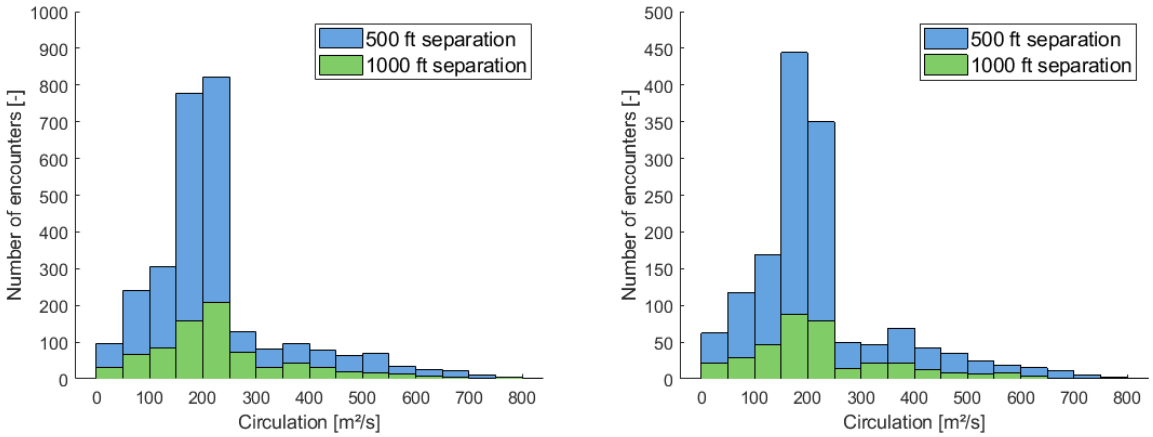

Fig.°2: Distribution of the encountered circulation in the low-wind-speed (left) and high-wind-speed scenario (right). Note the different vertical scaling.

An analysis of the aircraft separations at the start times of the wake encounters revealed that in the scenario with 500 ft vertical separation, most encounters happen 500 ft below the wake generating aircraft at a horizontal separation between 5 and 20 NM. In the scenario with 1000 ft vertical separation, far less encounters happen 1000 ft below the wake generating aircraft at a similar horizontal separation. Therefore, it can be concluded that the wake encounters 500 ft below the wake generating aircraft are not shifted from 1000 ft below to 500 ft below when changing the vertical separation, but instead, these are nearly exclusively additional encounters that would not happen with 1000 ft separation as used today. This is plausible because, even though wake vortices can descend more than 1000 ft (in some cases even 2000 ft [20]), they descend less than 1000 ft most of the time.

Conclusions and Further Work

As *Green-GEAR* is an exploratory research project with a relatively low TRL (Technology Readiness Level), some limitations of the fidelity of the results have to be accepted, notably due to restrictions in traffic flow modelling. Nevertheless, as many additional effects with respect to prior work have been modelled in relatively high detail, and large-scale scenarios have been used for the simulations, at least the relative results can be considered as representative.

With that caveat in mind, we find a substantial increase in the number of wake encounter occurrences with no significant change in average severity as expressed by the magnitude of the circulation encountered. In fact, there is an increase of the number of encounters in all ranges of circulation values, with a comparatively higher increase for lower circulation values (see again Fig.°2) so that the average is, if only slightly, decreased. The overall result means an increase in wake encounter risk (substantially increased frequency of occurrence at virtually unchanged average severity) and as such is not unexpected considering the nature of wake vortex transport and evolution. We therefore note a substantial relative decrease in wake turbulence safety.

Prior activities modifying separation standards have adopted a comparative approach, demonstrating no (unfavourable) change of risk through a new concept of operation – this is not the case here. However, with no official definition of a target level of safety (TLS) for the wake encounter risk, nor any means of quantification for the encounter severity defined by regulation, a formal statement that the new situation would be unsafe cannot be made at this point. It is reasonable to assume though that it would not be acceptable without modifications. Remedies can be mitigation means and/or limiting conditions for its application. Indeed, further analysis of the results especially regarding particular aircraft (category) pairings, relative flight path geometries or weather situations is desirable, so as to possibly identify criteria when or where the new

separation standards could be applied safely, or should not be applied. An alternative approach could be the introduction of a safety net: analogous to the Airborne Collision Avoidance System (ACAS) and Air Traffic Control's short-term conflict alert (STCA), a ground-based or airborne predictive tool to identify and prevent potentially hazardous wake encounters [21] could be employed, potentially rendering large benefits as operational limits, and thus capacities, would no longer need to be dictated by the worst-case assumption. Such a tool could already contribute to increase the safety of operations under current separation rules.

Keywords: Computational Fluid Dynamics, Supersonic/Hypersonic Flows, Shock Wave-Boundary Layer Interaction, Turbulence Modelling

Abstract. In this work, we carry out Reynolds-Averaged Navier-Stokes (RANS) simulations of the three-dimensional interaction between an oblique shock wave and a supersonic turbulent boundary layer. The analysis focuses on the canonical case of three-dimensional interaction with cylindrical symmetry, obtained by adding a crossflow velocity component to the incoming boundary layer, resulting in a two-dimensional, three-component (2D/3C) flow. In the RANS framework, the 2D/3C flow assumption leads to a simplified set of equations, which can be efficiently solved in a two-dimensional domain. The RANS results are compared with previous high-fidelity data-sets in the same flow conditions for two values of the sweep angle. It is shown that the RANS approach is able to predict the increased size of the interaction region for the swept case, in agreement with previous literature findings. However, we observe noticeable differences between RANS and DNS in the streamwise distributions of wall quantities.

Introduction

Recent years have seen a renewed interest in the development of air-breathing vehicles for supersonic/hypersonic flight. Commercial interest in hypersonic aircraft for intercontinental flight and the resurgence of world-wide military threats have pushed momentum into the high-speed aerospace research. The main challenges associated with the design of high-speed aerodynamic systems are related to the intense wall friction, heat flux and thermo-mechanical loads generated by the interaction between the vehicle and the surrounding flow. Improved understanding of the fluid-dynamic phenomena occurring in this regime is therefore necessary to provide fast and accurate design tools [1]. In this context, it is expected that computational fluid dynamics (CFD) should play a pivotal role, as using it would allow massive cost reductions if compared with full-scale experiments.

A well-known phenomenon in high-speed aerodynamics is related to the interaction between shock waves and turbulent boundary layers developing along the aircraft external walls (shock wave-boundary layer interaction, SBLI). SBLI often results in extensive flow separation, leading to aerodynamic efficiency loss, control reversal, wall heat transfer increase, and structural vibrations. Recently, high-fidelity numerical simulations have allowed to obtain important physical insights on this topic, and to shed light on the origin of shock-induced low-frequency oscillations [2]. However, direct numerical simulations (DNS) and wall-resolved large eddy simulations are typically characterized by very strict grid resolution requirements [3], which lead to very high computational costs, thereby hindering their use as a design tool.

A low-cost solution for the analysis of high-speed flows would be to extend Reynolds-averaged Navier-Stokes (RANS) turbulence models, which have been the workhorse of low-speed aerodynamic design for the last decades, to the hypersonic regime. However, there are several arguments against the use of RANS models in high-speed cases. First, turbulence models have been originally calibrated for incompressible flows, and they generally have significant loss of

accuracy when dealing with the strong temperature/density gradients occurring in diabatic high-speed conditions and/or in presence of SBLIs [4]. In addition, the vast majority of SBLIs are inherently three-dimensional, as the shock impingement line is rarely orthogonal to the incoming flow. The reliability of RANS models is entirely questionable in those cases, due to numerical issues in managing shock-dominated, three-dimensional flows and due to the intrinsic approximation of the Boussinesq gradient-viscosity hypothesis.

Based on the previous discussion, we deem very important to assess the performance of RANS models in simple three-dimensional SBLIs before applying them to real-world applications. In this work, we carry out a series of RANS simulations of three-dimensional SBLIs in supersonic regime. Specifically, we focus on a canonical configuration, namely the swept oblique shock reflection, which has been recently investigated through wind tunnel experiments [5] and high-fidelity numerical simulations [6,7,8]. As previous studies have demonstrated an increasing trend of the length of the interaction region with the sweep angle, it would be important that RANS models are able to replicate this behaviour.

Numerical setup

The analysis of the swept interaction between an oblique shock and a supersonic, turbulent boundary layer is carried out using the open-source code OpenFOAM. The density-based transient solver *rhoCentralFoam* is used to deal with the flow configuration under study in a finite-volume framework. The numerical setup used in this work is sketched in figure 1: an oblique shock of wave angle β impinges onto a flat plate and interacts with a turbulent boundary layer, whose streamwise direction is not orthogonal to the shock impingement line.

Following previous work on this topic, the swept interaction is obtained by adding a crossflow component to the upstream boundary layer at the inflow, making it swept by an angle γ_0 with respect to the x axis. On the other hand, the impinging shock wave is generated by a compression wedge of dihedral angle 2θ, whose lower surface is numerically treated as an inviscid wall (using a slip condition for the velocity) and constitutes part of the top boundary of the domain. The wedge geometry is properly designed to have shock impingement onto the flat plate at $x_{imp} = 64\ \delta_0$ (where δ_0 is the boundary layer thickness at the inflow plane). The flat plate is treated as an isothermal, nominally-adiabatic wall, as its temperature is set to the adiabatic wall temperature upstream of the shock $T_{aw,0} = T_0[1 + r\,(\gamma_g-1)/2\ M_0^2]$ (where γ_g is the heat transfer coefficient ratio, r the recovery factor, $M_0 = M_{0,x}\cos(\gamma_0)$ the free-stream Mach number and T_0 the inflow free-stream temperature). A turbulent boundary layer profile of thickness δ_0 is introduced at the inflow plane, with its wall-normal distributions of the thermo-fluid-dynamic variables being taken from a precursor simulation. Non-reflecting boundary conditions are imposed on the free portions of the top boundary and the outlet ($x=L_x$).

Materials Research Proceedings 69 (2026) 205-210 https://doi.org/10.21741/9781644904251-36

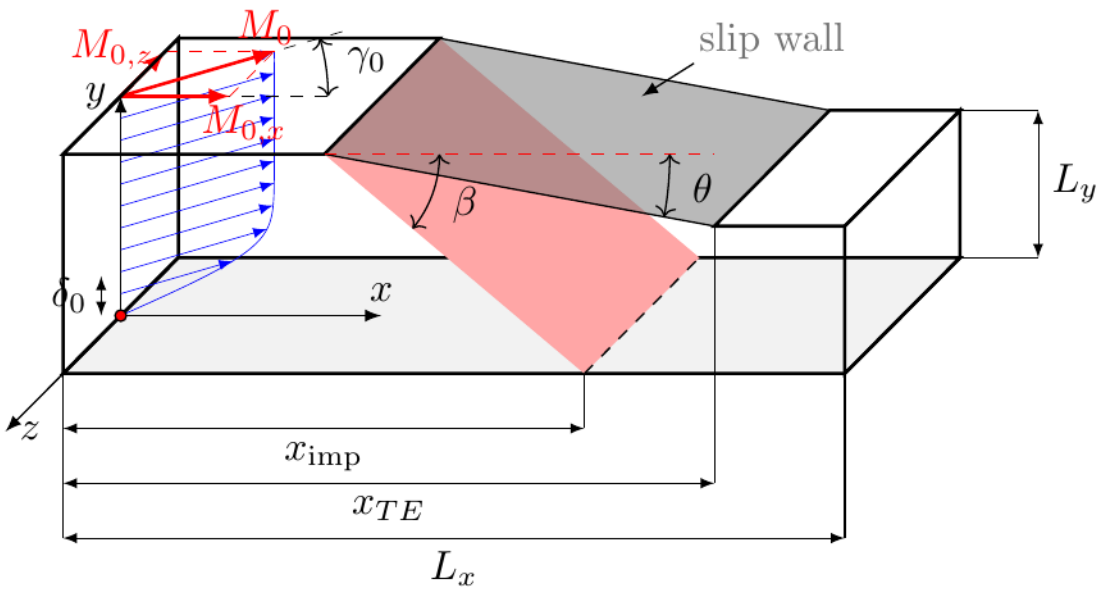

Figure 1 - Schematic of numerical simulations: δ_0 is the incoming boundary layer thickness, γ_0 is the incoming flow skew angle, β is the shock angle, θ the deviation angle, x_{imp} the nominal location of the shock impingement, x_{TE} the wedge trailing edge location.

It can be easily recognized that the SBLI configuration under study, despite being inherently three-dimensional, is statistically homogeneous along the *z*-direction. This feature yields a two-dimensional, three-component (2D/3C) flow behaviour, which provides a strong simplification for RANS modelling. In this framework, RANS equations can be recast in a simplified system of equations (infinite swept model, [9]), which can be solved in a two-dimensional domain at a very reduced computational cost. In this work, the 2D/3C swept model is solved using the following procedure: at each time step, we solve the two-dimensional continuity equation and the momentum equation in the longitudinal plane *(x,y)*. Then, the crossflow velocity component *w* is solved as a separate thermo-fluid-dynamic variable governed by a simplified momentum equation, which is mutually coupled with the longitudinal flow dynamics through the energy equation and the turbulence model. The numerical solution is then marched in time until a steady state is obtained.

The 2D/3C RANS equations are discretized and solved using an in-house modification of the aforementioned *rhoCentralFoam* flow solver. The turbulent flows considered in this work are solved using a RANS approach, based on the Spalart-Allmaras turbulence model. The flow conditions match previous DNS by our research group [7]: the *x*-projected Mach number is selected as $M_{0,x} = 2.28$, and two sweep angles, $\gamma_0=\{0°,30°\}$, are considered. The inflow Reynolds numbers $Re_{\delta 0}= \rho_0 u_0 \delta_0/\mu_0$ of the computations are chosen such as the same value of the Reynolds number $Re_{\delta 2}= \rho_0 u_0 \delta_2/\mu_w \approx 1100$ (where δ_2 is the boundary layer momentum thickness) is obtained at a reference location just upstream of the interaction region. It is worthwhile remarking that the same approach was followed in the reference DNS study.

Materials Research Proceedings 69 (2026) 205-210 https://doi.org/10.21741/9781644904251-36

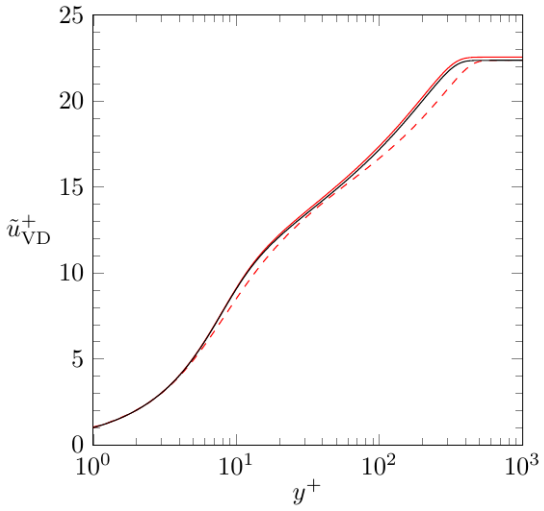

Figure 2 - Wall-normal profiles of Van Driest transformed velocity in the free-stream direction at a reference location upstream of the shock. Solid lines denote the results of the present RANS simulations, a dashed line denote Favre-averaged velocity obtained by DNS [7]. A red solid line is used for the unswept RANS case, a black solid line denotes the swept RANS case.

It can be noticed that the free-stream Mach number M_0 is different for the two simulations (M_0 = 2.28 for the unswept case, $M_0 \approx 2.63$ for the swept one), which yields a larger value of the ratio T_w/T_e for the swept case. Previous studies on the configuration considered in this work have demonstrated that this fact has a significant effect on the flow behaviour in the interaction region [10].

Results

The validity of the present numerical setup is first assessed by inspecting the wall-normal velocity distributions at the reference location. Figure 2 compares the inner-scaled velocity profiles along the free-stream direction obtained by RANS with the Favre-averaged velocity of the DNS dataset at the same location. Despite the different free-stream Mach numbers considered, it is shown that the RANS velocity profiles basically overlap, which is a result of fixing the same $\mathrm{Re}_{\delta 2}$ at the reference location. Overall, the RANS profiles are in good agreement with the DNS data-sets, which allows to state that the turbulence model is able to obtain reliable results in the zero-pressure-gradient region.

Wall pressure streamwise distributions (scaled by the inflow pressure) are depicted in figure 3 (top panel), along with the time-averaged wall pressure data obtained by DNS. It can be observed that all streamwise profiles have similar trends, with a steep increase at the onset of the interaction region and a pressure plateau just upstream of the inviscid impingement line position. All simulations slowly reach the pressure ratio given by the inviscid shock relations before the end of the computational domain.

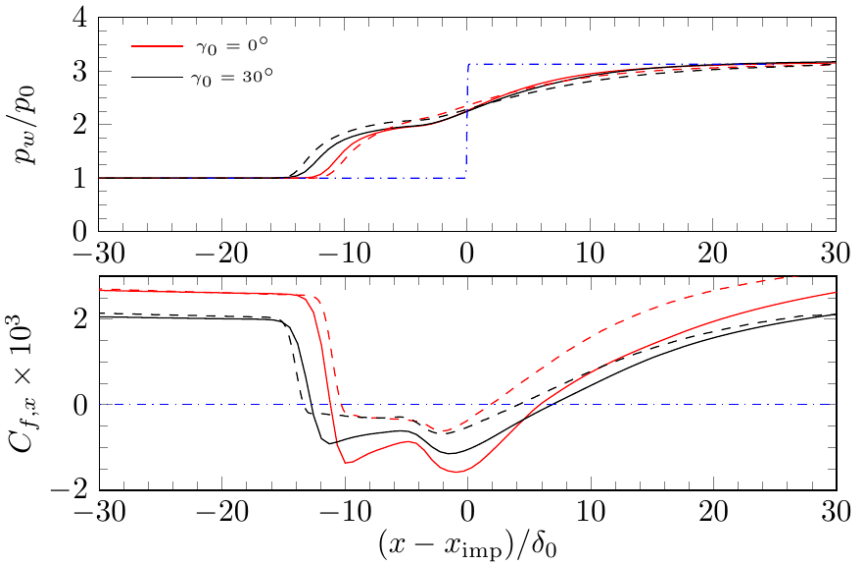

Figure 3 - Streamwise distributions of wall pressure (top) and x-projected friction coefficient (bottom). Solid lines denote the results of the present RANS simulations, dashed lines denote DNS data-sets [7]. Red lines indicate unswept interactions, black lines denote swept interactions. The blue dash-dotted line in the top panel ndicates the inviscid shock solution. The blue-dash-dotted line in the bottom panel represents $C_{f,x}$=0.

A closer look to the RANS pressure distributions past the nominal impingement line reveals that the swept case approaches the inviscid pressure jump more slowly than the unswept one, meaning that the interaction region is larger in the former case. Interestingly, the same trend is observed for the DNS data-set, meaning that RANS models are able to predict the slower relaxation towards the inviscid pressure value that is typical of swept interactions. However, it can be observed that the RANS turbulence model is not able to predict accurately the anticipated shift in the upstream influence observed by DNS in the swept case. In addition, the plateau region observed by the RANS computations is not in good agreement with the DNS data-set, and flow relaxation is retarded in RANS computations. Overall, it can be stated that the leading-order effect of sweep in this configuration, namely the increase in the size of the interaction region, is qualitatively well predicted by RANS. However, there are relatively large discrepancies between the present RANS results and the corresponding DNS data-sets, which are possibly due to the RANS inaccuracy in handling even the two-dimensional case.

Those remarks are further substantiated by the analysis of the x-projected wall friction coefficient, shown in figure 3, bottom panel. It can be observed that RANS models succeed in predicting the increased size of the separation region for the swept case. However, the streamwise length of the separation bubbles is clearly over-predicted, as the result of retarded reattachment. Moreover, the swept RANS case is characterized by retarded flow separation if compared with DNS, which confirms the previous conclusion that the modification of the upstream influence typically observed in swept interactions is not quantitatively retrieved by RANS.

Conclusions

A canonical three-dimensional shock-wave/turbulent boundary layer interaction has been examined using RANS simulations. The comparison between the present RANS results and previous DNS simulations in the same flow conditions has allowed to assess the validity of turbulence models in this regime. The analyses of the wall pressure distribution and the friction coefficient have shown that the RANS models appear to retrieve some salient features of swept interactions (for instance, the increased length of the interaction region in the swept case). Nonetheless, we found significant discrepancies between RANS and DNS for this kind of flow.

The present work emphasizes possible inconsistencies in the use of standard RANS models for high-speed separated flows in two- and three-dimensional configurations. Future work on this topic will extend the present study to a wider range of Mach and Reynolds numbers and will explore other RANS models.

Keywords: Circular Cylinder, Sonic Boom, Extreme Accelerations, Numerical Simulation

Abstract. The effect of extreme accelerations, namely 10^2 g, 10^3 g, and 10^4 g, on the intensity of the sonic boom generated by a circular cylinder accelerated from rest to a Mach number equal to 5 is investigated by a numerical simulation that uses a moving-body immersed boundary methodology, allowing to naturally capture the pressure level fluctuations generated over nearby stationary observers positioned in the opposite and orthogonal directions relative to the cylinder velocity. The compressible and unsteady Euler equations are numerically solved in a computational domain that is discretized using a finite-volume formulation. The cylinder moves through a regular Cartesian mesh where specific boundary conditions are applied to the immersed boundary volumes during the acceleration period. These boundary conditions are associated with the effect of the acceleration levels on the thermodynamic gradients in the normal direction over the surface of the cylinder. The numerical results show that the acceleration levels significantly influence the amplitude of the sonic boom measured by a stationary observer positioned in the opposite direction to the movement of the cylinder. However, they also show that the acceleration levels do not have any measurable influence on the intensity of the sonic boom measured by a stationary observer positioned in a direction orthogonal to the cylinder velocity.

Numerical Method and Boundary Conditions for Accelerating Bodies

The fundamental physics of inviscid, unsteady and compressible flows are modeled by the Euler equations, and the numerical method used in this work to solve them using a finite-volume discretization with a moving immersed-boundary approach is presented in detail by Miserda et al. [1]. To impose boundary conditions on the surface of accelerating bodies, the velocity of the fluid, $\mathbf{u}$, on the solid surface is decomposed into normal (subscript n) and tangential (subscript t) components as

$$\mathbf{u} = u\mathbf{i} + v\mathbf{j} = \mathbf{u}_n + \mathbf{u}_t = u_n\mathbf{n} + u_t\mathbf{t}, \tag{1}$$

where $\mathbf{i}$ and $\mathbf{j}$ are the unit vectors in Cartesian coordinates and $\mathbf{n}$ and $\mathbf{t}$ are the local unit vectors in the normal and tangential directions relative to the solid surface. Since the impenetrability condition on the solid surface establishes that the normal component of the fluid velocity must be equal to the normal component of the velocity of the moving body, v_{n_B}, the normal component of the velocity on the surface is given by

$$u_n = v_{n_B}. \tag{2}$$

It is important to note that for a static body, $v_{n_B} = 0$, and that for moving bodies the normal component of the velocity is simply given by

Materials Research Proceedings 69 (2026) 211-216 https://doi.org/10.21741/9781644904251-37

$$v_{n_B} = \mathbf{v}_B \cdot \mathbf{n}, \tag{3}$$

where $\mathbf{v}_B$ is the instantaneous velocity of the moving body.

However, thermodynamic properties are independent of the frame-of-reference of the observer, and the thermodynamic boundary conditions at the surface of an accelerating body immersed in a stagnant fluid must be the same as the boundary conditions for a static body that is immersed in an accelerating fluid, since the only difference between the two cases is the frame-of-reference. For this reason, the thermodynamic boundary conditions are deduced for the latter case and then applied for the first one. The boundary condition for the static pressure on the wall of a stationary body immersed in an accelerating flow is obtained considering the momentum equation in the normal direction

$$\frac{\partial}{\partial t}(\rho\, u_n) + \frac{\partial}{\partial x_n}(\rho\, u_n u_n) + \frac{\partial}{\partial x_t}(\rho\, u_n u_t) = -\frac{\partial p}{\partial x_n} + f_n, \tag{4}$$

where f_n is the normal component of the volume pseudo-force imposed on the entire flow to accelerate it from stagnation condition to operational condition. This local normal component is given by $f_n = \rho[(\mathbf{u}_\infty/t_a) \cdot \mathbf{n}]$, being $\mathbf{u}_\infty$ the free-flow velocity after the acceleration period. It is important to mention that after the acceleration time t_a, the value of the pseudo-force is $f_n = 0$.

Expanding all the terms of Eq. (4) and applying the impenetrability condition, $u_n = v_{n_B}$, for a stationary body,

$$v_{n_B} = \frac{\partial v_{n_B}}{\partial t} = \frac{\partial v_{n_B}}{\partial x_n} = \frac{\partial v_{n_B}}{\partial x_t} = 0, \tag{5}$$

immersed in an accelerating flow, yields

$$\frac{\partial p}{\partial x_n} = f_n. \tag{6}$$

The entropy relation for an ideal and calorically perfect gas is given by Anderson [2] as

$$ds = \left(\frac{c_p}{T}\right) dT - \left(\frac{R}{p}\right) dp, \tag{7}$$

is also valid in the outward normal direction from the wall, yielding

$$\frac{\partial s}{\partial x_n} = \left(\frac{c_p}{T}\right)\frac{\partial T}{\partial x_n} - \left(\frac{R}{p}\right)\frac{\partial p}{\partial x_n}. \tag{8}$$

By imposing the isentropic boundary condition in the normal direction,

$$\frac{\partial s}{\partial x_n} = 0, \tag{9}$$

in conjunction with the pressure boundary conditions obtained previously and the state equation for an ideal gas, $p = \rho RT$, Eq. (8) results in the temperature boundary condition,

Materials Research Proceedings 69 (2026) 211-216 https://doi.org/10.21741/9781644904251-37

$$\frac{\partial T}{\partial x_n} = \left(\frac{1}{c_p\ \rho}\right) f_n. \tag{10}$$

Differentiating the state equation for an ideal gas in the normal direction,

$$\frac{\partial p}{\partial x_n} = \frac{\partial}{\partial x_n}(\rho R T) = R\rho \frac{\partial T}{\partial x_n} + RT \frac{\partial \rho}{\partial x_n}, \tag{11}$$

results in the density boundary condition,

$$\frac{\partial \rho}{\partial x_n} = \left(\frac{1 - R/c_p}{RT}\right) f_n. \tag{12}$$

For a termically and calorically perfect gas, the relation between internal energy and temperature is given by $e = c_v T$. Deriving this relation in the normal direction and using Eq. (10) yields

$$\frac{\partial e}{\partial x_n} = \left(\frac{c_v}{c_p\ \rho}\right) f_n. \tag{13}$$

Numerical Setup

The numerical simulations are performed using a two-dimensional domain where the characteristic length of the setup, $D = 10$ m, is the diameter of the circular cylinder. The regular computational domain extends $30D$ in the horizontal direction, x, and $300D$ in the vertical direction, y. The diameter of the cylinder is discretized using 256 finite volumes, resulting in a regular Cartesian grid that has 589.82×10^6 of them. The initial undisturbed pressure and temperature for the whole domain are 1.01325×10^5 Pa and 3.0×10^2 K, resulting in a cylinder Mach number of 5 after the acceleration period to a maximum vertical velocity of 1,735.94 m/s. The cylinder is initially stationary and is positioned at $x = 15D$ and $y = 15D$. After the acceleration period, it is in the same horizontal position, but at $y = 168.59D$ for 10^2 g, $y = 30.36D$ for 10^3 g, and $y = 16.54D$ for 10^4 g. The boundary conditions for accelerating bodies were implemented in the Virtual Aeroacoustic Tunnel (VAT) code, developed and maintained by the Computational Aeroacoustics Laboratory (CAALab) of the University of Brasilia (UnB). The VAT code uses a hybrid MPI/OpenACC parallel processing paradigm to numerically solve the Euler equations [1], allowing a parallel execution using six NVIDIA GeForce RTX 4090, while using simple-precision floating point arithmetic (FP32). Using these computational resources, 2.44×10^{10} degrees of freedom are solved per second of wall-clock.

Materials Research Proceedings 69 (2026) 211-216 https://doi.org/10.21741/9781644904251-37

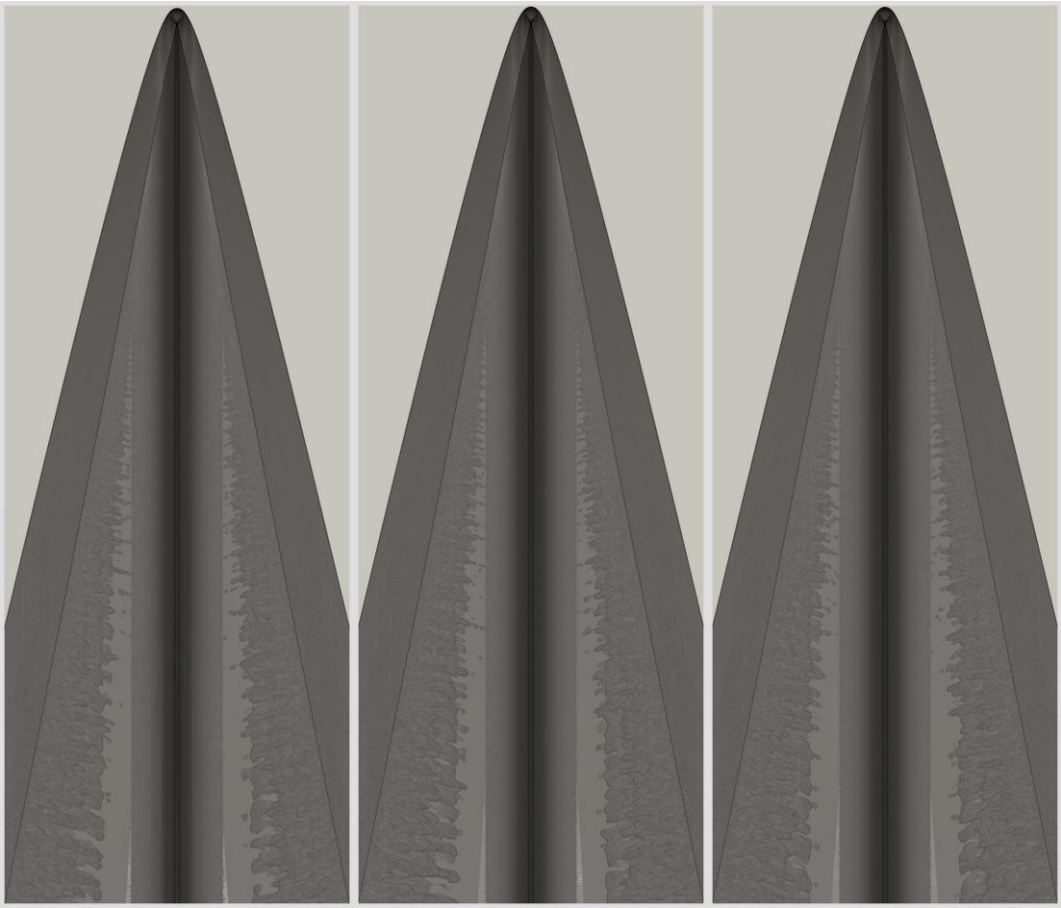

Figure 3: Comparative visualization of the aeroacoustic field using the variable $\beta_T = |\nabla T|^{1/10}$ at the same cylinder position, $y = 260.74D$, for 10^2 g (left), 10^3 g (center), and 10^4 g (right).

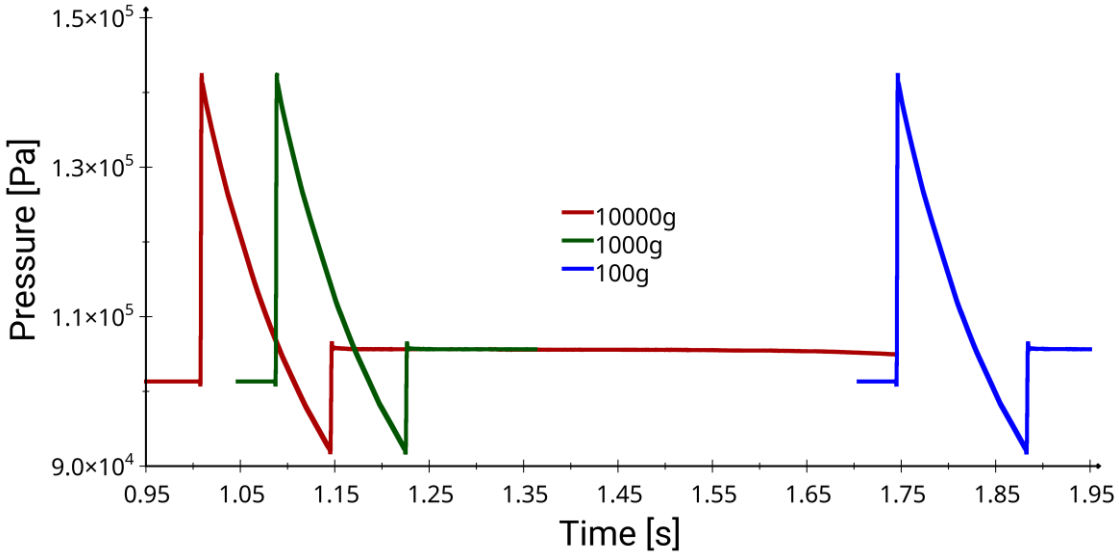

Figure 4: Pressure signal at coordinates $(30D, 135D)$ *associated with the passage of the shock-wave systems shown on each of the regular computational domains of Fig. 3.*

Summary

The numerical results show that the acceleration levels significantly influence the amplitude of the pressure fluctuations measured by a stationary observer positioned in the opposite direction to the movement of the cylinder (Fig. 2), at a distance $15D$ from its initial position. However, they also show that acceleration levels do not have any measurable influence on the intensity of pressure fluctuations measured by a stationary observer that is positioned, at a distance $15D$, in a direction that is orthogonal to the trajectory of the cylinder after it reaches Mach 5 (Fig. 4).

Keywords: Oblique Shock Reflection, Transition Criteria, SU2, Mach Stem

Abstract. We use a rectangular computational domain to study numerically the transition from regular to Mach reflection of oblique shock waves in steady The SU2 solver is used to solve the 2D Euler equation, where the desired shock conditions are obtained by imposing suitable boundary conditions. Results for the Mach stem height compare fairly well with those obtained on the conventional wedge geometry. Accurate Mach stem height requires a domain large enough to resolve the sonic throat.

Introduction

Oblique shock reflections are either regular reflections (RR) or irregular reflections (IR), further classified as Mach (MR), von Neumann (vNR), Guderley (GR) and Vasilev (VR) reflections [1]. Possible criteria for the transition between regular and Mach reflections are the detachment condition [2], the sonic condition [3], and the von Neumann condition [4]. RR can only exist below the detachment condition and MR only above the von Neumann condition. Both RR and MR are stable within the dual-solution domain. Identifying the correct transition point remains a challenge, but a length-scale criterion suggests that the sonic and the von Neumann conditions should be preferred, depending on the initial state of the flow [1].

Experiments conducted by Hornung and Robinson recorded transition at the von Neumann condition, supporting the length-scale principle [5]. Hysteresis effects, first discussed by Hornung et al. [3], were reproduced experimentally by Chpoun et al. [6]. Hysteresis was also observed in 2D numerical simulations, with the transition from RR to MR occurring at detachment, while the transition from MR to RR occurs closer to the von Neumann condition [7]. The discrepancy between numerical simulations and experiments lies in the strong three-dimensionality of the process. Small perturbations may also trigger the transition [8].

The geometry of the domain influences the transition and the shape of the reflection [9]. This study employs numerical simulations of oblique shock wave reflections to examine the transition in steady flows across different domain geometries and to define the optimal approach for obtaining consistent and reliable results.

Methodology

Euler 2D simulations were performed using SU2, an open-source CFD suite combined with the in-house adaptive mesh refinement tool Darwin. Unstructured triangular grids were generated using the in-house mesh software uhMesh.

The domain (Fig. 1) is rectangular: pre-shock inlet conditions are imposed on the left boundary, the bottom boundary is the symmetry plane where reflection occurs, while the right boundary is the outlet. The top boundary is divided into two segments: the shock is generated by imposing the post-shock state computed using the Rankine-Hugoniot jump conditions on the foremost segment (or gap); the aftermost segment is a wall.

Materials Research Proceedings 69 (2026) 217-220 https://doi.org/10.21741/9781644904251-38

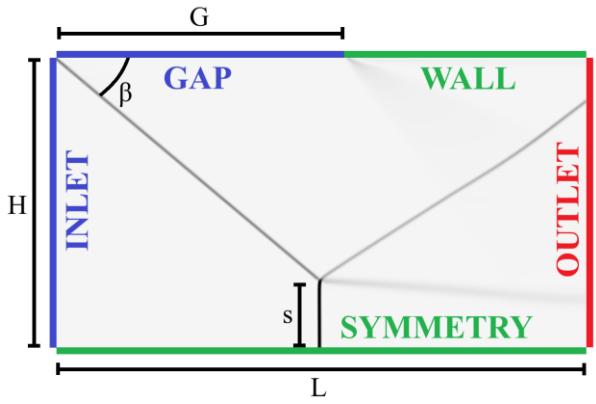

Figure 1: Numerical domain.

Table 1: Grid convergence.

Cell size h/H	Mach stem height s/H	Percentage variation
0.0100	0.223	–
0.0070	0.231	3.6
0.0050	0.238	3.0
0.0035	0.242	1.7
0.0025	0.244	0.8

The starting grid size is h/H = 0.05 as a balance between the advantage of better catching the transition at earlier steps of the iterations and the computational time. The mesh undergoes six levels of refinement. Mesh refinement is only used to assess the transition, but not when measuring the Mach stem height. In this case, a cell size of h/H = 0.005 is selected after performing a grid convergence study with parameters M_0 = 2.9, β = 40 deg, G/H = 1, reported in Table 1. Mach numbers range from 2 to 6, and incident shock angles from 31 degrees to 43 degrees.

Results

The simulation domain can be related to a corresponding configuration (Fig. 2) in which the shock is generated by the presence of a wedge by purely geometrical considerations, for any initial condition. In Fig. 3, a comparison of the normalized Mach stem heights in the two setups shows the expected agreement.

MR are not self-similar, thus requiring to define a length scale for a stable solution [8]. An expansion fan forms at the leading edge of the top wall and impinges on the slip line originating at the triple point of the MR. The region below the slip line behaves as a converging-diverging duct, selecting the required length scale [5]. The interaction of the expansion fan with the slip line can be controlled by changing the gap-to-height ratio, which is equivalent to changing the relative size of the wedge in the conventional configuration. As also observed by Bai [10], the Mach stem height is found to change linearly with the gap-to-height ratio as long as the fan does not interact with the incident shock, but uniquely with the reflected shock. The domain must be large enough to solve the sonic throat below the slip line to consistently predict the MR geometry (Fig. 4).

Conclusions

This numerical study investigates the transition of oblique shock reflections using a rectangular computational domain as an alternative geometry of generating the shock by imposing suitable boundary conditions. A constant number of elements between the symmetry plane and the wall is key to consistent, comparable results. This approach allows the use of fewer elements compared

Materials Research Proceedings 69 (2026) 217-220 https://doi.org/10.21741/9781644904251-38

to domains including wedges while preserving the overall number of cells when solving a wider range of initial conditions.

Reproducing accurate and reliable simulations can support theoretical findings, while also helping to predict the shape of shock reflections.

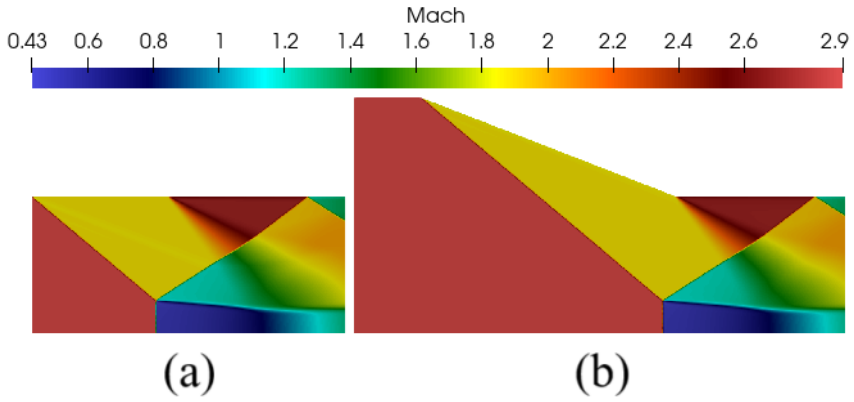

Figure 2: Rectangular domain (a) and corresponding domain with wedge (b) for M_0 = 2.9, β = 40 deg, G/H = 1.

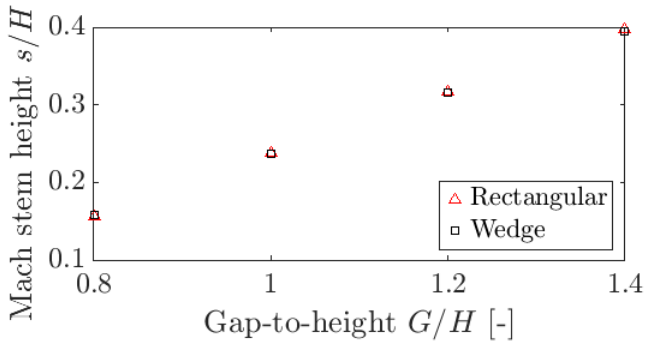

Figure 3: Comparison between the Mach stem height resolved in the rectangular domain and the domain with wedge (M_0 = 2.9, β = 40 deg).

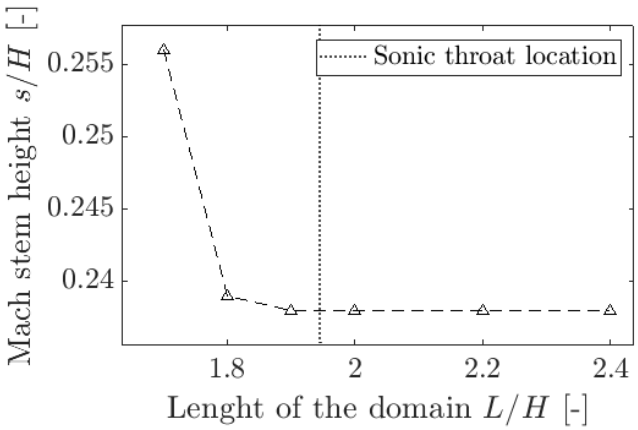

Figure 4: Mach stem height compared to the length of the domain. The height becomes constant only when the sonic throat is included inside the domain (M0 = 2.9, β = 40 deg, G/H = 1).

Abstract: This paper describes a novel use of the Matching Pursuit (MP) algorithm, originating in signal processing literature, in identifying aerodynamic coefficients as functions of wind and control surface deflection angles from Computational Fluid Dynamics (CFD) simulations results, as well as comparing MP to other commonly used methods of system identification. Due to the high number of variables that parametrise the aerodynamic coefficients of actuated airframes, traditional methods suffer from the so-called "curse of dimensionality", which requires a very large sample size for satisfactory identification. If the coefficient functions are known to be sparse in terms of an assumed function basis, MP lowers the number of samples needed to identify these coefficients down to a much more tractable size. As long as the function basis used is differentiable and continuous, the estimated coefficients will be as well, giving a form that is particularly convenient from a control system design perspective. The paper is structured as follows: the first section describes the definition of the problem. The second section details the Matching Pursuit approach in the context of identifying the aerodynamic forces and moments acting on a rigid body. The third section briefly states on traditionally used methods and how MP might perform better. Finally, MP is applied to CFD dataset obtained for canard-actuated sounding rockets created in collaboration of Attitude Control System Project of the PWr in Space Student Scientific Association with KTH Student Scientific Association Æsir under the UNITE! Program.

Introduction

Accurate knowledge of aerodynamic coefficients is essential for aircraft and flight control system design. These coefficients describe the relationship between aerodynamic forces and moments with respect to flight conditions and control inputs. However, due to the nonlinear nature of aerodynamic behavior, especially under real flight conditions, the precise estimation of these parameters remains a challenging and tedious task [1].

In this paper the algorithm called Matching Pursuit (MP) [2] is used for aerodynamic coefficient identification for canard-controlled student-built rockets . The analysis focuses on the accuracy and computational efficiency of the MP-based approach relative to the conventional least square estimation technique.

Problem definition

The objective of this study is to develop a sparse, continuous and differentiable representation of the aerodynamic coefficient functions for a rocket with movable canards. The model is based on a set of simulation data consisting of around 500 data points obtained from low- fidelity CFD simulations based on Spalart-Allmaras model [3, 4] that describes how input parameters affect aerodynamic forces and torques. Table 1 summarizes the input and output variables considered in the simulations.

Table 1: Summary of Input and Output Parameters

Symbol	Description	Units
Input Variables		
C_{zp}, C_{zm}, C_{yp}, C_{ym}	Canard deflection angles (pos./neg. Y,Z)	[deg]
M	Mach number	[-]
α	Angle of attack	[deg]
β	Sideslip angle	[deg]
Output Variables		
F_x, F_y, F_z	Aerodynamic forces (body axes)	[N]
T_x, T_y, T_z	Aerodynamic torques (body axes)	[N * m]

Figures 1 and 2 illustrate the rocket geometry and canard orientation in the *X-Z* and *X-Y* planes, respectively.

For the present analysis, the Mach number is assumed constant, as variations in M within the considered flight regime should have a limited influence on the relative trends of the aerodynamic coefficients. Furthermore, while the aerodynamic forces generated directly by canard deflections are negligible in comparison to those produced by the main rocket body, their contribution to the aerodynamic torques is significant due to the distance of the canards to the center of mass of the. Consequently, the focus is placed on accurately capturing the torque effects induced by canard motion, while the corresponding force variations are neglected.

In this work, we also restrict the identification to static aerodynamic coefficients. Modeling dynamic effects would require time-dependent simulations and substantially higher computational resources, which are beyond the current scope of this study and are left for future work [5].

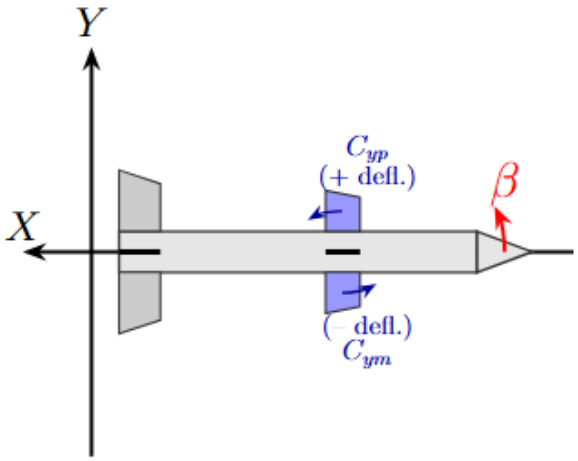

Figure 2: Rocket side view (X-Y plane)

Matching Pursuit for Aerodynamic Functions

In the MP framework, each aerodynamic coefficient function $f(x)$ (with x denoting angles and deflections) is treated as a "signal" to be approximated. We choose a dictionary $D = \{g_\gamma\}$ of smooth basis trigonometric functions. MP then proceeds by initializing the residual $R^0 f = f$ and iteratively selecting atoms that maximize the correlation with the residual. At iteration m, MP picks the atom g_{γ_m} satisfying

Materials Research Proceedings 69 (2026) 221-226 https://doi.org/10.21741/9781644904251-39

$$\gamma_m = \arg\max_{\gamma \in \Gamma} \left| \left\langle R^m f, g_\gamma \right\rangle \right|, \tag{1}$$

then updates the approximation via

$$f \approx \sum_{m=0}^{M} \left\langle R^m f, g_{\gamma_m} \right\rangle g_{\gamma_m}, \qquad R^{m+1} f = R^m f - \left\langle R^m f, g_{\gamma_m} \right\rangle g_{\gamma_m}. \tag{2}$$

This process is repeated until the residual norm is negligible or a maximum number of atoms M is reached. Variables used to construct atoms are described in table 2.

Table 2: Variable Definitions and Derived Parameters

Symbol	Definition	Description
Primary Variables		
a	α	Alpha angle (symbolic)
b	β	Beta angle (symbolic)
A	$\sqrt{\alpha^2 + \beta^2}$	Total angular magnitude
Derived Delta Parameters		
d_p	$\frac{C_{zp} + C_{yp} + C_{zm} + C_{ym}}{4}$	Average of all measurements
d_q	$\frac{C_{zp} - C_{zm}}{2}$	Half difference (Z-axis pair)
d_r	$\frac{C_{yp} - C_{ym}}{2}$	Half difference (Y-axis pair)

Because we use smooth, differentiable atoms, the fitted coefficient functions are themselves continuous and differentiable. In practice, MP was applied to CFD-generated force/torque dataset for rocket models. The algorithm produced very high R^2 fits for most force/torque components, yielding explicit series of trigonometric terms (see example table 3) that smoothly capture the input--output relationships. Thus MP provides a sparse, analytic model of the aerodynamics that is easy to evaluate and differentiate.

For this usage, the function dictionary D is constructed from a basis of trigonometric functions. A distinct dictionary is defined for each of the six aerodynamic coefficients (F_x, F_y, F_z, T_x, T_y, T_z), as each coefficient is modeled as a function of a different subset of the input variables defined in Table 2. For an aerodynamic coefficient f that depends on a set of d input variables, such as (α, β, A) for the force components, the dictionary is formed by the tensor product of one-dimensional function sets. For each variable x_k in the input set (e.g., $x_1 = \alpha$, $x_2 = \beta$, $x_3 = A$), we define a basis with a maximum frequency F_{max}:

$$B_k = \{1\} \cup \{\cos(j \cdot x_k)\}_{j=1}^{F_{max}} \cup \{\sin(j \cdot x_k)\}_{j=1}^{F_{max}} \tag{3}$$

The full dictionary D_f for the coefficient f is the set of all possible products where one function is chosen from each corresponding basis B_k:

$$D_f = \left\{ g(x) = \prod_{k=1}^{d} \phi_k(x_k) \;\middle|\; \phi_k \in B_k \right\} \tag{4}$$

To manage this large dictionary computationally, each atom $g_\gamma \in D_f$ is identified by a unique integer index γ. This index is mapped to a specific combination of trigonometric functions using a mixed-radix conversion, where the base is $b = 2F_{max} + 1$. This allows any atom in the high-

Materials Research Proceedings 69 (2026) 221-226 https://doi.org/10.21741/9781644904251-39

dimensional dictionary to be generated on-the-fly from a single integer, avoiding the need to store the entire dictionary in memory.

Traditional Identification Methods

The Least Squares (LS) method is one of the most frequently employed approaches for aerodynamic coefficient identification due to its simplicity and well-established statistical foundation. LS has been extensively used in estimating lateral–directional derivatives and other aerodynamic coefficients from various data [6, 7].

Despite these advantages, the LS method presents several limitations when applied to aerodynamic system identification. It relies on the assumption that the model structure is correctly specified and linear in its parameters—an assumption that may not hold for the inherently nonlinear aerodynamic phenomena observed in flight dynamics. Important limitation is that the classical LS formulation assumes error-free independent variables, an assumption that is rarely valid in practical flight-test scenarios, where sensor noise and measurement uncertainties can lead to biased parameter estimates [1, 7].

To address some of these shortcomings, the Matching Pursuit (MP) method offers an alternative perspective on coefficient identification. MP iteratively selects basis functions from a predefined dictionary to minimize the residual error at each step [2, 8]. Moreover, MP naturally promotes sparsity by retaining only the most relevant terms, which can enhance interpretability and prevent overfitting in complex aerodynamic models. Finally, its flexible dictionary structure allows for the inclusion of nonlinear terms, providing a more adaptable framework for capturing nonlinear aerodynamic effects compared to the strictly linear LS approach. Therefore, while LS remains an established baseline method, the MP approach may offer potential advantages in contexts where nonlinearity, collinearity, and measurement uncertainty limit the accuracy of traditional least-squares estimation.

Application of Matching Pursuit

Finally, MP is applied to CFD simulation data obtained for a canard-actuated sounding rocket created in collaboration with KTH Student Scientific Association Æsir under the UNITE! Program. The results from the function identification are visible in table 3 and figure 3.

Table 3: Calculated expressions for forces and torques

Component	Mathematical Expression	R^2
F_x	$0.23\cos\left(\sqrt{\alpha^2+\beta^2}\right)\cos(2\alpha)\cos(\beta)$	0.5014
F_y	$-7.6\,cos(\alpha)\sin(\beta)$	0.9725
F_z	$7.2\,cos(\beta)\sin(\alpha)$	0.9815
T_x	$0.018\,cos\left(8\sqrt{\alpha^2+\beta^2}\right)\cos(4\alpha)\sin(7\delta_p)$	0.4158
T_y	$-0.63\cos(4\beta)\sin(\alpha)-0.21\sin(2\delta_r)\cos(3\alpha)\cos(\beta)$	0.9535
T_z	$0.72\cos(3\alpha)\sin(\beta)+0.43\cos(4\beta)\cos(3\alpha)\sin(\delta_q)$	0.9700

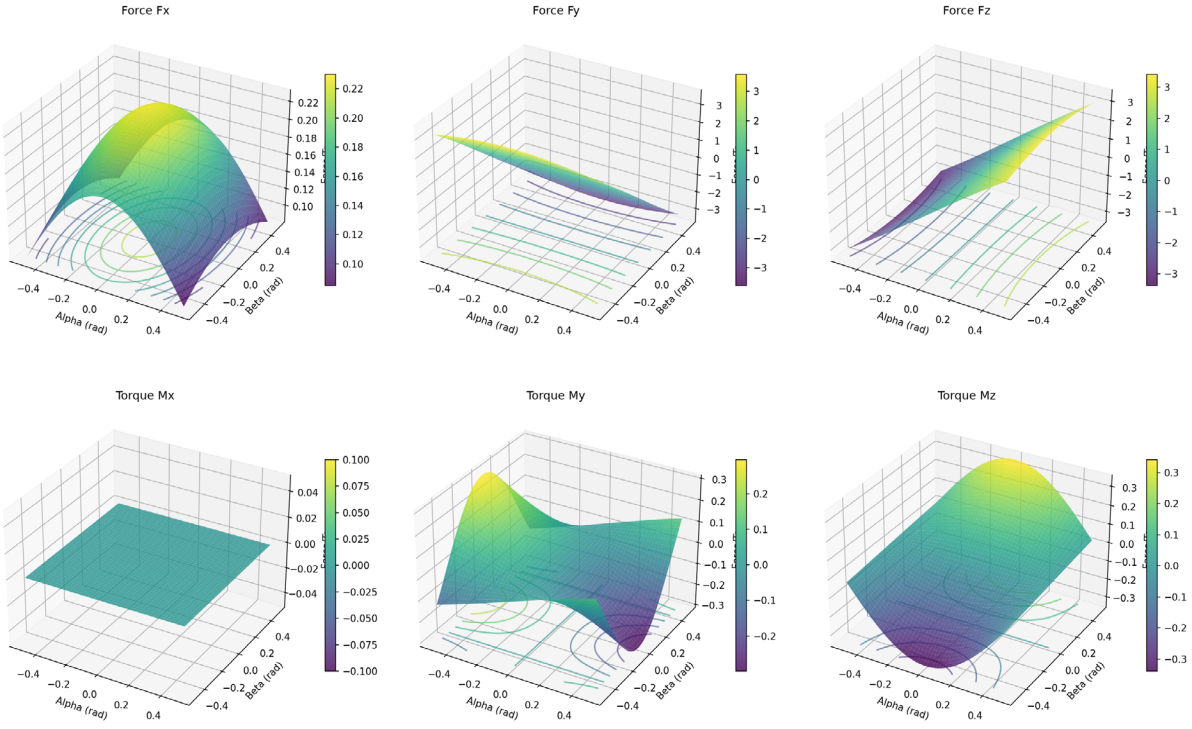

Figure 3: Aerodynamic coefficients visualization as functions of α, β for δ_p, δ_q, $\delta_r = 0$

Discussions

The preliminary results demonstrate that the Matching Pursuit (MP) framework is a promising approach for constructing aerodynamic coefficient functions. The method effectively identifies functions while maintaining interpretability and differentiability. However, further testing is required across a wider range of aerodynamic conditions and control settings. Future work should focus on expanding the dictionary to include a richer and more redundant set of basis functions, which may improve the accuracy and flexibility of the approximations.

Abstract. In many industrial applications, turbulent flow past bluff bodies separates, causing aerodynamic forces unsteadiness, structural vibrations, and noise. Wind tunnel experiments are commonly used to study wake dynamics, evaluate aerodynamic coefficients and perform spectral analyses. However, wind tunnel walls may significantly alter the wake topology, thereby leading to biased measurements. Predictive formulae for the effect of confinement are mainly available for simple bodies, such as circular and square cylinders. This study investigates the influence of wall confinement on the turbulent wake behind a missile-shaped airfoil using unsteady Reynolds-averaged Navier–Stokes (URANS) simulations. The analysis is performed at moderate Reynolds numbers and for various blockage ratios. Results show that drag, lift fluctuations, and shedding frequency all increase monotonically with blockage ratio. These findings extend previous observations on laminar confined wakes to turbulent bluff-body wakes, underscoring the importance of designing proper wind tunnel experiments.

Introduction

Flow unsteadiness behind bluff bodies is a critical issue in aerospace applications, as the shedding of vortical structures can affect vehicle performance, structural integrity, and generate acoustic emissions. Those phenomena are often the effects of vortical structures generated in the separated region behind the body. Numerous passive and active flow-control strategies have been proposed, whose design requires accurate knowledge of the characteristic frequency and spatial pattern of the wake structures.

Wind tunnel experiments have been the main source of knowledge about separated flows behind bluff bodies. However, the physical significance of those studies may be questioned when the separated flow dynamics is strongly influenced by the bounding walls of the test section. As demonstrated in [1], lateral walls can strongly affect experimental measurements, as confinement modifies both the mean flow topology and the large-scale wake dynamics. Moreover, blockage effects may alter vortex shedding frequencies, distort aerodynamic forces, and even promote coherent structures that are absent in unconfined conditions. Those long standing issues have been the object of several studies, as recently reviewed by [2].

Extensive studies have been performed for canonical geometries such as circular [3, 4, 5] and square [6, 7, 8] cylinders. Those studies span a very wide range of flow conditions, from very low-Reynolds number laminar flows, to subcritical/supercritical turbulent flow regimes. All those studies do recognize a strong effect of blockage on aerodynamic coefficients and their characteristic frequency (which is properly scaled to form a non-dimensional group, known as Strouhal number). By contrast, other geometries as elongated or rectangular bluff bodies have received less attention, despite their relevance for practical aerodynamic design. Addressing the lack of research on this topic may be particularly important because accurate wind tunnel measurements must account for confinement effects while still satisfying similarity laws.

Materials Research Proceedings 69 (2026) 227-232 https://doi.org/10.21741/9781644904251-40

In this study, unsteady Reynolds-averaged Navier–Stokes (URANS) simulations are em ployed to characterize the influence of wall confinement on the turbulent wake past a D shaped cylinder in subcritical conditions. Fully resolved simulations as direct numerical simulations or wall-resolved large eddy simulations would be computationally prohibitive, and dedicated experimental facilities quite demanding. In this sense, URANS computations provide a low-fidelity tool, able to obtain the unsteady distributions of drag and lift coeffi cients in relatively short time and with good accuracy. Blockage ratio, defined as the ratio between the thickness of the body and the wind tunnel crosswise width, is varied between 2% and 25%. The present study allows a systematic assessment of confinement effects in turbulent bluff-body wakes and provides insights for the design and interpretation of wind tunnel experiments. Specifically, we aim at investigating confinement effects on the time averaged value of the drag, lift fluctuations variance, and Strouhal number.

Methodology

The two-dimensional turbulent wake behind a thick flat plate in a confined wind tunnel is numerically analyzed by means of URANS simulations. The flow configuration under study is sketched in Fig. 1. It consists of an elongated D-shaped cylinder with aspect ratio $A = c/H = 10$, where *c* is the chord length and *H* is the trailing edge thickness. The longitudinal axis of the body lies along the mid-plane of a two-dimensional plane channel. The leading edge of the body is rounded in the form of a semi-ellipse, transitioning into a thick flat plate that terminates with a blunt trailing edge. This setup mimics the longitudinal mid-plane of a wind tunnel configuration, where the test model spans the full tunnel width in the spanwise direction.

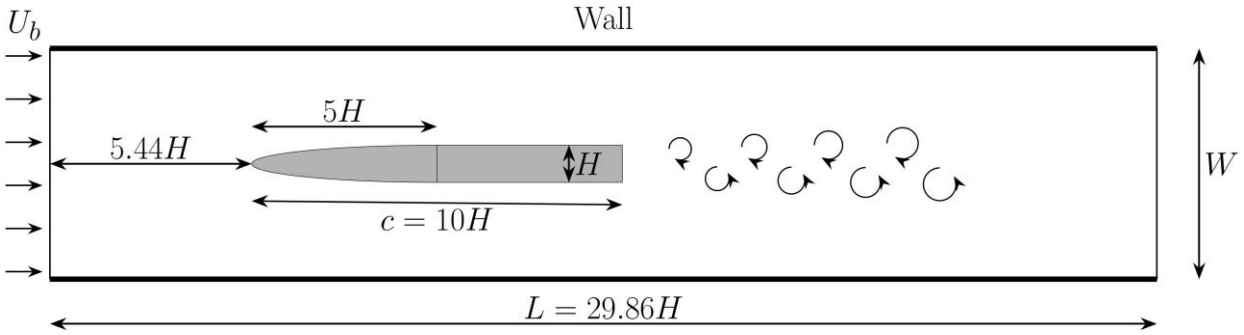

Figure 1: Sketch of the numerical setup and main notation used in this study.

The computational domain extends for a $L = 29.86H$ length in the streamwise direction, while the transverse width W is varied to analyze blockage effects. The plate leading edge is placed $5.44H$ downstream from the inflow section, where a uniform velocity profile is imposed. The governing equations considered in this work are the incompressible Navier-Stokes equations, made dimensionless using the bulk velocity U_b and the plate thickness H. This configuration is completely characterized by two non-dimensional parameters, namely the Reynolds number $Re = U_b H/\nu$ and the blockage ratio $B = H/W$. A fixed Reynolds number of $Re = 32000$ is considered in this work, with blockage ratios varying in the range $2\% < B < 25\%$ ($W/H \in [4,50]$). The present numerical setup allows direct comparison with the previous work [9], which investigated the same configuration, at the same Reynolds numbers for a single blockage ratio $B \approx 0.16$.

Simulations are performed with the OpenFOAM solver *pimpleFoam* [10] using the $k-\omega$ SST model [11]. Body-fitted meshhed are generated with the native OpenFOAM mesher *snappyHexMesh*. Fig. 2 shows the numerical mesh used to investigate the confined flow at $B = 0.16$. The figure highlights the wake refinement and the prismatic layers introduced on the body and the wind tunnel lateral walls. Near-wall mesh clustering ensures resolutions of $y^+ \approx 1$ on the

Materials Research Proceedings 69 (2026) 227-232 https://doi.org/10.21741/9781644904251-40

lateral walls and $y^+ \approx 0.5$ on the body. Within this framework, governing equations are spatially discretized using second-order schemes for p and U, whereas turbulent quantities are discretized using first-order upwind schemes. Time integration is performed with a second-order implicit scheme. Pressure-velocity coupling is handled with the PIMPLE algorithm, which merges the SIMPLE (semi-implicit method for pressure linked equations) and PISO (pressure implicit with split operator) [12]. At the inlet, a uniform velocity is prescribed, whereas the turbulent variables are obtained by fixing the inflow turbulence intensity to 2%.

The main output of the work ist o quantify blockage effects on the aerodynamic force coefficients, namely the aerodynamic drag coefficient $C_D = 2D/(\rho U_B^2 H)$ and the aerodynamic lift coefficient $C_L = 2L/(\rho U_B^2 H)$. Those quantities are obtained as the projection oft he aerodynamic force along the x and y axes. In this work, we mainly refer to the time-averaged drag coefficient $\overline{C_D}$, the lift coefficient root-mean square C_L' and their characteristic Strouhal number $S_t = fH/U_b$. The aerodynamic coefficients are sampled once the flow have reached a saturated vortex-shedding regime, and the Strouhal number is obtained as the peak of the lift frequency spectra.

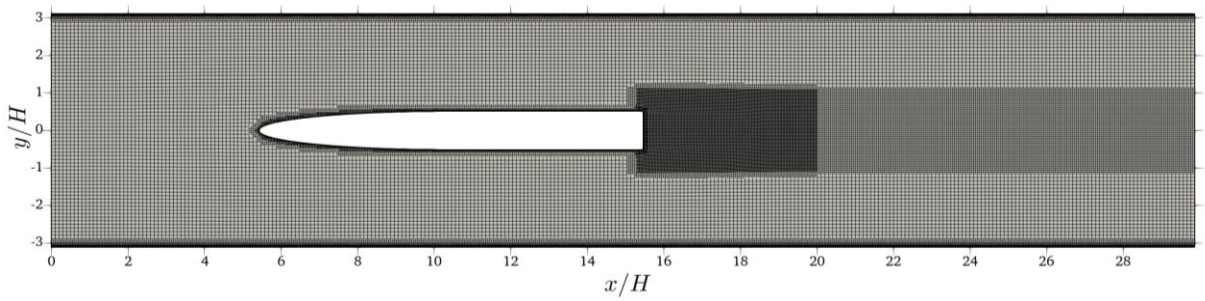

Figure 2: Mesh employed for the numerical analysis. Blockage ratio B=0.16.

Results

Fig. 3 shows the variation of the mean drag coefficient $\overline{C_D}$, with blockage ratio. We can distinguish two different trends as B is increased. For low blockage ratios ($B < 0.04$), $\overline{C_D}$ remains nearly constant. Outside of this range, the drag coefficient start deviating from its unconfined value, with an increasing slope as B increases. The present trend appears to be in very good agreement with the previous simulation by [9] in the same flow conditions.

The difference between the confined and the unconfined drag coefficient value exceed 3% for $B > 6\%$. Similar results have been reviewed by [2] for circular and square cylinders in both laminar and turbulent regimes. Hence, the present geometry appears to follow the same trend shown in those cases. However, for the thick D-shaped plate the viscous contribution to $\overline{C_D}$ should be larger than in the circular cylinder case making a direct quantitative comparison non readily available.

Materials Research Proceedings 69 (2026) 227-232 https://doi.org/10.21741/9781644904251-40

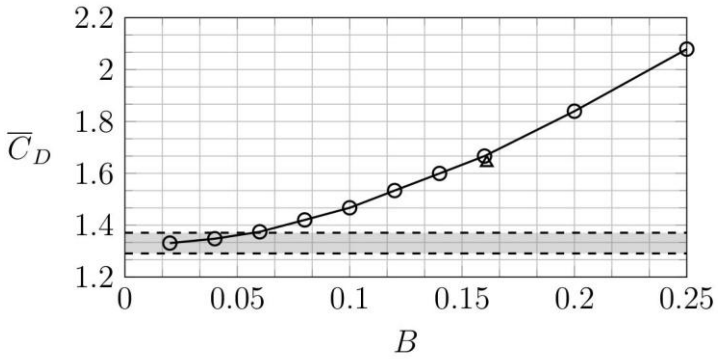

Figure 3: Time-averaged drag coefficient as function of blockage ratio B. Dashed lines represent ±3% difference band with respect to $\overline{C_D}$ at B=0.02. A triangle mark denotes the URANS results by [9] at B=1/6.2.

Fig.4 shows the standard deviation of the lift coefficient, C_L', which quantifies the intensity of unsteady lift fluctuations induced by vortex shedding, as a function of the blockage ratio B. For small blockage ratios $B < 0.04$, the variation of fluctuating lift coefficient remains weak, whereas at higher blockage ratios the growth becomes stronger, reflecting the increasing influence of wall confinement. The growth is monotonic, indicating that confinement amplifies the strength of the periodic vortex shedding, thereby increasing the unsteady aerodynamic loads on the body. This result is in very good agreement with turbulent wakes at subcritical Reynolds number (as reported in [2]) and, as expected, in contrast with laminar wakes and turbulent wakes in supercritical conditions.

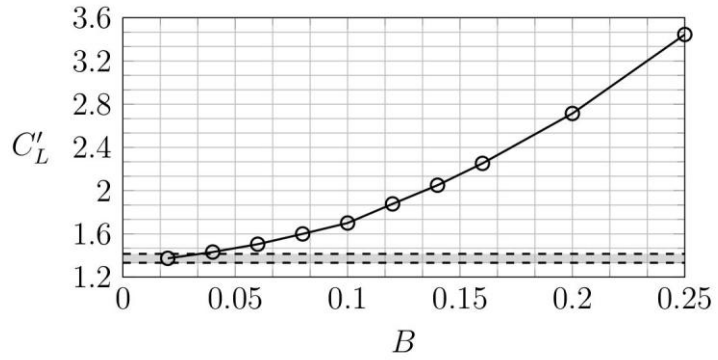

Figure 4: Lift coefficient root-mean-square C_L' as a function of blockage ratio B. Dashed lines represent ±3% difference band with respect to C_L' at B=0.02.

The dependence on B of the Strouhal number St is illustrated in Fig.5. The value of the Strouhal number is in excellent agreement with the experimental value found by [9] using particle image velocimetry (triangle mark in Fig.5). The present results show that St increases monotonically with B. Specifically, for very low blockage ratios $B < 0.1$, St is weakly influenced by confinement, consistent with observations summarized in [2]. The overall observed trend in Strouhal number well conforms with previous findings from circular and square cylinders in both laminar and turbulent regimes.

Finally, Fig. 6 shows an instantaneous snapshot of the vorticity field for $B = 0.16$. The classical vortex shedding is still visible, however their trajectory is closer to the x axis if compared with unconfined flow. A large amount of vorticity is also observed next to the wind tunnel walls, which is connected to boundary layer thickening and instantaneous lift-off of fluid from the near-wall region.

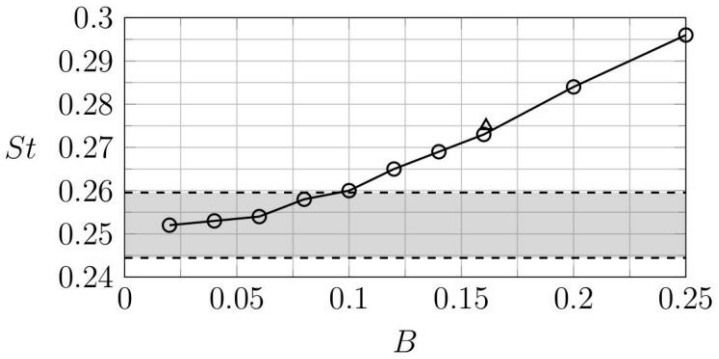

*Figure 5: Stouhal number as a function of blockage ratio **B**. Dashed lines represent ±3% difference band with respect to St at B=0.02. The triangle marker reports the experimental value of the Strouhal number obtained by [9].*

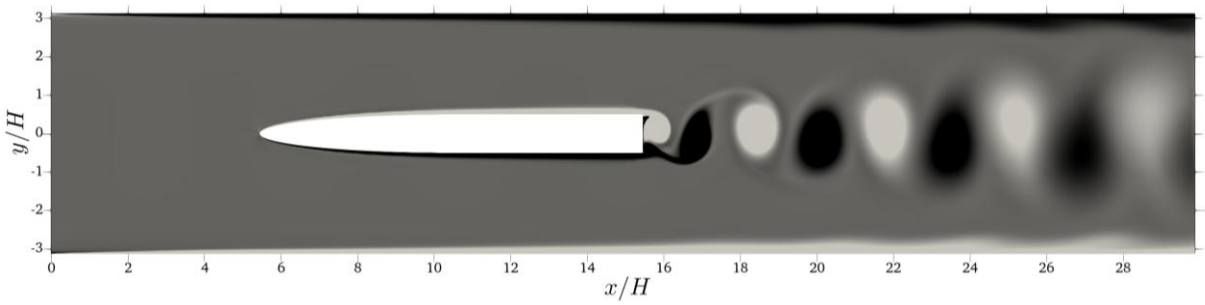

Figure 5: Instantaneous snapshot of flow vorticity for the B=16% case (extrema of the color map are 1.5, black and -1.5, white).

Conclusions

The present study quantified the influence of wall confinement on the turbulent wake past a missile-shaped airfoil using URANS simulations. The mean drag coefficient, lift coefficient and fluctuations, and Strouhal number all increase monotonically with blockage ratio. For low blockage ratios ($B < 0.1$), mean drag and shedding frequency remain within a $\pm 3\%$ band, indicating negligible confinement effects. At higher blockage ratios ($B > 0.1$), the aerodynamic coefficients and Strouhal number are markedly affected by the wind tunnel walls. These results provide a practical reference for estimating the influence of confinement in wind tunnel experiments of non-canonical bluff bodies in turbulent channels.

Abstract. The present study addresses the numerical simulation of wall-bounded flows with thermally perfect gases using structure-preserving spatial discretizations. The supersonic turbulent boundary layer and channel flow are chosen as numerical flow cases to highlight the differences with respect to the widely used calorically perfect gas model when relatively high temperature ranges are present. Specifically, we compare literature results obtained for air flows with the ones carried out for carbon-dioxide, which is likely to be treated as a thermally perfect gas in high-temperature cases. Results show non-negligible physical differences with the reference cases, and the numerical treatment of the convective terms of the integrated equations is taken into account as well.

Introduction

Supersonic wall-bounded flows are among the most extensively studied physical configurations and encompass a wide range of applications, including the aerodynamics of supersonic and hypersonic vehicles, aerospace propulsion and aerothermal heating and heat transfer. In most applications, when the working fluid is air, it is well known that the calorically perfect (CP) hypotheses hold, up to negligible differences, in a wide range of Mach numbers, even when strongly diabatic walls are studied [1]. However, dependency of specific heat capacities on temperature becomes relevant when chemical species with several thermodynamic degrees of freedom are considered; for instance, the case of carbon-dioxide represents a fitting example of a nonpolar molecule whose heat capacities strongly vary within temperature, and it is widely studied for applications like atmospheric re-entry. In this context, Direct Numerical Simulations (DNS) represent a powerful and reliable tool when it comes to build a physical understanding of configurations with severe thermo-fluid dynamic conditions, especially within an *ad hoc* numerical treatment of the discretized equations that aims to consistently represent important properties and symmetries of the continuous system also in the discrete framework [2]. In this work, computations of high-speed wall bounded flows are carried out with thermally perfect (TP) gas laws in the open-source, GPU-accelerated code STREAmS 2.1 [3]. We consider both channel flows and turbulent boundary layer, with the latter case being compared with the literature results in [1].

Organization of the Text

The three-dimensional Navier-Stokes equations are solved for a viscous, heat-conducing, Newtonian fluid

$$\partial_t \rho + \partial_{x_j}(\rho u_j) = 0 \tag{1}$$

Materials Research Proceedings 69 (2026) 233-238 https://doi.org/10.21741/9781644904251-41

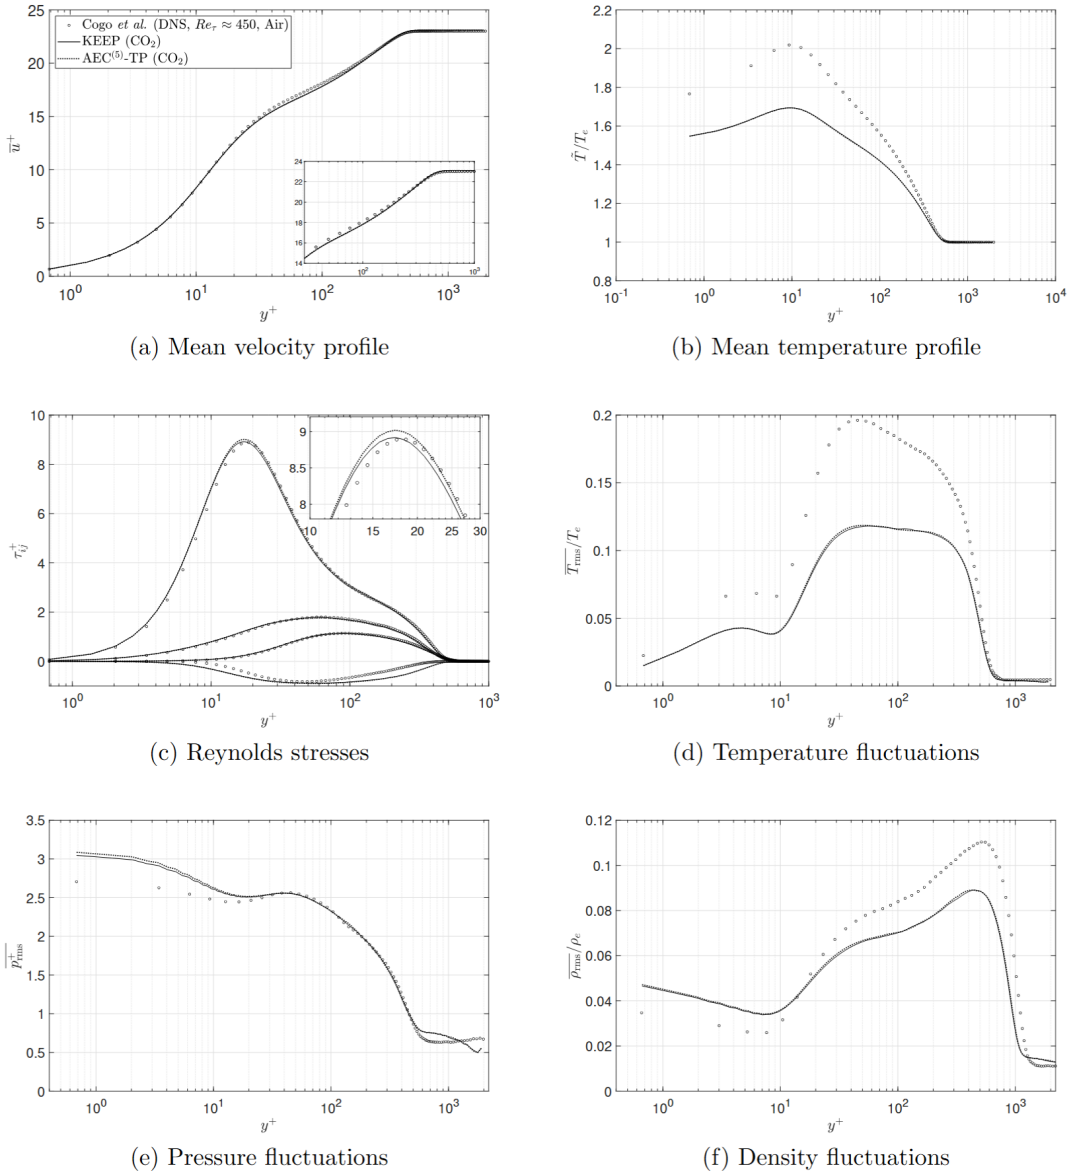
$$\partial_t(\rho u_i) + \partial_{x_j}\left(\rho u_j u_i + p\delta_{ij}\right) - \partial_{x_j}\tau_{ij} - f_1\delta_{i1} = 0 \quad (2)$$

$$\partial_t(\rho E) + \partial_{x_j}\left(\rho u_j H\right) - \partial_{x_j}\left[\left(u_j\tau_{ij} - q_j\right)\right] + \Phi - f_1 u_1 = 0 \quad (3)$$

with ρ the density of the fluid, u_i the Cartesian components of the velocity field, p the thermodynamic pressure, $E = e + u_i u_i/2$, the total energy and $H = E + p/\rho$ the total enthalpy. The standard constitutive relation are assumed for the dissipative part of the stress tensor $\tau_{ij} = \mu\left(\partial_{x_j}u_i + \partial_{x_i}u_j - 2/3\ \partial_{x_k}u_k\delta_{ij}\right)$, and the heat flux $q_j = -k\partial_{x_j}T$. Dynamic viscosity μ depends on temperature according to the Sutherland's law, whose general expression is $\mu/\mu_e = (T/T_e)^{1/2}(1 + C/T_e)/(1 + C/T)$, and it is linked to the thermal conductivity $\mu c_p\ /Pr$, with C the Sutherland's constant and the subscript "e " to indicate the asymptotic conditions. Finally, $T_e = 298.15$ K and Prandtl number is $Pr = 0.72$. The production terms Φ, f_i will only be taken into account to simulate compressible channel flows with a constant bulk temperature and mass flow rate. The system is closed upon specification of the equation of state $p = \rho RT$ and the relation that links internal energy to intensive thermodynamic variables, which, for thermally perfect gases, takes the form $de = c_v(T)dT$. Given the Mayer's relation $c_p - c_v = R$, the functional law for $c_v(T)$ is assumed from the 7-coefficient polynomial fittings of the NASA Glenn Coefficients [4].

Numerical treatment of the system of equations Eqs. (1) - (3) is carried out in a semi-discretized framework, where the spatial discretization enforces the Kinetic-Energy Preserving (KEP) property for all the compared simulations, such that the total energy equation is represented by the sum of the contributions of the (induced) kinetic energy and internal energy [2,5]. Additionally, a novel Entropy-Conserving (EC) formulation is considered [6], where the internal energy equation is discretized to ensure exact entropy-conservation by convection, that is no spurious contributions occur from the convective terms for interior points.

Given this background, Tab.1 reports the physical parameters and the computational setup for the presented simulations. The viscous scaling is given by the standard definitions $\delta_v = \nu_w/u_\tau$, $u_\tau = (\tau_w/\rho)^{1/2}$, with the subscript "$w$ " denoting conditions at the wall. Thus, we have$\Delta x^+ = \Delta x/\delta_v$ and $\Delta z^+ = \Delta z/\delta_v$, which are discretized with evenly-spaced points, and $\Delta y^+ = \Delta y/\delta_v$ clustered near the walls. To generate a turbulent inflow for the boundary layer case, the recycling-rescaling procedure in STREAmS is employed, setting the recycling plane at $x_{rec} = 80\delta_{in}$. Profiles and statistics are computed at $Re_\tau = \delta/\delta_v \approx 450$ with δ being the boundary layer thickness, to carry out the comparison with the results in [1]. On the other hand, the supersonic channel flow case is performed at a constant mass flow rate and enabling the cooling term Φ in total energy equation to keep the bulk temperature constant. As far as it concerns notations, we use the symbol $\overline{\phi}$ to denote the both in time and in spanwise direction - assuming homogeneity along z -direction itself- while the Favre averaging will be denoted as $\tilde{\phi} = \overline{\rho\phi}/\overline{\rho}$ for which we denote $\phi = \tilde{\phi} + \phi''$ instead of the standard Reynolds' decomposition.



Materials Research Proceedings 69 (2026) 233-238 https://doi.org/10.21741/9781644904251-41

Table 1: *Indication of the main flow and computational parameters for supersonic boundary layer at $M_e = 4.0$ (BLM4) and supersonic channel flow at $M_b = 2.0$ (CFM2). The definitions for the Mach numbers employed are $M_e = U_e/\sqrt{\gamma_e R\, T_e}$ and $M_b = U_b/\sqrt{\gamma_b R T_b}$. Recovery temperature, T_r, is likewise derived from the isentropic relations $T_r/T_e = 1 + rM_e^2(\gamma_e - 1)/2$ for the boundary layer case and, dually, $T_r/T_b = 1 + rM_b^2(\gamma_b - 1)/2$ for the channel flow case, with $r = P\, r^{1/3}$ the recovery factor. Finally, h is the half-height of the channel.*

CFM2–TP	CH_4	2.0	215	0.36	$4\pi h$	$2h$	$2\pi h$	7.6	0.4	3.8

Results and discussion

Fig.1 shows both velocity and temperature profiles, where the TP case is carried out with both the built-in "KEEP" discretization in STREAmS, EC for ideal gases only, and the EC formulation specifically designed for TP gases. Inner-scaled velocity profiles present an upward shift with respect to the incompressible log-law, which is due to the combined effects of compressibility and heat transfer at the wall. On the other hand, Fig.1(b) shows that air and CO_2, given the same asymptotic conditions, produce remarkably different temperature distributions. Specifically, higher values of c_p lead to smaller temperature variations. The region associated to larger $\partial_y T$ is indeed the one that better highlights the effects of the variable $c_p(T)$. Looking at Fig.1(b)-(d), the logarithmic layer and the buffer layer are the ones that exhibit the strongest deviation from the ideal gas behaviour, especially in temperature fluctuations, whose peaks appear to largely differ. Density fluctuations behave similarly, while pressure fluctuations have also been reported, showing higher values for the TP case around 15 % at the wall. As far as it concerns the role of the numerical discretization, the KEEP scheme and the Asymptotically Entropy-Conserving (AEC) [7] only differ in the treatment of the energy equation, and research is ongoing to understanding the impact on the final results, already observed for higher-order statistics. To check the generality of the previous results, we observe that similar trends are found for the channel flow case, although both physical and computational parameters are different. This time we carry out a comparison with the same chemical specie, once modelled as a CP gas and once as a TP gas. For the CP test, γ is evaluated at bulk temperature and kept constant. Results are shown in Fig.2, with the same definitions for scaling described in Fig.1. Given the more extreme cold wall conditions considered for the channel flow, the higher variation of $c_p(T)$ for methane and the lower Reynolds number, differences between the two gas models are emphasized in this case, still holding the same trend shown for the boundary layer simulations. A final, noteworthy observation addresses the effect of the heat capacities on the skin friction coefficients, defined as $c_f = 2\overline{\tau_w}/(\rho_e U_e^2)$ - for boundary layer, $\rho_b U_b^2$ used for channels instead - and the heat transfer coefficient $B_q = \overline{q_w}/\overline{\rho_w} c_p u_\tau T_w$.

Figure 2. T*hermo-fluid dynamic profiles for the supersonic channel flow. Scalings are performed with* $\gamma_b = \gamma(T_b)$ *to standardize comparisons between the two different thermodynamic models. Friction Mach number is defined, as usual, as* $M_\tau = u_\tau/(\gamma_b R T_w)$.

While we have not identified a general behaviour for the first one yet, exhibiting a variation with respect to the CP case within a range of ± 10 % in the second one tends to be closer to zero for higher values of $c_p$at the wall, consistent with the linear relation between the heat flux and the temperature variation, $\delta q = c_p dT$. Further research is however required to characterize both the physical and the numerical aspects of new thermodynamic frameworks.

Summary

We have presented simulations of wall-bounded supersonic flows using thermally perfect gas models and an *ad hoc* numerical formulation implemented in highly scalable GPU-based codes. Such results have been compared with the classical calorically perfect gas cases. Significant physical differences were observed, indicating that the calorically perfect gas assumption proves too restrictive in such configurations. Further research is ongoing to achieve improved modeling and numerical characterizations.

Abstract. Structure-preserving schemes have emerged as a powerful tool for simulating compressible, wall-bounded turbulence, offering improved robustness and physical fidelity. By preserving key invariants—such as kinetic energy and entropy—at the discrete level, these methods enhance numerical stability and accuracy in challenging flow regimes. This work evaluates the performance of a high-order, GPU-accelerated solver employing entropy-conservative and kinetic-energy-preserving fluxes in DNS and LES of turbulent boundary layers. Results demonstrate improved alignment with benchmark data and highlight the potential of structure-preserving schemes in capturing complex interactions between compressibility, turbulence, and wall effects in high-fidelity simulations.

Introduction

The numerical simulation of turbulent compressible flows plays a pivotal role in advancing aerospace engineering and fluid dynamics. These flows are characterized by complex interactions between turbulence, compressibility effects (such as shock waves and acoustic propagation), and wall-bounded behavior, posing challenges for computational modeling. Despite significant progress in computational power, reliably capturing such phenomena remains difficult due to the combined effects of high computational cost, numerical instability, and the need for physical accuracy. The recent availability of high-performance computing (HPC) platforms, including GPU-based architectures, has enabled more detailed simulations such as Direct Numerical Simulation (DNS) and Large Eddy Simulation (LES), making it increasingly feasible to study these flows with high fidelity.

A critical element in the successful simulation of compressible turbulence is the choice of numerical scheme, particularly in the discretization of convective fluxes. Classical methods may introduce spurious dissipation or numerical artifacts that compromise the physical accuracy of the solution. In response, several structure-preserving schemes have emerged. Kinetic Energy Preserving (KEP) schemes aim to retain the divergence structure of the convective term in the kinetic energy equation, thus enhancing robustness and suppressing unphysical energy growth [1]. Entropy Conservative (EC) schemes take this further by preserving entropy at the discrete level through non-linear flux formulations, although this often comes at the expense of higher computational cost. To mitigate this, research has explored low-cost asymptotic approximations [2]. Additionally, Pressure Equilibrium Preserving (PEP) methods are designed to suppress spurious pressure oscillations—an issue that can be critical in shock-dominated or multi-physics scenarios [3]. Despite extensive theoretical development, the application of these schemes to realistic wall-bounded flows remains relatively limited in the engineering community.

This study investigates the impact of structure-preserving numerical schemes, including KEP, EC, and PEP methods, on the LES of turbulent, compressible, wall-bounded flows. Unlike prior

works, focused primarily on theoretical benchmarks, the present analysis emphasizes practical application in large-scale simulations using GPU-accelerated solvers over a spatial developing turbulent boundary layer, a canonical configuration that represent the prototype of all external and internal aerodynamics problems. We demonstrate that these schemes improve the accuracy of turbulence statistics and reduce numerical artifacts, particularly for those associated with thermal quantities and in coarse-grid LES regimes where the scheme behavior strongly influences the solution. Thus, results confirm that high-order, structure-preserving discretizations play a critical role in enhancing both the reliability and predictive power of compressible turbulence simulations.

The remainder of the paper is organized as follows. Section *Theoretical Background* introduces the minimal theory illustrating structure-preserving schemes. Section *Numerical setup and computational results* summarizes the main findings while Section *Conclusions* states the conclusive remarks.

Theoretical Background

The discretization of compressible flow equations requires particular attention to the convective terms, which play a crucial role in ensuring the physical fidelity and numerical stability of the solution. The general convective term in compressible Navier-Stokes equations takes the form

$$\mathsf{C}_{\rho\phi} = \frac{\partial \rho u_i \phi}{\partial x_i}, \tag{1}$$

where ϕ is 1, u_j or E in the mass, momentum or total energy equations, respectively. A typical discretization for compressible flows requires that convective terms in Eq. 1 are expressed as a difference of numerical fluxes, i.e. in the form

$$\mathsf{C}^{i}_{\boldsymbol{\rho\phi}} = \frac{\mathbf{1}}{\boldsymbol{\Delta x_i}}\left(\boldsymbol{\mathcal{F}}^{\boldsymbol{i+\frac{1}{2}}}_{\boldsymbol{\rho\phi}} - \boldsymbol{\mathcal{F}}^{\boldsymbol{i-\frac{1}{2}}}_{\boldsymbol{\rho\phi}}\right), \tag{2}$$

where $\mathcal{F}_{\rho\phi}$ denotes the numerical flux across control volume interfaces. When the discretization of the convective term $\mathsf{C}_{\rho\phi}$ can be expressed as in Eq. 2, the quantity $\rho\phi$ is globally preserved by convection, and the divergence structure of Eq. 1 is mimicked at discrete level. However, preserving this structure in the continuity, momentum, and total energy equations does not automatically guarantee numerical robustness or accuracy. Particular attention must also be devoted to the conservation of derived physical quantities, such as kinetic energy, pressure, and entropy.

The kinetic energy balance in the inviscid limit is expressed as

$$\frac{\partial(\rho u_i^2/2)}{\partial t} + \frac{\partial(\rho u_j u_i^2/2)}{\partial x_j} + u_j \frac{\partial p}{\partial x_j} = 0, \tag{3}$$

which again exhibits a convective term in the conservative form of Eq. 1. To automatically retain this structure at the discrete level, it can be shown that a coordinate specification of the fluxes in mass and momentum equations is required. In particular, the numerical flux in the momentum equation should have the form [4]

$$\mathcal{F}_{\rho u} = \mathcal{F}_{\rho}\bar{u}, \tag{4}$$

Materials Research Proceedings 69 (2026) 239-243 https://doi.org/10.21741/9781644904251-42

where $\bar{u} = (u_i + u_{i+1})/2$ is the arithmetic mean and $\mathcal{F}_\rho$ is the mass flux. Schemes satisfying Eq. 4 are referred to as *Kinetic Energy Preserving* (KEP), and are known to improve the stability and robustness of scale-resolved simulations [1].

Another important property is the *Pressure Equilibrium Preserving* (PEP) condition, which ensures that initially uniform pressure and velocity fields remain unaltered during the evolution; an analytical property of the compressible Euler equations allowing the existence of traveling density-wave solutions. Violation of the PEP condition at discrete level can lead to the emergence of spurious pressure waves and nonphysical behavior. As discussed in [3], if the pressure equation is discretized in place of the total energy equation, this property is naturally satisfied. When total or internal-energy equations are employed, a more complex compatibility condition between the fluxes in mass and internal energy equations needs to be satisfied.

A third desirable property is that of *Entropy Conservation* (EC), which is particularly relevant in the context of under-resolved compressible turbulence. In the inviscid limit, the entropy equation reads

$$\frac{\partial \rho s}{\partial t} + \frac{\partial \rho u_j s}{\partial x_j} = 0, \tag{5}$$

where $s = \log(p/\rho^\gamma)$ for a calorically perfect gas. The nonlinear nature of this relation poses challenges for the design of discretizations that satisfy Eq. 5 at the discrete level. One possible strategy relies on the use of logarithmic means in the definition of fluxes [5]. However, despite their theoretical appeal, these flux formulations are computationally expensive due to the evaluation of transcendental functions. To reduce computational cost, alternative schemes have been proposed that replace the logarithmic mean with truncated series expansions, achieving *Asymptotic Entropy Conservation* (AEC) with significantly lower computational overhead [2,3]. These formulations preserve the leading-order entropy consistency while maintaining compatibility with the KEP and PEP frameworks. Their low-cost implementation makes them particularly attractive for high-fidelity simulations, including DNS and LES, of compressible wall-bounded turbulence.

Table 1 provides a selection of some popular and more recent structure-preserving schemes available in the literature and tested in this paper. All the formulations have numerical fluxes calculated by using only algebraic operations, and satisfy the Kinetic Energy Preserving (KEP) property. The recently proposed AEC schemes are also PEP and recovers the EC property in the limit $N \to \infty$. The schemes in Table 1 are recalled and analyzed in [2] and [3], where the references to the original papers can also be found.

In Table 1, the notation is as follows: $\bar{\phi}^H = \phi_i \phi_{i+1}/(2\bar{\phi})$ denotes the harmonic mean and the hat operator is defined as $\hat{\phi} = \delta\phi/(\phi_{i+1} + \phi_i)$. The symbol $\overline{\overline{\phi\psi}} = (\phi_i\psi_{i+1} + \phi_{i+1}\psi_i)/2$ denotes the product mean associated with the advective formulation $\phi\partial\psi + \psi\partial\phi$ [4]. In the scheme definitions, N indicates the order of the truncated series expansion, while $\mathcal{F}^*_{\rho E}$ refers to the total energy flux including the (conservative) pressure contribution.

Numerical setup and computational results

To evaluate the impact of structure-preserving schemes on the prediction of thermal and dynamic quantities in compressible wall-bounded turbulence, we perform WRLES of a supersonic boundary layer at $M_\infty = 2$ using the GPU-accelerated solver URANOS [6,7]. Turbulent inflow conditions are generated at $Re_{\tau,0} = 450$ and statistics are collected downstream where $Re_\tau = 840$. The domain size is $L_x \times L_y \times L_z = (150 \times 10 \times 10)\delta_0$, discretized with $N_x = 2048$, $N_z = 256$, and $N_y = 384$ points. Uniform spacing is used in the streamwise and spanwise directions, while a hyperbolic-sine stretching is applied in the wall-normal direction for adequate near-wall resolution. Boundary conditions are periodic in z, adiabatic no-slip at the wall, and fully 3D Navier–Stokes Characteristic Boundary Conditions (NSCBC) at the top and outlet. The subgrid-scale model is WALE [6], chosen for its compatibility with compressible flows and improved near-wall behavior. Initialization and inflow generation strategies follow Refs. [6,7].

Fig. 1 provides the results of the analysis. It is observed that the introduction of these advanced schemes brings clear benefits in capturing pressure and temperature fluctuations, particularly PEP in the former case and AEC in the latter. It should be emphasized that both KEEP and AEC0, although strictly not EC, are documented to have good entropy conservation properties, and exhibit good performance in reproducing temperature fluctuations; this has also been shown in Refs. [3,2] for the Eulerian case. No significant advantages are observed in terms of velocity profiles or Reynolds stresses. Overall, the scheme that shows the poorest performance is JP, which does not satisfy the PEP or AEC properties.

Conclusions

In this work, a range of structure-preserving schemes for the discretization of convective terms in the compressible Navier–Stokes equations has been presented and critically analyzed. Unlike much of the existing literature, which focuses on idealized or inviscid test cases, these schemes were assessed in the context of high-fidelity LES of wall-bounded, supersonic turbulent flows. The results demonstrate that structure-preserving formulations—particularly those satisfying pressure-equilibrium and entropy-consistency properties—offer benefits in capturing pressure and temperature fluctuations. These quantities are crucial for a wide range of engineering applications, such as heat transfer prediction, noise generation, and shock–boundary-layer interactions. The observed improvements highlight the relevance of these methods beyond theoretical analysis, reinforcing their applicability to realistic turbulent flow simulations.

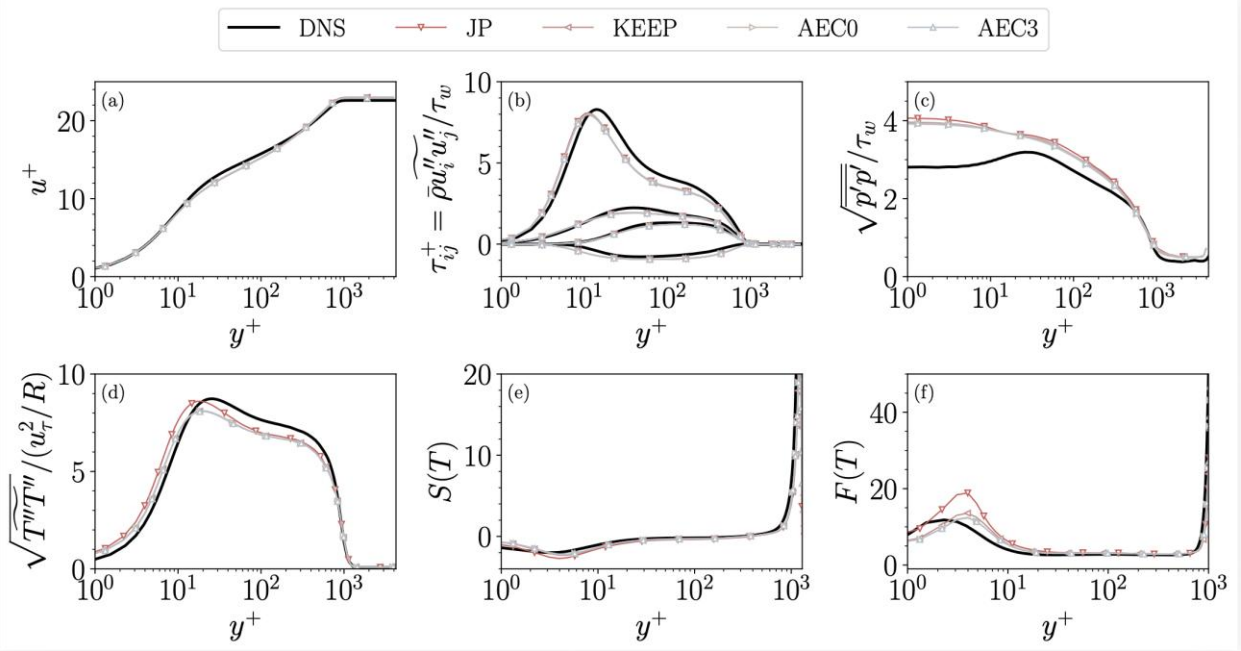

Figure 1. WRLES of a turbulent boundary layer at $M_\infty = 2$ and $Re_\tau = 840$. Distributions of (1a) mean velocity, (1b) Reynolds stresses, (1c,d) root-mean-square of pressure and temperature fluctuations, and (1e,f) skewness and flatness of temperature fluctuations, plotted against y^+. All results are compared with DNS data from Ref. [8]. Favre decomposition is denoted by $\tilde{\phi} = \overline{\rho\phi}/\bar{\rho}$ and $\phi = \tilde{\phi} + \phi''$.

Keywords: CFD, Aerodynamics, Steering, Dynamic Response

Abstract. FOK 2 is the second iteration of the FOK rocket developed by the Students' Space Association at the Warsaw University of Technology. It is an aerodynamically controlled, subsonic rocket powered by a solid rocket motor with an impulse of 1000 Ns. The second iteration differs from the first by employing a seeker, which houses a vision system, instead of a von Karman nosecone. Such drastic changes in the geometry necessitate the re-examination of the rocket's aerodynamics. Since FOK 1 missions were relatively simple [1], there was no need to perform computational analysis of the rocket's dynamic coefficients [2]. FOK 2's mission is more involved: guidance towards a target using visual navigation. Numerous flight simulations and prior flight tests must be conducted to ensure the mission's success. Having precise aerodynamics, including static and dynamic coefficients, enables good predictive capabilities of the simulations, which allow the design of the guidance and steering algorithms. This is especially important for ensuring both mission success and the safety of the flight test. While static coefficients are relatively straightforward to obtain, dynamic ones require including the motion of the rocket, which demands the usage of the Unsteady Reynolds-Averaged Navier Stokes model. In this paper, the FOK 2's aerodynamics have been investigated. Both static and dynamic derivatives were calculated. Static analysis was performed for a range of Mach numbers, angles of attack and canard deflection configurations. The generated data served as a basis for conducting the dynamic analysis. The process of obtaining dynamic derivatives differs significantly from the one used to obtain static ones, thus the influence of the canards' deflection rate on the rocket's loads will be investigated. As the end goal is to provide an accurate model for controlling a guided rocket, especially in the later phases of flight, where the reaction time is very low and the response of the missile to canard input may sometimes not reach a steady state, more attention must be focused on the oscillations induced by canard motion. Some efforts regarding this can be found in: [3]. In the case of FOK 2, transient analysis was used to study the dynamic response of the rocket under rolling motion. The canards were dynamically deflected, and the angular response was examined in relation to signals of varying frequencies. The performance of the model created as a result of the conducted analysis has been evaluated using flight data and compared against the prior model [1]. Expanding the accuracy of the aerodynamic model used in the association through the application of transient analysis has been a major leap in the numerical capabilities available and has furthered the efforts into creating an accurate guidance system at hand.

Introduction

FOK 2 is a an aerodynamically controlled missile equipped with an optoelectronic seeker developed by the Student's Space Association at Warsaw University of technology since 2021 [4]. It is steered using 4 independently controlled canards placed in front of the rocket's centre of mass (Fig. 1a). The missile is capable of steering itself both in pitching/yawing motion or rolling one. This paper focuses on the control of the missile in the roll axis.

Materials Research Proceedings 69 (2026) 244-249 https://doi.org/10.21741/9781644904251-43

In order to accurately reproduce the flight in simulation, it is necessary to analyse both static aerodynamic coefficients and dynamic ones. In light of the fact that the object of analysis is the impact of canards on the dynamic coefficients, it was established that the coefficients would be determined from the constant angular velocity of the canards for varying canard configurations, roll angular velocity and angles of attack of the rocket.

Case description

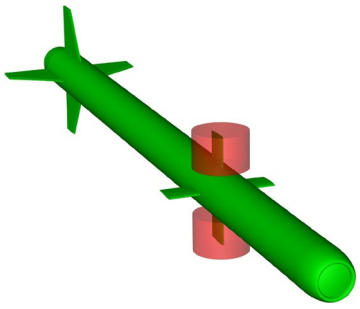
The simulations were done in ANSYS Fluent and the viscous model chosen was the Spalart-Allmaras model, due to its low processing costs from it being a one-equation model. During the simulation, the rocket's canards were moved step by step up to their maximum deflection angle of ±10◦ (Fig. 1b). The frame of reference around the rocket was also rotated to simulate rolling motion, with the fluid angle at the inlet being changed to provide a varying angle of attack (Fig. 1a).

(a) Definition of the rocket's body coordinate frame and incidence angles

(b) Definition of the canards' deflection angle

Figure 1: Aerodynamic definitions, as shown in [5]

Due to limitations in the interface method, the geometry near the canards had to be simplified and the canard was modelled separately with a gap of 0.25 mm between it and the main fuselage. This allowed for the creation of a rotating mesh interface between the fluid domain and the canards (Fig. 2). The mesh (Fig. 3) has approximately seven million cells, in accordance with y+ values that are less than one.



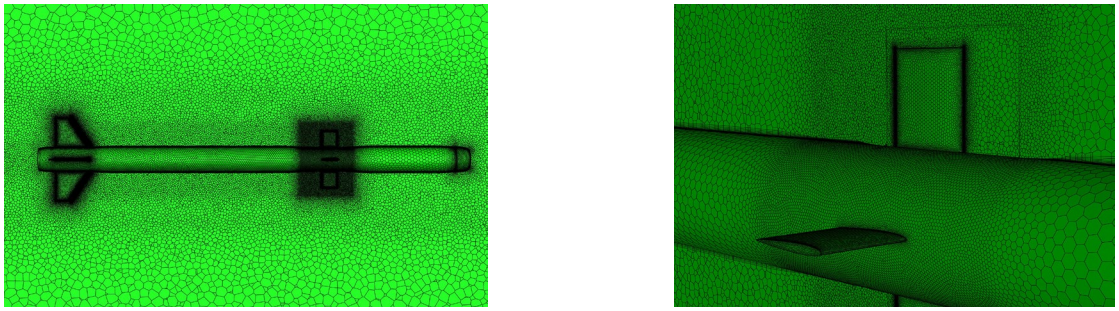


Figure 2: Rocket geometry, with red interface zones

Materials Research Proceedings 69 (2026) 244-249 https://doi.org/10.21741/9781644904251-43

(a) Rocket mesh (b) Canards' mesh

Figure 3: Mesh used in calculations

Chosen from previous flights of the rocket are the different input variables for the simulation. Those are:

- Mach number Ma = 0.4
- Angular velocity of the canards ωc = 2 rad/s
- Angular velocity of the rocket ωr = {0, 0.5, 1} rad/s
- Angle of attack α = {0, 2, 4, 6, 8, 10}°

Model Validation

To assess the validity of the case setup, a standardised geometry – the generic Army-Navy finner missile (ANF) of length 600mm, as in [6]. The mesh used was also similar, with the leading and trailing edges on the canards and fins sized to 0.08mm, with the face sizing from 1mm to 6mm on the body. As in the final model, the coefficients were calculated with a moving reference frame.

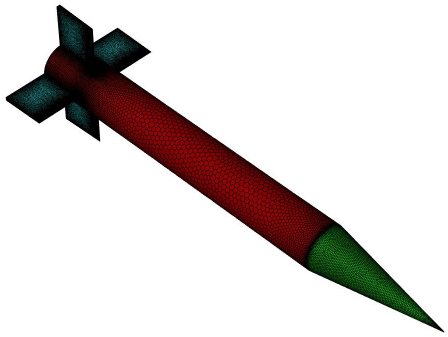

Figure 4: ANF rocket mesh

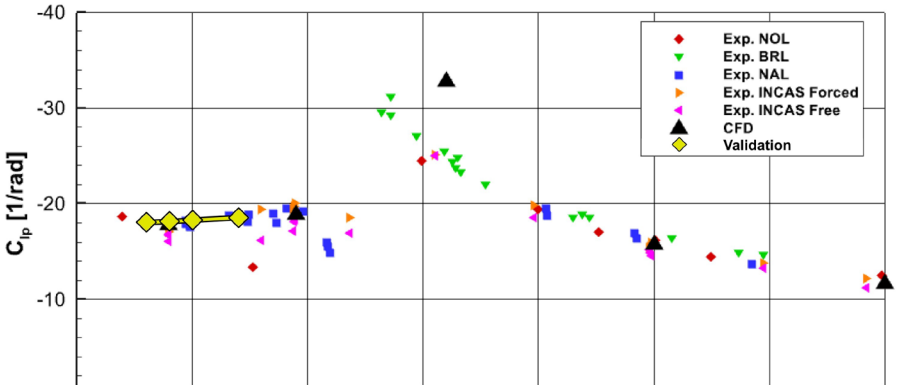
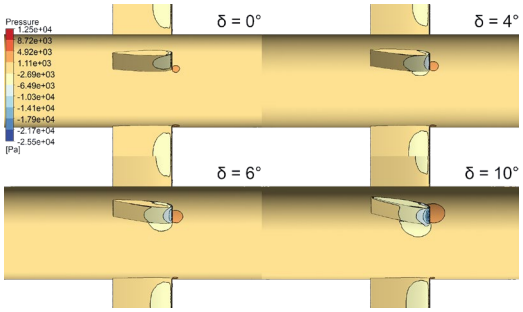
Even though the model used was different (Spalart Allmaras rather than K-ω), the obtained results of the rolling moment coefficient Clp calculated from (Eq. 1) aligned with the ones in the paper, as shown in Fig. 5, where Cl is the rolling moment in a given case and Cl0 is the rolling moment for a nonrotating case (in cases where the canards were not deflected, this moment is assumed to be zero, as the rocket is symmetric.

$$C_{lp} = \frac{2|v|}{Pd_{\text{ref}}} C_l - C_{l_0} \quad (1)$$

Materials Research Proceedings 69 (2026) 244-249 https://doi.org/10.21741/9781644904251-43





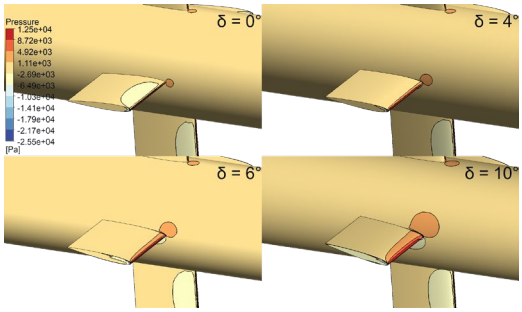


Figure 5: Graph of Clp versus the mach number as per [6]. The validation results are shown in yellow

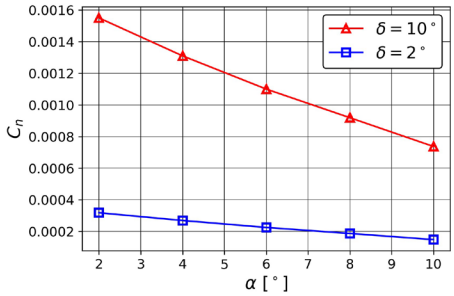
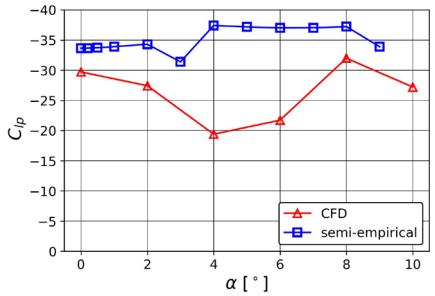
Calculation results

As illustrated in Figure 6, it is evident that the area of reduced pressure on one side of the canard increases in proportion to the augmented deflection angle of the canard. A similar phenomenon occurs on the other side, where the area of higher pressure increases in size. It has been determined that, commencing at deflection angle 6 degrees, an area of underpressure is observed on the canard's side face. This phenomenon may be attributed to the strengthening of edge vortices, which initiate their influence on the lateral face once a critical deflection angle is reached.



(a) Underpressure side



(b) Overpressure side

Figure 6: Pressure contours for different canards' deflections, Ma = 4 , $\alpha = 0°, \omega_r = 1 \frac{rad}{s}$

The yaw calculations yielded results that are to be expected – the canards being less efficient at higher angles of attack as well as the yaw moment rising linearly, as we are dealing with small deflections, as seen in Fig. 7a and 7b. The calculations also showed a present non-linearity in the rolling moment coefficient due to roll rate. This was also (more qualitatively than quantitatively) reflected in the data from other, non-empirical models. The calculated coefficients were also used to simulate the rocket in a rolling manoeuvre and compare the model to a real world test. The results shown in Fig. 9 are very promising, showing significant improvement over the previous model shown in green.

(b) Cn vs canard deflection at α=0

Figure 7: Yaw moment graphs

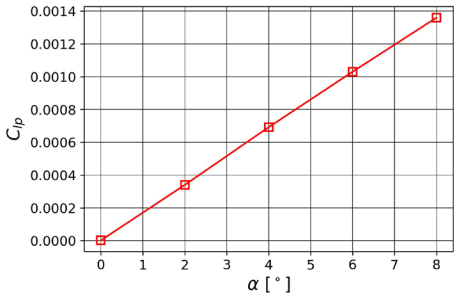

Figure 8: Graph of C_{lp} versus α at no canard deflection

Summary

Overall, this study presented a computational framework for analysing the aerodynamic behaviour of the FOK rocket. If more simulations were to be performed on a wider scope, a dynamic model of the rocket could be obtained. The approach offers a basis for future refinements in geometry, turbulence modelling, and higher-fidelity unsteady simulations.

Instability Mechanisms in the Compressible Falkner–Skan Boundary Layers with A Cooled Wall

Keywords: Falkner-Skan Boundary Layer, Hypersonic Flow, Spectral Method, Linear Stability Analysis, Energy Analysis

Abstract. We study the stability of compressible Falkner Skan boundary layers over a wedge at hypersonic speeds (target location $Ma_e = 7$). For a cooled wall with temperature ratio $T_{ratio} = 0.25$ (wall temperature scaled by the corresponding adiabatic value), we compute accurate basic solution via Laguerre spectral method and perform a temporal linear stability analysis to locate the critical Reynolds number Re_c and streamwise wavenumber α_c. A key result is quite unexpected: as the favorable pressure-gradient parameter β increases, Re_c decreases (from 115.3 at $\beta = 0$ to 83.5 at $\beta = 0.3$), opposite to the classical incompressible Falkner-Skan boundary layer. In contrast, for an adiabatic wall ($T_{ratio} = 1$), Re_c increases with β (from 107.7 to 153.1), recovering the classical behavior. A fluid–thermodynamic energy decomposition shows that vortical contributions to the instability are predominantly stabilizing, whereas the thermal and acoustic contributions strengthen with β under cooled wall conditions, thereby lowering the stability threshold.

Introduction

The Falkner–Skan equation, introduced by Falkner and Skan in 1930 [1], provides similarity solutions work for boundary layers over wedges subject to pressure gradients depending on the parameter β. While the incompressible case is classical, its compressible counterpart in hypersonic regimes remains less explored. We employ a Laguerre spectral method based on modified Laguerre bases [2] to solve both the base flow as well as the linear stability equations in a temporal setting. By satisfying the far-field boundary condition naturally, this method avoids the singularities of mapping [3] and the domain-size-dependent truncation error [4], delivering spectral accuracy on semi-infinite domains. After a high-accuracy basic solution is obtained, we apply the temporal linear stability analysis [5] to determine Re_c and α_c for adiabatic and cooled walls. For the latter, we interpret the observed trends using a fluid–thermodynamic energy decomposition [6] that separates the perturbation energy into vortical, thermal, and acoustic energy components.

Theory and Numerical Methods

Referring to the work of A. F. Stephansen and L. Quartapelle [7], the compressible Falkner- Skan boundary layer equation is shown as follows:

$$\begin{cases} f'''(\eta) + f(\eta)f''(\eta) + \beta\left(g(\eta) - f'^2(\eta)\right) = 0, \\ g''(\eta) + Prf(\eta)g'(\eta) = 2(1 - Pr)\left(f'(\eta)f''(\eta)\right)', \end{cases} \tag{1}$$

where $f(\eta)$ and $g(\eta)$ represent the dimensionless stream function and total enthalpy, respectively. The parameter β denotes the pressure-gradient factor, while the Prandtl number Pr is fixed at $Pr = 0.72$ in the present study. The corresponding boundary conditions are:

Content from this work may be used under the terms of the Creative Commons Attribution 3.0 license. Any further distribution of this work must maintain attribution to the author(s) and the title of the work, journal citation and DOI. Published under license by Materials Research Forum LLC.

Materials Research Proceedings 69 (2026) 250-253 https://doi.org/10.21741/9781644904251-44

$$\begin{cases} f(0) = 0, f'(0) = 0, \lim_{\eta\to\infty} f'(\eta) = 1, \\ g(0) = g_{\text{wall}}(\text{isothermal wall}), \lim_{\eta\to\infty} g(\eta) = 1. \end{cases} \tag{2}$$

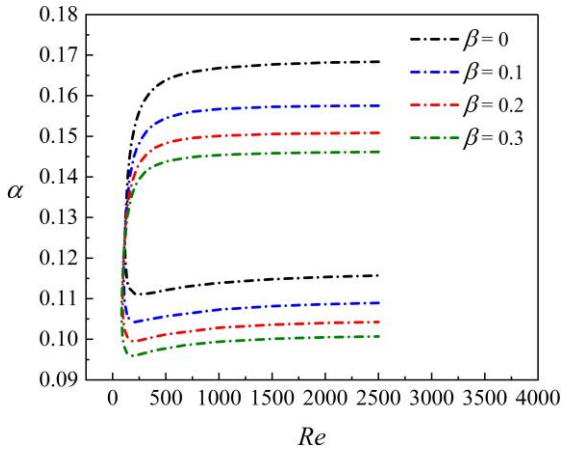
After computing the basic solution, a linear stability analysis is carried out following Malik [5] to extract the critical curve (Re, α). To interpret the physics, we adopt the fluid– thermodynamic decomposition of Unnikrishnan and Gaitonde [6].

Results and Discussion

Table 1: Summary of flow parameters at the inlet for different pressure-gradient parameters β. (The subscript 'e0' indicates external conditions evaluated at the inlet).

β	ρ_e [kg/m^3]	μ_{e0} [kg/[m·s]]	T_{e0} [K]	Ma_{e0}	P_{e0} [Pa]	U_{e0} [m/s]
0.000	0.0175	0.00000504	74.0740	7.000	371.626	1207.636
0.100	0.1169	0.00001082	158.416	4.500	5315.808	1135.316
0.200	0.3031	0.00001505	231.884	3.500	20170.761	1068.337
0.300	0.8824	0.00002099	355.556	2.500	90043.072	944.928

The inlet parameters listed in Table 1 correspond to different pressure-gradient factors β. They are selected so that, for each case, the external flow conditions at the target location (Ma_e = 7) match those of the Blasius flow (β = 0). Particularly, the wall temperature T_{wall} (cold wall) is obtained by T_{wall} = 0.25 T_{adb}, where T_{adb} is defined as$T_{adb} = T_e(1 + Pr^{1/2}(\gamma\text{-}1)\, Ma_e^2/2)$. With a cooled wall ($T_{ratio}$ = 0.25), increasing the favorable pressure-gradient parameter from β = 0 to 0.3 lowers the critical Rynolds number from Re_c = 115.3 to 83.5 (Fig.1), in contrast with the classical incompressible Falkner-Skan boundary layer where Re_c increases with β. The critical wavenumber α_c also decreases with β, indicating longer wavelengths at the onset of instability, while the shape of the neutral curves is independent of β, suggesting a common instability mechanism. For an adiabatic wall (T_{ratio} = 1) opposite trend is observed as shown in Table 2. Re_c rises from 107.7 to 153.1 as β increases from 0 to 0.3 (≈42%). α_c grows slightly (0.082→0.085), in line with the incompressible case, highlighting the important role of wall temperature in hypersonic boundary-layer flows.



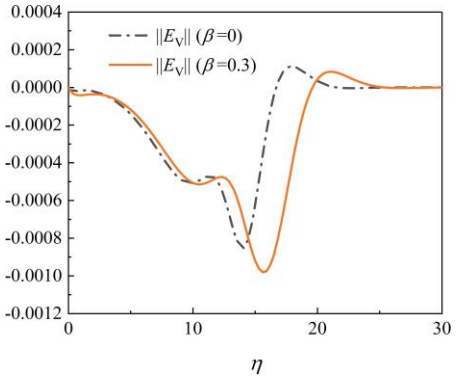


Figure 1: Neutral stability curves for four pressure-gradient parameters β, plotted in theReynolds number–streamwise wavenumber (Re-α) plane (T_{ratio} = 0.25, Pr = 0.72, Ma_e = 7)

Materials Research Proceedings 69 (2026) 250-253 https://doi.org/10.21741/9781644904251-44

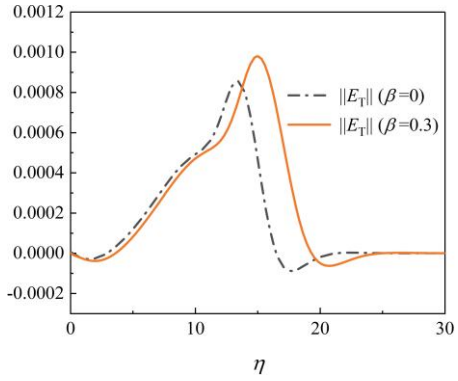

Table 2: Critical parameters for an adiabatic wall T_{ratio} = 1 with pressure-gradient parameters β = 0, 0.1, 0.2, and 0.3.

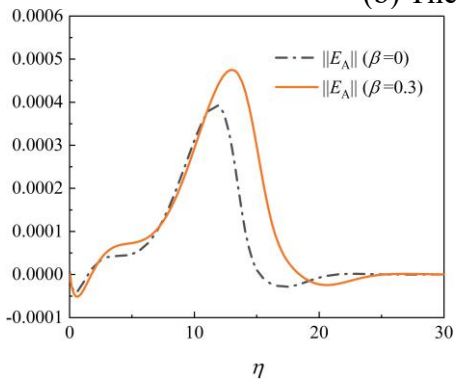
β	Re_c	α_c
0.000	107.7	0.082
0.100	125.3	0.083
0.200	140.3	0.084
0.300	153.1	0.085



To elucidate the physics behind the surprising decrease of Re_c with increasing β under a cooled-wall condition, we employ a fluid-thermodynamic decomposition as shown in Fig. 2, which compares the spatial distributions of the perturbation-energy components: vortical (E_V), thermal (E_T), and acoustic (E_A). The vortical contribution E_V is negative over most of the boundary-layer thickness and reaches its largest magnitude in the outer region, indicating a stabilizing effect. By contrast, the compressible E_T and E_A are predominantly positive and peak toward the outer edge, thereby supplying energy to the disturbance and enhancing the instability. Under the cooled-wall condition (T_{ratio} = 0.25), increasing the favorable pressure-gradient from β = 0 to β = 0.3 amplifies the compressible components: both E_T and E_A show higher peaks and wider positive support. This shift increases the perturbation energy gain and leads to the reduction in Re_c observed as β grows.

(a) Vortical energy

(b) Thermal energy

(c) Acoustic energy

Figure 2: Comparison of the perturbation energy components E_V (vortical), E_T (thermal), and E_A (acoustic) for β = 0 and β = 0.3 (cooled wall with T_{ratio}=0.25).

Summary
We analyzed hypersonic ($Ma_e = 7$) compressible Falkner-Skan boundary layers under cooled ($T_{ratio} = 0.25$) and adiabatic ($T_{ratio} = 1$) wall conditions. Using a spectral discretization for the basic solution and linear stability analysis, we mapped the neutral curves in the Re-α plane for $\beta \in [0, 0.3]$. A robust unexpected trend emerges for cooled walls, where Re_c decreases when β increases—while in the adiabatic case the classical increase is observed. The decomposition of perturbation energy indicates stabilization of the vortical contribution and a destabilization of the thermal/acoustic contributions with increasing β, which explains the decreases in the instability threshold.

Keywords: Exergy-Balance, Drag Decomposition, IDDES, Vortex Shedding

Abstract This study investigates the application of the exergy balance to an unsteady turbulent wake using a Hybrid-LES methodology. A circular cylinder at Re = 5000 is simulated in ANSYS Fluent using IDDES, and the far-field exergy balance is evaluated across multiple control volumes to assess its accuracy and behaviour in a turbulent regime. The closest control volume shows reasonable agreement with the near-field drag with an error of 3.58%, but a progressive underestimation develops as the Trefftz plane is positioned further downstream. Analysis of the drag power components indicates that the reduction in mechanical exergy is not compensated by an equivalent increase in viscous dissipation, suggesting that part of the mechanical energy is being artificially dissipated or not fully captured within the IDDES framework. The findings highlight the sensitivity of exergy-based drag decomposition to numerical error in turbulent flows and provide a basis for future work aimed at identifying error sources and mitigating these errors.

Introduction

The accurate evaluation and decomposition of aerodynamic forces remains a key challenge in the design and optimisation of efficient vehicles. Traditional near-field methods based on surface integration can only recover pressure and viscous drag and cannot separate thrust from aerodynamic contributions, motivating the development of far-field, control-volume-based approaches.

Several formulations have been proposed, including the momentum balance of Destarac and van der Dooren [1] and Drela's mechanical energy balance [2], each providing improved physical insight, but limited in their treatment of thermodynamic effects. More recently, the exergy balance introduced by Arntz et al. [3] has become the preferred method, as it incorporates temperature gradients, entropy production, and all irreversible losses, offering a complete thermodynamic picture of drag generation [3, 4]. Its recent applications [5, 6] have demonstrated strong potential in steady state flows. Furthemore Ruscio et al.'s transient vortex-shedding study [7] and studies by du Plessis [8] and Westley [9] have demonstrated its capabilities and high accuracy in periodically repeating transient flows.

Outside aerospace, Norman and Howard [10] recently applied the mechanical energy balance to a road vehicle using a DES methodology, noting acceptable agreement with nearfield forces, but also increased error compared to previous studies. This increase in error was determined to be a result of a non-physical loss of mechanical energy due to numerical diffusion, highlighting the need to further examine these balances in hybrid-RANS-LES methods.

This work extends the use of the exergy balance to an unsteady turbulent wake using a Hybrid-LES methodology. A circular cylinder at Re = 5000 is selected as a continuation of Ruscio's study, where periodic vortex shedding transitions into a turbulent wake. The aim of this study is to provide a preliminary assessment of the accuracy and behaviour of the exergy balance within a

hybrid-RANS-LES framework, and to generate reference results that help identify sources of artificial energy loss, informing future aerodynamic design workflows.

Methodology

The time-resolved incompressible Navier–Stokes simulation is performed in ANSYS Fluent 2024R2 using IDDES with the k–ω SST model in the near-wall region. A pressure-based solver with non-iterative time advancement and fractional-step pressure–velocity coupling is employed. The simulation consists of a cylinder of Diameter $0.01m$ in an incompressible flow at Reynolds number $Re = 5000$, while a time step of $\Delta t = 1.6096 \times 10 - 5\, s$ is used to maintain a maximum CFL ≈ 1.

A grid convergence study is conducted using the time-averaged nearfield drag coefficient (C_d NF). The selected 11.8×10^6 cell mesh yields $C_d = 1.0306$ and $St = 0.2085$, in close agreement with values of Massey [11] and Roshko [12] (3% and 0.7% error respectively). The domain extends 15D upstream, 20D downstream, and uses a span AR = 2.5 with periodic spanwise boundaries.

The exergy formulation used in this study is adapted from Arntz's work to operate in the Absolute Reference Frame (ARF) rather than the Relative Reference Frame (RRF) typically used in CFD. As detailed by Lamprakis, Sanders and Laskaridis [13], this change in reference frame provides a more intuitive and physically meaningful interpretation of work done, since the body is viewed as performing work on the flow rather than vice versa. The transformation is achieved through the velocity shift in Equation 1, where V denotes the ARF velocity and V' the RRF velocity.

$$V = V' - V\infty \tag{1}$$

As the test case is an adiabatic flow around a no-slip stationary wall, and features no source terms, the balance can be simplified to only represent the drag power. The simplified balance is presented in equation 2, where the left hand side represents the near-field drag power, while the right hand side represents the far-field recoverable energy (exergy $[\dot{X}]$) and the irreversibly lost energy (anergy $[\dot{\mathcal{A}}]$).

$$\overbrace{\iint \left(p_g \mathbf{V}_\infty - \bar{\bar{\tau}} \cdot \mathbf{V}_\infty\right) \cdot d\mathcal{S}_{\mathcal{B}}}^{\text{Near-Field Drag Power}} = \overbrace{\frac{d}{dt}\iiint \left(\rho \frac{\mathbf{V}_\infty{}^2}{2}\right) d\mathcal{V} + \frac{d}{dt}\iiint \rho \mathcal{X}_s d\mathcal{V}}^{\text{Far-}Field\ Exergy} + \overbrace{\iint \rho \mathcal{X}_s \mathbf{V}' \cdot \mathbf{d}\mathcal{S}_{\mathcal{TP}}}^{\dot{X}_{th}}$$
$$+ \overbrace{\iint \left(\frac{\mathbf{V}^2}{2}\rho \mathbf{V}' + p_g \mathbf{V} - \bar{\bar{\tau}} \cdot \mathbf{V}\right) \cdot d\mathcal{S}_{\mathcal{TP}}}^{\text{Far-Field Exergy}} + \overbrace{\iiint \frac{T_\infty}{T}\left(\bar{\bar{\tau}} : \nabla \mathbf{V}\right) d\mathcal{V}}^{\text{Far-Field Anergy}} + \overbrace{\iiint T_\infty \mathcal{K}\left(\frac{\nabla T}{T}\right) d\mathcal{V}} \tag{2}$$

Figure 1 shows a 2-dimensional example of how the balance is applied to a selected Control Volume (CV) and Trefftz Plane (TP) during the simulation. This study focuses on three distictly sized CV's where the distance W is shown in Table 1.

Table 1: Control Volume Dimensions

CV	TP Distance (W)
CV1	2.5D
CV2	5D
CV3	10D

Materials Research Proceedings 69 (2026) 254-259 https://doi.org/10.21741/9781644904251-45

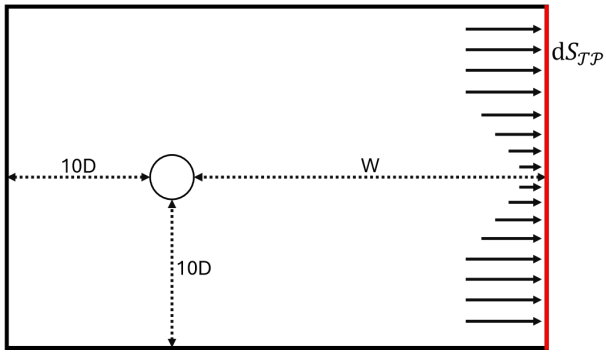

Figure 1: Control Volume Diagram

Results

To investigate the effect of CV size on the accuracy of the balance, the near-field drag coefficient was compared with the exergy-based prediction at the three CV's, as shown in Table 2. The results show reasonably good agreement at the closest control volume, with progressively larger errors as the Trefftz plane is positioned further downstream.

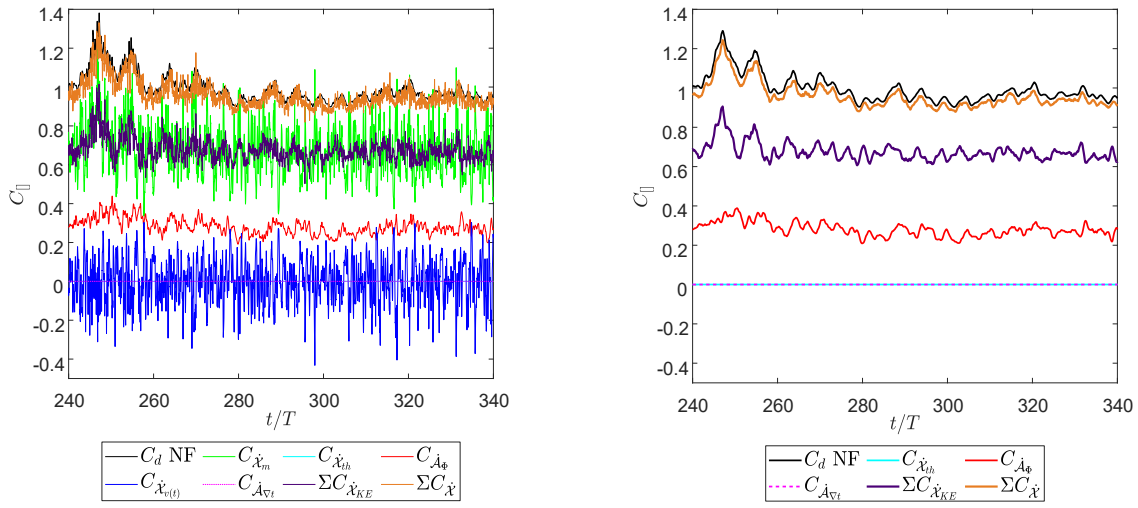

Table 2: Time Averaged C_d Comparison for final 100 Shedding Cycles

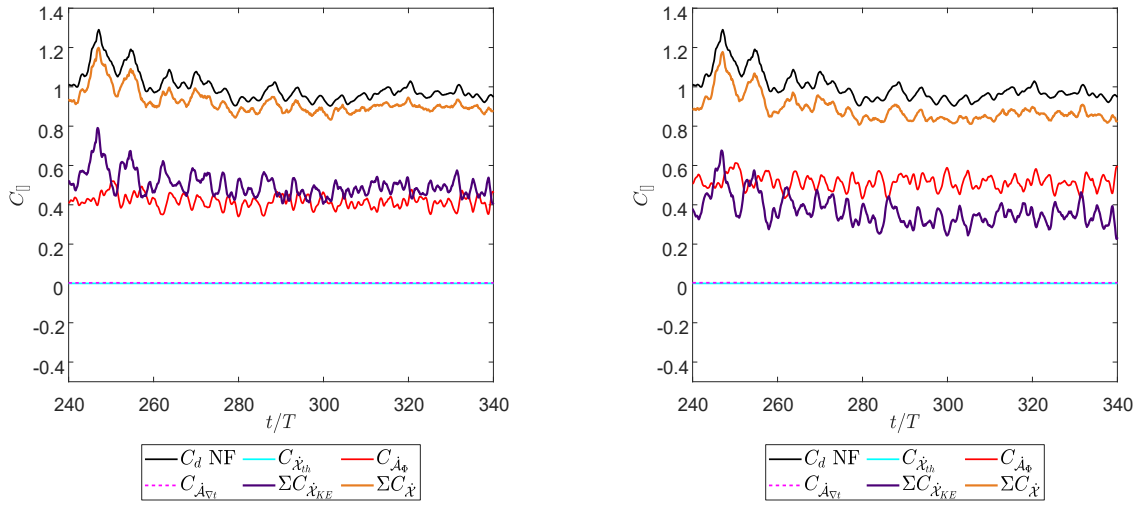
Location	**NF**	**CV1**	**CV2**	**CV3**
C_d	0.9971	0.9614	0.9244	0.8880
% Error	-	3.58	7.29	10.94

Overall, the results in Table 2 indicate that the error is not solely a consequence of grid stretching. Even at CV1, where the Trefftz plane is positioned very close to the body, a noticeable deviation from the near-field drag is already present. This suggests that a portion of the missing mechanical energy originates in the near-field itself, likely due to numerical diffusion, with grid stretching further amplifying the error as the control volume is extended downstream.

To further assess the nature of the drag being produced, the individual components of the drag power at CV1 were evaluated, as shown in Figure 2. The raw data (Figure 2a) shows the drag power being dominated by heavy fluctuations in mechanical exergy contributions ($\dot{X}_m$ and $\dot{X}_{(v)t}$), due to the highly turbulent nature of the wake. These terms are summed together to give a representative contribution of the mechanical exergy on the drag ($\Sigma\dot{X}_{KE}$). The filtered results in Figure 2b highlight how at the close control volume the drag is entirely composed of mechanical exergy ($\Sigma\dot{X}_{KE}$) and viscous dissipation ($\dot{\mathcal{A}}_\Phi$).



Materials Research Proceedings 69 (2026) 254-259 https://doi.org/10.21741/9781644904251-45

(a) Raw (b) Filtered

Figure 2: Drag Power Decomposition at CV1

The transfer of mechanical exergy to viscous dissipation is visualised in the plots for CV2 and CV3 (Figures 3a and 3b), where it can be seen how the mechanical energy component reduces with increasing CV size, while the energy is transferred to viscous dissipation. It is also noted how the amount of error between the NF C_d and total far-field balance increases with distance but remains as a constant underestimation as distance increases.

(a) CV2 Filtered (b) CV3 Filtered

Figure 3: Drag Power Decomposition at CV2 and CV3

To quantify how the mechanical exergy is transferred across the control volumes, the net change in $\Sigma\dot{X}_{KE}$ and viscous dissipation ($\dot{\mathcal{A}}_\Phi$) between successive CVs is shown in Figure 4. The results make it clear that the reduction in mechanical exergy does not correspond to an equal increase in viscous dissipation. Instead, a portion of the mechanical energy appears to be dissipated or lost without being recovered through $\dot{\mathcal{A}}_\Phi$. This imbalance indicates that part of the energy transfer is being artificially damped or is not correctly accounted for within the hybrid RANS-LES framework, explaining the increasing underestimation of the C_d from the exergy balance as the CV size increases.

Materials Research Proceedings 69 (2026) 254-259 https://doi.org/10.21741/9781644904251-45

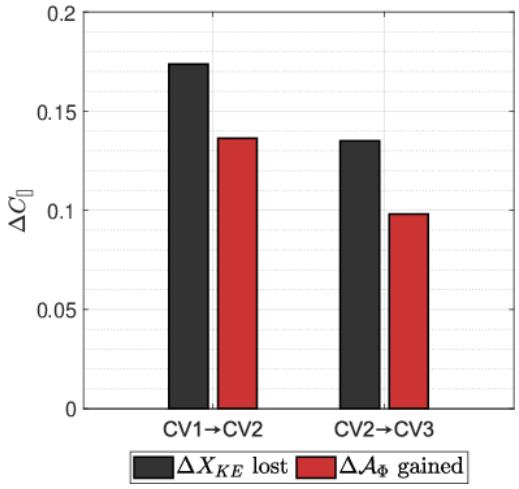


Figure 4: Change in Exergy and Anergy Between CV's

Conclusion

This study has successfully demonstrated the application of the exergy balance to an unsteady turbulent wake using a Hybrid-LES methodology to assess its behaviour and accuracy. The results show that reasonable agreement with the near-field drag is achieved at a small control volume, but a persistent underestimation develops as the Trefftz plane is moved downstream. Examination of the drag power components further reveals that the loss of mechanical exergy is not matched by a corresponding rise in viscous dissipation, indicating that part of the mechanical energy is being artificially damped or not properly captured within the hybrid RANS-LES framework. The exact source of this numerical dissipation remains unclear, with grid stretching a likely contributor in the far-field, but not explaining the imbalance on the small control volume. Future work will focus on better understanding the source of the error.

Keywords: Aerodynamics, Computational Fluid Dynamics, Drag Reduction, Rocket Wave Drag, Fluid Mechanics, Offset Rocket Fins

Abstract. Sounding rockets are unmanned rockets which carry instruments to perform experiments during their suborbital flights. These rockets are typically equipped with fins to ensure stability throughout the ascent. The fins, however, can be a significant source of wave drag, especially at transonic Mach numbers. Increased drag can lead to reduced apogee, decreased velocity, greater fuel consumption, increased drag-induced stresses, and overall performance degradation. The purpose of this study is to investigate the effect of longitudinal fin offset on the aerodynamic drag of a transonic sounding rocket. The use of staggered tail sections and their impact on drag, especially in rocketry, remains largely unexplored and warrants further investigation. Therefore, in this study, three-dimensional, compressible computational fluid dynamics (CFD) analyses in Ansys Fluent were conducted. The simulations were performed using Reynolds-Averaged Navier-Stokes (RANS) equations and the k-ω SST turbulence model. A preliminary stability analysis was also performed. The rocket under analysis features two pairs of fins, mounted near the bottom of the rocket, 90° apart, with one pair longitudinally offset. This staggered configuration alters the cross-sectional area distribution which more closely aligns with the transonic area rule, promoting wave drag reduction. The results demonstrate a significant aerodynamic drag reduction at transonic Mach numbers. The findings provide insight for researchers aiming to optimize fin configurations for improved aerodynamic efficiency and higher apogee in sounding rocket designs.

Introduction

The concept of staggered tail sections has been explored and used primarily in aircraft design to improve aerodynamic efficiency at transonic and supersonic speeds [1,2]. However, its application in sounding rockets remains largely unexplored. The staggered fin configuration, shown in Fig. 1, modifies the rocket's cross-sectional area distribution [2,3], aligning it more closely with the transonic area rule, which leads to lower wave drag.

In this study, the concept is tested using computational fluid dynamics (CFD) to assess the impact of longitudinally offset fins on aerodynamic drag [4] of a rocket moving at a Mach number (M) equal to one.

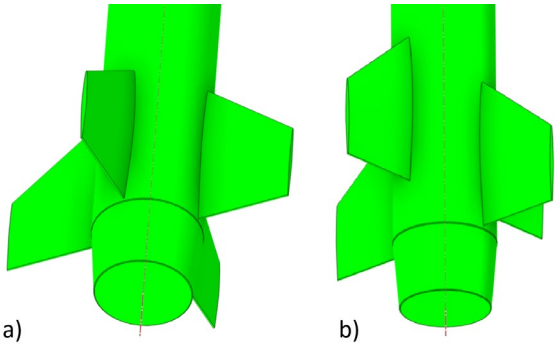

Figure 1: Comparison of rocket tails a) with a traditional fin configuration b) with staggered fins.

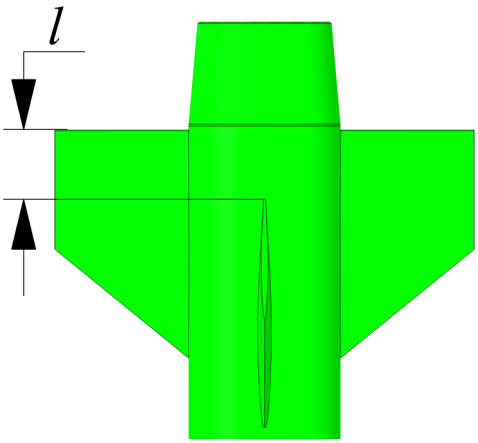

Figure 2: Rocket tail with staggered fins with the offset length l.

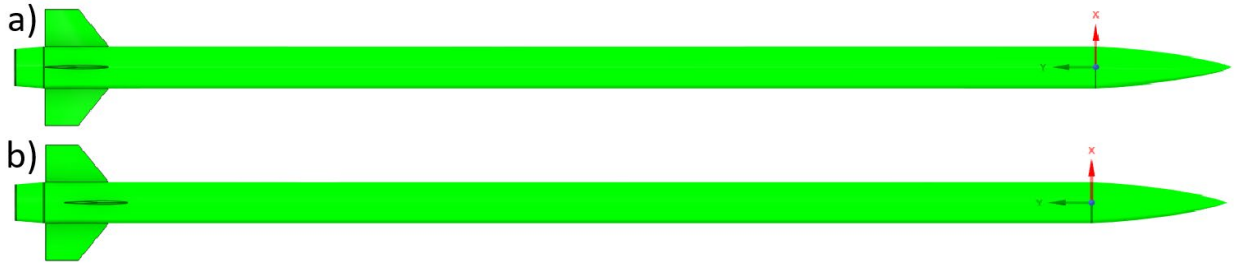

Figure 3: 3D model of the tested rocket a) with a traditional fin configuration b) with staggered fins. The rockets are identical besides the offset fins.

Methodology

The tested rocket had a length l_r of 4.5 m and a diameter of 0.152 m. The rocket included a set of four identical fins with a trapezoidal planform and NACA 66-006 symmetrical aerofoil. Additionally, for $l = 40\%$ of root chord, an additional simulation was conducted with a modified fin which's semi-span was increased to 145 mm to compensate for the decrease in aerodynamic stability around one of the axes. With baseline fin, the stagger was causing stability margins around one of the axes to decrease by 73 mm. Stability analysis was conducted using *OpenRocket* software [5,6]. Baseline fin dimensions are shown in Table 1.

Table 1: Baseline fin dimensions

Semi-span [mm]	Root chord (c) [mm]	Tip chord [mm]	Leading edge sweep angle [°]
135	230	120	39.2

The computer-aided design (CAD) models of the rocket and fluid domain were created using *Ansys SpaceClaim*. The computational domain was a rounded cylinder with the dimensions of: $2l_r$ upstream from rocket nose, $5l_r$ downstream, and a radius of $2l_r$. The domain with boundary conditions can be seen in Fig. 4.

Materials Research Proceedings 69 (2026) 260-265 https://doi.org/10.21741/9781644904251-46

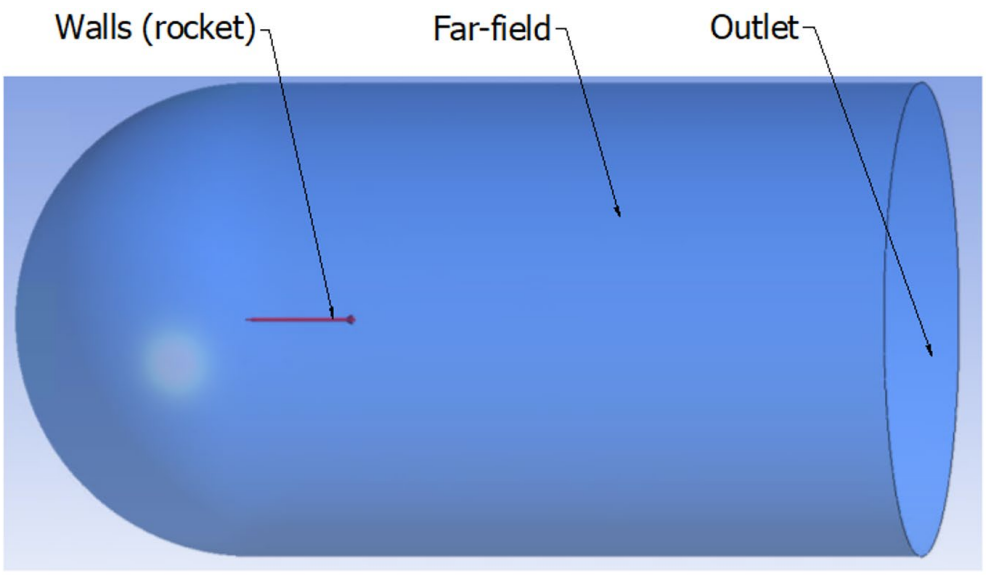

Figure 4: Computational domain with boundary conditions.

The fluid domain was discretized using *Ansys Fluent with Meshing* software into an unstructured hexahedra-based mesh. Mesh resulted in y^+ values seen in Table 2.

Table 2: Maximum and average values of y_+. The values are within the recommended range for the k-ω SST turbulence model [7].

y^+_{max}	y^+_{avg}
1.41	0.61

To ensure the results are not mesh dependent, a mesh sensitivity study was conducted (see Table 3). Medium mesh was selected.

Calculations were performed in *Ansys Fluent* using Reynolds-Averaged Navier-Stokes equations and the k-ω SST turbulence model. The density-based solver was employed for all cases to account for compressibility effects present at $M > 0.3$ [8,9].

Table 3: Mesh independence study results.

Grid size	Cell count	C_D	ΔC_D [%]
Coarse	6.08×10^6	0.6158	4.99
Medium	11.6×10^6	0.5839	-0.45
Fine	15.7×10^6	0.5866	-

Results

In total, 6 simulations were performed with l ranging from 0% to 50%c resulting in a maximum drag coefficient C_D (reduction of 14.5% at 50%c (0.499 compared to 0.584). On all simulations C_D was observed to decrease with the increase of l (see Fig. 6). Two simulations were conducted at 40%c, one with a baseline fin and one with the fin modified by increasing its semi-span to account for the stability margin decrease around one of the axes. Modified fin at 40%c increased

Materials Research Proceedings 69 (2026) 260-265 https://doi.org/10.21741/9781644904251-46

C_D from 0.521 to 0.530 allowing a net drag decrease of 9.3% compared to the rocket without staggered fins.

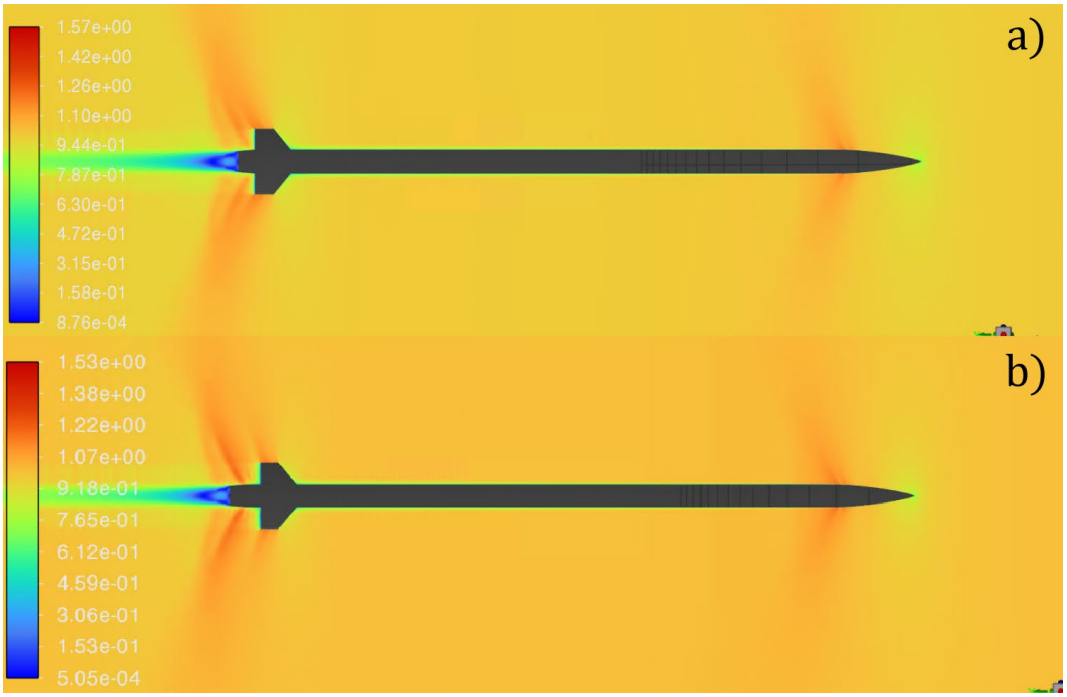

Figure 5: Contours of Mach number at M = 1 for a) a rocket with traditional fins b) a rocket with staggered fins ($l = 40$).

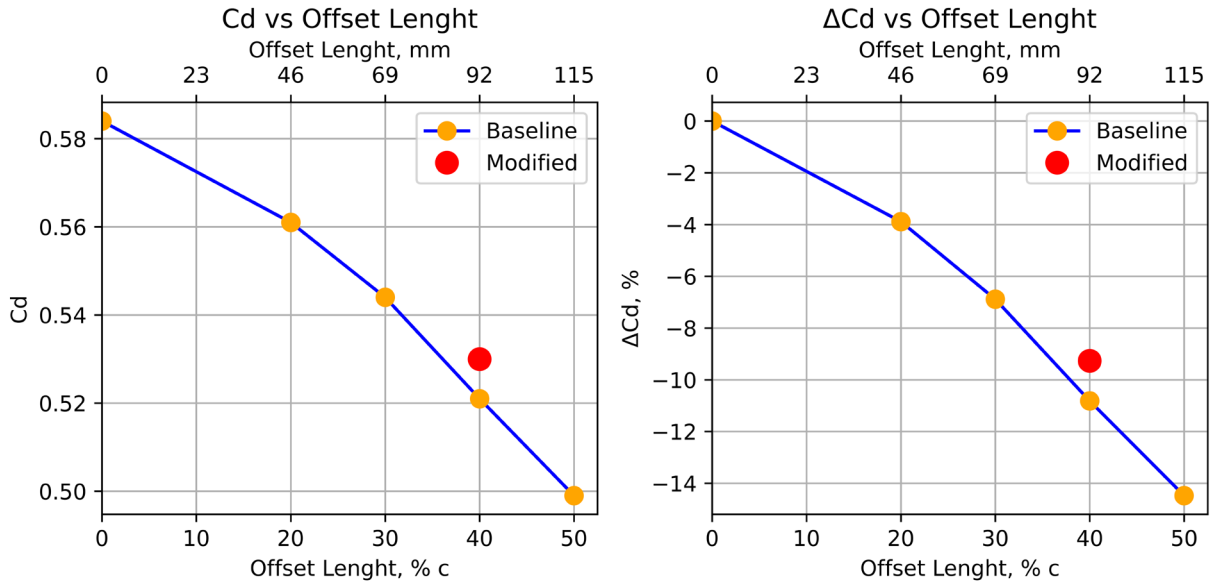

Figure 6: Plots of C_D against l (left) and difference in C_D (ΔC_D) compared to a traditional rocket (right). Modified denotes the result for the fin with increased semi-span to account for decreased stability margin around one of the axes.

Discussion

The results presented in this study clearly indicate a significant relationship between fin offset and the aerodynamic drag experienced by the rocket. The observed trend wherein an increase in l

corresponds to a decrease in total drag has profound implications for future rocket design and mission performance.

A reduction in aerodynamic drag directly translates to several key performance benefits. Most notably, it implies lower overall fuel consumption, as less thrust is required to overcome air resistance during atmospheric ascent. This efficiency gain could, in turn, enable rockets to achieve higher apogees, increase their effective range, or carry heavier payloads with the same fuel load. Furthermore, lower drag-induced stresses on the airframe could enhance structural margins, improve reliability, and potentially reduce manufacturing costs by allowing for a lighter structure.

While these findings are promising, they also open new avenues for future investigation. A next step would be to analyze the effect of fin stagger on aerodynamic drag across different Mach number values.

Moreover, the current study was conducted using a specific rocket configuration. To generalize these findings, it is imperative to test the observed effect across a wider variety of designs, particularly those with different fin planform shapes, sizes and aerofoils.

Finally, while this work focused primarily on aerodynamic performance, a preliminary stability analysis was also conducted. It is recognised that such modification of a rocket might warrant a more rigorous follow-up. Future research should, therefore, include an in-depth assessment of the impact of fin stagger on aerodynamic stability.

Keywords: Vibroacoustics, Carrera Unified Formulation, Lagrange Polynomials, Taylor Expansion, Simply-Supported Boundary, Free Edge, Fluid-Structure Interaction, Modal Assurance Criterion, High-Order Finite Elements

Abstract. A higher-order Carrera Unified Formulation is presented for fluid-loaded slender plates, employing orthogonal Lagrange and total-degree Taylor polynomials to capture cross-sectional kinematics. Comparison with three-dimensional finite-element models shows that moderate-order Lagrange expansions predict coupled eigenfrequencies with an error of less than 1%. In contrast, fourth- and fifth-order Taylor models achieve engineering accuracy with approximately 100 times fewer degrees of freedom. Parametric studies reveal that changing the lateral boundaries from simply supported to free lowers the fundamental frequency by approximately 3% and accentuates in-plane motion, especially in the mid-frequency range where plate and cavity modes coalesce. The method thus offers an efficient and validated alternative to complete 3-D analysis, with future extensions envisioned for nonlinear effects, damping layers, and gradient-based design optimization.

Introduction

Lightweight aircraft panels and launch-vehicle fairings often operate in strong fluid-structure interaction (FSI) regimes where classical first-order theories become inaccurate [1][2]. Recent Carrera Unified Formulation (CUF) studies have demonstrated rapid convergence for composite beams and shells [3][4]. By adopting a structured ML pipeline, a reliable predictive methodology for structural health monitoring was derived, following the strategy proposed by Magliacano *et al.* [5]. Nevertheless, realistic edge constraints and mid-frequency validation remain open issues [6][7][8]. This comprehensive framework represents a natural evolution of the authors' previous studies on FS systems with clamped or cantilever boundary conditions [9] and delivers a self-contained, substantially novel contribution.

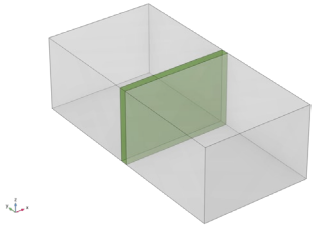

Figure 1: Schematic of the model domains; the aluminum plate is green, while the air volumes are gray.

Methodology

Cross-sectional displacements and pressure fields are approximated by linear, quadratic, or cubic Lagrange polynomials, or, for the uncoupled domains, by total-degree Taylor polynomials up to

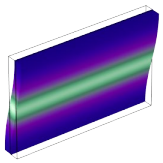
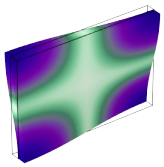
fifth order. The axial field employs one-dimensional Lagrangian elements, allowing the formulation to recover three-dimensional behavior hierarchically [10].



A 15[cm]×10[cm] aluminum plate of thickness 1[cm] is surrounded by 15[cm] air layers on both faces, as illustrated in Figure 1, following ISO 9613-1 guidelines. Reference three-dimensional solutions are obtained with Comsol Multiphysics 6.2.

Results and Discussion



The predictive capability of the higher-order scheme is assessed by juxtaposing *in-vacuo* solutions with those of the fully coupled fluid–structure model. The analysis focuses on (i) the global downshift of the eigenvalue spectrum caused by added mass, and (ii) the preservation of modal shape integrity, paying special attention to the influence of realistic edge constraints. The Lagrange LE9B3 expansion is singled out because it reproduces the three-dimensional benchmark while keeping the numerical cost moderate.

4th modal shape of the coupled model, 2139[Hz].

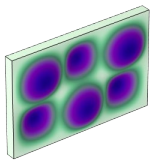

Figure 2: Comparison of the first three non-rigid modal shapes between in vacuo (displacement) and coupled (displacement-pressure) models. Aluminum material, simply supported structural, and absorbing fluid boundary conditions.

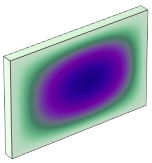
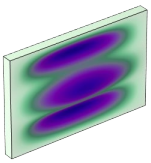
Acoustic loading produces a mode-dependent frequency reduction: the fundamental pair remains virtually unchanged, whereas higher modes experience a drop of up to 20%. Mode shapes plotted in Figure 2 retain their nodal patterns, confirming that the hierarchical CUF kinematics accurately captures fluid–structure coupling without sacrificing shape fidelity.



Releasing the lateral restraints lowers the first significant eigenfrequency from 2140[Hz] to 2073[Hz], a reduction of roughly 3% in line with the expected loss of bending stiffness. Despite

Materials Research Proceedings 69 (2026) 267-270 https://doi.org/10.21741/9781644904251-47



this shift, Figure 3 shows that the modes remain bending-dominated; only a mild intensification of in-plane displacements is observed near the free edges.

8th modal shape of the coupled model, 2138[Hz].

9th modal shape of the coupled model, 2140[Hz].

Figure 3: Comparison of the first three non-rigid modal shapes between in vacuo (displacement) and coupled (displacement-pressure) models. Aluminum material, free structural, and absorbing fluid boundary conditions.

The fluid medium produces a pronounced added-mass effect, shifting the plate's eigenfrequencies to lower values compared with the *in vacuo* case and activating additional hybrid resonance modes. Numerical results confirm that the CUF-based formulation retains high fidelity while achieving marked computational savings: high-order cross-sectional expansions cut the number of required degrees of freedom by up to two orders of magnitude yet still yield mesh-independent predictions. This approach makes it attractive for large-scale or high-frequency analyses under stringent resource constraints. Across all test cases, the model reproduces benchmark data with excellent accuracy, displays robust convergence, and faithfully captures the essential physics of fluid-structure interaction.

Conclusions

The present research confirms that high-order CUF elements [11], when combined with a weak interface coupling, provide a numerically parsimonious yet accurate tool for fluid-loaded plate analysis. Frequency errors stay below 1% with two orders of magnitude fewer unknowns than complete three-dimensional meshes. This efficiency paves the way for integration into multi-disciplinary optimization loops.

Abstract. Accurate monthly solar activity forecasting is vital for satellite operations and ionospheric modeling. We developed a lightweight, interpretable machine-learning framework using the complete SILSO record (1749–2024) to predict the 13-month smoothed sunspot number (SSN) for solar cycles 20–24 and the rising phase of cycle 25. We tested linear regression, tree-based models, their stacked ensemble, and a symbolic regressor, assessing robustness by injecting Gaussian noise (σ = 0, 1, 3 SSN) in to training data. Across 75 experiments, median performance was r^2 = 0.86 and RMSE< 31 SSN. The framework delivers deep-learning-class accuracy with negligible computational overhead and full transparency, offering an operationally practical tool as solar cycle 25 approaches its peak.

Introduction and Related Works

Solar activity (sunspots, flares, CMEs) impacts critical infrastructure like power grids, satellites, and GNSS, necessitating accurate 13-month smoothed SSN forecasts [1]-[3], especially given societal risks like geoelectric hazards and GNSS degradation [4]-[6]. Recent SSN forecasting increasingly uses diverse hybrid and ensemble ML models (e.g., XG-SN, LSTMs) and physical proxies [7]-[12], while NOAA's operational nonlinear forecast [2] and physics-based precursors [13] remain strong comparators. However, few studies report per-cycle generalization. Grounded in SILSO V2.0 [10] and the SWPC context [5],[4], our work addresses this gap by presenting a compact, cycle-aware ML pipeline. This framework (i) contrasts transparent linear baselines with stacked ensemble and symbolic regression, (ii) reports per-cycle R^2/RMSE across Cycles 21–24, and (iii) stress-tests robustness to label-noise.

Methodology

1. Data and Feature Engineering

We utilized the monthly 13-month smoothed International Sunspot Number (V2.0, WDC-SILSO) for cycles 21–24 (1976–2019), training models on past data (raw data: SN_m_tot_V2.0.csv) via an expanding one-step-ahead setup with per-cycle metrics. A compact, interpretable regressor for smoothed SSN (y_t) was built using z-scored features, including: SSN lags (6, 12, 24 months), rolling statistics, cycle phase (raw, normalized, asymmetric), 11-year sine/cosine harmonics, and interaction terms.

2. Models

In this study we three models, these models are: (a) LinearReg: A ridge-regularized linear baseline predicting smoothed SSN from all features, penalizing large coefficients to prevent overfitting. (b) Stacked: A stacked ensemble combining diverse base learners (e.g., Elastic Net, Gradient-Boosted Trees, RF) using a ridge meta-learner, trained on K out-of-fold (OOF) predictions from expanding windows to prevent leakage. (c) Symbolic: Symbolic regression using a small operator set (add,

Materials Research Proceedings 69 (2026) 271-274 https://doi.org/10.21741/9781644904251-48

subtract, multiply, etc.), selecting compact formulas via a Pareto trade-off between prediction error and complexity.

3. Training, Settings, Hyper-parameter Tuning and Evaluation Metrics

Training utilized an expanding-window cross-validation setup to generate one-step-ahead monthly predictions for solar cycles 21–24. Hyperparameters were tuned for each model-ridge/elastic net for linear, boosted/random forests for trees, and population-based search for symbolic regression-with early stopping based on validation RMSE. Light Gaussian noise was added during training for robustness. All features were z-scored per window, using a fixed scaler for validation and test months. Performance was assessed using "per-cycle metrics," specifically calculating the RMSE and the R^2 independently for each cycle.

Results and Discussion

1. Overall accuracy

Across Cycles 21–24, LinearReg achieved R^2 = 0.876 / RMSE = 23.28 SSN, Stacked = 0.878 / 23.17 SSN (≈0.5% gain), and Symbolic = 0.856 / 25.04 SSN, showing all models perform well with Stacked only slightly ahead. As shown in Fig. 1(a–b), rolling means and short lags are highly collinear (ρ ≈ 0.92–0.98) while CyclePhase adds complementary cues (ρ ≈ 0.3), justifying ridge regularization. Linear and Stacked capture cycle peaks and troughs closely, whereas Symbolic appears smoother and slightly off near extrema.

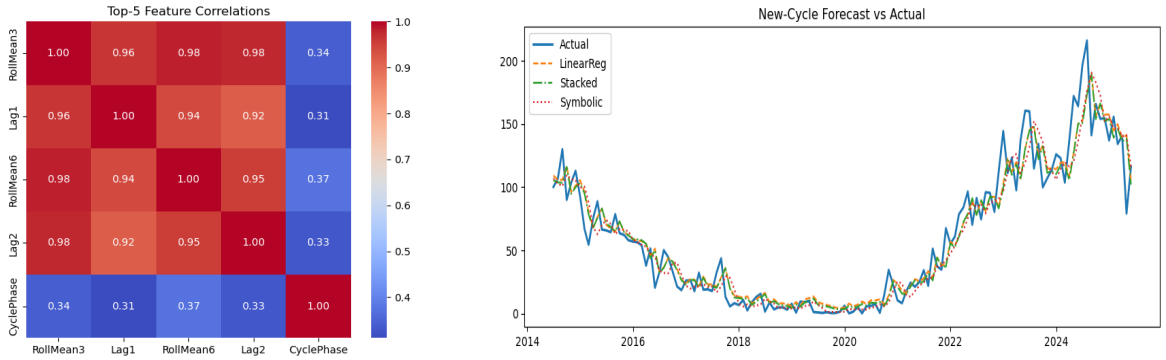

Fig. 1(a):*Collinearity Among Lag/Trend and Cycle-Phase Features,* ***(b)****Monthly SSN Forecasts vs. SILSO Truth During the Cycle-24 Minimum and Rise to Cycle-25 (2014–2025)*

2. Per-cycle behavior

Cycle-level R^2 is stable across methods: in Cycles 21–23, Stacked is about +0.001–0.003 over LinearReg, while in Cycle 24 they are essentially tied. The Symbolic model is competitive (≈0.86–0.87 in Cycles 21–23; ≈0.833 in Cycle 24) but consistently below LinearReg/Stacked, and per-cycle RMSE likewise shows small gains for Stacked—most evident in higher-amplitude cycles; while Symbolic carries a modest penalty; see Fig. 2(a) for R^2 and Fig. 2(b) for RMSE.

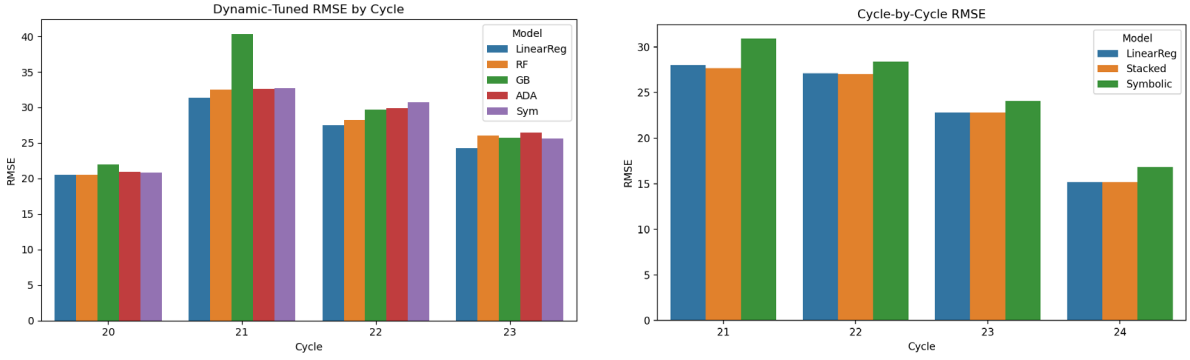

Fig. 2*.Cycle-by-Cycle RMSE (a) Dyanamic (b) Static Settings, Cycles (21–24)*

Materials Research Proceedings 69 (2026) 271-274 https://doi.org/10.21741/9781644904251-48

As shown in Figs. 2, RMSE decreases with declining cycle amplitude (≈28–31 SSN in C21 to ≈15–17 in C24). Stacking slightly improves accuracy in strong cycles, while Symbolic regression trades precision for simplicity. Under dynamic tuning, Linear and RF remain most consistent (R^2 ≈ 0.82–0.88), Gradient Boosting spikes in C21, and Symbolic overestimates peaks as tree ensembles occasionally overshoot.

3. Computation versus benefit

LinearReg runs ~0.018s per cycle versus ~35.6s for Stacked and ~28.8s for Symbolic—about 2,000× and 1,650× slower; while Stacked cuts average RMSE by <0.5% and Symbolic is modestly worse. Per-cycle results mirror this: Stacked offers tiny gains in C21–C23 and ties Linear in C24, whereas Symbolic is consistently slower and less accurate, as shown in Table (1).

Table 1: Per-Cycle Accuracy and Runtime for Monthly Smoothed Sunspot Number Predictions

Cycle	Linear (RMSE / R^2 / s)	Stacked (RMSE / R^2 / s)	Symbolic (RMSE / R^2 / s)
21	27.98 / 0.885 / 0.03	27.65 / 0.888 / 34.67	30.9 / 0.86 / 28.9
22	27.11 / 0.879 / 0.01	27.02 / 0.880 / 37.07	28.36 / 0.867 / 28.85
23	22.82 / 0.878 / 0.02	22.80 / 0.878 / 35.04	24.06 / 0.864 / 28.86
24	15.19 / 0.864 / 0.01	15.19 / 0.864 / 35.75	16.83 / 0.833 / 28.7

4. Interpretation of the symbolic form

The optimal symbolic expression reduces to a quasi-linear, interpretable ARX-style law combining lag-1 and lag-2 SSN, a minor cycle-phase correction, and 11-year harmonics (sine/cosine), utilizing inputs for SSN lags (X_3, X_4) and cycle phase (X_5). This simplicity mirrors the high performance of LR and explains why the Stacked ensemble yields only marginal gains without exogenous precursors. At the monthly horizon, the most predictive content is already captured by autoregressive memory plus smooth cycle phase and seasonality.

5. Operational alignment and robustness

Per-cycle reporting matches operational reality shown in Fig.3, and under label-noise stress (σ=0–3 SSN) the linear model shifts by less than one SSN while the stacked ensemble keeps its slight edge. Across Cycles 20–23, all models retain high fit (R^2≈0.80–0.88) with RMSE tracking amplitude; light noise (σ=1) regularizes (damping GB Cycle-21 spike), σ=3 raises errors but preserves rankings. Linear and AdaBoost (RF close) are most stable, Symbolic is consistent but higher RMSE—supporting L2-style regularization or light target jitter for robust monthly updates.

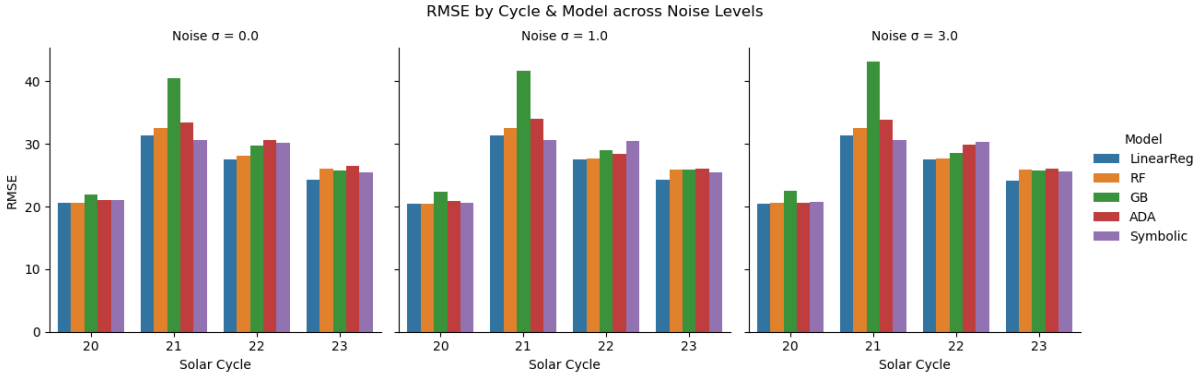

Fig 3. *Noise-Robustness Across Solar Cycles: RMSE vs. Label-Noise Levels (σ∈{0, 1, 3})*

Regularized linear models on lags/phase/Fourier are a strong monthly SSN default; stacking is worthwhile mainly with strong cycles or added covariates due to compute cost, while symbolic models aid auditability and physics insight. Our study used SSN-only features; future work should add physical precursors and include phase-specific and peak-timing metrics to pinpoint operational value.

Conclusion

We developed a lightweight, interpretable framework for monthly 13-month smoothed SSN forecasting (Cycles 20–24, rise of 25) using endogenous predictors (lags, rolling means, harmonics, time/phase). We compared linear regression, tree-based models (RF/GB/ADA), a stacked ensemble, and symbolic regression, testing robustness via Gaussian label noise. Across 75 runs, median performance was $R^2 \approx 0.86$ (RMSE <31SSN). Linear regression proved near-optimal (Cycle-24 RMSE ≈15–24), while stacking offered minor RMSE gains at high compute cost. Symbolic regression was competitive ($R^2 > 0.83$) but missed peaks. Errors scaled with amplitude; light noise regularized. Linear models are favored operationally. Future work should add physics-based inputs and peak-timing metrics.

Abstract. This paper presents a comprehensive analysis of the air supply system implemented at the Măgurele Air Test Stand, an essential infrastructure for experimental research in noise reduction devices for turbojet engines. The paper meticulously details the system configuration, component integration, instrumentation, and control methodologies designed to simulate realistic engine operating conditions, including subsonic and transonic flow regimes. Experimental procedures focused on evaluating system stability, thermal response, and pressure regulation accuracy, providing critical data for validating the performance of a home-developed air injection system aimed at noise suppression through fluidic chevron simulation. The experimental air supply system at the Măgurele Air Test Stand has proven to be a critical infrastructure for advanced research in noise reduction technologies for turbojet engines. Its precise flow control, robust safety mechanisms, and modular design establish it as an indispensable asset for dynamic experimental setups involving pressure-gain combustion and detonation-based propulsion studies. Therefore, this paper serves not only as a detailed documentation of the existing experimental setup but also as a compulsory reference for future research activities, ensuring that all subsequent experimental investigations build upon a validated and thoroughly characterized technical foundation.

Introduction

The air supply system serves as the backbone for all experimental tests that involve high-frequency ignition, pressure gain cycles, and visual flow analysis through Schlieren techniques. Its role is not just to provide a stable airflow, but also to ensure the correct thermal and pressure conditions that allow a realistic simulation of engine operations [1].

Through its modular design, it enables researchers to simulate various flow configurations, including subsonic, transonic, and limited supersonic regimes. Additionally, the system is designed with full safety interlocks and redundant control paths to avoid hazardous over-pressurization or thermal damage during long-duration tests [2,3]. The air supply system implemented at the experimental testing facility located at Măgurele plays a central role in enabling pulsed detonation and pressure-gain combustion studies [4].

This report provides a detailed technical breakdown of the high-pressure air system, incorporating static documentation and experimental configurations from validated articles [5,6]. Additional systematization and augmentation were applied to adapt the report for personal use, specifically to test the ability of my jet nozzle to reduce noise by a certain number of decibels.

System configuration

The design further integrates a safety buffer before entering the experimental section. This is implemented using a high-precision needle valve that regulates backpressure while ensuring no significant temperature drop across the bypass module. The system also features real-time feedback loops integrated into the PLC software. These are responsible for performing corrective actions in less than 100 ms, which is essential when testing dynamic systems such as pulsed detonation combustors. Moreover, the use of high-quality stainless steel piping, flexible joints, and vibration dampers ensures mechanical robustness, particularly in tests involving rapid pressure oscillations.

The system architecture of the Măgurele test stand consists of a high-pressure compressor (11 bar nominal, 1.2 kg/s peak output), two buffer tanks: 500 L (x1), 1000 L (x1), max pressure: 12 bar, an electric heater unit: OSRAM SYLVANIA SFI-8D-192-38, 5 kW, flow sensors: CS Instruments VA500, pressure sensors: WIKA Digital PG + backup Bourdon gauge, temperature sensors: K-type thermocouples, control valves: Burkert Type 8802, 3-way modulating, one data acquisition: NI CompactDAQ + LabVIEW interface, one PLC: Siemens S7-1200 with PID logic, some emergency stop and safety relief systems and connecting pipes, gaskets and nipples

Fig. 1. Air supply line components

The core of the air line is built around a compressor that maintains a maximum absolute pressure of 11 bar. Compressed air is stored in buffer tanks (500L and 1000L) to ensure flow stability. Flow is managed via motorized three-way valves and throttling valves that direct the airflow either to the experimental area or through a heating loop that includes an OSRAM SYLVANIA SFI-8D-

Materials Research Proceedings 69 (2026) 275-280 https://doi.org/10.21741/9781644904251-49

192-38 electric resistor heater. The bypass mechanism allows switching between heated and ambient air flows without interrupting the experiment.

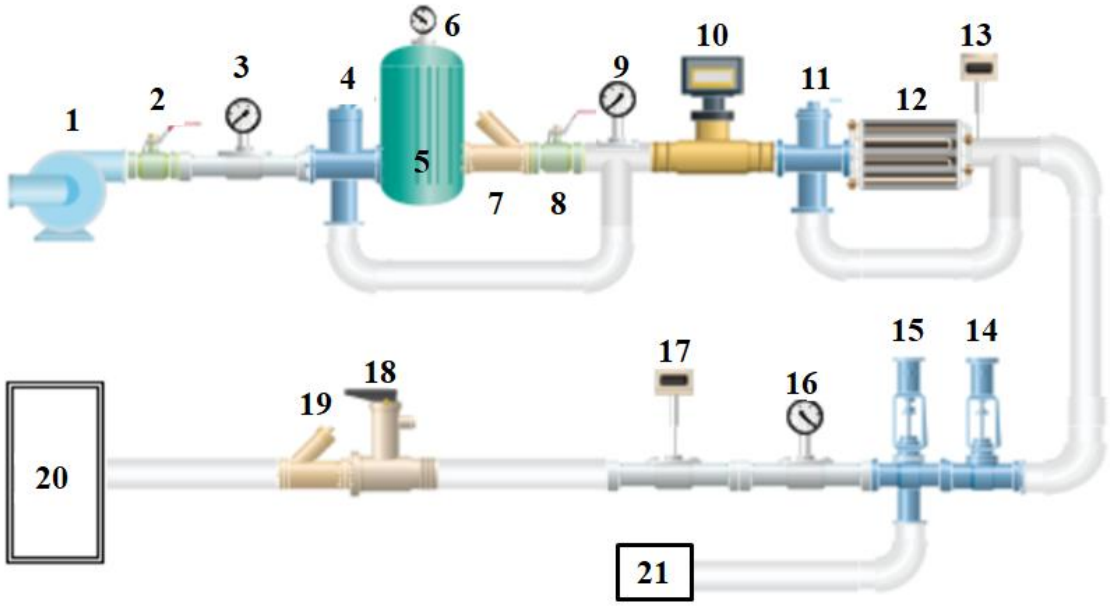

Fig. 2. Graphic diagram of the air supply line (1-compressor; 2-adjustment tap; 3,6,9-pressure gauge; 4,11,15-three way valve; 5-tank; 7,19-one way valve; 8,14-adjustment valve; 10-flow meter; 12-heater;13-temperature sensor; 16-thermometer; 17-gauge; 18-safety valve; 20-experimental zone; 21-atmospheric exhaust).

In addition to what was listed above, the system will also have a home-made injection air system designed especially for this research. The flange is 3D printed from PLA and the air injection system is made of a 15 mm diameter pipe, welded together with eight other pipes with an internal diameter of 4 mm that can be oriented at various angles in order to simulate the fluidic chevrons.

Fig. 3. The home-made injection air system in different views.

Instrumentation and monitoring

From a control systems standpoint, the instrumentation is coupled with a time-synchronized logging unit that records at 1 kHz sampling frequency. This resolution ensures precise matching between physical events (e.g., spark ignition, shock wave propagation) and measured signals (pressure, temperature, flow). Sensor calibration is performed prior to every test session using

NIST-traceable calibration units to ensure traceability and data integrity. An online dashboard is also available for operators to visualize trends and receive system alarms in real-time.

A combination of flow, temperature, and pressure sensors are distributed along the line to ensure accurate parameter tracking. These include:

- Thermocouples for upstream and downstream thermal monitoring.
- Pressure gauges (pre- and post-regulation).
- CS Instruments VA500 flowmeter for mass flow measurement.

All sensors are integrated with a PLC-based data acquisition and control system, which also handles PID regulation for fine-tuned valve adjustment and interlocking safety logic.

Experimental results (Calibrations and checks)

Initial tests conducted using the air test bench focused on system stability, pressure regulation accuracy, and temperature response when switching between bypass and heating modes.

The following results summarize key performance indicators recorded during these runs.

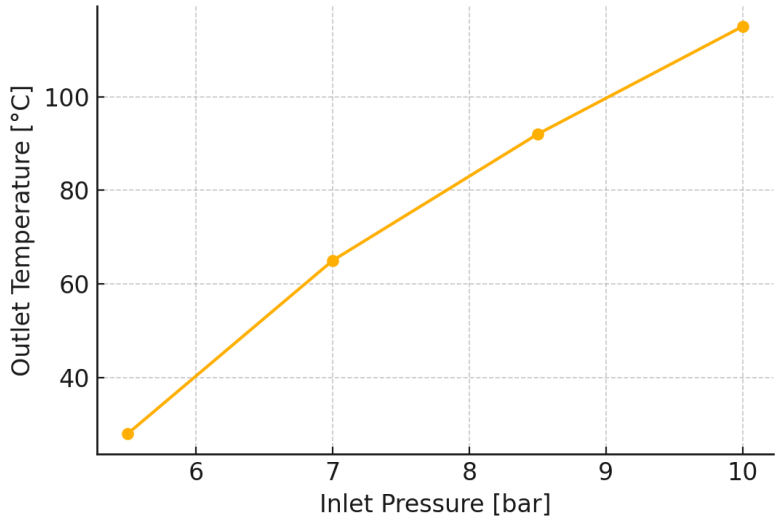

Fig. 4. Variation of outlet temperature with inlet pressure (heater active)

Additional validation tests were performed using stepped flow rate increments to determine the response time and thermal inertia of the system under various loads.

The bypass and heater loop were cycled to simulate real experimental transitions. It was observed that the heater exhibited a delay of 8–12 seconds before stable output.

Three full cycles under 7.5 bar inlet pressure yielded:

- Flow rate fluctuation: ±1.5%
- Temperature deviation: ±3.2 °C
- Pressure consistency: ±0.2 bar

These confirm the system's reliability under both steady-state and transient flow scenarios.

The home-made injection air system designed especially for this research was tested under pressure from 9 bar to almost atmospheric pressure. The results can be seen in the graph below, from which it can be concluded that there are no inappropriate variations or choked elements in the air flow through the eight ducts.

After connecting the air supply line to my air injection system with 8 tubes fed from a compressor to practically simulate fluid chevrons, several tests will be carried out and the resulting total noise as well as the distribution of the jets will be measured with a sound level meter. I will use a Schlieren-type system for viewing the jets and the tests will be performed on different configurations of reactive nozzles with a smaller or larger number of chevrons.

Materials Research Proceedings 69 (2026) 275-280 https://doi.org/10.21741/9781644904251-49

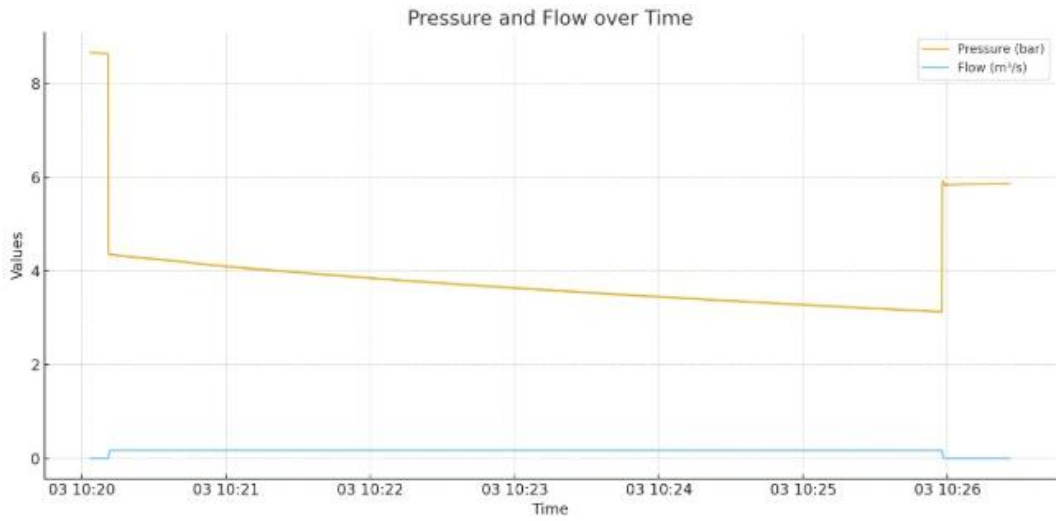

Fig. 5. Variation of the pressure air flow through the air injection system

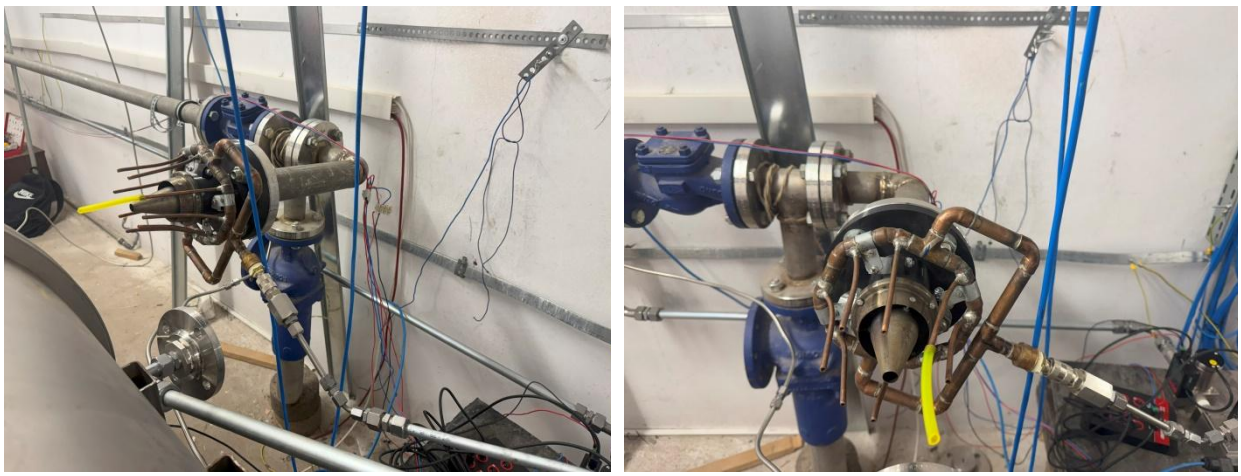

Fig. 6. The final assembly of the system

Future research directions

Unfortunately, the validation tests performed affected the inner section of the 3D printed PLA flange, yielding unsatisfactory results.

To overcome this situation, we have already made an improved flange, which can be seen in the following figure. This is the third version of the flange and should withstand the pressure and thermal inertia of the system under various loads.

Fig. 7. The third version of the home-made injection air system in different views

Future developments of the air supply system aim to improve measurement resolution, system modularity, and enable advanced measurments of total noise of the system. Key upgrades under consideration include:

- Integration of real-time gas composition sensors for exhaust analysis
- Installation of a mass spectrometry module for hydrogen leak detection
- Implementation of automatic flow balancing between dual feed lines
- Expansion of data acquisition channels to >50 for multipoint instrumentation

Furthermore, a comparison between the real data obtained from the practical tests will be compared with the data from the CFD analysis performed on the same model in ANSYS. Several tests will be carried out and the resulting total noise as well as the distribution of the jets will be measured with a sound level meter. I will use a Schlieren-type system for viewing the jets and the tests will be performed on different configurations of reactive nozzles with a smaller or larger number of chevrons orientated at different angles.

Summary

The system in use at the Măgurele facility is a robust and adaptable high-pressure air supply configuration capable of supporting advanced experimental combustion research. Its architecture emphasizes flow control precision, safety redundancy, and modular design suited for rapid changes in experimental needs. In future upgrades, the integration of mass spectrometry for gas composition and high-speed thermographic cameras will further expand the diagnostic capabilities of the air supply system. In parallel, the facility's modular design makes it possible to introduce scramjet or rotating detonation test modules without major structural changes to the existing infrastructure. Through careful design and system validation, the air line at Măgurele has demonstrated reliability, safety, and flexibility for advanced propulsion experiments.

Abstract. The acoustic energy dissipation mechanisms of a single-degree-of-freedom liner under grazing turbulent flow are investigated using high-fidelity lattice-Boltzmann very-large-eddy simulations. Viscous and vortex-shedding contributions are quantified through stress-based integration and Howe's energy corollary. Results confirm that grazing flow modifies local shear structures and enhances dissipation at more downstream locations. The evolving flow field alters liner impedance and shifts the balance between viscous and vortical losses, emphasizing the importance of flow development in liner characterization.

Introduction

Acoustic liners are widely used in aircraft engines to mitigate fan noise, which has become a dominant source in modern ultra-high-bypass-ratio configurations. The simplest liner, a single-degree-of-freedom (SDOF) design, consists of a perforated face sheet backed by a cavity and behaves as a Helmholtz resonator. Its acoustic response is typically characterized through the impedance, which depends on geometric parameters, sound pressure level (SPL), and flow conditions. While the dissipation mechanisms of SDOF liners under purely acoustic excitation are well understood, their behavior under realistic conditions—where strong acoustic waves interact with high-speed grazing turbulent flow—remains only partially characterized.

In the absence of flow, dissipation arises from viscous losses and vortex shedding within the orifices. However, when grazing flow is present, additional nonlinear effects modify the impedance. The coupling between flow topology, boundary layer state, and acoustic-induced motion within the orifices plays a critical role in determining the overall energy dissipation.

This study investigates the relative contributions of viscous and vortex-shedding mechanisms to acoustic energy dissipation in an SDOF liner, including the effects of streamwise flow development. Dissipation due to viscous effects is quantified following Ref. [1], while vortex-induced dissipation is evaluated using Howe's energy corollary [2, 3]. High-fidelity lattice-Boltzmann very-large-eddy simulations (LB/VLES) of a fully resolved liner geometry, representative of a geometry investigated at the Federal University of Santa Catarina [4], are employed. The results provide new insights into how the development of the grazing flow alters local flow structures and the balance between viscous and vortex-shedding dissipation mechanisms.

Methodology

Following the formulation in Ref. [1], the instantaneous viscous dissipation rate, $D(t)$, is obtained by integrating the stress tensor over the orifice wall region where a boundary-layer-like flow develops

$$D(t) = \iint_{walls} \sigma_{ij} \frac{\partial u_i}{\partial x_j} dxdy \quad (1)$$

Content from this work may be used under the terms of the Creative Commons Attribution 3.0 license. Any further distribution of this work must maintain attribution to the author(s) and the title of the work, journal citation and DOI. Published under license by Materials Research Forum LLC.

Materials Research Proceedings 69 (2026) 281-286 https://doi.org/10.21741/9781644904251-50

where the stress tensor is defined as

$$\sigma_{ij} = \mu\left(\frac{\partial u_i}{\partial x_j} + \frac{\partial u_j}{\partial x_i}\right) \tag{2}$$

and μ is the dynamic viscosity. To capture the periodic variation over the acoustic cycle, *D(t)* is phase-averaged with respect to the excitation phase ϕ. The time-averaged viscous energy dissipation per unit area is then

$$E_{viscous} = \frac{1}{T}\int_0^T D(t)dt \tag{3}$$

providing a measure of viscous losses under both linear and nonlinear acoustic conditions. The conversion of acoustic energy into vortical motion is quantified using Howe's energy corollary [2, 3]. The instantaneous power density exchanged between the acoustic and vortical fields is given by

$$\Pi_g = \rho_0(\boldsymbol{\omega} \times \boldsymbol{u}') \cdot \boldsymbol{u}_{ac} \tag{4}$$

where ρ_0 is the mean density, $\boldsymbol{\omega}$ the vorticity, $\boldsymbol{u}' = \boldsymbol{U} + \boldsymbol{u}_{aero} + \boldsymbol{u}_{ac}$ the total velocity field, where $\boldsymbol{u}_{ac}$ is the acoustic-induced velocity, $\boldsymbol{U}$ is the time-averaged velocity and $\boldsymbol{u}_{aero}$ is the turbulent velocity fluctuation.
The total acoustic-to-vorticity energy transfer within the orifice is

$$\Pi(t) = \iint_{orifice} \Pi_g dxdy \tag{5}$$

where positive values indicate absorption of acoustic energy by the vortical field, and negative values indicate acoustic generation. The mean energy exchanged over one oscillation period is expressed as

$$E_{shedding} = \frac{1}{T}\int_0^T \Pi(t)dt \tag{6}$$

To evaluate Howe's corollary, the acoustic-induced velocity must be isolated from turbulent fluctuations associated with grazing flow. Spectral Proper Orthogonal Decomposition (SPOD) is employed following Ref. [5]. SPOD extracts coherent, energy-dominant modes from statistically stationary flow data, combining the advantages of POD and DMD. The MATLAB routines of Ref. [6] are used to perform the decomposition and velocity reconstruction. A reduced-order model is built from the leading SPOD mode within a narrow frequency band centered on the forcing frequency, yielding the coherent, phase-locked acoustic-induced velocity field. This reconstructed velocity represents the dominant coherent component relevant to acoustic–flow coupling and dissipation, rather than the irrotational part of the flow obtained through a Helmholtz decomposition.
The local flow impedance is obtained by computing at each point in the fluid domain the ratio

$$\frac{S_{pp}(f)}{S_{pv}(f)} \tag{6}$$

where $S_{pp}(f)$ is the auto-spectrum of the pressure and $S_{pv}(f)$ is the cross-spectrum between the pressure signal and the vertical velocity component. The real part of the ratio is the

Materials Research Proceedings 69 (2026) 281-286 https://doi.org/10.21741/9781644904251-50

local flow resistance, while the imaginary part is the local flow reactance. In the following, the flow resistance at a frequency equal to that of the acoustic plane wave is shown.

Test case

The simulations were conducted in a rectangular duct with the liner mounted on the upper wall. An acoustic liner with a rounded orifice geometry, as the one described as scanned in Ref. [7], is investigated. The liner has 11 cavities in the streamwise direction. A zig-zag trip upstream generated turbulence, while sponge layers at the outlet prevented reflections. The inlet Mach number was M=0.3 (U_0 = 110 m/s) or M=0. Periodic lateral boundaries reproduced the experimental setup. A variable-resolution mesh (Δx = 0.02d near orifices, 40 cells across diameter) was used. Flow-only simulations were run until convergence, after which plane acoustic waves were imposed using the OptydB toolkit. This two-step LBM-VLES approach efficiently captured nonlinear flow-acoustic coupling at 145 dB and 1400Hz.

Results

Fig. 1 reports the phase-averaged acoustic dissipation rate obtained through both viscous and vortex-shedding mechanisms. The top figures refer to the case in the absence of flow, while the bottom ones refer to the case with the grazing turbulent flow. In each subfigure, three cavities, i.e., the most upstream (cavity 1), the central one (cavity 6), and the most downstream (cavity 11), are shown.

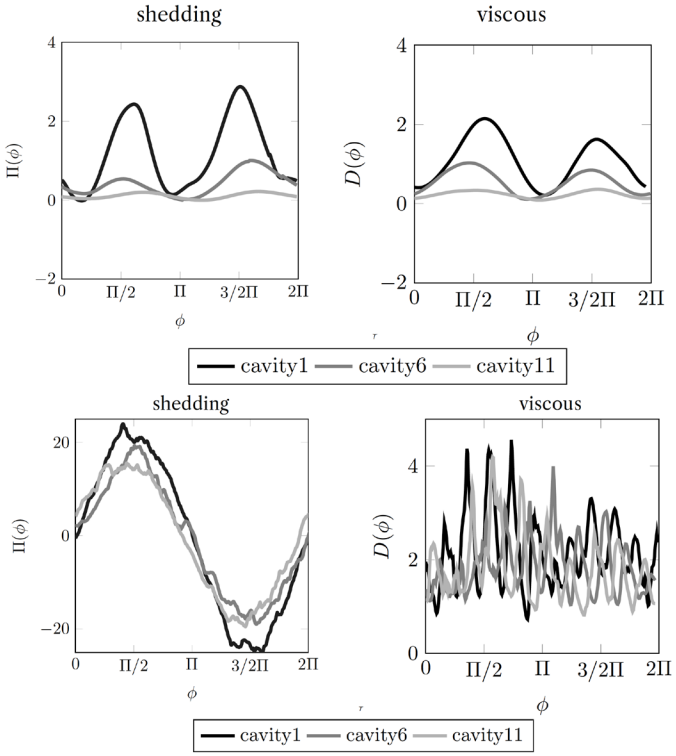

Figure 1. Phase averaged shedding and viscous dissipation in the absence (top) and in the presence of grazing turbulent flow (bottom). SPL equal to 145dB and frequency equal to 1400Hz.

In the absence of grazing turbulent flow, both acoustic energy dissipation mechanisms contribute similarly. In particular, acoustic energy is dissipated during both the inflow and outflow phases in a similar way. However, at more downstream cavities, the rate of dissipation for both mechanisms diminishes. This is due to the reduction of acoustic amplitude in the streamwise direction.

Materials Research Proceedings 69 (2026) 281-286 https://doi.org/10.21741/9781644904251-50

In the presence of the grazing flow, differences between the two acoustic dissipation mechanisms are present. The rate of dissipation due to vortex shedding exhibits a positive rate, i.e., noise dissipation, during the inflow and a negative one, i.e., noise generation, during the outflow phase. The possible reason is that during the outflow phase, the acoustic-induced velocity ejected by the cavity interacts with the convecting turbulent flow, thus generating vorticity responsible for noise generation. When comparing different cavities, it can be observed that the maximum and minimum values at the first cavity are larger than at the more downstream ones. This can be caused by the flow development and the consequent reduction of the shear layer strength over the orifices, as reported in Ref. [7]. On the other hand, the contribution due to viscous effects is always positive, and minor differences are found between cavities. The high-frequency fluctuations visible in the figures are due to amplified acoustic fluctuations caused by a resonant cavity depth noise [7]. The total balance, including both noise dissipation mechanisms, is positive, i.e., noise reduction. Fig. 2 (left) reports the integrated rate of dissipation of the two noise dissipation mechanisms at different cavities, while Fig. 2 (right) reports the sum of the two contributions. It is interesting to notice that the sound energy dissipation varies differently between the cases with and without turbulent grazing flow. As a matter of fact, without grazing flow, the acoustic dissipation decreases at more downstream cavities because of the streamwise reduction of the SPL; conversely, it increases in the presence of flow caused by the streamwise development of the turbulent flow and shear strength over the orifices. These findings confirm that it is essential to account for the development of the flow when computing impedance in grazing flow facilities.

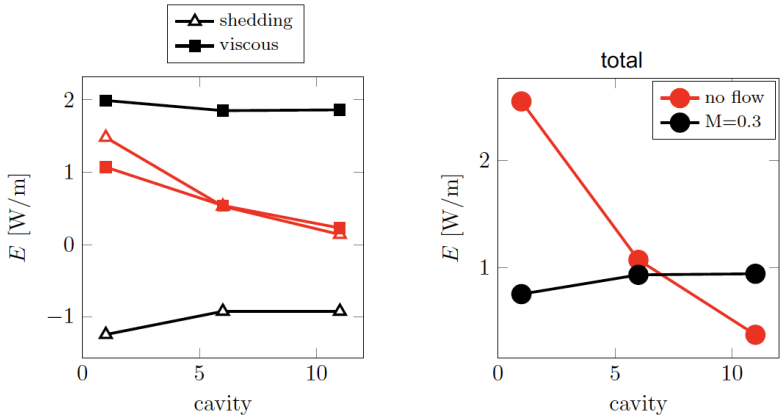

Figure 2. (left) Contribution of the energy dissipation through viscous and vortex shedding for the injection (full symbol) and ejection (empty symbol). (Right) Total energy dissipated with and without grazing flow.

To confirm the above statement, the real and imaginary parts of the flow impedance, named resistance and reactance, at the frequency of interest are shown in Fig. 3. The top figures display results for the grazing flow case, while the bottom ones display the no-flow case.

In the presence of turbulent grazing flow, it can be noticed that the flow field within the channel can be split into two parts: for $0.5<y/H<0$ or $5<y/\delta^*<0$, where H is the half channel heigh and δ^* the boundary layer displacement thickness upstream of the liner, the local effects of the facesheet orifice and of the solid surfaces between cavities are clearly visible, demonstrating that the liner is locally perturbing the flow. Conversely, for $y/H<0.5$ or $y/\delta^*<5$, local effects are not visible. This suggests that at this location, the assumption of uniform impedance is more valid. However, it can be observed that there is a change in the fluid flow resistance in the streamwise direction

Materials Research Proceedings 69 (2026) 281-286 https://doi.org/10.21741/9781644904251-50

with larger variations close to x/L=0 where L is the liner length. This finding suggests that the change in the flow over the facesheet orifices, as explained before, modifies the local flow impedance, which flattens at approximately x/L>0.5. Similar findings are found for the flow reactance in the presence of flow. Results are different without flow, where the localized impact of the vortex shedding, which penetration decreases in the streamwise direction because of the lower SPL, is visible. However, the two regions, differently from what is found with grazing flow, cannot be distinguished.

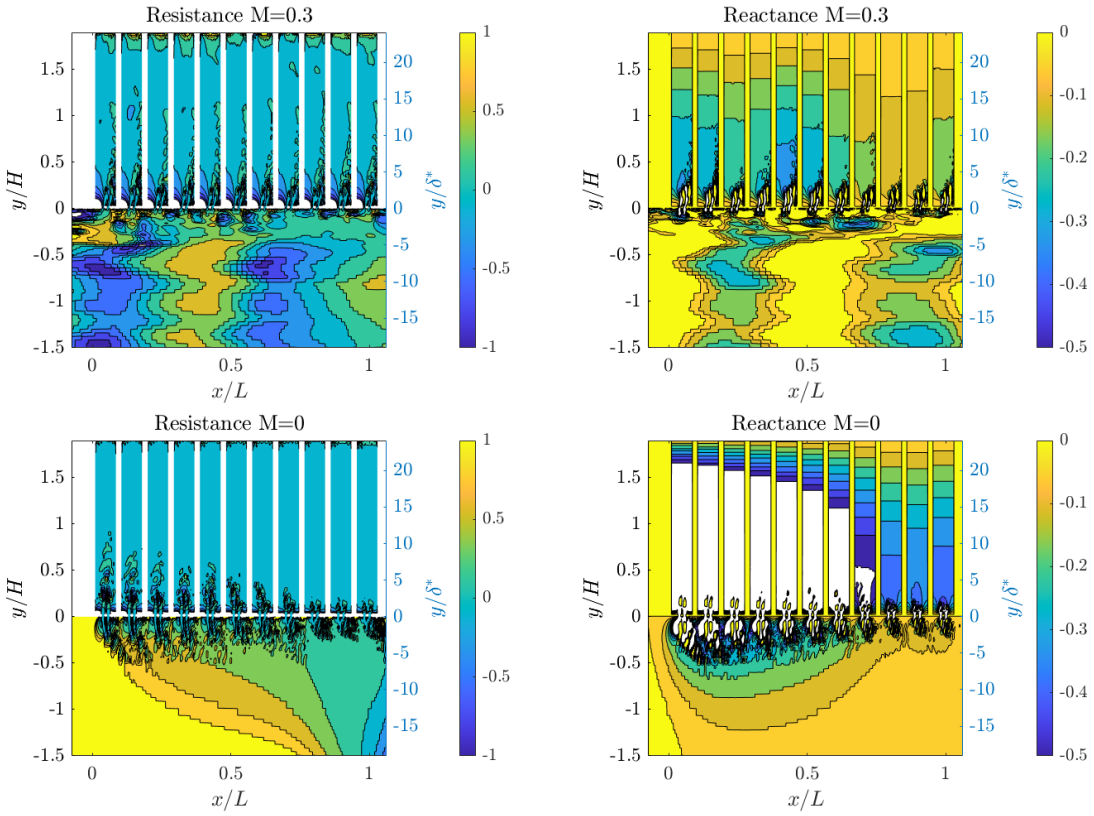

Figure 3. Flow resistance components with (top) and without (bottom) grazing flow.

Conclusions

This study investigates the impact of the flow development over an acoustic liner on both the acoustic energy dissipation and the flow impedance. It is found that the acoustic dissipation increases in the streamwise direction, reaching a plateau. This is due to the change in the shear strength over the liner orifice. As a consequence, the flow impedance changes in the streamwise direction, thus resulting in a larger variation at the interface between the solid and lined surfaces. It is also found that, in the presence of the flow, the local effects of the flow through the orifices are less visible at y/H < 0.5. Future studies on a longer liner with more geometries and acoustic conditions will shed further light on what is presented in this paper.

Abstract. High-fidelity computational aeroacoustic simulations are often too computationally expensive for rapid evaluation of aircraft noise, especially when assessing full-system acoustic footprints during operations. This work introduces a physics-informed multipolar-expansion methodology that generates equivalent acoustic sources capable of accurately reproducing complex pressure fields in both near- and far-field regions at a fraction of the computational cost. The method employs expansions from monopoles to higher-order terms for noise modeling and prediction, using spherical harmonics as a complete basis of the Helmholtz equation. Acoustic moments coefficients are identified through linear regression analysis of pressure data obtained from numerical or experimental sampling, enabling the accurate reconstruction of the acoustic field once the coefficients are determined. The methodology is assessed using two representative aeroacoustic problems: a helicopter rotor operating in Blade–Vortex Interaction conditions and a subsonic jet at Mach 0.9 with varying nozzle temperatures. The results show excellent agreement with reference data, maintaining amplitude accuracy up to the far field while drastically reducing computational time. The proposed reduced-order model demonstrates strong robustness and generalizability, offering a fast and physically grounded tool for aerodynamic optimization, real-time control, and digital-twin frameworks, enabling efficient and scalable noise prediction in complex aeroacoustic environments.

Introduction

High-fidelity computational aeroacoustic simulations are prohibitively expensive for rapid evaluation of noise propagation from aeronautical sources [1], especially when assessing the acoustic footprint of complete aircraft in operational phases [2]. Many recent papers have focused on developing metamodels for acoustic problems to reduce this computational burden [3, 4]. This work presents a physics-informed multipolar-expansion methodology that generates equivalent acoustic sources capable of accurately reproducing the complex pressure field in both near-field and far-field regions, with a low computational cost. The source of interest may be the entire aircraft or single components (rotors, engines), since the equivalent sources can also be used in scattering problems.

Materials Research Proceedings 69 (2026) 287-292 https://doi.org/10.21741/9781644904251-51

Building upon the framework introduced in [5], this work extends the use of spherical harmonics as a complete basis for solving the Helmholtz equation, providing an efficient and physically grounded representation of acoustic fields. The core idea of the proposed approach is to identify the acoustic moment coefficients through a linear regression procedure applied to pressure data sampled at a set of control points, which can be obtained either numerically or experimentally. The methodology follows a structured sequence of steps. First, a training set is defined by collecting pressure values on grids surrounding the emitting source, at all frequencies of interest. Then, a suitable multipolar expansion is selected: typically centered on, or aligned with, the symmetry axis of the source. The expansion coefficients are estimated by minimizing the mean square error between the reconstructed and sampled pressures, using the Moore–Penrose pseudoinverse of the measurement matrix. Once these coefficients are determined, the model can predict the acoustic pressure distribution at arbitrary spatial locations, both in the near and far field. To evaluate the accuracy and generalizability of the proposed procedure, two representative aeroacoustic test cases are considered: the noise footprint generated by a rotor operating under Blade-Vortex Interaction conditions, and the sound radiation from a round free jet in a high-subsonic regime. In both cases, the results demonstrate excellent agreement with reference data, showing accurate reproduction of noise amplitudes up to the far field. Moreover, once the multipolar coefficients are available, the acoustic field can be evaluated in milliseconds across thousands of observer positions, highlighting the computational efficiency of the approach.

Multipolar expansion

This work proposes to approximate the reference acoustic field with a series Nexp of multipolar linear expansions of arbitrary order N, each one defined by elementary sources using spherical harmonics as a basis [6] ($e^{i\omega t}$ time convention):

$$p(r,\phi,\theta,\omega) = \sum_{i=0}^{N_{exp}} \sum_{l=0}^{N} \sum_{m=-l}^{l} A_{l,m}^{i} Y_{l,m}(\phi_i,\theta_i) h_l^{(2)}(\kappa r_i)$$

where $\kappa = \omega/c$, $h_l^{(2)}(x)$ is the l-th order spherical Hankel function of the second kind, providing the radial dependence of the solution, and the real (Laplace's) spherical harmonics $Y_{l,m}$ of degree l and order m are a set of functions orthonormal over a sphere, obtained as the angular-dependent portion of the solution of Laplace's operator in spherical coordinates [5]. In this work, multiple multipolar expansions are introduced along the jet axis line, extending in from the nozzle exit up to z_{max} .

For simplicity, all the expansions share the same order N. Each i-th spherical harmonic multipolar expansion involves $L_{ind} = \sum_{m=0}^{N} 2m + 1$ independent sources. Hence, the total number of free parameters in the model is $a = N_{exp} L_{ind}$, namely the coefficients $A_{l,m}^{i}$, which are adjustable to tune the equivalent sources to reproduce the acoustic field produced by the actual sources. To define the values of the coefficients of the expansions $A_{l,m}^{i}$, some monitoring points where the acoustic field is known are defined. Those are subdivided into two sets: the first, Q, contains q points, whose acoustic measurements will be used to *train* the multipolar model; the second, S, contains s points, whose acoustic pressures are only used to *validate* the performance of the equivalent source model at different locations not used in its training. To retrieve the coefficients $A_{l,m}^{i}$ of the approximation in eq. (1), the difference between the reference acoustic field and the field produced by the multipolar expansions is minimized in a least square sense. Since the position of the equivalent sources is fixed, the problem can be conveniently formulated in matrix form as:

$$\mathrm{V}_Q \mathbf{x} = \mathbf{b}_Q$$

Materials Research Proceedings 69 (2026) 287-292 https://doi.org/10.21741/9781644904251-51

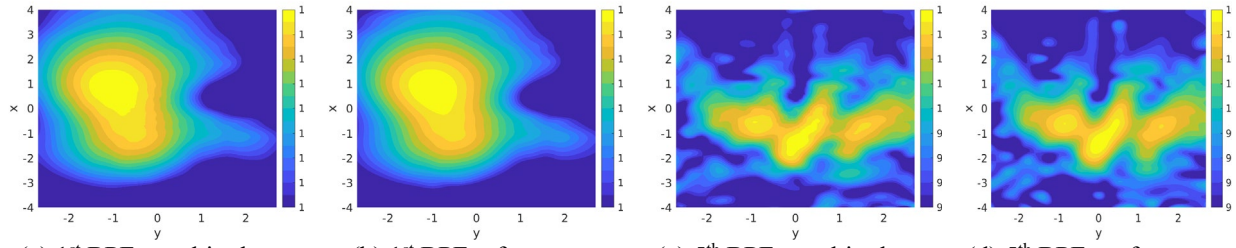
Where $\boldsymbol{x} \in \boldsymbol{C}^{\boldsymbol{a}}$ collects the $\boldsymbol{N}_{\text{exp}}\boldsymbol{L}_{\text{ind}}$ coefficients $\boldsymbol{A}_{\boldsymbol{l},\boldsymbol{m}}^{\boldsymbol{i}}$; the vector $\boldsymbol{b}_{\boldsymbol{Q}} \in \boldsymbol{C}^{\boldsymbol{q}}$ collects the values of the reference field at all the monitoring points Q; and the complex-valued terms resulting from the evaluation of each spherical harmonics term $\boldsymbol{Y}_{\boldsymbol{l},\boldsymbol{m}}(\boldsymbol{\phi}_{\boldsymbol{i}},\boldsymbol{\theta}_{\boldsymbol{i}})\boldsymbol{h}_{\boldsymbol{l}}^{(\boldsymbol{2})}(\boldsymbol{\kappa r}_{\boldsymbol{i}})$ at the Q monitoring points populate the matrix $\boldsymbol{V}_{\boldsymbol{Q}} \in \boldsymbol{C}^{\boldsymbol{q}\times\boldsymbol{a}}$. The number of monitoring points in the training set limits the maximum order of the multipolar expansion as the system is solved using a Moore-Penrose pseudo-inverse (the condition $\boldsymbol{q} > \boldsymbol{a}\left(\boldsymbol{N},\boldsymbol{N}_{\text{exp}}\right)$ - ideally $\boldsymbol{q} \gg \boldsymbol{a}(\boldsymbol{N},\boldsymbol{N}_{\text{ind}})$ - has to be satisfied), namely:

$$\mathbf{x} = \mathbf{V}_{\boldsymbol{Q}}^{\dagger}\mathbf{b}_{\boldsymbol{Q}} = \left(\mathbf{V}_{\boldsymbol{Q}}^{*}\mathbf{V}_{\boldsymbol{Q}}\right)^{-\mathbf{1}}\mathbf{V}_{\boldsymbol{Q}}^{*}\mathbf{b}_{\boldsymbol{Q}}$$

where the superscript $*$ indicates the complex conjugate operation. Then, the acoustic pressure at the validation points $\widehat{\boldsymbol{b}}_{\boldsymbol{S}}$ is obtained by:

$$\widehat{\boldsymbol{b}}_{\boldsymbol{S}} = \mathbf{V}_{\boldsymbol{S}}\,\mathbf{x}$$

where $\boldsymbol{V}_{\boldsymbol{S}} \in \boldsymbol{C}^{\boldsymbol{s}\times\boldsymbol{a}}$ is the matrix collecting the evaluation of each spherical harmonics term $\boldsymbol{Y}_{\boldsymbol{l},\boldsymbol{m}}(\boldsymbol{\phi}_{\boldsymbol{i}},\boldsymbol{\theta}_{\boldsymbol{i}})\boldsymbol{h}_{\boldsymbol{l}}^{(\boldsymbol{2})}(\boldsymbol{\kappa r}_{\boldsymbol{i}})$ at the S validation points.



Results on landing helicopter rotor model

In this test case, a single multipolar expansion ($\boldsymbol{N}_{\boldsymbol{exp}} = \mathbf{1}$) is used to model the noise footprint of the scaled-down baseline version (BL) of the hingeless four-bladed main rotor of the Bo-105 helicopter. The rotor, investigated in the HART II test campaign [7, 8, 9], has a radius of R = 2 m, a blade chord length of c = 0.121 m, a linear twist of $\boldsymbol{\theta}_{\boldsymbol{tw}} = -\mathbf{8}$ deg/R, and rotates at Ω = 109.12 rad/s. The rotor is also subjected to a free stream (advance ratio equal to 0.15, shaft angle of 5.3 deg) as in a descent flight.

The numerical data set for the identification of the multipolar expansion consists of the numerical results presented in [10].In particular, the complex-valued acoustic pressure on a carpet of virtual microphones placed under the rotor and the fuselage, at a distance of 2.215 m, is extracted for the first five multiples of the blade passing frequency (BPF) and used as reference pressure fields for the multipolar approximation. A convergence analysis has allowed us to consider N = 20 as the converged value. The good quality of the prediction obtained with N = 20 is demonstrated by the comparison between the reference and the reconstructed field shown in Fig. 1. In particular, the reconstructed acoustic fields using N = 20 are almost indistinguishable from the reference data for the first two BPF multiples, and negligible differences are present at higher frequencies (comparisons are shown in the Supplementary Information up to the fifth BPF multiple). In general, higher BPFs show multiple peaks in the directivity pattern, progressively narrower in space. Reproducing such pressure fields requires higher orders of the multipolar expansion to be used.

In this case, the model benefits from training points at various distances from the multipolar source, as they lie on a planar surface. This distribution helps the multipoles in obtaining a good approximation of the radial propagation of noise. At the same time, however, the multipolar expansion does not have information about the whole directivity, but only on a spherical sector as defined by the planar array of virtual microphones. Hence, when interrogated on points outside the bounding box of the original data set, the model tries to extrapolate information with poor results. This limitation is well known for interpolative models and can be overcome using training points covering the entire spherical angle surrounding the sources of the expansion, which, however, were not available in this case.

Results on jet noise

Large Eddy Simulations of round free jets at a Reynolds number $Re = 10^5$ and Mach number $M = 0.9$ have been used for the analysis reported in this paper. The jets originate from a short pipe nozzle at the inlet of which a boundary layer velocity profile is prescribed [11, 12, 13]. An in-house solver, based on the three-dimensional filtered compressible Navier–Stokes equations in cylindrical coordinates, has been used to perform the LES simulations. The LESs were carried out using grids containing an amount of points ranging between 250 million and 1 billion, with low-dissipation finite-difference schemes and relaxation filtering as a subgrid-scale dissipation model [11]. The LES are detailed at length in several references [14, 15, 13]. Data from a fixed nozzle-exit turbulence intensity $TI = 9\%$, and three thermal conditions were considered, corresponding to nozzle-exit temperatures of $T = T_a$, $T = 1.5\ T_a$, and $T = 2.25\ T_a$, with T_a being the ambient temperature, were used in this work. The dataset consists of pressure time series recorded over a domain extending in the streamwise direction from $x = 0$ to $x/D = 20$, and in the radial direction from $r/D = 0.5$ (nozzle centerline) to $r/D = 3$, where D denotes the jet exit diameter. After transforming the signals in the frequency domain, four values of Strouhal number ($Sr = 0.25$, 0.5, 0.75, 1) are considered. The number of multipolar sources is fixed to $N_{exp} = 6$ equally distributed along the jet axis up to $z_{max} = 15D$. Each multipolar source included monopolar, dipolar, and quadrupolar terms only, $N = 2$. For each Sr, a ROM is built, using the absolute value of the axial pressure distribution at $r/D = 2$ and $r/D = 2.5$ as training data. The prediction of the resulting model is validated against axial pressure data at $r/D = 3$. The training set includes multiple axial lines at various azimuthal angles ϕ spaced by $\Delta\phi$ to give information about the axial symmetry of the jet in the training phase. The axial symmetry of the ROM prediction improves as $\Delta\phi$ decreases; however, reducing $\Delta\phi$ below 15 deg does not yield further improvements with the current settings of N_{exp}, N, and z_{max}. Despite using information at multiple azimuthal lines in the training, the model could not achieve perfect axial symmetry due to the truncated nature of the multipolar expansion. Nevertheless, the difference for a fixed axial position along the azimuthal angular direction is very limited. Results are shown in Fig. 2: the ROM predictions are presented using a solid line for the mean azimuthal value and a shaded area representing a ±STD range. The prediction is good for the points outside the jet core. The points farther from the nozzle may fall inside the jet mixing region, where the noise cannot be approximated by a simple propagation, resulting in higher errors. This is particularly evident for the $r/D = 2$ case.

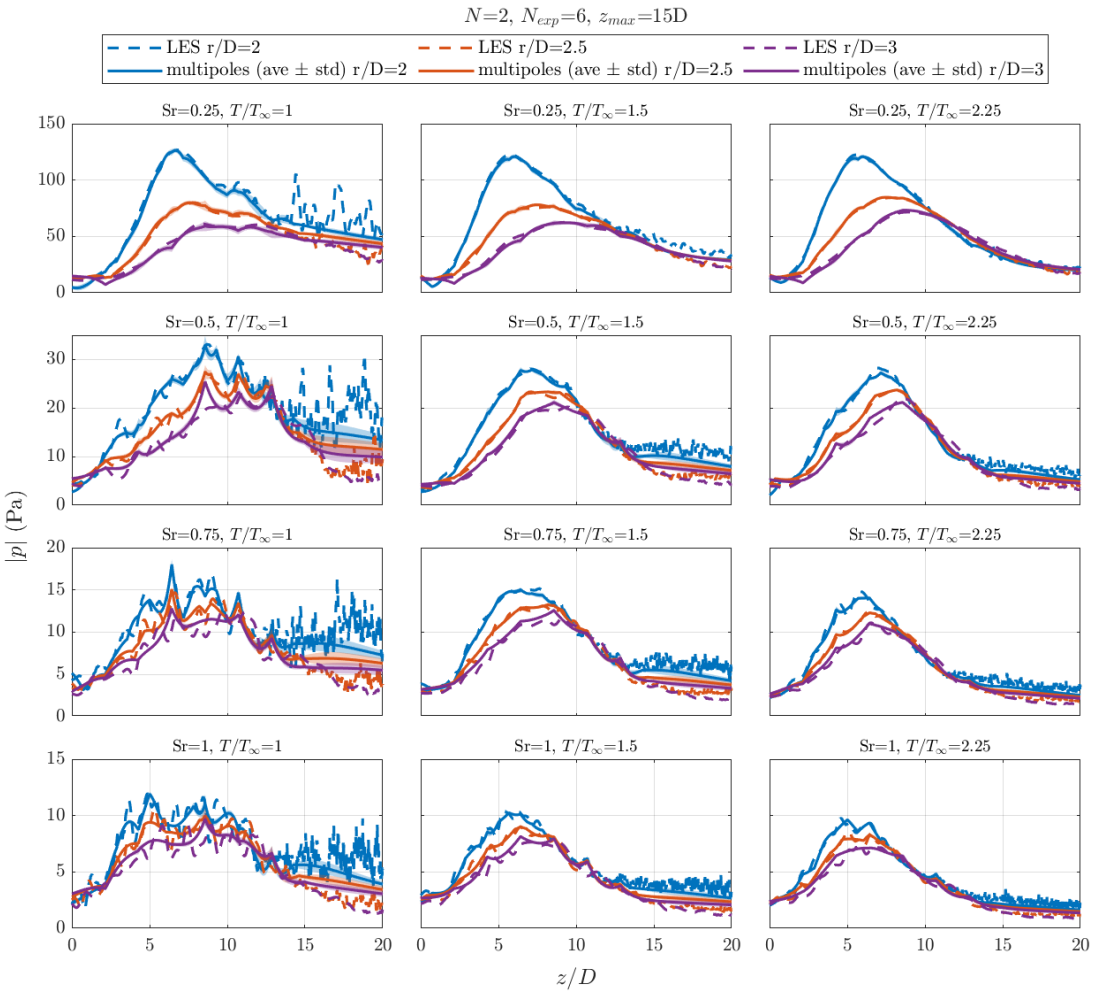

Figure 2: absolute value of pressure, comparison between LES and multipolar reconstruction, $N = 2$, $N_{exp}=6$, $z_{max} = 15D$.

Final remarks

This work investigated the applicability and performance of multipolar expansion techniques for the reduced-order modeling of complex aeroacoustic fields. Two representative configurations were analyzed: the scaled-down baseline version of the Bo-105 hingeless four-bladed main rotor tested in the HART II experimental campaign, and subsonic turbulent round jets computed via high-fidelity Large Eddy Simulations (LES). For the Bo-105 rotor, a single multipolar expansion accurately reproduced the reference acoustic fields, showing excellent agreement for the first two BPF harmonics and capturing key directivity features at higher harmonics. For subsonic jets, six multipolar sources were used to mimic the axially distributed characteristics of jet noise sources, with monopole, dipole, and quadrupole terms capturing key acoustic features across different thermal conditions

Abstract. This study presents a novel acoustic liner configuration developed using additive manufacturing, which enables precise geometric control. The proposed design modifies traditional honeycomb sandwich structures with microperforated plates (MPPs) by integrating a labyrinth channel inside the honeycomb core. MPPs provide both structural integrity and acoustic functionality by serving as inlets to the labyrinth, inducing thermal and viscous dissipation. A numerical model was developed in COMSOL Multiphysics using the Pressure Acoustics module, with MPPs modeled through dedicated boundary conditions and thermo-viscous effects applied to cavity walls. The predicted Transmission Loss results were validated experimentally using an impedance tube with grazing incidence. Numerical and experimental data showed good agreement, confirming the reliability of the model and demonstrating that the proposed liner achieves Noise Transmission Loss (NSTL) values exceeding 50 dB at the first resonance frequency. These promising results highlight the potential of this configuration for future aero-acoustic applications.

Introduction

The evolution of aircraft engines, characterized by large bypass ratios, will require advancements in liner designs to have an acceptable value of noise reduction, in a different frequency range and reduced space for which the current acoustic liner concept may be not sufficient [1] (Fig. 1). For this reason, novel configurations are object of research, such as variable depth liners [2], distributed face-sheets [3], slanted septum embedded [4, 5].

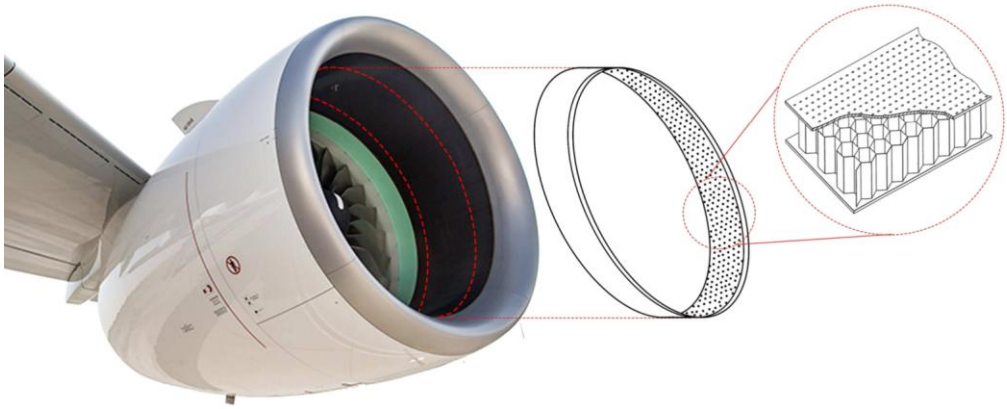

Figure 1 - Conventional liner [1]

To achieve good acoustic performances in a reduced space is a huge challenge, and the use of additive manufacturing technologies provides some flexibility in designing the final test article with specific characteristics. In this paper, a novel configuration of acoustic liner is proposed. The test article consists in a modification of the actual design of the conventional liners, consisting in

sandwich structures with a honeycomb core embedded in microperforated plates (MPPs). In particular, a labyrinth has been drawn and built in the honeycomb removing a small part of a cell wall from the internal honeycomb (Fig. 2), which mitigates tonal noise [6]. MPPs are fundamental to close the test article for structural integrity, and the holes work as inlet for the labyrinth, introducing at same time thermal and viscous dissipation.

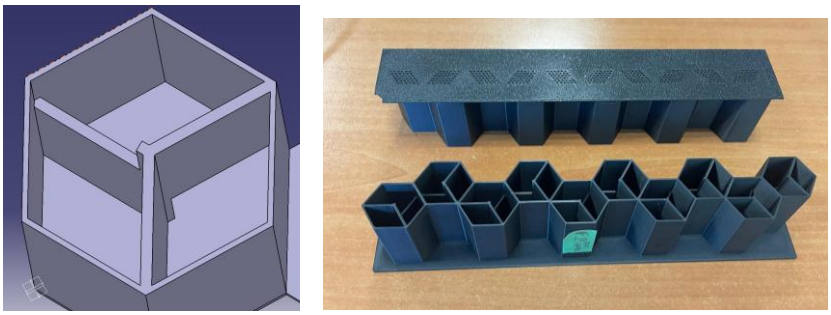

Figure 2 - acoustic metamaterial for liners

A numerical model has been first developed using COMSOL Multiphysics software (Fig. 3). Both the impedance tube and honeycomb cavities have modelled the Pressure Acoustics module in which the MPP is modelled with MPP boundary condition, while the Thermo-viscous Boundary Layer Impedance boundary condition is applied to the remaining walls. The results, in terms of Transmission Loss, carried out from numerical model (Fig. 4a) have been compared and validated with the ones coming from experimental tests in an impedance tube with grazing incidence holder (Fig. 4b).

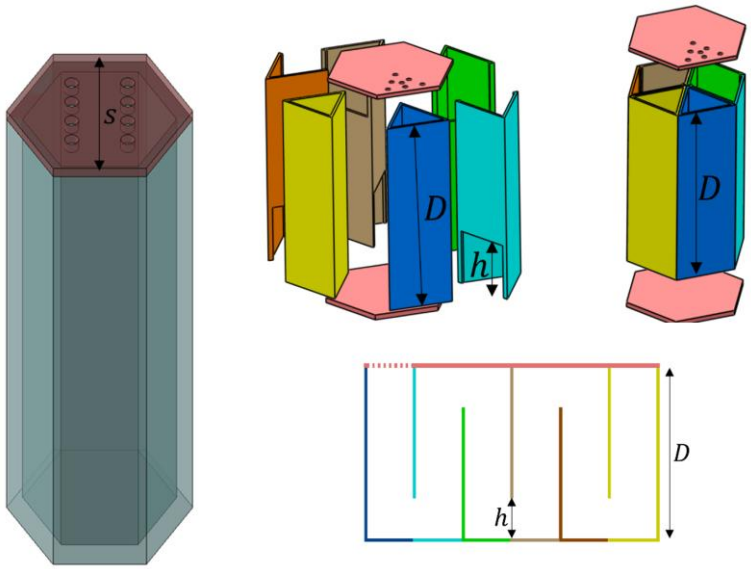

Figure 3 - numerical model of the unit cell of the proposed liner

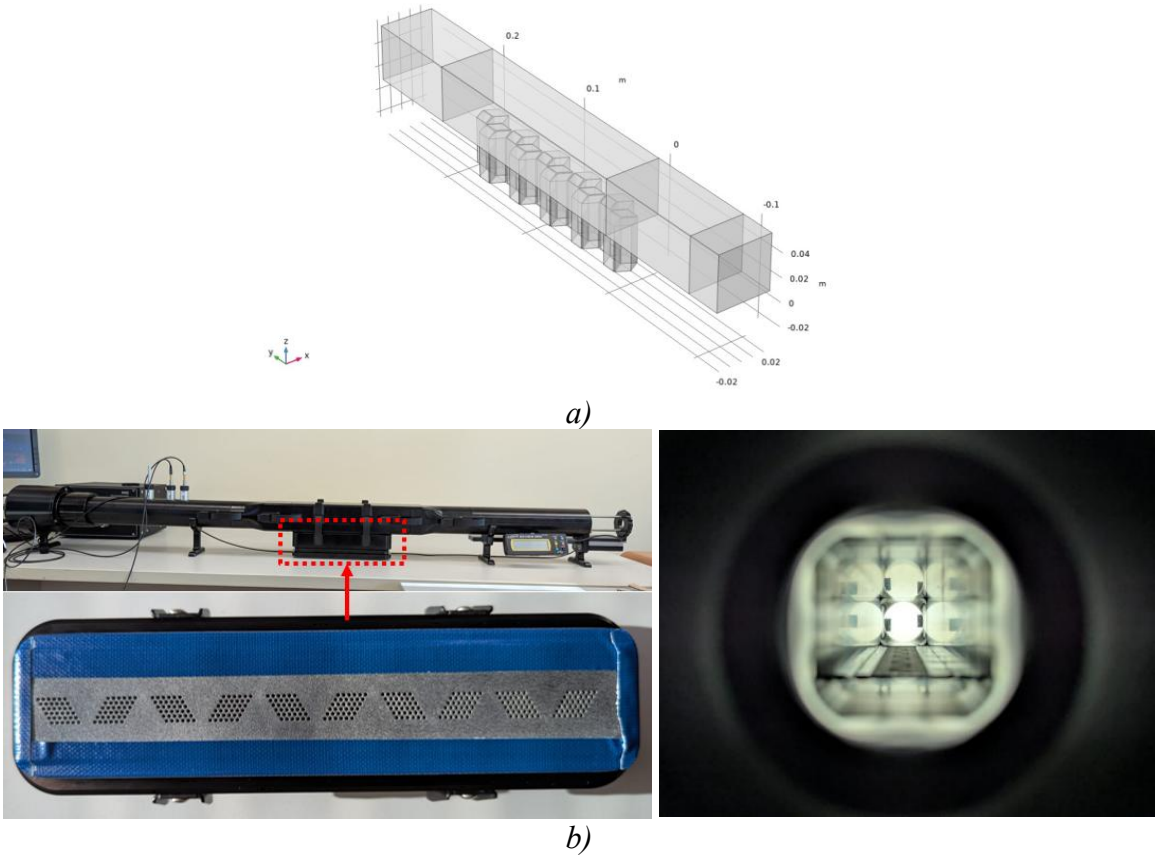

Figure 4 - Impedance tube with grazing incidence holder: a) numerical model and b) experimental tool

A comparison of numerical and experimental results carried out from the standard liner is reported in Fig. 5 and it can be noted that there is a good overlap of the two curves, which means that the numerical model.

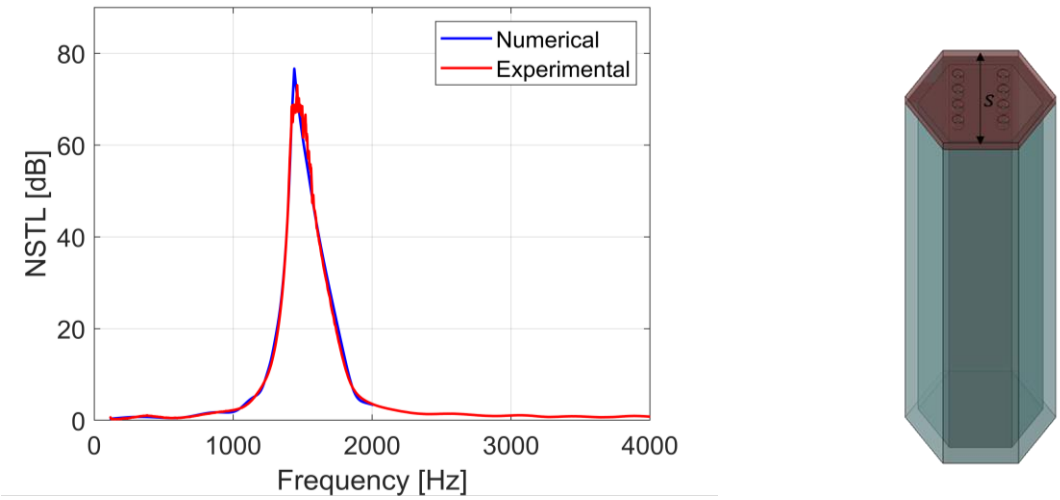

Figure 5 - Numerical and experimental comparison of NSTL of a standard liner

In Fig. 6. the same comparison for the proposed liner is reported and once it can be highlighted a good overlap of the curves, the numerical and experimental ones, especially for the first peak

followed by a small shift for the other two peaks at higher frequencies probably due to manufacturing defects. Moreover, the proposed liner show high acoustic performances with more peaks respect the standard ones, according to the effect of the labyrinth, and with values of NSTL high, more than 50 dB at the first frequency.

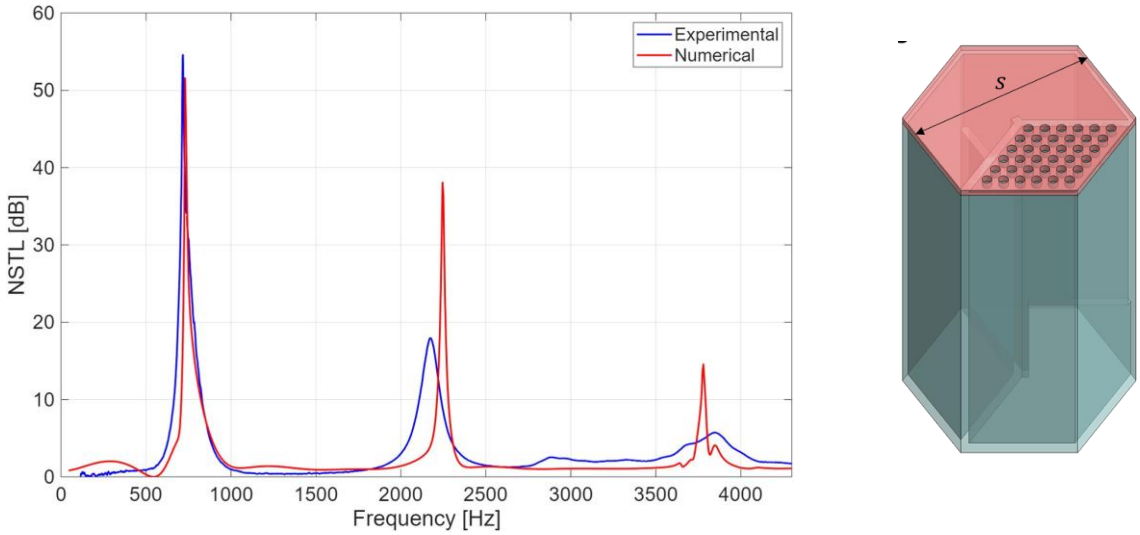

Figure 6 - Numerical and experimental comparison of NSTL of the proposed acoustic liners

Conclusion

This work introduced a novel acoustic liner configuration based on labyrinthine metamaterials, manufactured through additive techniques that enable high geometric precision and design flexibility. By integrating a labyrinth channel within a conventional honeycomb core closed by microperforated plates (MPPs), the proposed concept enhances acoustic absorption through combined thermal and viscous dissipation mechanisms.

Numerical simulations performed with COMSOL Multiphysics showed good agreement with experimental results obtained from grazing incidence impedance tube tests, confirming the reliability of the developed model. The proposed liner demonstrated superior acoustic performance compared to the standard configuration, achieving Noise Transmission Loss (NSTL) values above 50 dB at the first resonance frequency and exhibiting multiple attenuation peaks due to the labyrinth structure.

These preliminary findings highlight the effectiveness and potential of the proposed labyrinthine liner concept for advanced aero-acoustic applications. Future work will focus on further optimization of the geometry, detailed parametric analyses, and experimental validation under more representative operating conditions to support integration into real aeronautical systems.

Keywords: Wavenumber Space, Vibroacoustics, Isotropic Plates, Distorted Similitude

Abstract. Similitude methods are an important tool to address typical obstacles of structural testing, such as impractically large dimensions relative to laboratory space, as well as excessive cost and time. However, methods in the literature typically require the fulfillment of similitude conditions to achieve accurate, reliable reconstructions of full-scale responses. The approach proposed here overcomes this limitation by exploiting the dispersion relation to link the frequency scale factor to the wavenumber scale factor, the latter estimated from the model's mode shapes via a wavenumber transform, finally obtaining local scale factors to apply to each eigensolution. Numerical validation on two distorted models under simply supported boundary condition shows accurate reconstructions, supporting the robustness of the method.

Introduction

Similitude theory is widely used across many engineering branches, as testing scaled models, rather than full-scale prototypes, leads to cost reduction, lower complexity, and time savings [1], with significant impact not only on experimental testing, but also on numerical simulations [2]. In fact, similitude methods, rooted in this theory, enable the reconstruction of the structural response (whether static, dynamic, or due to impacts, etc.) of the prototype from that of the scaled model. Over the past seventy years, several methods have been proposed, such as dimensional analysis (DA) based on Buckingham's Π Theorem [3], similitude theory applied to governing equations (STAGE) [4], asymptotically scaled modal analysis (ASMA) [5], and sensitivity analysis (SA) [6].

The majority of these methods rely on the definition of scale factors, scaling laws and similitude conditions, the latter being mandatory requirements to fulfil to achieve the complete similitude condition. In this case, the scale factors are invariant terms enabling the mapping from the model to the prototype's behaviour through univocal scaling laws. However, when even one similitude condition is violated, the scaling laws are no more unique, with consequent reduction of the predictive capabilities of any similitude method.

When attempting the reconstruction of the structural response in frequency domain, the similitude methods proposed up to now fail to address the issue of distorted similitudes as the invariance of the scale factors cannot account for the changes of the modal sequence. The shift of the modes becomes more pronounced with larger geometrical distortions. This issue is of particular relevance, as distorted models may be the only solution to meet manufacturing limits and errors, as well as limited size of testing facilities [1].

The method herein proposed aims at reconstructing the dynamic response of isotropic thin plates under distorted similitude. The method exploits the spatial vibration pattern of mode shapes and their transform to the wavenumber space to determine ad hoc scaling factors for each natural frequency. Therefore, the scale factors of the natural frequencies and, consequently, of the frequency response are no more invariants, rather they act locally on each eigensolution.

Materials Research Proceedings 69 (2026) 298-302 https://doi.org/10.21741/9781644904251-53

Moreover, the derivation of the scaling laws relies only on very general expressions, such as the dispersion relation and the equation of the bending waves in thin plates, that do not involve dependencies on the boundary conditions, and do not lead to the imposition of similitude conditions. The entire procedure can be carried out only knowing geometrical and material properties of the prototype, and it requires only the response characteristics of the scaled model.

Derivation of the scaling laws

The convention on the scale factors r used in this work is the following:

$$r_X = \frac{X_p}{X_m} \tag{1}$$

where X denotes a generic physical variable, the subscript p refers to the prototype, and m to the model.

The equation of the bending waves speed c_b in thin isotropic plates [7] can be written in terms of scale factors as

$$r_{c_b} = \left(\frac{r_D}{r_\rho r_h}\right)^{1/4} r_\omega^{1/2} \tag{2}$$

where D is the bending stiffness, ρ is the mass per unit volume, h is the plate thickness, and ω is the angular frequency. Applying the same procedure on the dispersion relation leads to

$$r_{c_b} = r_c r_k = \left(\frac{r_D}{r_\rho r_h}\right)^{1/4} r_\omega^{1/2} r_k = \left(\frac{r_D}{r_\rho r_h}\right)^{1/2} r_k^2 \tag{3}$$

where k is the wavenumber.

Eq. 3 allows to estimate the frequency scale factor once the wavenumber scale factor is known. When $k = k_{m,n}$, i.e., when the wavenumber is equal to the modal wavenumber, then Eq. 3 provides the scale factor of the natural frequency associated with the mode (m, n), provided the modal wavenumber scale factor is known for both prototype and model. While the model's modal wavenumbers are available from experiments or numerical simulations, typical operating conditions of similitude methods assume that only the prototype's geometry and material properties are known, with no information about its frequency response. This issue can be easily bypassed by noting that, for a plate with length a and width b, the wavevector components along the sides of the plate (assumed parallel to the x and y axes) scale as $k_x \propto 1/a$ and $k_y \propto 1/b$, so that

$$r_{k_x} = \frac{k_{x_p}}{k_{x_m}} = \frac{a_m}{a_p} = \frac{1}{r_a} \tag{4}$$

Consequently, the x component of the wavevector of the prototype can be estimated as

$$k_{x_p} = \frac{k_{x_m}}{r_a} \tag{5}$$

and the y component can be estimated in a similar fashion through the width scale factor r_b.

Once the natural frequency scale factor is known, the velocity frequency response can be reconstructed through the scaling law [8]

Materials Research Proceedings 69 (2026) 298-302 https://doi.org/10.21741/9781644904251-53

$$r_V = \frac{1}{r_M r_\omega} \tag{6}$$

where V is the velocity, and M is the mass of the plate, provided that the corresponding frequency range is remodulated with the right frequency scale factor.

Numerical validation of the proposed method

The procedure is numerically validated on three plates under simply supported boundary conditions. The plates are prototype (P), model with small distortion (SD), and model with large distortion (LD). The geometrical characteristics of the plate are summarized in Table 1.

Table 1 - Dimensions of the plates and corresponding scale factors.

Plate ID	a [m]	b [m]	h [m]	r_a	r_b	r_h	r_a/r_b
P	0.658	0.478	0.0025	-	-	-	-
SD	0.616	0.382	0.002	0.94	1.25	1.25	0.75
LD	0.585	0.273	0.002	1.125	1.751	1.25	0.64

To ensure a satisfactory estimation of the wavevector components, the same mesh with 66 × 48 elements is applied to all the plates. Numerical modal and frequency response analyses are performed, and the mode shapes of the plates are processed through 2D Fast Fourier Transform with padding factor 100 to estimate the spectrum in the wavenumber space. The modal wavevector component along the x direction is calculated as [9]

$$k_m = k_z - \frac{2\pi}{a} \tag{7}$$

with k_z indicating the wavenumber corresponding to the first zero of the spectrum along the $x > 0$ semiaxis. The wavenumber component k_n can be determined analogously introducing the width b.

Fig. 1 displays the results of the reconstruction of the natural frequencies of the model SD (top row) and LD (bottom row) within the 0-500 Hz frequency range. In particular, the figures on the left column compare three sets of frequencies: the prototype, the model, and the prototype reconstructed from the model. The figures on the right column show histograms of the error distribution. The percent MAE (Mean Absolute Error) is the chosen metric. The results indicate low reconstruction error, within the 0%-0.3% and 0%-0.5% ranges for the models SD and LD, respectively.

The reconstruction of the root mean square (RMS) velocity is shown in Fig. 2 for SD and LD models, respectively. Due the local nature of the scale factors, both the frequency range and the velocity amplitude must be remapped peak by peak. The overall accuracy of the reconstruction is very good, with slight discrepancies in amplitude due to sampling matters rather than shortcomings of the method.

Materials Research Proceedings 69 (2026) 298-302 https://doi.org/10.21741/9781644904251-53

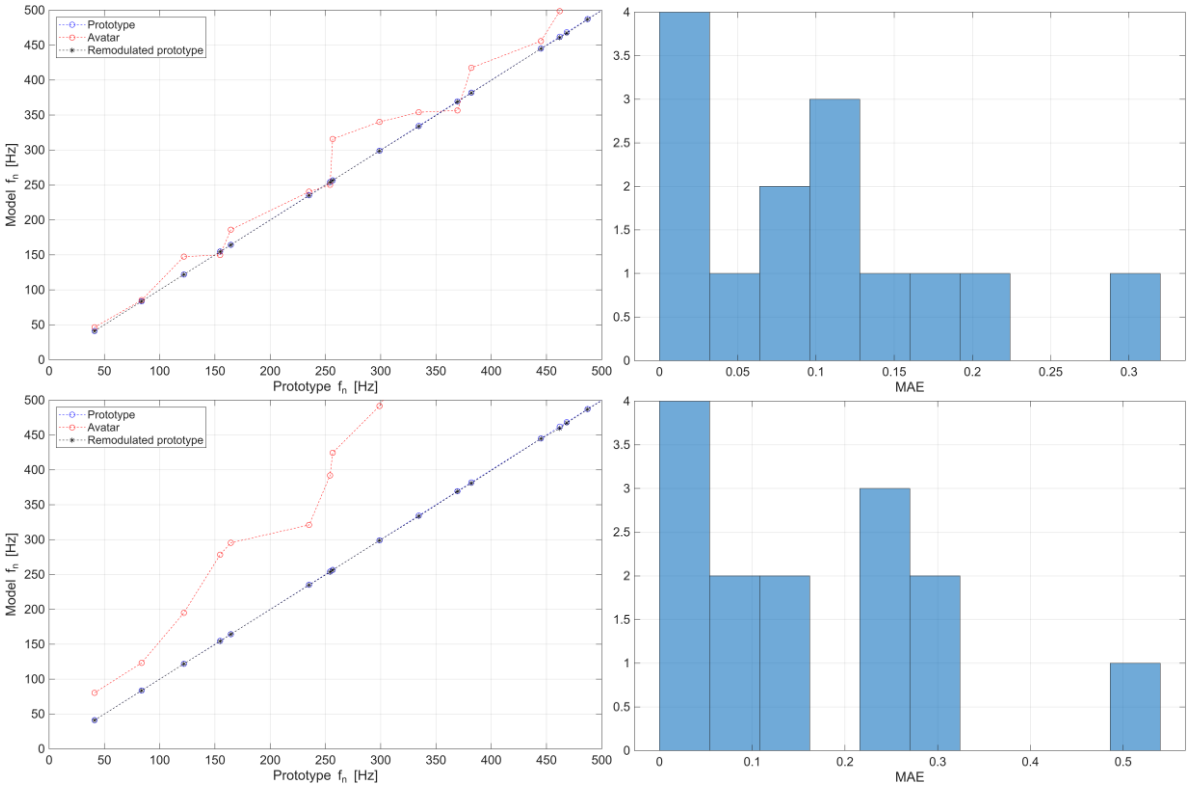

Figure 1 - Remodulation of natural frequencies and corresponding errors. Top-left: natural frequencies of P, SD, and remodulated P. Top-right: error histogram of the remodulated frequencies from SD. Bottom-left: natural frequencies of P, LD, and remodulated P. Bottom-right: error histogram of the remodulated frequencies from LD.

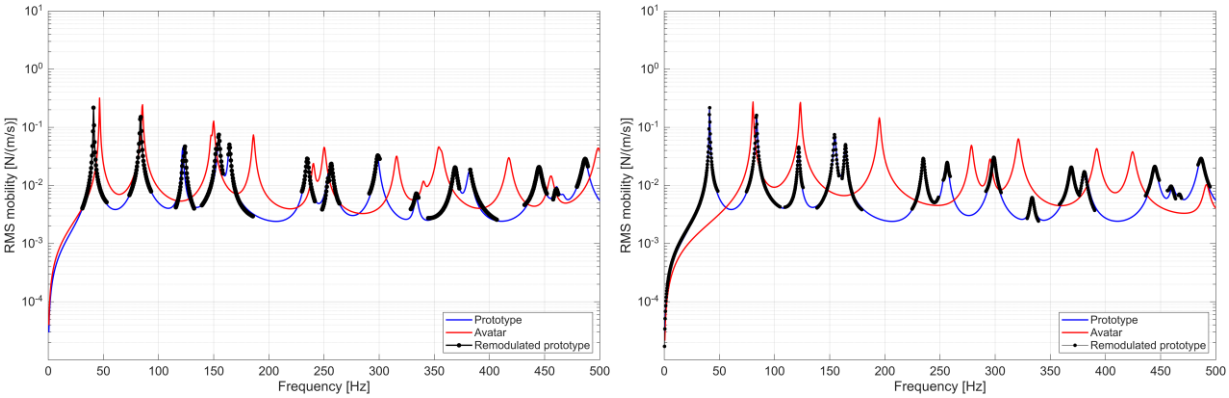

Figure 2 - Reconstruction of the RMS velocity. Left: SD model. Right: LD model.

Conclusions

This work proposes a wavenumber-based method to reconstruct the structural response of plates under distorted similitude. By applying a 2D spatial Fourier transform to the plates' mode shapes, the modal wavevector of the mode and its scale factor are estimated, then the scale factor of each natural frequency is obtained via dispersion relation. Numerical tests on two plates, exhibiting small and large distortions, yield accurate reconstructions, indicating that the method is both robust and reliable. The approach rests on general relationships (dispersion relation and bending-wave speed), avoiding boundary condition-dependent expressions. Finally, it requires only prototype scaling information (geometry and/or material properties), with no need for response data, which makes the method easy to implement and suitable in operating conditions.

Keywords: Sandwich Panel, Higher-Order Models, Dynamic Analysis, Vibroacoustic Analysis

Abstract. Lightweight sandwich panels are widely used in aeronautical engineering for their high specific strength, stiffness, and multifunctional performance. Their applications have expanded from interior components to secondary and even primary load-bearing structures, as they offer excellent acoustic insulation and cabin noise and vibration reduction. Recent research focuses on enhancing acoustic performance through modified core materials, geometries, or absorptive layers. The present work is devoted to the development of high-fidelity multilayered plate models within the Carrera Unified Formulation (CUF) methodology, including the description of the physical nonlinearities of soft cores using a hyperelastic constitutive law. Within this framework, the linearized modal and frequency response analyses of lightweight sandwich structures with soft cores are proposed, examining the influence of prestress on natural frequencies, transmission ratios, and overall dynamical properties.

Introduction

Lightweight sandwich panels have been increasingly adopted in aeronautical engineering due to their excellent specific strength and stiffness, as well as their potential for multi-functional performance [1]. Sandwich panels in aircraft are also typically employed for their notable acoustic performance, providing better sound and vibration insulation, as well as noise isolation and absorption [2]. The enhanced acoustic properties expressed by the core (honeycomb, foam, acoustic liners, etc.) and face sheets are typically measured by metrics like sound transmission loss (STL), thus, several solutions and designs have been proposed to enhance the performance of such structures in various applications.

Due to the complexity of the involved structures, numerical simulations based on the Finite Element Method have emerged as a common approach, as they provide a flexible and efficient tool for the complex dynamic characterization of such structures (vibrations, frequency response) and design investigations [3], effectively including material anisotropy, boundary conditions, viscoelasticity, and frequency-dependent core behavior [4,5]. To simulate these features, high-fidelity models have been proposed within the well-established Carrera Unified Formulation (CUF) framework, where 2D plate models with three-dimensional capabilities for the dynamic analysis of multilayered sandwich structures have been shown to be effective [6,7]. These high-fidelity FE models, based on higher-order kinematics and structural theory, provide reliable results for static, modal, and dynamic behavior, as shown in many works [8,9].

In addition, the prestress condition in sandwich structures plays a critical role in enhancing acoustic isolation; it can affect the natural frequencies, mode shapes, and dynamical properties of the panel, thereby improving the acoustic performance and sound transmission loss (STL) of the structure. These features can also be used as tuning parameters to tailor acoustic performance,

Materials Research Proceedings 69 (2026) 303-307 https://doi.org/10.21741/9781644904251-54

modify the structure's damping characteristics, and reduce wave transmission. Moreover, prestress can induce beneficial geometric stiffening, which limits large-amplitude vibrations and enhances structural integrity or creates frequency band gaps.

Higher-order structural theories

The Unified Formulation for development of higher-order plate theories has been already established in the literature, and here extended to the analysis of multilayered sandwich plates in pre-stressed conditions. The linearized frequency response analysis is exploited in a numerical framework adopting higher-order multilayered plate (2D) models, defined under the CUF formalism: :

$$\boldsymbol{u}(x,y,z) = F_\tau(z)\boldsymbol{u}_\tau(x,y) = F_\tau(z)N_i(x,y)\boldsymbol{u}_{\tau i} \quad \tau = 1,\dots,\mathrm{M}, \quad i = 1,\dots,\mathrm{N_n} \tag{8}$$

where M is the related to the order of the structural theory adopted, $\boldsymbol{F_\tau(z)}$ is the set of expansion functions, representing the theory of structure approximation, $\boldsymbol{N_i(x,y)}$ is the set of 2D shape functions of the discrete $\mathrm{N_n}$ finite nodes along the mid-surface, and finally $\mathbf{u_{\tau i}}$ is the vector of generalized displacement component.. In the present work, Lagrange Expansion (LE) class are considered, starting from the set of Lagrange's polynomials [6].

Governing equations

The equilibrium equations for the static and linearized frequency response analysis are carried out by means of the Principle of Virtual Displacements (PVD), written as:

$$\delta\mathcal{L}_{ine} + \delta\mathcal{L}_{int} = \delta\mathcal{L}_{ext} \tag{1}$$

where $\boldsymbol{\delta\mathcal{L}_{ine}}$ is the virtual variation of the work done by inertial forces, $\boldsymbol{\delta\mathcal{L}_{int}}$ and $\boldsymbol{\delta\mathcal{L}_{ext}}$ represents instead the virtual variation of the internal strain energy and work done by the external forces, respectively. Adopting the same indices notation introduced for the displacement field also for the Green-Lagrange strain tensor and the virtual quantities, one can derive the FN (Fundamental Nuclei) of the internal and external forces vector and mass matrix, obtaining the matrix form of the governing equation.

$$\delta\boldsymbol{u}_{sj}: \ \boldsymbol{M}^{\tau sij}\ddot{\boldsymbol{u}}_{\tau i} + \boldsymbol{F}_{int}^{sj} = \boldsymbol{F}_{ext}^{sj} \ \rightarrow \ \boldsymbol{M}\ddot{\boldsymbol{u}} + \boldsymbol{F}_{int} = \boldsymbol{F}_{ext} \tag{9}$$

The nonlinear governing equation is then linearized to implement an incremental numerical solver based on path-following constraints. Through a Taylor expansion truncated at the first order, one can derive the incremental equation:

$$\boldsymbol{M}\Delta\ddot{\boldsymbol{u}} + \boldsymbol{K}_T\Delta\boldsymbol{u} = -\boldsymbol{\phi}_{res}(\boldsymbol{u}_0, \ddot{\boldsymbol{u}}_0, \boldsymbol{p}_0) + \boldsymbol{I}\Delta\lambda\boldsymbol{p}_{ref} \tag{9}$$

Finally, imposing a harmonic solution of the type $\boldsymbol{\Delta u = \Phi e^{i\omega t}}$ when an harmonic load of the type $\boldsymbol{p_{ref} = \bar{p}e^{i\omega t}}$ the frequency response problem around pre-stressed conditions are obtained, that provides the amplitude of the displacements $\boldsymbol{\Phi}$ around the computed non-trivial equilibrium state for each excitation frequency $\boldsymbol{\omega}$:

$$(\boldsymbol{K}_T - \omega^2\boldsymbol{M})\boldsymbol{\Phi} = \bar{p} \tag{9}$$

The analysis of multilayered structures via higher-order finite elements based on CUF has already been established in many works, including also physical nonlinearities.

Numerical results

The proposed approach is applied to the analysis of a multilayered sandwich structure with a natural rubber-like core and composite skin, evaluating its dynamic properties via frequency response analysis under various pre-stressed conditions. The proposed case studies have been

Materials Research Proceedings 69 (2026) 303-307 https://doi.org/10.21741/9781644904251-54

proposed by Selvaraj et al. [10]. A composite plate of length L = 300 mm, width B = 300 mm and overall thickness H = 10.05 mm is considered, with two laminated skins of thickness h_s = 2.01 mm made of natural composites with lamination 0°/90°/0° and core with thickness $h_c = 6.03$ mm. The resulting structure is then a final composite laminate with stacking sequence 0°/90°/0°/rubber-core/0°/90°/0°. The material constants adopted in the case of natural composite for the skin sheets are $E_1 = 5.16$ GPa, $E_2 = 4.70$ GPa, $\nu_{12} = 0.15$, $G_{12} = 0.81$ GPa and $\rho = 1197$ kg/m^3. Different from the reference work, the core layer is modeled using the Neo-Hookean hyperelastic model [11], with calibrated constants matching the original infinitesimal elastic constants, namely $\mu = 1.61$ MPa and $k = 10.72$ MPa. In all the models considered, a single parabolic LE2 model per layer will be adopted, for a total of seven LE2 elements along the through-the-thickness discretization. Figure 1 shows the graphical representation of the geometrical features and finite element model adopted.

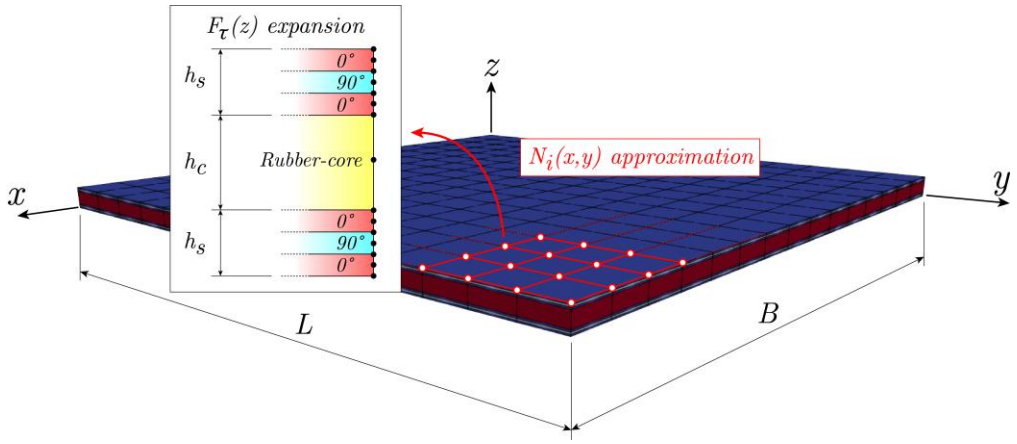

Figure 1: Rubber-core sandwich plate: geometrical features and finite element approximation

The first analysis addressed is the modal analysis of the plate in a clamped-free-free-free (CFFF) configuration, validating the proposed approach and investigating the influence of the mid-surface discretization on the results. Table 1 shows the first five natural frequencies of the CFFF plate, comparing the results obtained against the available literature reference ones, including the relative percentage difference between the 2D CUF results and the actual reference, reported in brackets

Ref. [1]	25.82	39.32	96.48	115.29	129.99	-

For the considered discretizations, furthermore, the nonlinear static analysis of the clamped plate for an applied pressure at the top surface in the transversal direction is considered, to analyze the influence of highly-deformed states and pre-stress effects to the linearized frequency response analysis. Adopting instead the 20x20 Q9 + 7 LE2 discretization, also the linearized vibration problem is solved around specific equilibrium conditions. The results for both these analysis are proposed in Fig. 2, uniquely defined introducing the tangent stiffness matrix at the specific equilibrium point reported and applying a load variation of $\bar{p} = 1$ Pa. All the results are measured at the tip free-end point, at location $x = L$, $y = B/2$ and $z = H$, as reported in Fig. 1. The

equilibrium path instead is reported in terms of transversal displacement u_z measured at the same location.

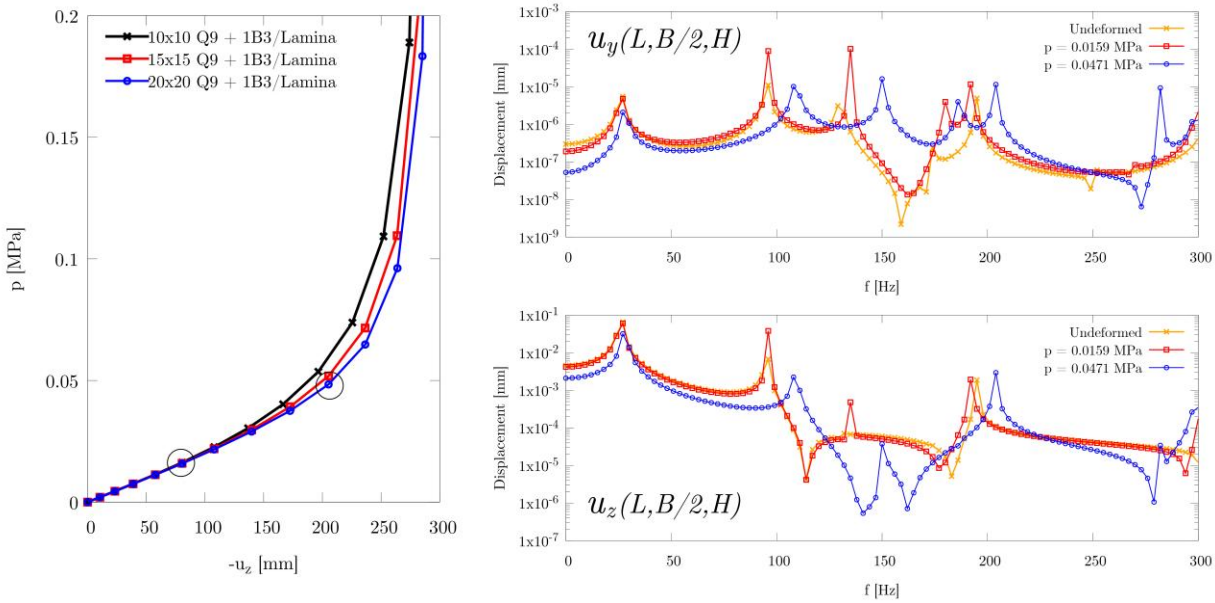

Figure 2: Rubber-core sandwich plate: static and linearized frequency response analysis. Comparison between higher-order 2D CUF solutions and influence of pre-stressed condition on the dynamic response around highly-deformed states.

Conclusions

This manuscript discusses the implementation of linearized frequency response analysis for the mechanical characterization of composite sandwich plate with soft cores, implementing physical nonlinearities to accurately represent the complex response of the core layer. The linearized dynamic problem around a generic non-trivial equilibrium state is solved implementing a finite element procedure that exploits the adoption of higher-order CUF-based finite element, an efficient tool for the generation of accurate and efficient numerical models for multilayered plate structures based on higher-order theory of structure approximation. The proposed results suggest the consistency of the proposed approach and the capabilities of the modeling strategies when coupled problems are considered. In particular, the effects of pre-stressed conditions on the frequency response analysis are analyzed, including the evolutions of resonance peaks and dynamic properties for varying pre-stressed states.

Abstract. This study investigates the influence of different Ffowcs Williams and Hawkings (FW–H) formulations on far-field noise prediction for a propeller-driven strut-braced wing aircraft. High-fidelity flow data were obtained using the Lattice–Boltzmann Very-Large-Eddy Simulation (LB-VLES) solver PowerFLOW®, and acoustic predictions were carried out using the permeable-surface, solid-surface, and volumetric FW–H analogies included in the $Opty\partial B$™ toolkit. Results show that the permeable formulation reproduces both the amplitude and directivity of the dominant tonal lobes in good agreement with the noise directly extracted from the CFD simulation. The solid formulation, instead, exhibits discrepancies in regions exposed to the impingement of propeller-generated sound waves, where pressure fluctuations are detected but not correctly propagated. The volumetric approach, while computationally demanding, provides valuable physical insight by confirming the absence of actual radiating sources on that part of the fuselage. For similar configurations, the permeable formulation represents the most reliable and computationally efficient choice for predicting far-field noise.

Introduction

The prediction of far-field aircraft noise has become a critical component in the design of next-generation low-noise aircraft. Most aeroacoustic simulations rely on acoustic analogies, with the Ffowcs Williams–Hawkings (FW-H) method being a standard in both academia [1] and industry [2].

Two main formulations of the FW-H method are commonly employed: the solid surface formulation, which records pressure fluctuations on the aircraft surface, and the permeable surface formulation, which samples the data on a surface located within the flow, enclosing the entire noise-generating region, and capturing both surface and volume sources [3]. Each has its own practical advantages and theoretical limitations. Recent studies have provided valuable insights into the performance of both approaches. For instance, Spalart et al. [4] emphasized the sensitivity of the permeable formulation to numerical errors and surface placement, while Ribeiro et al. [2] showed that even in large-scale simulations, solid surface methods can lead to overprediction or misidentification of key sources, particularly in the presence of shielding and complex geometries.

In this context, this work aims to assess the performance of the solid and permeable FW-H formulations when applied to a high-fidelity simulation of a propeller-driven regional aircraft with a strut-braced wing configuration. The simulation is carried out using the LBM-VLES solver PowerFLOW®, and results are assessed in terms of their acoustic directivity, spectral content and noise source density.

Materials Research Proceedings 69 (2026) 308-313 https://doi.org/10.21741/9781644904251-55

The manuscript is organized as follows: first, the methodology is described; next, the results of the analysis are discussed; finally, the main conclusions are presented.

Methodology

The flow field was computed using the flow solver PowerFLOW®, version 6-2022-R3 from 3DS Dassault Systèmes, which implements the Lattice-Boltzmann Method (LBM). The software used has been extensively used to accurately predict noise generated in complex flow problems, including full-vehicle configurations [5], and propulsion systems [6] [7]. A detailed description of the solver can be found in Ref. [8]. For the present computation, the high-subsonic solver, extended to transonic regime, is used.

Far-field noise predictions were obtained using three approaches: the permeable-surface formulation of the FW–H analogy ($Opty\partial B$-FWHFREQ™), the solid formulation ($Opty\partial B$-SOLID™), and the complete volumetric analogy ($Opty\partial B$-LIGHTHILL™). The solid surface consisted in the aircraft surface. The permeable surface was defined as an offset from the aircraft plus a cylinder, which includes the propeller's wake, to reduce spurious noise sources. Three equally shaped FW-H surfaces, placed 25 cm apart, were used to average noise signals. For the full volumetric formulation, the integration domain corresponds to the volume enclosed by the previously defined permeable surface. The tailored Green's function was obtained using the quasi-Dirac pulse method described in Ref. [9]. Since acoustic reciprocity does not hold in a rotating frame, the local rotating frame (LRF) associated with the propeller was excluded from the volume integral and accounted for through an additional permeable surface surrounding the LRF. The additional Green's-function simulation required about 5k CPU-h compared to the 70k CPU-h for the main run. The subsequent volumetric FW–H calculation, performed for one microphone over a narrow frequency range, lasted around three hours on a fat node of the Dutch national supercomputer Snellius (dual AMD EPYC Rome 7H12 @ 2.6 GHz, 128 cores, 1 TiB RAM). Consequently, the full spectrum is not shown in the next section, and only source-localization results are presented for this case.

Results

An overview of the instantaneous flow field is provided in Fig. 1, which shows a λ_2 isosurface coloured by the velocity magnitude and normalized by the freestream value. The insets in the top-left and top-right corners highlight the interaction of the tip vortices with the wing and the strut, respectively. This visualization intends to introduce the reader to the aerodynamic features underlying the acoustic mechanisms under investigation. A more detailed flow analysis is intentionally omitted to comply with the page limitations and to maintain focus on the acoustic analogy assessment.

Materials Research Proceedings 69 (2026) 308-313 https://doi.org/10.21741/9781644904251-55

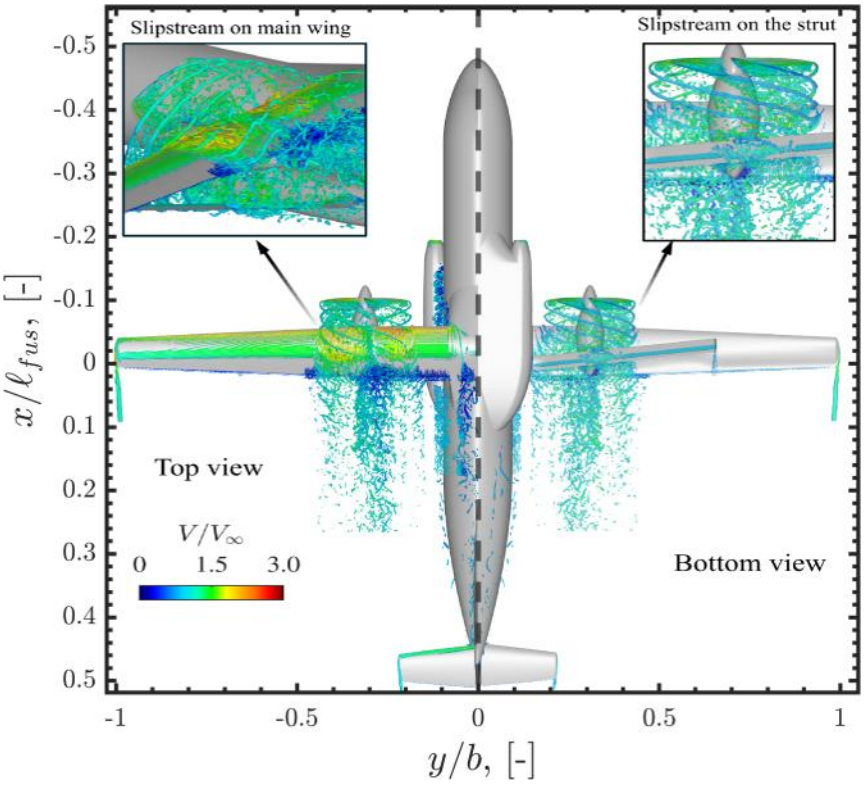

Figure 1: Isosurface of λ_2 colored by the magnitude of velocity, V, normalized by the cruise speed, V_∞.

Figure 2(a) shows the aircraft geometry, the FW–H integration surface, and the microphone array used for the acoustic analysis. The Overall Sound Pressure Level (OASPL) at the microphone locations for both FW–H formulations, compared with the direct noise extracted from the simulation, is displayed in Fig. 2(b). The permeable formulation shows good agreement with the direct results, except in the angular regions upstream and downstream (grey areas in the Fig. 2(b)), likely due to the impingement of the propeller wake on the FW–H surface. Despite these local deviations, the overall agreement is very satisfactory, confirming the reliability of the results obtained with the permeable formulation. In contrast, the solid formulation exhibits a marked discrepancy, particularly at $\theta = 250°$, where it fails to reproduce the acoustic lobe. To investigate this discrepancy, Fig. 3 shows the sound pressure spectra at the microphone located at $\theta = 250°$. The results obtained with the permeable formulation are compared with those from the solid formulation, which is also decomposed into its individual surface contributions. The spectra show that the solid formulation underpredicts both the first and second Blade-Passing-Frequency (BPF) tones. Focusing on the first BPF, it can be seen that the fuselage contribution has an intensity comparable to that of the propeller. A phase analysis, not shown here for conciseness, shows that these two signals are nearly out of phase at the first BPF, resulting in a destructive interference between the fuselage and propeller contributions.

Materials Research Proceedings 69 (2026) 308-313 https://doi.org/10.21741/9781644904251-55

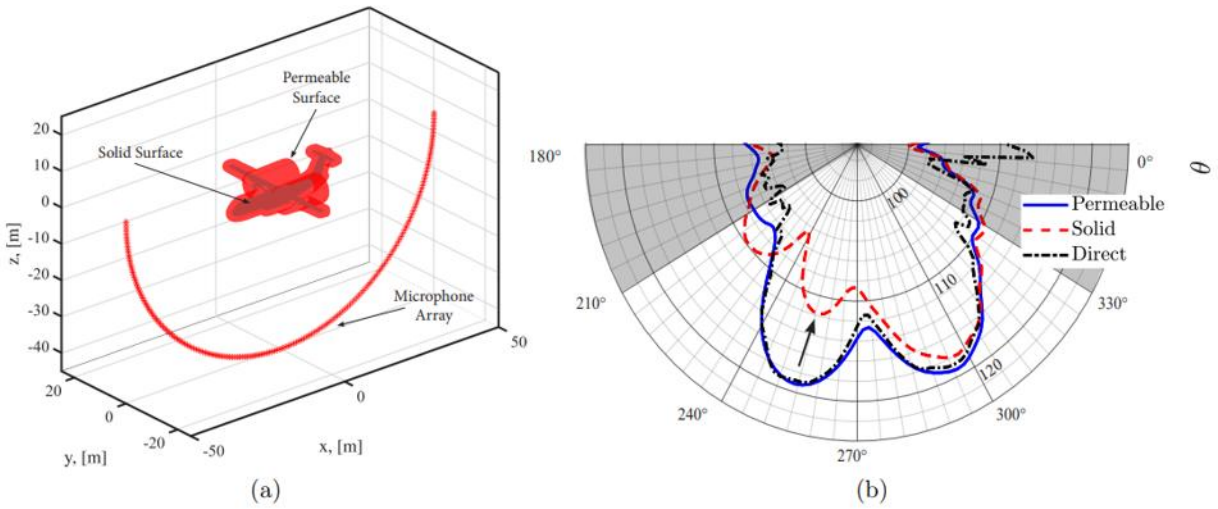

Figure 2: (a) Far-field directivity arc together with the aircraft geometry and the FWH surface used for the analyses. (b) Comparison between the noise computed by means of solid and permeable FWH formulation.

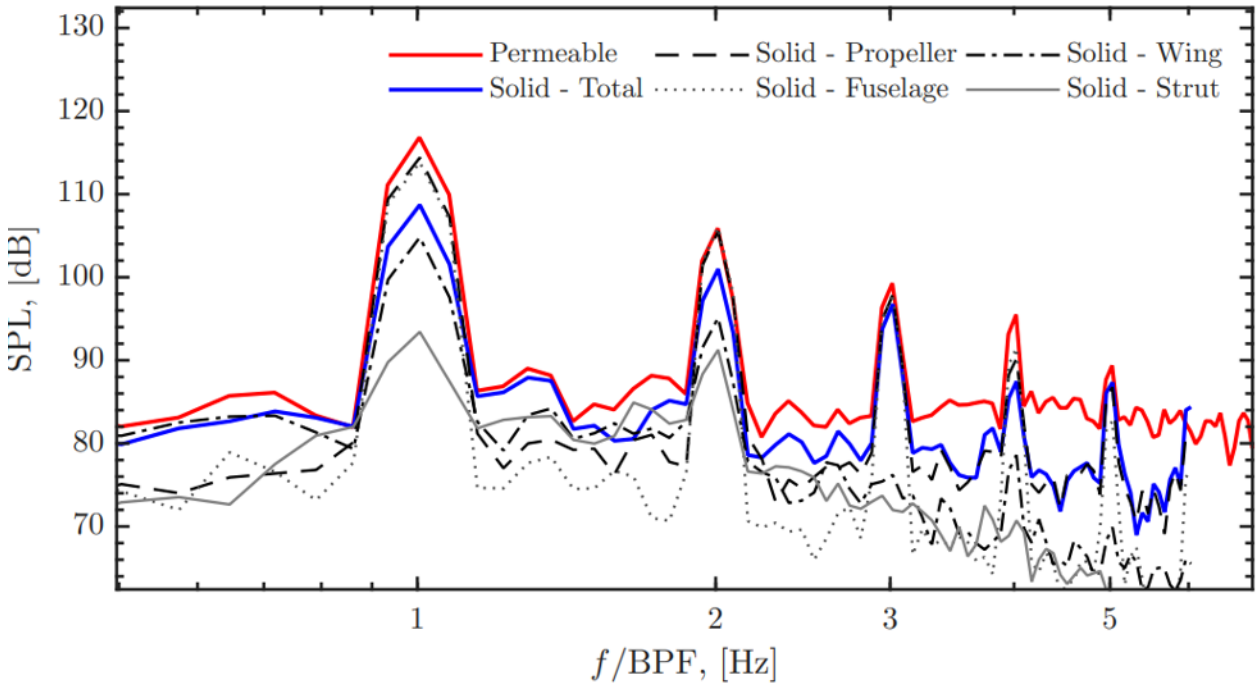

Figure 3: Sound level spectra at the microphone located at θ = 250◦ . Comparison between Permeable and Solid FWH formulation.

Furthermore, the inspection of the acoustic source amplitude per unit area obtained with the solid formulation (see Fig. 4(a)) shows that this contribution originates from the upper side of the fuselage sponson. In fact, the fuselage sponson is exposed to the impingement of the propeller-generated sound waves during rotation, resulting in high pressure fluctuations sampled on the solid surface.

Figure 4(b) shows the noise sources computed using the volumetric FW–H analogy at the first BPF. According to this formulation, the main source is the propeller. However, this contribution is not shown in the Fig. 4(b) since the local rotating frame is excluded from the integration volume (see Sec. Methodology). The secondary volumetric sources, displayed as isosurfaces of noise

Materials Research Proceedings 69 (2026) 308-313 https://doi.org/10.21741/9781644904251-55

source amplitude per unit volume, show pronounced distortion effects on the wing and strut, while no contribution from the fuselage sponson is observed. This comparison suggests that the solid formulation identifies apparent sources on surfaces affected by the impingement of acoustic waves, as its propagation model does not account for local flow refraction. In contrast, the permeable and volumetric formulations correctly interpret these fluctuations as non-radiating. In addition, it is worth noting that no source appears on the lateral side of the fuselage in Fig. 4(a), indicating that the discrepancy occurs only when the reflecting surface is oriented with its normal in the observer direction.

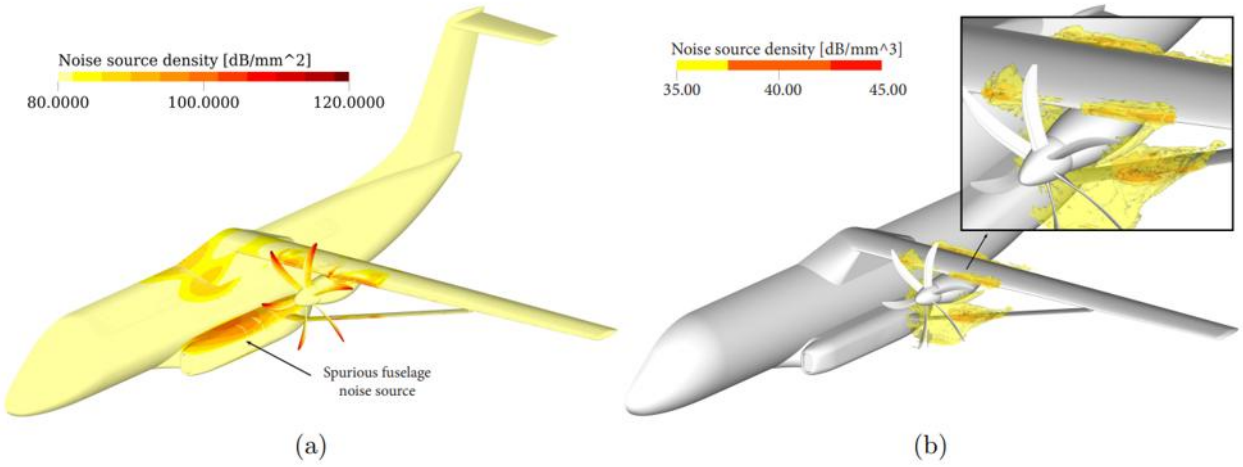

Figure 4: Noise source density at the first BPF computed with (a) solid FW-H formulation and (b) the volumetric acoustic analogy.

Conclusion

The study presented a comparative assessment of three acoustic analogy formulations: permeable FW–H, solid FW–H, and volumetric FW-H applied to the prediction of far-field noise from a propeller-driven strut-braced wing aircraft. The flow field was computed using the Lattice–Boltzmann solver PowerFLOW®.

The results show that the permeable formulation provides a consistent agreement with the noise extracted from the CFD simulation, accurately reproducing both the directivity and amplitude of the dominant acoustic lobes. The solid formulation, instead, exhibits discrepancies in regions influenced by the impingement of sound waves generated by the propeller, such as on the fuselage sponson. In these areas, pressure fluctuations are detected but are not correctly propagated as acoustic waves, since the underlying propagation model does not account for local flow refraction. This interpretation is supported by the volumetric FW–H analysis, which confirms that no actual radiating sources are present in those regions.

Although the volumetric approach offers valuable physical insight, it is computationally expensive and not feasible when many microphones or frequency bands are of interest. The permeable formulation is therefore recommended for practical far-field predictions, while caution should be exercised with the solid formulation in regions affected by strong mean-flow gradients or acoustic reflections.

Abstract. In this work, we propose a multi-fidelity approach to optimize the geometry of a small fixed-pitch propeller to reduce its acoustic impact. This way, the advantages of low-fidelity methods (low cost and fast results) can be combined with those of higher-order ones (better resolution and more reliable results) to obtain an optimized solution within a reasonable timeframe. We train a fully connected network surrogate that maps propeller geometry (chord and twist) and thrust to optimal rotating speed, torque, and sound pressure level (SPL) at the blade passing frequency (BPF) at 17 different angles, and benchmark it on three datasets: low-order blade element momentum theory (BEMT), higher-order vortex particle method (VPM), and a balanced Mixed set.

Introduction

Advanced Air Mobility (AAM) has experienced significant development in recent years, and this trend is expected to continue [1]. Among these developments, small electric Unmanned Aerial Vehicles (UAVs) promise to improve small cargo transport, such as last-mile shipping, medical emergency delivery, surveillance, traffic management, etc. However, some drawbacks also emerge, including security risks and environmental impact. Among these drawbacks, one of the most important is noise pollution, which can contribute to reducing social acceptance.

Propellers are the primary noise source in small electric UAVs. Thus, reducing the noise produced by the propellers is the best approach to mitigate the acoustic footprint of UAVs and, therefore, facilitate their social acceptance [2]. These fixed-pitch propellers typically operate at low Reynolds regimes and Mach numbers below 0.3, setting them apart from traditional aircraft propellers. As a result, certain complex phenomena may gain importance, such as laminar-turbulent transitions and the emergence of laminar separation bubbles. For this reason, low-order models cannot always fully predict the complex aero-acoustic processes involved.

Numerical models and validation

The proposed numerical models are a combination of Blade Element Momentum Theory (BEMT) and the Hanson model [3], implemented as an in-house code, as the low-fidelity approach; and a reformulated Vortex Particle Method (VPM), implemented in FLOWUnsteady [4] as a mid and high-fidelity model —depending on the number of particles—, coupled to a Ffowcs-Williams and Hawkings (FW-H) solver to compute the acoustics. A fourth, high-fidelity Finite Volume Method (FVM) model, implemented in OpenFOAM, was also tested, using the improved delayed detached eddy simulation (IDDES) technique coupled again with the FW-H method.

The main advantage of the proposed methodology is that the same common propeller plain text description file is used as an input for all the fidelity levels, and a custom toolchain has been implemented to programmatically simulate each fidelity level. In the case of the FVM-CFD method, which of course requires the actual geometry to be meshed, advantage is taken of NASA's Open-VSP software [5] to automatically build an STL format representation of the propeller, which is then meshed and solved by OpenFOAM.

To validate the models, a commercial propeller (XOAR 9x7") was also tested in the anechoic chamber available at the CMT Institute, to provide experimental validation to the proposed numerical approaches. As can be seen in Figure 1, which focuses on the Blade Passing Frequency tonal noise, good agreement is found for this acoustic feature at the propeller plane (0º), and some of the downstream orientations (-30º and -60º). However, as expected, upstream acoustic propagation in the propeller axis direction (90°) was not achieved by either the low-fidelity model or the mid-fidelity VPM settings. Increasing the VPM fidelity level, or switching to the FVM approach, yielded good agreement even in the 90º direction. However, the FVM model required significantly more computational resources than the VPM approach, and therefore, it was not used in this work.

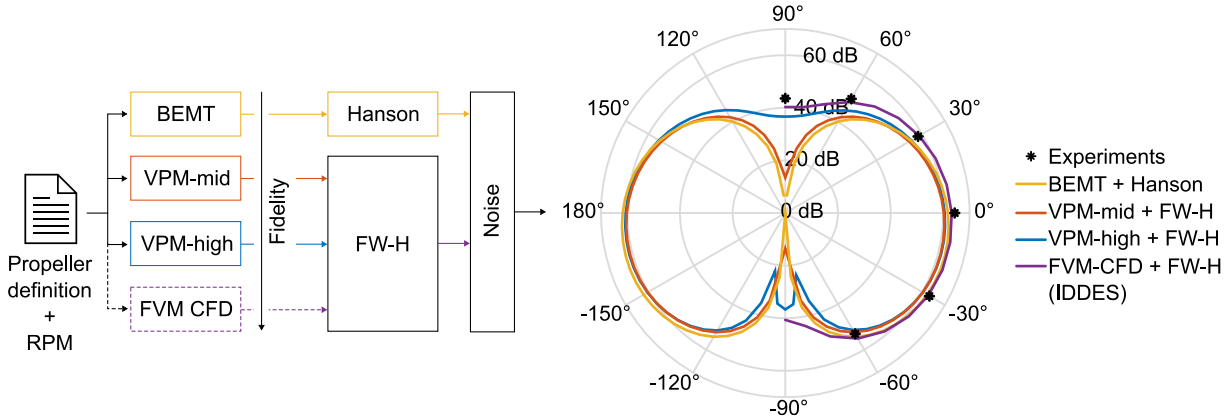

Figure 1: Experimental validation of Sound Pressure Level directivity at Blade Passing Frequency

Surrogate model, training datasets, and performance assessment

In order to avoid running the numerical model for each optimization step, we then train a data–driven surrogate that maps UAV propeller inputs to operating and acoustic outputs. The input vector $\mathbf{x} \in \mathrm{R}^7$ contains three geometric dimensions [m], three installation angles [°], and target thrust [N]. The geometric parameters define the chord and twist angle of the blade at 10%, 70%, and 100% of the blade span. The output vector $\mathbf{y} \in \mathrm{R}^{19}$ contains the optimal rotational speed ω [rpm], torque [Nm], and the SPL value [dB] at the BPF at 17 different locations (equispaced 10º from -80º to 80º at a 2m radius). Angles are encoded as $\{\sin \theta_i, \cos \theta_i\}$ to avoid wrap–around, and all features/targets are standardized (z–score) using training statistics.

We use a compact fully connected network that maps the preprocessed inputs (three geometry dimensions, thrust, and three angles encoded as sin / cos) to the outputs (optimal ω, torque, and 17 SPL values). The architecture has four hidden layers with widths [256, 256, 128, 64], ReLU activations, and a linear output layer. Inputs and targets are standardized (z-score) using training statistics only. Models are trained with Adam (10^{-3}) to minimize MSE, using a 70/15/15 train/validation/test split, batch size 128, and up to 200 epochs. We apply *ReduceLROnPlateau* (factor 0.5, patience 10, min lr = 10^{-6}) and *EarlyStopping* (patience 20, restoring the best weights); the best checkpoint by validation loss is used for testing. We report MSE/MAE on the held-out test set, and per-output errors in physical units after inverse scaling with the stored target mean and standard deviation.

Materials Research Proceedings 69 (2026) 314-318 https://doi.org/10.21741/9781644904251-56

Evaluation protocol. We consider three training sets: (i) BEMT (low fidelity), (ii) VPM (mid fidelity), and (iii) Mixed (balanced union of BEMT and VPM). These datasets are computed using a Clark-Y as the airfoil of the propeller. The hi-fi VPM setting is reserved for analysis of the optimized case due to longer computing times. Each case is split 70/15/15 into train/validation/test, trained with a fully-connected neural network (FCN), and evaluated on its own held-out test split. Reported metrics are RMSE/MAE in physical units per output; SPL rows are aggregated across the 17 angles using mean/median/95th percentile (see Fig. 2, left plot).

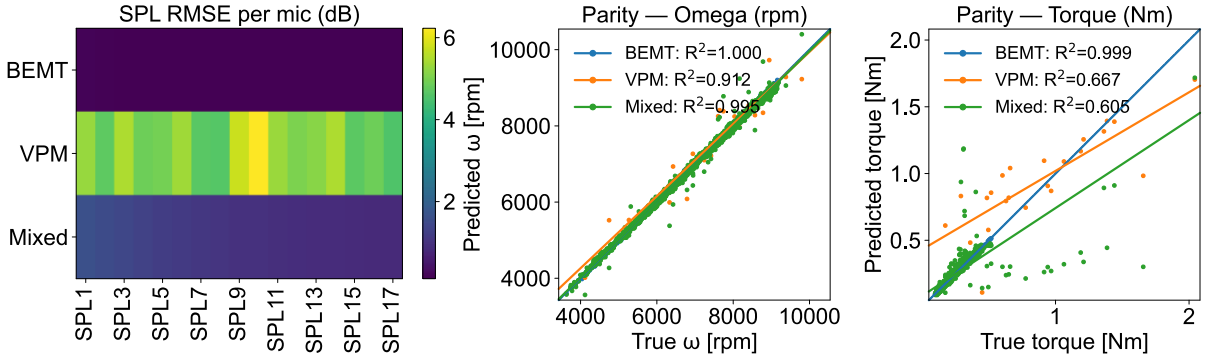

Figure 2: Surrogate evaluation results. Per-microphone SPL RMSE (dB) for the three surrogates (left). BEMT exhibits uniformly small errors, VPM shows systematically larger errors across every angle position, and the Mixed model lies in between with sub-1.5 dB errors across most microphones. Parity plot for rotational speed (center) and torque (right). Points are colored by surrogate, solid lines are least-squares fits. For rotational speed, the Mixed model closely tracks BEMT and remains near-unbiased across the range, while VPM shows a mild slope bias; for the torque it only partially mitigates the intercept bias but retains slope shrinkage.

Table 1 summarizes test performance. The BEMT-only model attains very low errors (e.g. SPL mean RMSE 0.130 dB). Including VPM data makes the learning problem harder: the VPM-only model shows larger errors and lower SPL R^2 (mean 0.699), consistent with a more complex input–output mapping and broader dynamic range. The Mixed model trades a small degradation relative to BEMT (SPL mean RMSE 0.971 dB; Δ Mixed–BEMT = 0.842 dB; SPL mean R^2 = 0.984) for substantially improved robustness across fidelity sources. For operating metrics, the same trend holds ($RMSE_\omega$: 24.9 rpm BEMT vs. 79.2 rpm Mixed; $RMSE_\tau$: 0.002 Nm BEMT vs. 0.074 Nm Mixed). Overall, the Mixed surrogate remains accurate (sub-1.5 dB at the 95th percentile across microphone locations) while generalizing across the two simulation schemes.

Table 1: Test performance of the three surrogates. SPL rows are aggregated across 17 microphones.

	BEMT	VPM	Mixed	Δ Mixed–BEMT
$RMSE_\omega$ [rpm]	24.932	440.657	79.238	54.306
$RMSE_\tau$ [Nm]	0.002	0.281	0.074	0.071
SPL RMSE (mean) [dB]	0.130	5.116	0.971	0.842
SPL RMSE (median) [dB]	0.124	5.016	0.882	0.758
SPL RMSE (95th pct) [dB]	0.164	5.839	1.403	1.239
SPL $\overline{R^2}$ (mean)	1.000	0.699	0.984	-0.016

For the rotational speed ω (see Fig. 2, center plot), the BEMT surrogate is nearly perfect and the Mixed model remains close to the identity ($R^2 \approx 0.996$), indicating that combining fidelities preserves high accuracy for operating speed. The VPM-only model shows a slope < 1 with a positive intercept, consistent with a mild high-end underprediction. For torque (see Fig. 2, right plot), BEMT again aligns with $y=x$ ($R^2 \approx 1$), whereas both VPM and Mixed display slope shrinkage

(≪ 1) and lower R^2 (~ 0.63–0.67), pointing to a systematic domain shift or coverage mismatch in torque across fidelities. The Mixed model reduces the intercept bias relative to VPM but still underestimates high torques. These trends suggest using a domain flag and/or per-domain target normalization, additional high-torque samples, torque-weighted loss to correct residual calibration differences between BEMT and VPM, or the addition of higher fidelity levels.

Propeller optimization results

Once the multifidelity surrogate model was built, a Pareto front was generated using a genetic optimization algorithm based on the surrogate model. In this optimization, as in the surrogate, the required thrust and propeller diameter are fixed. To compare against a single-fidelity surrogate, the Pareto front is also generated using only the BEMT-trained surrogate. The Mixed model results in some discontinuities, probably due to the training dataset and mixing procedure as outlined above. More crucially, there are differences in trends towards both extremes of the front, highlighting the importance of considering multifidelity models.

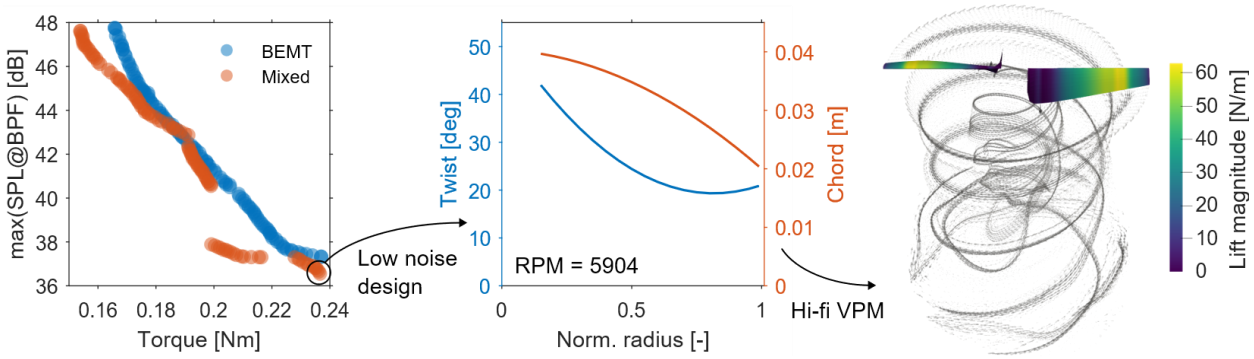

Figure 3: Pareto front resulting from a genetic optimization algorithm, proposed propeller geometry for reduced noise emissions, and sample result from the high-fidelity VPM simulation.

As an example of such optimized designs, the geometric distribution of the Pareto front extreme resulting in a lower BPF sound pressure level is shown in the center plot of Figure 3, together with the required RPMs as computed by the surrogate. This data was then used to run the high-fidelity VPM model, leveraging the unified propeller representation. A sample result from this high-fidelity model is shown in the right plot of Figure 3.

Conclusions and future works

In this work, a methodology for simulating a propeller with varying levels of fidelity (BEMT, VPM with mid and high fidelity, and full FVM CFD) from the same geometric definition has been demonstrated and experimentally validated for a 9-inch commercial propeller.

This methodology has been used to generate two datasets using the two fastest fidelity levels. This datasets has been used to build and validate a compact FCN surrogate for UAV propeller aerodynamics–acoustics with three approaches (only using the BEMT dataset, only using the VPM one, or mixing both); the BEMT model gives the best in-domain accuracy, while the Mixed model retains high fidelity across sources with a modest error increase (torque remains the most sensitive to domain shift).

Discrepancies have been observed between the model results, mainly in the torque obtained, which is substantially higher when using VPM compared to BEMT for some geometries. These discrepancies will be studied to determine whether they are due to limitations in the models for certain geometries, whether they also appear in higher-order models, and whether they can be resolved by fine-tuning the lower-order models.

To further close the gap between the surrogate and higher-order models, we plan to adopt *transfer learning*: pre-train on the large BEMT set and then fine–tune on higher fidelity levels by

restarting from the BEMT weights with a reduced learning rate and early stopping. This methodology can be further extended to consider higher-fidelity VPM settings or the high-fidelity FVM IDDES solver, by taking advantage of the common geometric representation and processing toolchain developed in this work.

Keywords: Auralization, Air Taxi, Perceptual Noise Assessment, Urban Air Mobility

Abstract. To integrate human perception into the noise assessment of novel aircraft concepts, researchers resort to auralizations based on simulated noise-source data. This study presents a workflow for auralizing level flyovers of representative Urban Air Mobility vehicles for a stationary ground observer, based on noise source data generated via Computational Fluid Dynamics. The framework incorporates established methods for signal synthesis, spreading losses, atmospheric absorption, and Doppler shift, while enabling the imitation of rotational speed variations, spatialization via head-related transfer functions, and the addition of background noise. A listening test examined how these stimuli affect perceived annoyance. All three factors had a significant impact, with more realistic audio rendering consistently leading to lower ratings.

Introduction

Traditional noise assessment within the aviation sector is often based solely on compliance with regulatory sound level metrics, such as the maximum A-weighted sound pressure level ($L_{A,max}$) or the Sound Exposure Level (SEL) [1]. While a general trend of increasing annoyance with higher noise metric level exists, it does not ultimately hold true when comparing sounds with different characteristics. As demonstrated by the psychoacoustic hearing test conducted in [2], a drone flyover and a car drive-by with the same SEL can evoke different levels of perceived annoyance. Drone flyovers were generally rated as more annoying, partly because of their unfamiliar sound. In view of introducing new aircraft concepts, this finding underscores the need to incorporate subjective evaluations of aviation noise into aircraft design.

Subjective annoyance ratings can be obtained via listening tests. The corresponding audios are either based on measurements or generated via auralization - a technique that transforms simulated noise sources at vehicle level into a full acoustic pressure-time signal at an observer location [1]. A general workflow for the auralization of flyovers has been established in [1-4]. Accordingly, such a state-of-the-art auralization framework for level steady-state flyovers of two representative Urban Air Mobility (UAM) vehicles is presented herein. Assuming a stationary observer on the ground, a set of auralized scenarios is selected for a listening test campaign to investigate the effects of rotational speed (RPM) variations, spatialization, and background noise (BGN) on the perceived annoyance of a flyover event.

Methodology

The auralization workflow comprises three main stages: (1) noise signal generation, (2) propagation modeling, and (3) perceptual rendering. The workflow implemented here is depicted in Fig. 1 and concisely explained in the following.

Generation of the Emitted Signal. The emitted acoustic pressure signal of a level steady-state flyover is constructed from two components: the noise sources, in the form of a noise sphere storing the time-dependent acoustic pressure $p'(t)$ over a range of emission angles, and the aircraft's flight trajectory, described by a sequence of waypoints. Since measurement data for UAM vehicles are scarce, the noise spheres were derived from Computational Fluid Dynamics (CFD) simulations, focusing on the resolution of tonal noise sources [5]. To investigate the

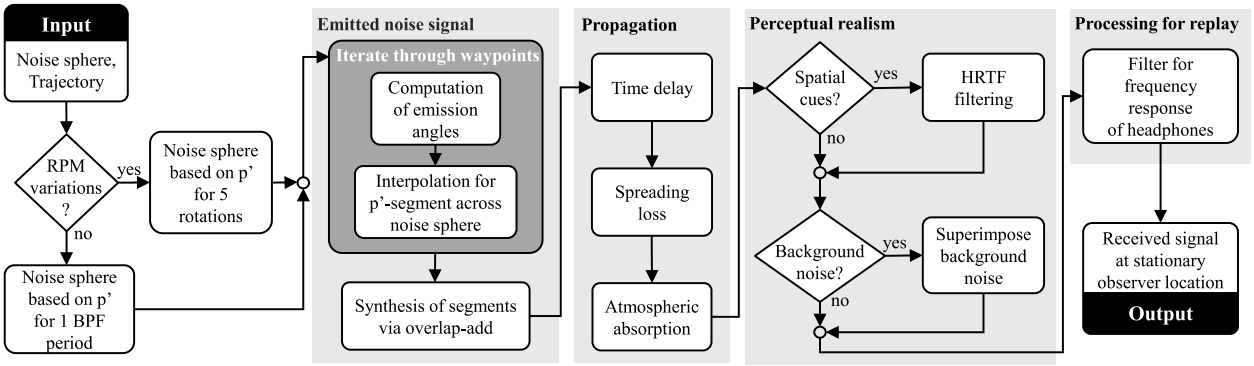
Materials Research Proceedings 69 (2026) 319-324 https://doi.org/10.21741/9781644904251-57

perceptual impact of RPM variations, two types of noise spheres were generated: one containing the acoustic pressure over a single blade-passing frequency (BPF) period, and another storing the pressure over five rotor revolutions. The latter includes apparent RPM variations arising from unsteady thrust-induced pressure fluctuations captured by the CFD simulation. Although these are not true RPM changes, they perceptually mimic such variations.



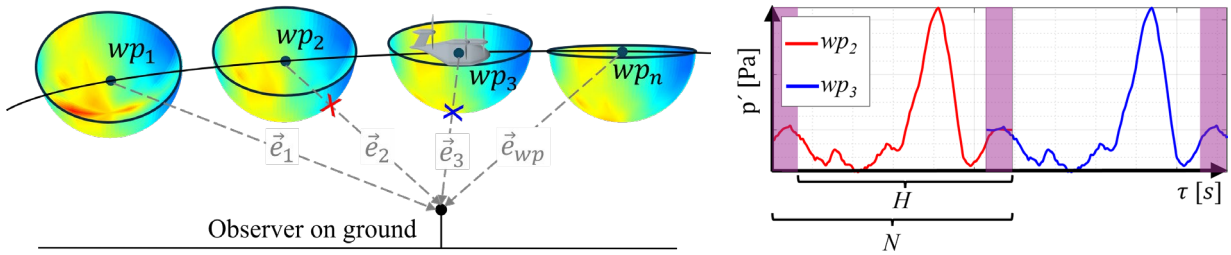


Figure 1: Flow diagram of the auralization workflow, where p' represents the emitted acoustic pressure extracted from the noise source sphere.

At each waypoint, the noise sphere is positioned and oriented along the local flight path. Then, the emission vector $\vec{e}_{wp}$, being the shortest vector between waypoint wp and observer, is computed. Its intersection with the noise sphere determines the query coordinates for a 2D-spline interpolation to extract a short pressure segment from the noise source data (marked with an 'x' for $\vec{e}_2$ and $\vec{e}_3$ in Fig. 2a). While not guaranteeing perfect phase coherence between neighboring data points on the noise sphere, this time-domain interpolation offers efficient and perceptually smooth results for the intended application.

(a) (b)

Figure 2: (a) shows the extraction of waypoint-specific pressure segments p', with $\vec{e}_{wp}$ as emission vector of waypoint wp. (b) visualizes the cross-fade OLA synthesis. τ, H, and N denote emission time, hop size, and segment length. The overlap region is shown in purple.

The interpolated segments are then concatenated to form a continuous emission signal using a cross-fade overlap-add (OLA) method [6]. This implies that consecutive segments overlap by 1/8 of the hop size H, i.e., the number of samples by which the signal synthesis advances. It is derived from $\Delta\tau_{wp} \cdot f_s$, with $\Delta\tau_{wp}$ being the waypoint time step, set to 1 BPF period, and $f_s = 44.1$ kHz as the desired sampling frequency. This results in an effective pressure segment length of $N = H + H/8$ (see Fig. 2b). If the interpolated p'-snippet is shorter than N, it is wrapped using shape-preserving cubic interpolation to ensure smooth continuity and phase alignment with the preceding segment. If the snippet exceeds N, the following segment resumes from the endpoint index of the previous extraction. Within the overlap region (highlighted purple in Fig. 2b), complementary Hann windows are applied before addition to guarantee a smooth transition between segments.

Materials Research Proceedings 69 (2026) 319-324 https://doi.org/10.21741/9781644904251-57

Propagation Mechanisms. Under free-field conditions, three propagation mechanisms altering the amplitude and spectral content of the emitted signal were implemented: time delay, spherical spreading, and atmospheric absorption. The arrival time at the observer is obtained by the summation of emission time and sound propagation time, where the latter is determined by the instantaneous distance between source and observer, divided by the speed of sound [4]. The amplitude attenuation with distance follows the inverse-distance law [3]. Frequency-dependent atmospheric absorption is modeled according to [7], assuming a uniform standard atmosphere (15°C, 1 atm, 70% relative humidity) [4].

Rendering for Perceptual Realism. To generate a spatially realistic auditory impression, a set of Head-Related Transfer Functions (HRTFs) from [8] is applied to the propagated signal. HRTFs represent the acoustic filtering introduced by the listener's head, torso, and pinnae, thereby enabling the perception of sound source direction. The implementation was performed in the frequency domain using a segment-wise convolution approach. Each audio segment is Hann-windowed, transformed to the frequency domain, filtered with observer angle- and orientation-dependent HRTFs for both ears, and converted back to the time domain. Before segments are recombined, a second Hann window is applied for smooth synthesis via OLA. The large overlap of $0.75 \cdot N$ ensured compliance with the constant OLA constraint [6], to ensure artifact-free signal reconstruction. Optionally, BGN can be superimposed onto the synthesized flyover audio. In cases where the BGN is binaural but the flyover signal is not HRTF-processed, both BGN channels are averaged to obtain a compatible track prior to mixing.

Listening Test Campaign. The auralization workflow was implemented for 9 flyover scenarios combining different vehicle types, trajectory definitions, and BGN settings (refer to Fig. 4). The operational conditions of the reference vehicles are listed in Table 1. Three left-to-right flight paths were considered: a direct overhead flyover, one passing 200 m in front of, and one 500 m behind the observer. Three BGN conditions were considered: 'none', 'busy street', and 'suburb', with the latter two tracks obtained from [9]. For every scenario, four audio variations were produced by toggling the inclusion of RPM variations and HRTF processing (on/off combinations), leading to a total of 36 audios. To ensure playback compatibility, monaural tracks were duplicated into two identical channels. Each flyover audio was trimmed to a total duration of 35 s, starting 15 s before and ending 20 s after the occurrence of $L_{A,max}$. For smooth playback, 2s fade-in and fade-out ramps were applied.

Table 1: Tilt-rotor and multicopter air taxi operational parameters for cruising flight.

	Speed [m/s]	Altitude [m]	RPM [min^{-1}]	Number of rotors [-]
Tilt-rotor	77.77	305	1002.5	6
Multicopter	25.00	305	1900.0	18

The listening test included 24 participants, rating the perceived annoyance of each flyover on a 7-point scale (1 = not annoying, 7 = very annoying). The presentation order of the audio samples was randomized, including two repeated samples to assess response consistency. Playback was conducted using Beyerdynamic DT 1990 PRO MK II headphones. Hence, the recordings were equalized to the headphones' frequency response before being played back through a HEAD acoustics SQadriga III audio interface and amplifier.

Data Post-processing. For the analysis, the first five audio ratings of each participant were excluded to eliminate potential outliers related to participants' initial adaptation to the stimuli and their expectations. To present the results, the arithmetic mean of the annoyance ratings of all participants was plotted against the corresponding audio SELs. These were computed from the average of the left and right audio channels.

Materials Research Proceedings 69 (2026) 319-324 https://doi.org/10.21741/9781644904251-57

Results and Discussion

Following [2], Fig. 3 analyzes the linear relationship between noise metric level and annoyance rating, distinguishing between vehicle type and BGN. Across the full dataset, no clear linear trend is apparent. The linear fit, shown as a dashed line, yields a squared correlation coefficient of R^2 =0.08. This indicates that only 8% of the variance in annoyance rating can be explained by this regression line [2], meaning that a linear fit fails to capture the underlying trend. Notably, the 'busy street' condition consistently produces lower ratings for a given SEL. The corresponding data points rather appear as "outliers", motivating a shift of focus to the subset considering only the BGN scenarios 'none' and 'suburb'. The linear relationship improves substantially, as indicated by the dotted fit achieving $R^2 = 0.78$. The complex 'busy street' environment likely distracts listeners, and possible masking effects partially obscure the aircraft sound, reducing its perceptual prominence. This leads to lower perceived annoyance and, presumably, to a less predictable regression model. Overall, this indicates that ambient noise has a systematic and measurable effect on perceived annoyance.

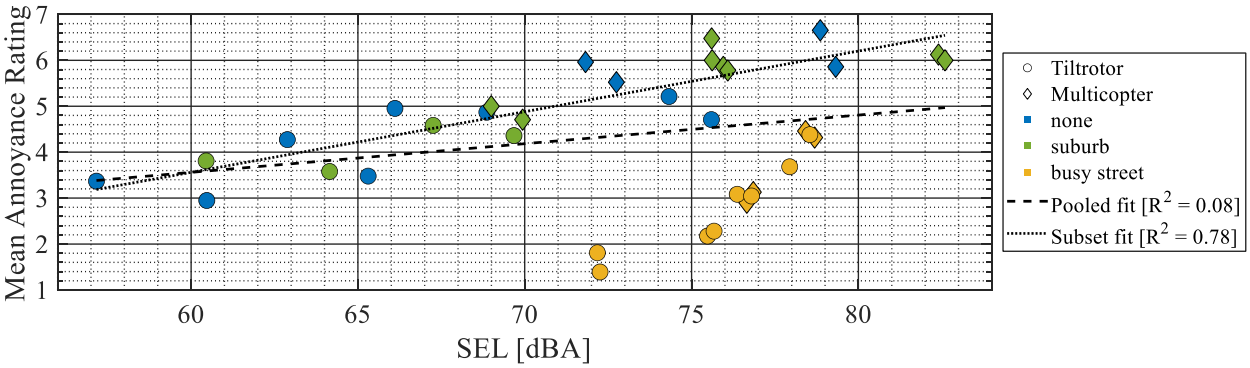

Figure 3: Mean annoyance rating versus SEL by aircraft type and BGN setting, with linear fits for the pooled data and for the subset excluding 'busy street' BGN.

Figure 4 reorganizes the data by scenario and stimuli to evaluate the effects of spatialization and RPM variations on the annoyance rating. Scenarios are labeled A – I and color-coded, with the RPM-off/HRTF-off conditions (●) marked by the corresponding letters. Focusing on spatialization, HRTF-processed audios (♦ and ▲) consistently exhibit lower SELs than unprocessed ones (● and ■), a consequence of the spatial filtering that reduces the acoustic energy reaching the observer. Excluding scenarios A and F, spatialization also leads to lower annoyance ratings, as seen when comparing HRTF-off versus HRTF-on conditions for the same RPM model (● vs. ♦, or ■ vs. ▲). Considering RPM variations, scenarios that include them are generally rated less annoying, despite showing higher SEL values. This is apparent when comparing RPM-off and RPM-on audios within an HRTF setting (● vs. ■, or ♦ vs. ▲). Exceptions occur for scenarios E and H, both featuring the 'busy street' BGN, a complex acoustic environment previously shown to deviate from overall trends. Nevertheless, these findings suggest that monotone sounds are perceived as more disturbing, whereas introducing realistic RPM fluctuations reduces perceived annoyance. When both models - HRTF and RPM - are activated simultaneously (▲), all scenarios show lower SELs and annoyance ratings compared to the default case (●). This underlines the importance of incorporating realistic acoustic and spatial cues in noise simulations to better reflect actual listening conditions and to foster public acceptance of emerging aircraft concepts.

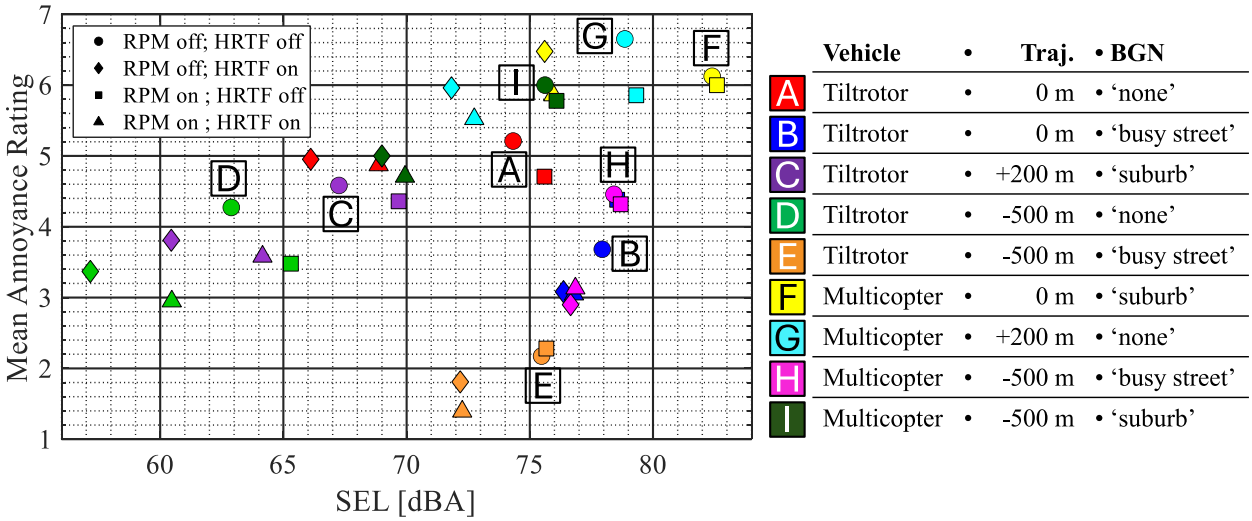

Figure 4: Mean annoyance ratings plotted against SEL, categorized by scenario, RPM model, and spatialization condition.

Conclusion

This study used a state-of-the-art auralization framework to examine the effects of spatialization, RPM variations, and background noise on perceived annoyance of UAM flyovers. Listening tests with 24 participants showed that audios including spatialization reduced the SEL and annoyance ratings. Realistic RPM variations further lowered perceived annoyance, despite slightly higher SELs, highlighting that perception can differ from objective sound levels. Background noise, particularly complex environments like busy streets, masked aircraft sounds and reduced annoyance, demonstrating the role of environmental context. The combination of HRTF processing and RPM variations yielded the lowest annoyance, confirming that investing in accurate, reality-close auralization models is worthwhile, as realistic scenarios reduce annoyance and can support public acceptance of UAM concepts.

Keywords: Acoustic Liners, Cremer Impedance, Nonlocal, Noise Control, Advection Boundary Law

Abstract. The Cremer impedance is, so far, the only analytical result concerning optimal locally reacting impedances for acoustic liners. Nevertheless, the unfulfillment of the reality condition makes the Cremer impedance unachievable in a broadband sense. Moreover, the maximization of the attenuation of the principal duct mode in an infinite lined duct, as in Cremer, does not take into account the influence of backward reflection at the interface between rigid and lined portions of the duct. Therefore, the actual optimal impedance for locally reacting liners is usually obtained by numerical optimization of the insertion loss. Nevertheless, leveraging nonlocality, both in active and passive acoustic metamaterials, has allowed to achieve anomalous reflection, dispersion tailoring, higher isolation and nonreciprocity. These extraordinary control capabilities should be explored to conceive innovative concepts towards generalized impedance behaviours, where also nonlocality is contemplated and optimized. This paper first questions the optimality of Cremer-like impedances, and then it investigates an alternative boundary operator taking into account nonlocal interactions in the acoustic liner.

Introduction

The noise transmission mitigation in waveguides by parietal acoustic treatment interests heating and air-conditioning ventilation systems and aircraft turbofan engines. Its main challenge is the need to provide noise attenuation along the direction which is parallel to the surface where acoustic liner is applied. This is necessary as the liner should have minimal impact on the aerodynamic flow going through the duct. The Cremer's optimal impedances [4, 19, 18] are analytical solutions to the problem of maximizing the attenuation of specific duct-modes in an infinite waveguide. This problem is formulated in the frequency domain, and indeed, unfortunately, leads to non-real impedance operators, in the sense that their inverse Fourier transform does not produce a real function in the time domain (the reality condition [17] is unfulfilled). Therefore, the Cremer impedance can only be achieved at discrete frequencies [12, 1]. Moreover, the Cremer's impedance is not optimal for maximizing the Insertion Loss (IL) out of a finite size lined segment, as it will be shown below. Meanwhile, the progress in impedance control strategies has allowed to digitally program the impedance of an Electroacoustic Liner (EL) as an array of tunable Electroacoustic Resonators [3, 2, 11]. The model-inversion strategy has been employed for controller to synthesize nonlinear behaviours at low excitation amplitudes [8, 5, 15, 14, 16], or a nonlocal (generalized) impedance, as the so-called Advection Boundary Law (ABL) [13, 6, 10, 9, 7]. In this contribution, we first demonstrate the non-optimality of Cremer local impedance for

scattering problems (Section 1), then we demonstrate how the potentialities of locally-reacting liners can be enlarged by including nonlocal interactions as in the ABL (Section 2). Finally, conclusions are given in Section 3.).

On the optimality of the Cremer local impedance operator

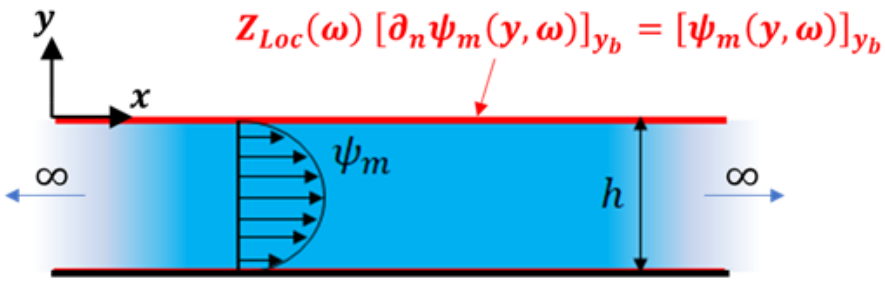

Figure 1: Problem for analytical optimization of $\boldsymbol{Z_{Loc}(\omega)}$ studied by Cremer, Tester and Spillere [4, 19, 18].

Fig. 1 sketches the 2D problem studied in [4, 19, 18] to find the analytical optimum of $\boldsymbol{Z_{Loc}(\omega)}$, defined as the ratio between the local pressure p(ω) and normal velocity $v_y(\omega)$ on the boundary $y = y_b$. The function $\psi_m(y,\omega)$ refers to the duct mode m describing the pressure distribution along the cross-section of the waveguide, which is solution of the dispersion problem of the wave equation coupled with the boundary condition given by the impedance operator of the liner. The corresponding eigen-function, is the duct-mode wave number $k_{x,m}(\omega)$. The solutions of such dispersion problem form a basis to the pressure $p(\omega,x,y)$ (see Eq. (1)), inside the duct of infinite size along x, lined on the top wall, for all $x \in R$, by the local impedance $Z_{Loc}(\omega)$.

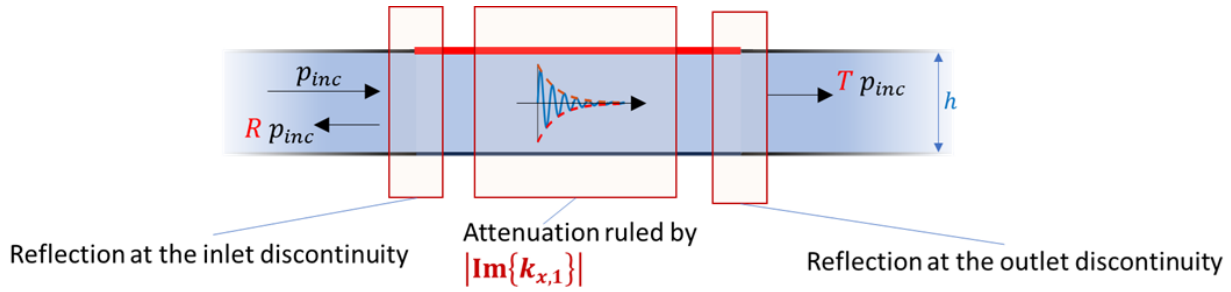

Figure 2: Scattering problem, defining the reflection R and transmission T coefficients.

$$p(\omega,x,y) = \sum_m \psi_m(y,\omega)e^{-jk_x(\omega)x} \quad . \tag{1}$$

Cremer and the others looked for the value of $Z_{Loc}(\omega)$ producing the highest attenuation along x in the sense of the highest value of $|\mathrm{Im}\{k_{x,m}(\omega)\}|$, with m the lowest duct mode of interest. The optimal dimensionless impedance $\zeta_{Loc} = \frac{Z_{Loc}}{\rho_0 c_0}$ (with $\rho_0 c_0$ the characteristic impedance of air) providing the maximum value of $|\mathrm{Im}\{k_{x,1}(\omega)\}|$ (where $k_{x,1}$ corresponds to the least attenuated duct mode), found in [4, 19], has the form:

$$\zeta_{Loc}(\omega) = \zeta_{Cre}(\omega) = (a_{Cre} - jb_{Cre})\frac{k_0 h}{\pi}, \tag{2}$$

with $a_{Cre} \approx 0.929$ and $b_{Cre} \approx 0.744$ according to the corrections of [19]. This analytical value

Materials Research Proceedings 69 (2026) 325-330 https://doi.org/10.21741/9781644904251-58

provides the merging of the least attenuating dispersion solution $k_{x,1}$, with $k_{x,2}$, where the subscript numbering $m = 1, 2, \ldots$ is according to growing $|\mathrm{Im}\{k_{x,m}(\omega)\}|$. Nevertheless, such optimization does not take into account the finiteness of the lined segment in actual scattering problems, where reflections at the discontinuities play a crucial role. Fig. 2 sketches the scattering problem, with $p_{inc}(\omega)$ the incident, $R(\omega)p_{inc}(\omega)$ the reflected, and $T(\omega)p_{inc}(\omega)$ the transmitted pressure fields' amplitudes. The definition of the scattering coefficients R(ω) and T(ω) follow. We solve, by Finite Elements, the scattering problem in a 2D waveguide of crosssection size $h = 0.11$ m, with the upper wall lined for an extension of $L = 0.25$ m, by a Single- Degree-Of-Freedom local impedance $\zeta_{SDOF}(\omega) = m_d j\omega + r_d + k_d/j\omega$, where m_d, r_d and k_d the dimensionless acoustical mass, stiffness and resistance. Fig. 3 shows the scattering solutions for varying r_d, along with the scattering solutions obtained by the Cremer impedance defined above. The scattering coefficients are provided in terms of $IL = 10\log_{10}\left(\frac{1}{|T|^2}\right)$, $|R|^2$ and $\alpha = 1 - |T|^2 - |R|^2$. It is clear that the Cremer impedance does not maximize IL. Reasonably, the Cremer impedance shows to be mostly related to the highest α.

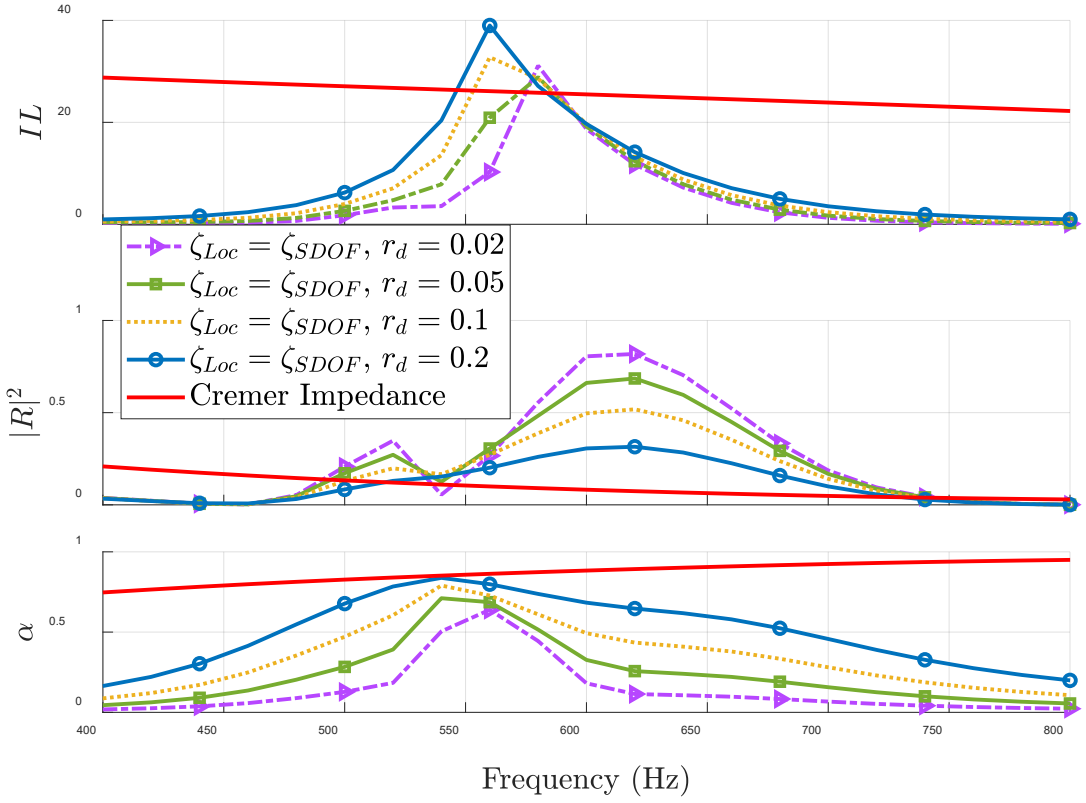

Figure 3: Scattering coefficients in case of a SDOF local impedance liner, with varying resistance, compared to the Cremer outcomes.

A nonlocal impedance operator

In this section we introduce the ABL non-local impedance operator, as an extension of the classical local impedance one, along the boundary $y = y_b$ and $x \in [0, L]$:

$$\rho_0 c_0 \zeta_{Loc}(\omega) j\omega v_n(x,\omega) = j\omega p(x,\omega) + U_b \partial_x p(x,\omega), \tag{3}$$

where $U_b = M_b c_0$, called the advection speed on the boundary, multiplies the x-gradient of pressure ∂xp(x, ω). Fig. 4 compares the scattering coefficients obtained by applying the ABL, with

those featured by the Cremer impedance. Notice that, for $M_b = 0$, we retrieve a classical local impedance operator, and in Fig. 4, this is set in such a way to achieve the Cremer value at the resonance $f_t = \frac{\sqrt{\frac{k_d}{m_d}}}{2\pi}$. The case with $M_b = 0.5$ features the highest IL, demonstrating the importance of including nonlocal terms in programmed generalized impedances.

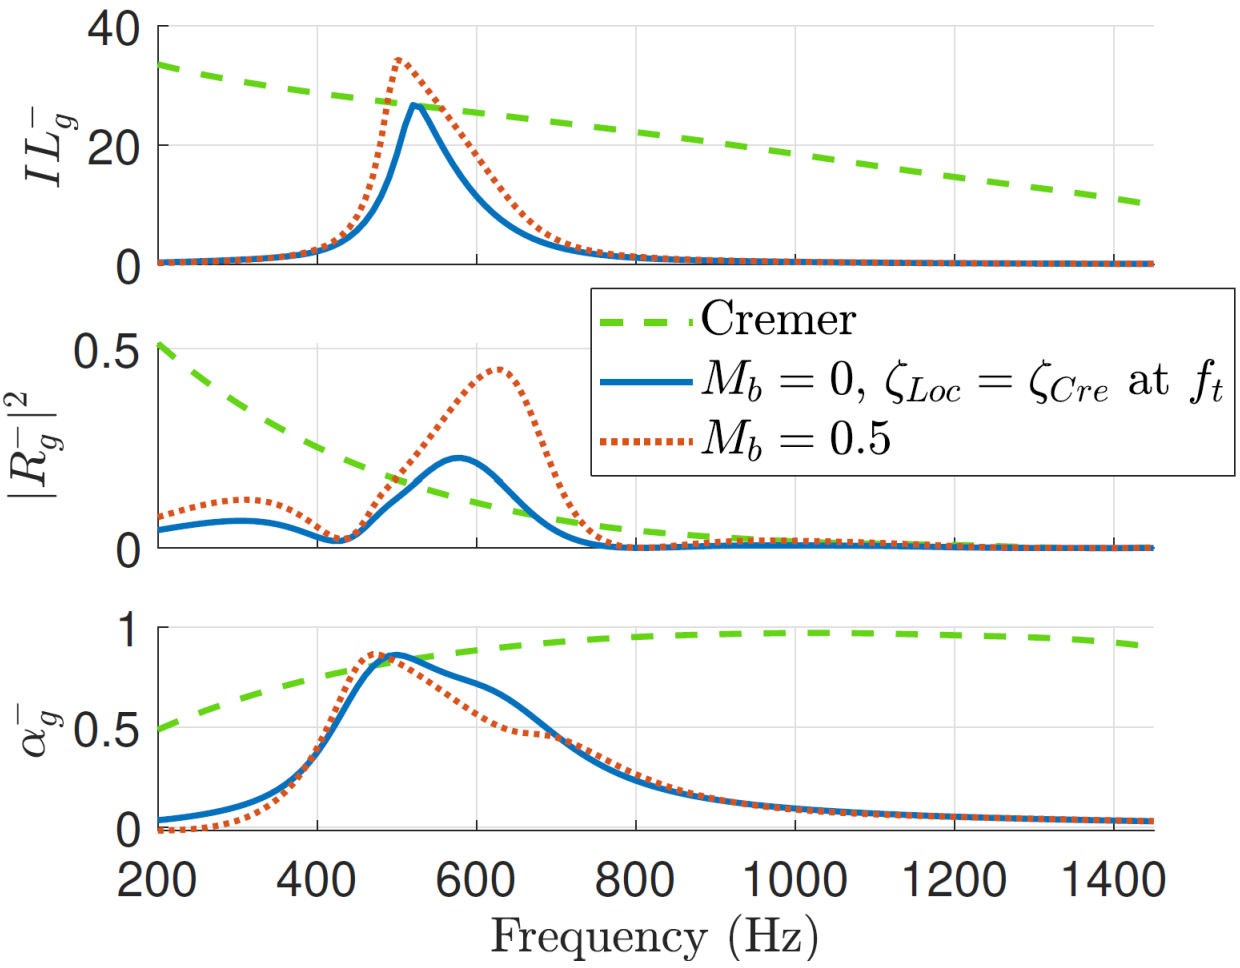

Figure 4: Scattering coefficients in case of the ABL, with varying Mb, compared to the Cremer outcomes.

Conclusions

In this contribution, we have showed the non-optimality of the Cremer impedance for the scattering problem faced with low resistive SDOF resonators, and nonlocal boundary operators. The ABL, as the first form of nonlocal boundary operator synthesized by the programmable EL, indicates the importance of nonlocality to overcome the classical optimal solutions for acoustic liners.

Keywords: Electric Vertical Take-Off and Landing (eVTOL), Tiltrotor, Blade-Vortex Interaction (BVI), Hub Vibratory Loads, BVI Noise, Anhedral Angle

Abstract. In this study, a notional eVTOL tiltrotor model is developed and analyzed using the rotorcraft comprehensive analysis code, CAMRAD II, to investigate the effects of blade tip anhedral angles (Γ = 0°, 15°, and 25°) on hover performance, rotor hub vibratory loads, and BVI noise at a low-speed descending flight condition (C_T/σ=0.107, μ=0.15, and α_s=+6°)**.** For the hover performance the model with Γ=25° showed a 1.54% lower rotor power than the baseline model with Γ=0°**.** In the low-speed descend flight, the model with Γ=25° reduces hub Vibration Index (VI) by 21.24% compared to the baseline model. Furthermore, BVI noise is predicted using the CII-Sound code based on the FW-H equation, the baseline result shows a maximum BVI noise of 91.3dB, the case with Γ=25° yields the BVISPL of 88.7dB, a 2.62dB reduction compare to the baseline value

Introduction

Electric Vertical Take-Off and Landing (eVTOL) aircraft are being intensively developed for Urban Air Mobility (UAM), which is regarded as the next generation of air transportation [1,2]. The configurations of eVTOL aircraft are categorized into three types: Multicopter, Lift + Cruise, and Vectored Thrust [3]. Among these, vectored thrust aircraft use mixed RPM and pitch controls along with variable tilting angles, which enables various flight modes such as helicopter, airplane, and transition modes.

eVTOL aircraft require low vibration and low noise compared to conventional rotorcraft. In particular, during low-speed flights, rotors experience Blade-Vortex Interaction (BVI). BVI occurs when vortices approach the rotor blades, and its intensity increases when tip vortices collide with subsequent blades [4]. This interaction results in unsteady pressure fluctuations on the blades, causing severe rotor vibration and noise. Therefore, a study on rotor vibration and noise caused by the BVI phenomenon is required for eVTOL aircraft.

This study investigates the change in vibration and noise induced by BVI when applying different blade tip anhedral angles to a notional eVTOL tiltrotor (Figure 1). An aeromechanics model is developed using CAMRAD II, a rotorcraft comprehensive analysis code. Furthermore, BVI noise is predicted with CII-Sound, a rotorcraft noise analysis code, utilizing the CAMRAD II prediction results. The present paper summarizes the authors' recent work [5]; therefore, further detailed explanation and more results can be found in the reference [5].

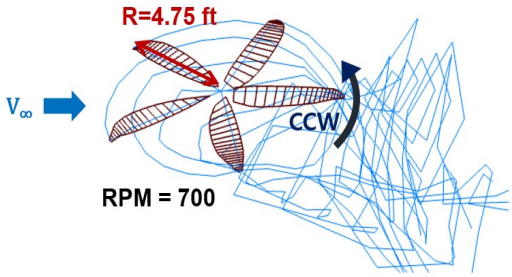

Figure 1. A notional eVTOL tiltrotor model

Methodology

Based on the reference [6], anhedral angles (Γ) of 0°, 15°, and 25° are applied at the 94% of blade radius. The blade sectional properties for the present proprotor model are obtained from a 1/4-scaled model of the V-22 Osprey tiltrotor (R=4.75 ft, [7]), with the geometric scaling considering different blade chord lengths. Each blade is modeled with seven finite beam elements for the blade structural dynamics modeling. For unsteady rotor aerodynamics using the second-order lifting-line theory, 19 aerodynamic panels are applied per blade. The Selig stall-delay model represents stall delay phenomena caused by a large built-in twist angle, and a general free-wake model is used for the rotor wake. This study assumes that the present model uses electromechanical actuators to control both collective and cyclic pitch motions of the blades for tiltrotor trim. The rotor, for a given flight speed (advance ratio, μ) and rotor shaft tilting angle (α_s), is trimmed to match the assumed rotor thrust and 1P lateral and longitudinal flapping angles of 0°.

Results

Figure 2 presents the hover performance (rotor power) analysis results obtained when different anhedral angles are considered for the eVTOL tiltrotor. The model with Γ=25° shows a 1.54% lower rotor power than the baseline model with Γ=0°. Therefore, these results indicate that the anhedral angle enhances hover performance. Figure 3 shows the hub vibratory loads in low-speed descending flight (C_T/σ=0.107, μ=0.15, and α_s=+6°), using the Vibration Index (VI). As the anhedral angle increases, VI decreases; therefore, the model with an anhedral angle of Γ=25° shows a 21.24% lower VI than the baseline model.

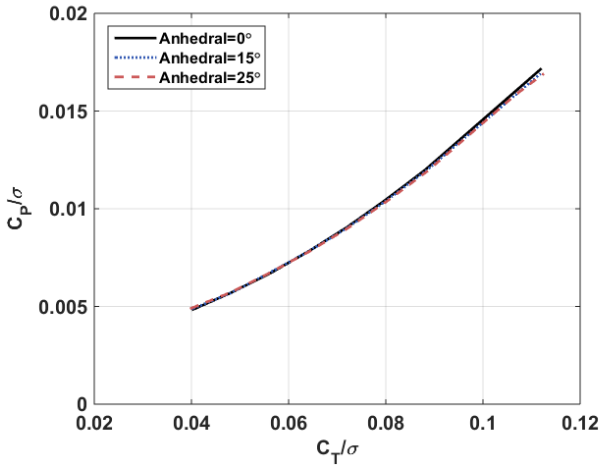

Figure 2. Rotor power in hover

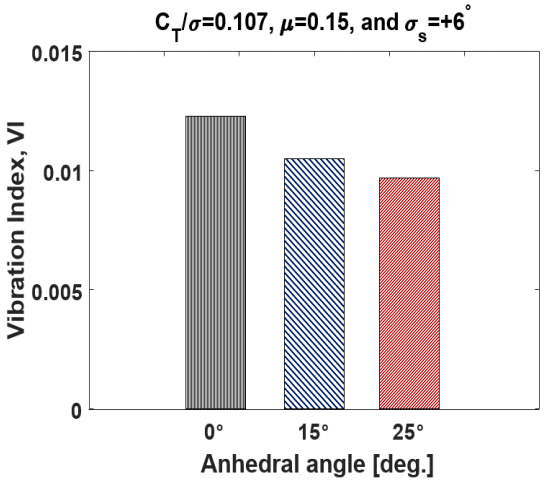
Materials Research Proceedings 69 (2026) 331-334 https://doi.org/10.21741/9781644904251-59



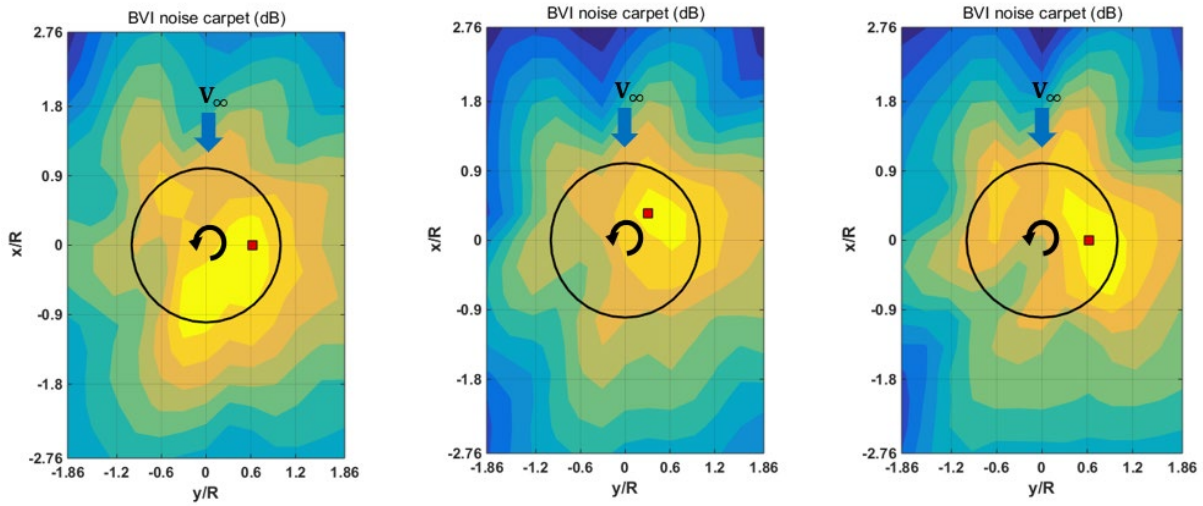


Figure 3. Vibration Index (VI) in low-speed descending flight (helicopter mode)

The CII-Sound code based on the Ffowcs Williams and Hawkings (FW-H) formulation is applied to predict BVI noise with different anhedral angles at a low-speed dsecending flight condition in helicopter mode (C_T/σ=0.107, μ=0.15, and α_s=+6°). BVISPL is determined by applying bandpass filtering to the acoustic analysis results in the 5th to the 42th Blade Passage Frequency (BPF) range. Figure 4 displays the BVI noise carpets for the eVTOL tiltrotor with different anhedral angles. While the baseline result shows a maximum BVISPL of 91.3 dB, the Γ=25° case yields 88.7 dB, a 2.62 dB reduction. This clearly indicates that an anhedral angle at the blade tip significantly reduces the eVTOL tiltrotor BVI noise. Furthermore, the locations of maximum BVISPL vary with the different anhedral angles, indicating changes in the directivity.

(a) Γ =0° (Max. BVISPL=91.3 dB) **(b) Γ=15° (Max. BVISPL=89.3 dB)** **(c) Γ =25° (Max. BVISPL=88.7 dB)**

Figure 4. BVI noise carpets in low-speed descending flight (helicopter mode)

Summary

This study developed a notional eVTOL tiltrotor model using the rotorcraft comprehensive analysis code, CAMRAD II, to investigate the effects of blade tip anhedral angles (Γ = 0°, 15°, and 25°). In hover flight, the model with Γ=25° showed a 1.54% lower rotor power than the baseline model with Γ=0°. In the low-speed descend flight (C_T/σ=0.107, μ=0.15, and α_s=+6°), the

model with Γ=25° reduced hub Vibration Index (VI) by 21.24% compared to the baseline model. Furthermore, BVI noise predicted with the CII-Sound code decreased from 91.3 dB for the baseline model to 88.7 dB for the model with Γ = 25°, with a 2.62 dB reduction. Therefore, applying blade tip anhedral to an eVTOL tiltrotor improved hover performance while simultaneously reducing hub vibratory loads and BVI noise during low-speed descending flight.

Abstract. With growing global awareness of environmental impacts from the transport sector, significant attention is now being directed at reducing noise emissions. In aviation, the dominant source of noise emissions is the engine, which produces intense acoustic energy during take-off and landing phases, often exceeding 140 dB close to the source. Efforts to address this issue are increasingly tied to advancements in propulsion technologies, particularly novel propulsion systems such as electric and hybrid-electric engines are altering the noise signature of aircraft and rendering conventional noise reduction technologies less effective. This study proposes an innovative acoustic liner design based on modified honeycomb sandwich structures. The objective is to enhance low-frequency sound absorption performance while ensuring the design remains suitable for industrial application in nacelle liners and other aircraft interior components. In the proposed design, a standard honeycomb strut is retained but modified by reducing the inlet hole diameter, thereby tuning the system's resonance behavior. This reduction causes a downshift in the peak absorption frequency, enabling better performance in the low-frequency range (below 1000 Hz), which is critical for jet engine noise. By varying geometrical parameters—such as cell size, wall thickness, and perforation diameter—the frequency response can be tailored to target specific tonal components of engine noise

Introduction

In response to growing concerns about environmental impact, the European community has introduced increasingly stringent regulations aimed at reducing CO_2 emissions and minimizing aircraft noise during takeoff and landing phases [1]. One of the primary sources of such noise is the aircraft engine. To address this, acoustic liners are employed to attenuate the tonal components of fan noise. These liners are typically constructed as sandwich structures, consisting of a rigid bottom panel—often perforated or slotted for drainage—a honeycomb core with defined hexagonal geometry, and a micro-perforated sheet that seals the structure[2, 3] as visible in Fig.1.

Materials Research Proceedings 69 (2026) 335-340 https://doi.org/10.21741/9781644904251-60

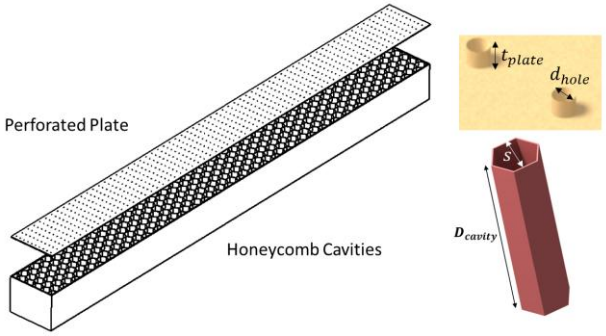

Fig. 1:Example of a liner section (left-hand side) with perforated facesheet and honeycomb cavities backed by rigid walls, with single cell of perforated plate plus honeycomb

The sound absorption mechanism of these liners is fundamentally based on Helmholtz resonator principles. By adjusting parameters such as the flat-to-flat dimension of the honeycomb cells (s), the cavity depth ($D_$cavity), the diameter of the perforations ($d_$holes), and the thickness of the plates ($T_$plates), the resonance frequencies can be tuned to coincide with tonal sources like Blade Passing Frequencies, thereby reducing acoustic disturbances. These structures are strategically installed in the engine intake area, where space constraints—especially at the bypass outlet—necessitate compact designs. As engine bays are increasingly optimized for lower emissions, higher bypass ratios (e.g., GE9X.) are becoming more common [4].

Beyond aviation, acoustic liners are also utilized in various sectors such as helicopter cabin noise reduction, automotive interiors, and offshore installations, all sharing similar manufacturing and structural concepts[5;6;7]. Enhancing these liners within the strict confines of aeronautical standards can thus yield benefits across multiple industries. Recent advancements in 3D printing have opened new possibilities for designing complex geometries that significantly improve acoustic performance. The concept proposed in this study is to retain the conventional honeycomb manufacturing process while innovating its internal configuration. For this preliminary investigation, a simplified model is adopted where each cell lacks internal substructures and is tuned to a single frequency, effectively functioning as a large cavity.

The structure of the paper is as follows: it begins with a description of the numerical methodology, followed by the experimental procedures and results, and concludes with the main findings.

Numerical model and experimental setup

To correctly validate the experimental setup, a digital twin of the initial stage of the impedance tube experiments was first created. In the laboratory, alongside the Mecanum Alpha-cabin, there is a 44 mm impedance tube from the same manufacturer. This tube size matches perfectly with the dimensions of a single cell of the device, making it ideal for preliminary analysis. To ensure that the device was properly tuned to the target frequency of 500 Hz, a digital model replicating the laboratory tube was developed using the COMSOL Multiphysics simulation environment. Several analyses were performed to investigate how variations in specific geometric control parameters influence the position of the absorption coefficient peak. The model structure utilized two acoustic modules from the Acoustics Interfaces package—Pressure Acoustics and Thermo-Viscous Acoustics. This combination was selected to balance computational efficiency with physical accuracy, ensuring that the simulated setup closely replicated the real experimental apparatus. The Pressure Acoustics module was employed to model the impedance tube and the honeycomb cavities, with a Plane Wave Radiation boundary condition applied on the side opposite to the sample placement (see Fig. 2(a)).

Materials Research Proceedings 69 (2026) 335-340 https://doi.org/10.21741/9781644904251-60

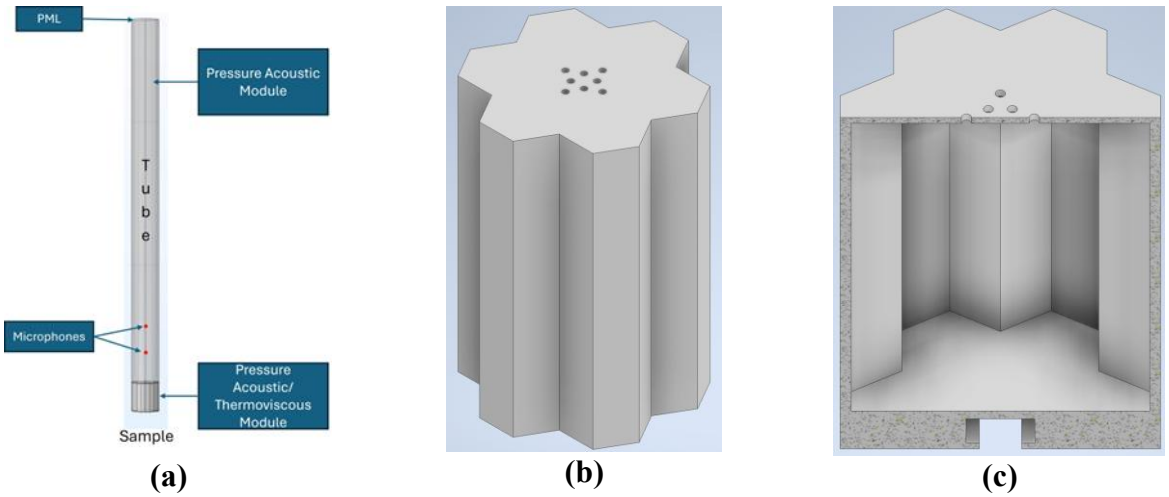

Fig. 2: (a) Digital Twin Impedance tube in Comsol Multiphysics; (b) Cad sample model; (c) Section of the sample

For the perforated plate, the Thermo-Viscous Acoustics module was used to accurately capture acoustic behavior in small-scale geometries. Although this module incurs a higher computational cost than the simpler Pressure Acoustics module, it is essential for detailed analysis of the hole regions. All structural domains and walls were assumed to be acoustically rigid. A comprehensive description of the boundary conditions and physics implementation can be found in the COMSOL Multiphysics Acoustics Module User Guide [8].

At this stage, the investigation focuses exclusively on the acoustic performance of the proposed device. The results obtained from the simulations are presented in the following section, alongside those from the Alpha-cabin experiments. Once the geometry and effectiveness of the digital model were validated, physical testing within the cabin commenced. It is important to note that the impedance tube and the Alpha-cabin determine the absorption coefficient using different methodologies. The impedance tube technique determines the sound absorption coefficient by analyzing the pressure variations of incident and reflected acoustic waves. This is achieved through the evaluation of the complex reflection coefficient, which is derived using the following standard expression:

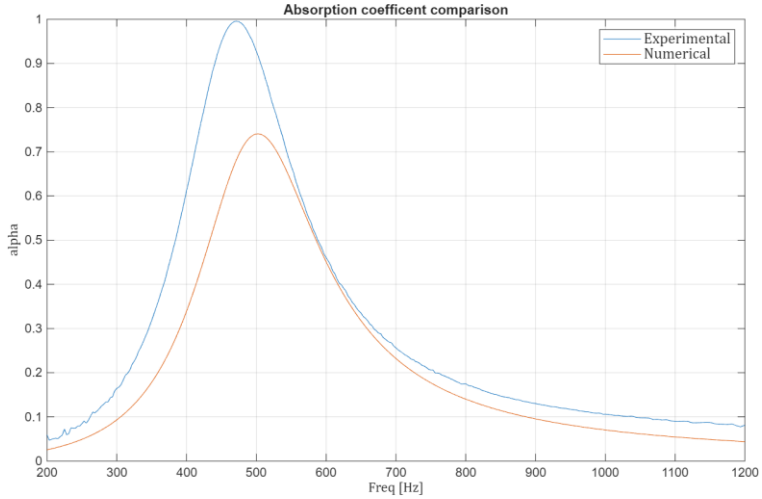
$$\boldsymbol{R = \frac{H_{12} - e^{-jk_0 s}}{e^{jk_0 s} - H_{12}} \cdot e^{2jk_0 x_1}} \tag{1}$$

In this formulation, $\boldsymbol{H_{12}}$denotes the complex acoustic transfer function measured between microphones 2 and 1. Corrections for amplitude and phase discrepancies are applied using the switched microphones method. The term $\boldsymbol{k_0}$represents the wave number under plane wave excitation conditions, as outlined in standardized methodologies [9,10].

The sound absorption coefficient under plane wave excitation is subsequently evaluated using the relation

$$\boldsymbol{\alpha = 1 - |R|^2} \tag{2}$$

Conversely, the Alpha-cabin estimates the absorption coefficient—known as $\boldsymbol{\alpha_{sabine}}$—based on the reverberation time of the room, denoted as T_{60}. The subscript "60" refers to a 60 dB decay within a reference volume. Consequently, as shown in the results section, α_Sabine values can exceed 1.



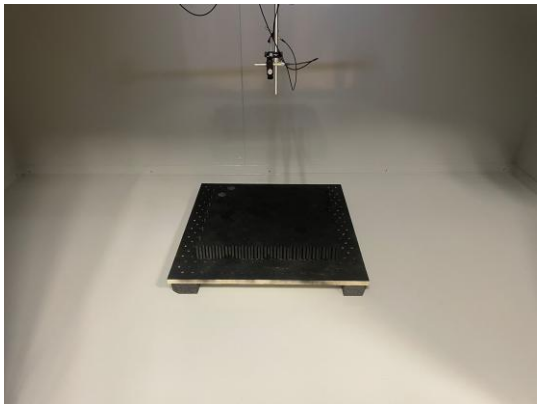
$$\boldsymbol{\alpha_{sabine} = \frac{0.966}{S}\left(\frac{1}{T_1} - \frac{1}{T_0}\right)} \qquad \boldsymbol{T_i = 0,16\frac{V}{S\bar{a}}} \tag{3}$$

Materials Research Proceedings 69 (2026) 335-340 https://doi.org/10.21741/9781644904251-60

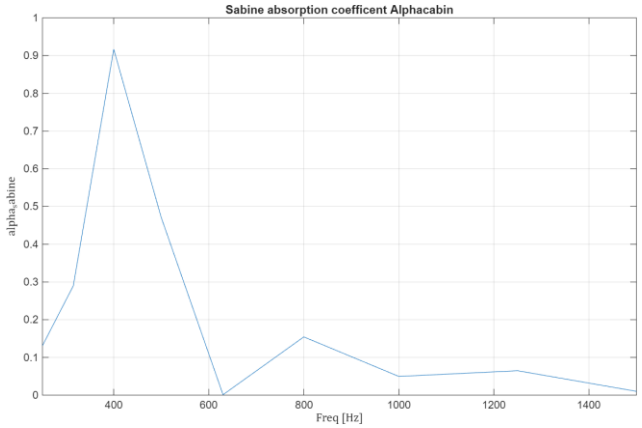
From the Sabine formulation in possible to understand that the absorption coefficients is referred to a surface and could be more than 1. This is not a physical inconsistency but rather a reflection of the different evaluation methodology used.

Experimental results

Following the validation of the numerical model, experimental verification was performed on the fabricated samples to substantiate the computational results. Acoustic characterization was carried out using two distinct measurement techniques, the first employing an impedance tube in accordance with ASTM E1050 and ISO 10534-2 standards. The comparison presented in the figure 3(a) demonstrates an excellent correspondence between the numerical predictions and the experimental measurements obtained in our laboratory. This strong agreement substantiates the accuracy and robustness of the proposed model, thereby validating its applicability to other multi-tonal configurations beyond the scope of the present study.



(a)



(b)

Fig. 3:(a) Numerical and Experimental absorption curve comparison; (b) 3D printed model

After validating the performance of the individual samples, the study progressed to the second phase. A total of 250 unit cells were 3D-printed and subsequently mounted onto an 18 mm thick marine plywood panel. This panel served as a means of minimizing potential vibrations of the single element induced by the acoustic field within the cabin. Prior to testing, the cabin was acoustically mapped to determine the optimal measurement locations. The analysis indicated that positioning the panel at the geometric center—equidistant from the surrounding boundaries as visible in figure 4a—was most effective in mitigating edge effects. The experimental tests were then conducted, and the corresponding results are presented in the diagram below.

(a)

(b)

Fig. 4: (a) Experimental set-up for Alpha Cabin Mecanum; (b) Sabine absorption coefficient diagram

A noticeable discrepancy was observed between the results obtained using the impedance tube and those recorded in the cabin environment. Although the resonators were specifically designed to absorb sound at 500 Hz, the diagram in Fig. 4b reveals no absorption peak at this frequency. Instead, the only discernible peak appears at 400 Hz. Following a series of investigations conducted in collaboration with the cabin manufacturer's team, it was hypothesized that an interaction may exist between the first modal shape of the cabin and the resonators. This phenomenon has not been previously encountered, likely due to the novelty of testing resonant cavity materials tuned to frequencies near the lower limit of the cabin's measurement capabilities. A similar condition is discussed in the work of Strasberg [11]. Further investigations are deemed necessary to accurately validate the performance of the proposed samples.

Conclusion

In summary, the numerical model has demonstrated a strong capability to accurately predict the behavior of the samples tested in the impedance tube. The observed discrepancies between the numerical and experimental curves are primarily attributed to the manufacturing process, which, for reasons of expediency and prototyping, currently relies on 3D printing. The adoption of higher-grade materials is expected to significantly reduce these discrepancies, as suggested by the comparison shown in Figure 3b. Additional configurations, including multi-tonal designs, have already been developed and validated both numerically and experimentally—through impedance tube testing and a more advanced experimental campaign conducted in the anechoic wind tunnel at TU Delft. However, the acoustic behavior of these samples under a diffuse sound field remains to be thoroughly investigated. This condition is particularly critical, as it would enable the validation of these devices not only for use in nacelle liners but also for interior aircraft cladding and other applications where enhanced acoustic comfort is required through structurally advanced solutions.

Keywords: Origami, Acoustic Metamaterial, Carrera's Unified Formulation, Wave Finite Element Method

Abstract The objective of this work is to define a method for evaluating the dynamic characteristics of a Miura-origami acoustic metamaterial panel. The metamaterial must be able to absorb the noise generated by an aircraft and shield the passenger cabin from it. The Miura-origami metamaterial is a periodic corrugated plate. The acoustic properties can be derived from the calculation of the dispersion curves, given the mechanical properties of the structure. The former are obtained using the Wave Finite Element Method, the latter using a Layer-Wise approach based on Carrera's Unified Formulation. The method is applied to a starting configuration of the metamaterial's unit cell.

Introduction

Acoustics, a branch of physics concerning the generation, propagation, detection, and conversion of sound waves, is playing an increasingly important role in modern engineering. With the advent of acoustic metamaterials (AMMs), the manipulation of complex sound and vibrations has become possible. Due to their distinctive engineering properties determined by the precisely structured geometries at the macro level, they have been artificially designed to address the noise and vibrations problem which cannot be solved with naturally occurring materials and are often used for efficient sound absorption and insulation as well as negative refraction, wave steering, and filtering.

AMM for aeronautical use has been developed in various studies [1, 2, 3], particularly for low-frequency noise, which is the primary source of noise in an aircraft. The advantage is the possibility of obtaining efficient, lightweight materials. In particular, AMM panels can be inserted into the cavity between the fuselage and the cabin as the core of a sandwich, replacing the traditional material [4, 5] (usually Nomex). In this case, the AMM must also guarantee a minimum level of mechanical strength. In this work, Miura-origami-shaped panels were chosen [6]. These materials are suitable for insertion into a sandwich and offer various production options for different materials, ranging from plastics to carbon fiber.

The presence of complete and partial bandgaps will be evaluated employing the wave finite element method (WFE) [7, 8]. The developed method enables the calculation of dispersion curves for periodic materials. The structure is described according to the Carrera's Unified Formulation (CUF) framework for beams, plates, and shells, which embeds a wide class of powerful refined 2D plate theories exploiting the finite element (FE) approximation

[9].

Among these, layer-wise (LW) approaches, that suppose the composite structure as made of independent layers so that it is possible to have a 3D description of the stress-strain state in the material, makes it possible to evaluate the power radiated by the plate in a given layer, so the one opposite to the layer on which the acoustic wave breaks. LW theories have also been proved to be able to model the vibro-acoustic behaviour of structures with low computational costs and high accuracy, particularly in the case of multilayer orthotropic materials, which gives the opportunity for future developments in the manufacturing and analysis of the Miura-Ori structure as a carbon fibre reinforced polymer (CFRP) composite material. Finally, numerical simulations will be validated against experimental results, conducted by impedance tube system and anechoic chamber.

In conclusion, the development and characterization of an acoustic origami-inspired metamaterial is proposed in this work in order to address the noise and vibration problem in aircraft cabins. The aim is to obtain an accurate evaluation of the dynamic behaviour of an ABS Miura-Ori plate, an origami-inspired acoustic metamaterial, parametrized according to the unit cell shown in Fig. 1.

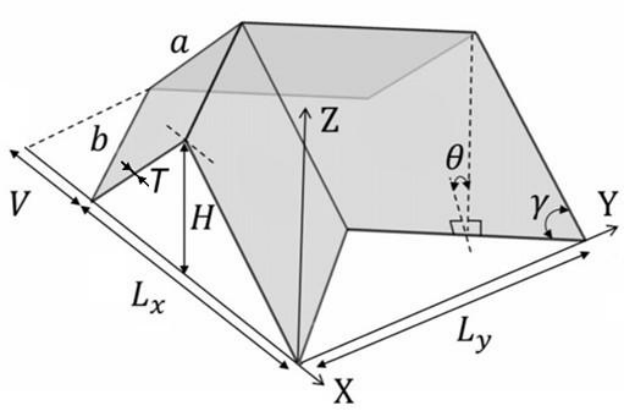

Figure 1: Periodic unit cell of the Miura-Ori plate.

Wave finite element and numerical approximation

The WFE is a powerful tool for understanding the energy transfer mechanism of a structure. This method has gained popularity in the study of infinite periodic structures, enabling the calculation of dispersion curves [10].

Considering a $x - y$ plate made of an infinite periodic repetition of unit cells with N degrees of freedom (DOFs) and assuming both forces and displacements are harmonic in time, the kinematic field is described in the frequency domain by the following relation:

$$(\boldsymbol{K} - \omega 2\boldsymbol{M})\boldsymbol{q} = \boldsymbol{F} \qquad \widetilde{\boldsymbol{D}}(\omega)\boldsymbol{q} = \boldsymbol{F} \tag{1}$$

with **K**, **M** being the $N \times N$ stiffness and mass matrices, and **q** and **F** the $N \times 1$ nodal displacement and external forces vectors. The angular frequency is ω. The mass and stiffness matrices are merged in the dynamic stiffness matrix $\widetilde{\boldsymbol{D}}$.

According to the Bloch's theorem, due to the periodicity of the medium and the equilibrium of the forces, the propagation of the free waves depends only on the reduced displacement vector $\widetilde{\boldsymbol{q}}$:

$$\boldsymbol{q} = \boldsymbol{R}\widetilde{\boldsymbol{q}} \qquad \boldsymbol{R}'\boldsymbol{F} = 0 \tag{2}$$

where **R** is the periodicity matrix and $\mathbf{R}'$ is the conjugate transpose of **R**. Combining Eq. 2 in Eq. 1, the generalized dispersion eigenvalue problem is obtained:

Materials Research Proceedings 69 (2026) 341-345 https://doi.org/10.21741/9781644904251-61

$$\left(\boldsymbol{R}'\widetilde{\boldsymbol{D}}(\boldsymbol{\omega})\boldsymbol{R}\right)\widetilde{\boldsymbol{q}} = \boldsymbol{0} \tag{3}$$

in which $\widetilde{\boldsymbol{D}}$ is a function of the wave numbers k_x and k_y ($\lambda_x = e^{-jk_x\Delta x}$ and $\lambda_y = e^{-jk_y\Delta y}$, where Δ_x and Δ_y are the dimensions of the unit cell in x and y).

Solving the problem for λ_y with a direct approach (providing ω and λ_x), Eq. 3 becomes a quadratic equation:

$$\left(\boldsymbol{A_2}\lambda_y^2 + \boldsymbol{A_1}\lambda_y + \boldsymbol{A_0}\right)\widetilde{\boldsymbol{q}} = 0 \tag{4}$$

The full definition of the matrices for different finite elements is reported in [7, 8].

According to the CUF, the displacement vector **u** for a plate in the finite element approximation is written as:

$$\mathbf{u}(x,y,z,t) = F_\tau(z)N_i(x,y)q_{i\tau}(t), \quad 1 \le i \ge n_e, \quad 1 \le \tau \ge M \tag{5}$$

with $F_\tau(z)$ the thickness functions, $N_i(x,y)$ the Lagrangian finite element shape functions. The order of the shape function is defined by the number of nodes in the element, n_e (i is the nodal index in the element), while the order of the thickness depends on the number M which define the structural theory (τ is the nodal index through the thickness). The WEM has been already validated in [8] for different thickness functions. In this work, Lagrange polynomials are used.

Case study

In this work, the use of WEM is extended to a corrugated metamaterial plate. The unit cell, derived from [6], is shown in Fig. 1. As a case study, an ABS (Young modulus E =2.2 GPa, Poisson ratio ν = 0.35 and density ρ =1040 kg/m^3) cell is used for future experimental comparisons, with a thickness of 1.5 mm and dimensions as shown in Tab 1. The FEM analysis is made using 16 quadrangular elements with four nodes Q4 (four Q4 per face) and three nodes along the thickness (LW2). To manage the edges, the formulation in [11] is used, which allows for unconventional, distorted 3D elements (a combination of 2D FEM and 1D thickness functions). The periodic conditions are shown in Fig. 2. The problem has 19 independent nodes, with a total of 171 DOFs. Results are calculated from 0 Hz to 20000 Hz. The dispersion curves of the real part of the wave number are reported in Fig. 3 and Fig. 4 for k_x and k_y respectively.

Table 1: Dimension of the unit cell in Fig. 1. Lengths are in mm and angles in degrees.

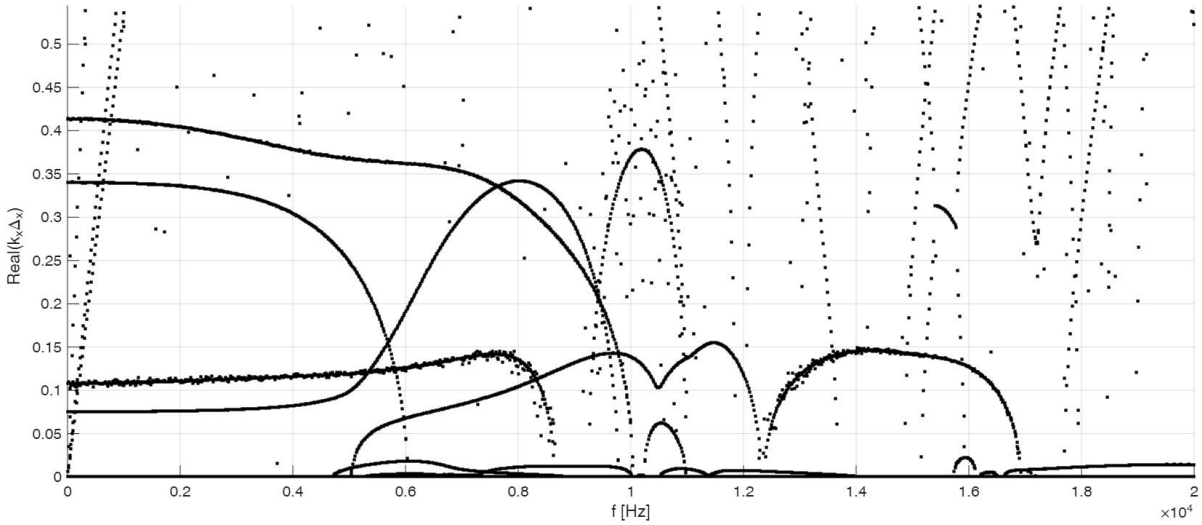

Figure 3: Real part of the dispersion curve in x.

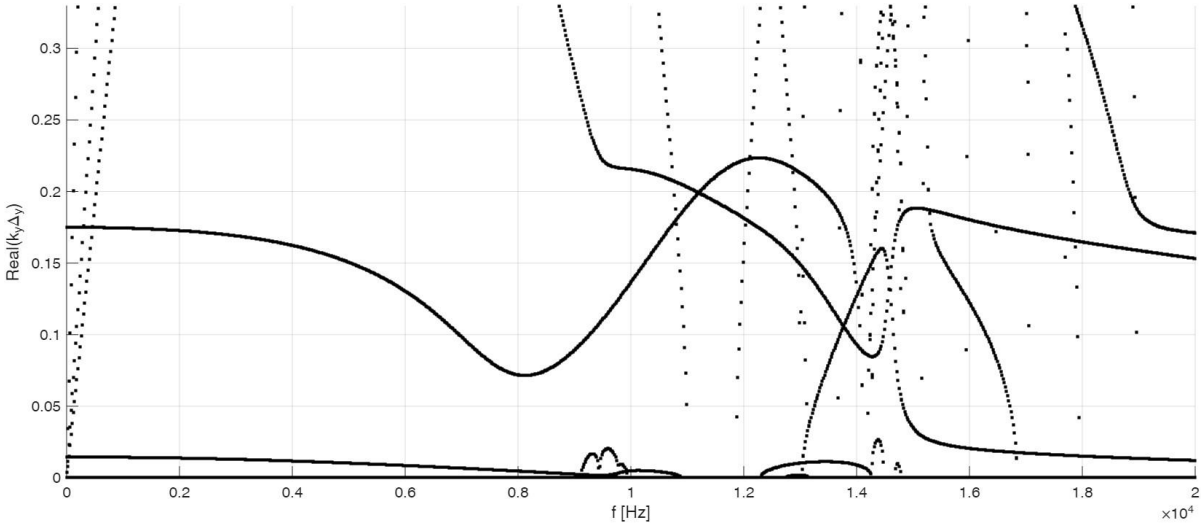

Figure 4: Real part of the dispersion curve in y.

Conclusions

Thanks to WFE, it is possible to calculate dispersion curves for a periodic material. In this work, we combine the potential of a LW approach with that of WFE to calculate dispersion curves for a corrugated metamaterial. A future development will be to calculate transmission loss based on the results obtained.

Keywords: Aircraft Noise, Auralisation, Cabin Design, Virtual Reality

Abstract This work develops a method for converting the results of vibroacoustic numerical simulations into virtual perceived noise. The goal is to evaluate solutions for reducing noise in passenger cabins in virtual mock-ups using a user-centred approach. Passengers wearing augmented reality headsets are immersed in the cabin environment, both visually and auditorily. This article describes the virtual auralisation process and presents a case study of a business jet cabin to evaluate the quality of the developed method.

Introduction

The acoustic footprint of an aircraft not only affects the structure through vibrations, but also plays a key role in the flight experience in the passenger cabin and the cockpit. In the former, the problem mainly concerns user comfort [1], although novel aircraft configurations could bring noise levels above the recommended thresholds; in the latter, in addition to the comfort problem, excessive noise levels could compromise pilot performance and increase pilot workload. For these reasons, users should take a central role in assessing interior noise for new aircraft configurations or evaluating the effectiveness of new acoustic solutions. Nevertheless, noise impact assessment has been conventionally carried out using human-based metrics, i.e. comparing measured noise levels with parameters derived from physical and physiological laws and data from experience. While this assessment method can be valid for regulatory compliance, it fails to assess qualitatively the impact of noise variation on users. To make a qualitative and reliable evaluation of the effect of an acoustic variation on passengers and crew, users need to be directly involved in the design and evaluation process, thus using a human-centred approach. Studies have already been carried out in the comfort assessment field utilising this type of approach [2]. In particular, the evaluation must pass through the "immersion" of the user in the environment by constructing a mock-up. Given the complexity of creating an aircraft cabin and considering the acoustic aspect, it is preferable to use virtual mock-ups, which guarantee less time and cost and greater flexibility in trying out different designs and acoustic solutions [3, 4]. This aspect proves essential in preliminary design phases. The present work aims to define a human-centred approach for assessing interior noise in the passenger cabin and cockpit [5, 6]. The origin of the noise, or instead of its variation, can be manifold; in this study, we focus on a decrease given by applying acoustic metamaterials capable of absorbing certain frequency bands. Given the acoustic footprint of the aircraft, the aim is to construct a virtual mock-up containing both the visual layer (what the user sees), defined by the cabin design, and the auditory layer (what the user hears). The former is conventionally called visualisation; similarly, the latter is called auralisation [7]. In addition, to increase the realism of the experience by incorpoating the inertial effects of flight, and

to avoid having to virtualise the cockpit due to the complexity of both design and gestures, the virtual environment is implemented within a full-motion flight simulator, in which both the cockpit and a section of the passenger cabin are present. The core objective is to import the numerical results into the virtual environment and then deploy the virtual environment in head-mounted display [8, 9]. The integration of the simulation data is achieved by condensing some of the numerical data issues, i.e. acoustic pressures as a function of frequency and position in the aircraft:

- The results are in the frequency domain and therefore need to be returned to the time domain with the inverse of the Fourier transform and then converted to an audible audio format.
- Some simplifications are made in numerical simulation, particularly on sound sources and frequency range. This compromises the realism of the generated audio files, which are thus used as filters applied to a baseline noise to avoid having an unrealistic audio track or one with anomalous sound levels. This process is possible by knowing the actual tracks of the aircraft or, in general, of the most relevant sources (e.g. the engine).

The primary objective of this work is to validate the methodology and feasibility of the cabin virtualisation process, focusing on the realism of both visual and aural components. A secondary goal is to assess the effectiveness of the implemented soundproofing solutions in a preliminary manner. The final design was deployed on a Microsoft™ HoloLens 2 Augmented Reality (AR) device, chosen for its 3D rendering capabilities, world-locking features, and integrated spatial audio system. The cabin layout was designed as a CAD model and imported into Unity, where it was refined using a scanned 3D model of cabin section represented in the full-motion aircraft simulator at Enna Kore University.

Auralisation process.

The auralisation workflow consists of three stages:

- The aircraft's acoustic footprint is obtained through numerical analyses estimating cabin sound pressure distributions across frequency, used to evaluate soundproofing materials.
- Simulation results are processed to obtain impulsive responses in the time domain (IRs), thus convolved with the dry sound of an aircraft engine, generating convolved sounds, which are integrated into the virtual aircraft model.
- Participants experience both visual and acoustic stimuli representative of a cruise flight phase in an immersive virtual environment, enabling subjective assessment of realism and comfort.

Vibroacoustic analysis is performed over a representative half-section of the aircraft cabin, corresponding to the flight simulator at the Enna Kore University. The vibroacoustic model is reduced to a half longitudinal section for symmetry optimisation. The cabin walls are modelled as an external 3 mm-thick aluminium panel (equivalent to the thickness of a real panel plus ribs and frames), jointed with an internal 24 mm soundproofing panel. Two solutions are compared, using Nomex and an acoustic metamaterial as the soundproofing material of the panels of the cabin. To simulate an impulsive analysis, the simulation utilises a point source emitting modal frequency sound (one frequency at a time) over a range of 20 Hz to 1000 Hz, with a constant step size of 5 Hz up to 500 Hz and of 20 Hz up to 1000 Hz. The source is positioned externally to the cabin, at a location equivalent to the engine position on the real aircraft. Probes placed at key cabin locations record complex acoustic pressure values at each location, representative of the transfer function of the cabin footprint. The analyses are performed based on the data in for the metamaterial, panels of melamine foam with cylindrical inclusions of aluminum, that was already tested in a fuselage environment in [10, 11]. The metamaterial is developed to absorb low-frequency noise, and for this reason, FEM is chosen as the numerical solution and COMSOL Multiphysics® as software. Once

Materials Research Proceedings 69 (2026) 346-350 https://doi.org/10.21741/9781644904251-62

the analysis is performed for both materials, these frequency-domain data are then converted into time-domain IRs via inverse real FFT to enable audio convolution. The data are interpolated on a uniform grid, smoothed to highlight the overall transmission characteristics, and band-limited to 14 kHz. A global normalisation is applied across the two analyses to prevent clipping in the final audio files, ensuring consistency between Nomex and metamaterial measurements and retaining the respective soundproofing capacities. The resulting IRs are exported as 48 kHz WAV files and convolved with a dry source signal toobtain simulated audio outputs:

$$y(t) = s(t) \cdot h(t) \tag{1}$$

The two convolved sound sets (Nomex and metamaterial) are further refined for seamless looping and prepared for integration.

The processed sounds are integrated into Unity to create a coherent audio-visual experience. Probe positions from the vibroacoustic model are used to position corresponding sound sources in Unity as shown in Fig. 1. Each probe features two audio sources reproducing the Nomex or metamaterial convolved sound obtained for that location, respectively. Each set of sounds relates to a specific audio group in the sound mixer. Application commands enable toggling among the two audio groups at runtime, allowing the user to hear the different sound presets for each solution, one at a time. The cabin geometry is that of a business jet, developed as part of the European CASTLE (CAbin Systems design Toward passenger welLbEing) project. Only a section with three seats and other design elements is used.

The active audio group's volume distribution is controlled through Gaussian interpolation based on the user's (camera) position relative to each probe. Each probe contributes proportionally to the total perceived sound according to its distance from the user. A global normalisation ensures that the sum of all source volumes equals unity, reflecting the fact that the probes represent measurement points inside the cabin, rather than physical sound emitters, thus no distance-based absolute attenuation is applied. Since point sources are used, the sound is rendered in the entire cabin.

The final application is deployed on HoloLens 2 and spatially aligned with an equivalent simulator for testing, ensuring the virtual seats are positioned in alignment with their real-world counterparts.

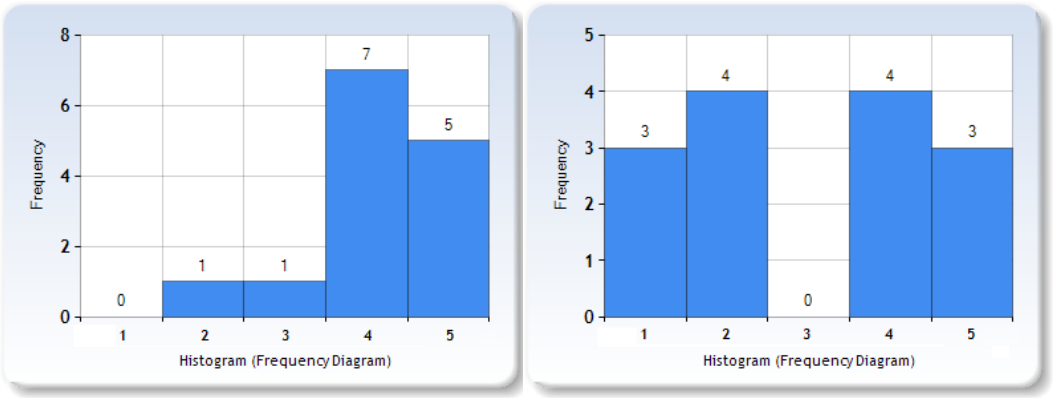
Materials Research Proceedings 69 (2026) 346-350 https://doi.org/10.21741/9781644904251-62

User Testing Experiment Design.



The user testing phase evaluates the realism of the virtualised cabin and user perception of acoustic treatments. A within-subjects design is adopted, where each participant experiences both the Nomex and one of the two available metamaterial conditions, with the order of presentation of the solution changed between participants to minimise habituation effects. Each participant completes two sessions, one for each of the two presented conditions: first, seated for two minutes, and then walking through the virtual cabin for two minutes. After both sessions, users complete Likert-scale (from 1 to 5) questionnaires to assess the perceived realism of the visual and aural layers, as well as the differences between acoustic configurations.

The questions and answers for each participant are reported in the Tab. 1, along with their mean value.

The realism of the scenarios is satisfying, with a mean value above 4 and low standard deviation below 1. Participants are also able to perceive the difference in sound between the two scenarios, as reported in Fig. 2(a). This difference is expressed in a decrease in low-frequency noise. The main problem lies in understanding which of the noises is louder, with about half of the participants incorrectly assigning the difference in noise, Fig. 2(b). The results give a perfect average of 3 and a standard deviation of 1.57. The reasons for this can be found in the exposure time which is very short.

Table 1: Results of the questionnaires, using Likert-scale where 1 is the minimum (Strongly disagree) and 5 the maximum (Strongly agree). The first scenario, panel in Nomex, is the louder than the second, panel in metamaterial.

	1	**2**	**3**	**4**	**5**	**6**	**7**	**8**	**9**	**10**	**11**	**12**	**13**	**14**	**Mean**

Conclusions

The method presented starts from a numerical simulation and basic audio to recreate internal noise through signal convolution. The results show that the noise is realistic, but future experimental campaigns are needed to test its use in assessing acoustic comfort.

Abstract. This work presents the development and comprehensive analysis of an open-source aeroelastic model for the Douglas DC-3 with some modifications. The model serves as a platform for software testing, capturing essential aeroelastic phenomena. It features a conventional configuration with two engines, control surfaces, and a wing with a leading-edge sweep angle of 15.5°, dihedral angle of 5° and aspect ratio of 9.2, operating in a subsonic regime. The development process included finite element modeling using beam elements, aerodynamic modeling with the Doublet Lattice Method (DLM), and mass modeling with a dedicated fuel mass model. Trim case analyses were performed using both *Loads Kernel* and SOL144 in *MSC Nastran*, revealing significant differences between rigid and flexible configurations. Maneuver load analyses were conducted exclusively using *Loads Kernel*. Additionally, gust loads were studied using the (1-cos) Discrete Gust Model, demonstrating coupling with the short-period mode due to high static margin. Flutter checks showed matching results between *Loads Kernel* and *MSC Nastran*, with flutter speeds of 195 m/s and 203 m/s, respectively, confirming the model's plausibility for aeroelastic analysis.

Introduction

The sparseness of open-source generic aeroelastic simulation models poses a significant challenge, as existing options are invariably limited. For demonstration and software testing, it is essential to have a generic model that includes key aircraft components and balances simplicity with fidelity. FERMAT, based on the NASA Common Research Model (CRM) [1,2], resembles a wide-body transport aircraft. However, its design for Mach $Ma = 0.85$ introduces transonic complexities — such as shock-induced separation and nonlinearities — that affect flutter boundaries and reduce its suitability for demonstration. It also lacks flexibility to tune properties or exaggerate effects to highlight aeroelastic phenomena. The Active Aeroelastic Aircraft Structures (3AS) project [3] explored active aeroelastic concepts across several aircraft types, but the models were only shared among project partners. Furthermore, the Aeroelastic Prediction Workshop (AePW) [4] used the Benchmark Supercritical Wing (BSCW), which includes only a wing model. To address this gap, an aeroelastic model of the Douglas DC-3 has been meticulously established. It serves as a demonstrative platform for software testing, supporting both the Deutsche Zentrum für Luft- und Raumfahrt (DLR) in-house tool *Loads Kernel* [5] and *MSC Nastran* [6]. This model fills a critical need by offering a publicly available, representative aeroelastic platform. It supports further development and highlights the role of Aeroelasticity in Aircraft Design, Performance, and Flight Dynamics, particularly the interplay between unsteady flow and flexible structures, and the differences between rigid and flexible configurations.

Aircraft Selection

To ensure the generality and representativeness of the aeroelastic model, an existing aircraft was selected based on specific requirements, with minor modifications introduced to highlight aeroelastic phenomena. The selected aircraft needed to balance simplicity and complexity while capturing relevant aeroelastic effects. Key criteria included: a conventional configuration; non-rectangular wing with significant leading edge sweep (Λ_{LE}), dihedral (Γ), washin/washout (Φ), cambered airfoil, and aspect ratio AR > 8; conventional or T-tail empennage; standard control surfaces (excluding flaps); a maximum of two engines; subsonic flight regime (Ma < 0.6); public availability of geometric, aerodynamic, structural, and performance data; and clear aeroelastic phenomena such as wing bending, torsion, and flutter. The Douglas DC-3 was selected as it best met all criteria. Its historical relevance and widespread use further support its suitability. The DC-3 is a low-wing, all-metal monoplane with retractable landing gear, powered by two Pratt & Whitney R-1830 engines. It features a cruise speed of 339 km/h, a range of 2,540 km, and a wing with a 15.5 ° sweep and 5 ° dihedral, and an aspect ratio of 9.2.

Aeroelastic Model

Structural Modeling

The finite element model (FEM) of the Douglas DC-3 was developed using DLR's in-house tool *ModGen* [7]. The lifting surfaces were modeled as beam elements along the Load Reference Axis (LRA), with stiffness properties assigned via *Python* scripts. Each wing was divided into 30 sections, with cross-sectional properties calculated based on spars, skin, and stringers. Stringer effects were included using an equivalent stiffness method to ensure realistic bending and torsional behavior. All structural components were assumed to be made of a single aluminum alloy, with typical properties: density 2710 kg/m³, Young's modulus 70 GPa, shear modulus 26.9 GPa, and Poisson's ratio 0.3. The fuselage was simplified as a rigid body with distributed grid points to preserve dynamic characteristics. Engines and empennage were connected to the aircraft via rigid elements to ensure consistent load transfer and structural integrity. The model was tuned iteratively to match reference mass and stiffness distributions, providing a reliable foundation for aeroelastic analysis. Fig. 1 illustrates the structural discretization used in the model, along with the positions of the LRA, the leading edge (LE), and the trailing edge (TE).

Mass Modeling

Mass estimation for each aircraft component was performed using statistical methods based on historical data and geometric parameters, following guidelines from Raymer, Torenbeek and Anderson [8,9,10]. A scaling factor was applied to align the total estimated mass with the aircraft known empty weight. Component masses were distributed across structural nodes using weighted averages based on cross-sectional areas. Wing-like components were assigned mass along the LRA, while fuselage mass was distributed over 11 nodes. System masses — including landing gear, avionics, and furnishings — were placed according to reference data and aircraft layout. Fuel modeling was handled separately using *ModGen*, with discretized fuel tanks per wing to capture mass and inertia effects. Fig. 2 illustrates the complete mass distribution used in the aeroelastic model.

Aerodynamic Modeling

The aerodynamic model was developed using the Doublet Lattice Method (DLM). This approach requires the construction of an aerodynamic mesh composed of quadrilateral panels. While the DLM enables modeling of control surface motions, its accuracy in capturing control surface effects is influenced by discretization, often necessitating empirical corrections [11]. To ensure accuracy, the meshing process must be performed rigorously. The aerodynamic mesh was generated using *ModGen*. Fig. 3 presents the final aerodynamic mesh for the Douglas DC-3 model.

Materials Research Proceedings 69 (2026) 352-357 https://doi.org/10.21741/9781644904251-63

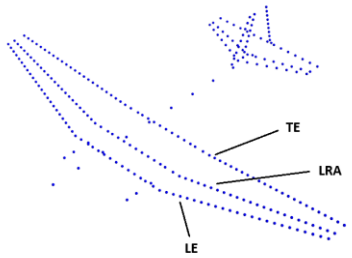

Figure 1: Structural discretization.

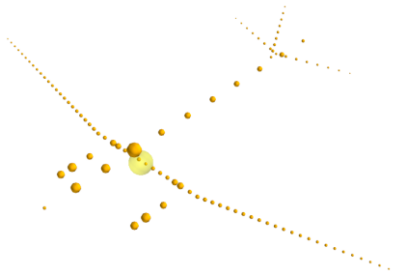

Figure 2: Mass discretization.

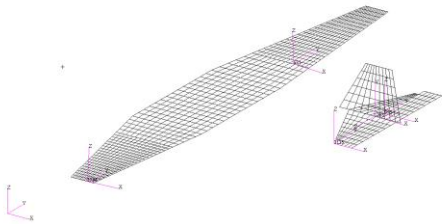

Figure 3: Aerodynamic panels.

More Flexible Models

The models of the Douglas DC-3 were modified to enhance aeroelastic effects. Compared to the original, the final modified model incorporates reduced wing stiffness, updated inertial properties, and a repositioned elastic axis (LRA). These changes were introduced to amplify the coupling between bending and torsion and to ensure that elastic deformation contributes meaningfully to aerodynamic behavior. In this model, the elastic contribution to the total lift coefficient reached approximately 4.7%, a significant increase compared to 0.7% observed in the original configuration. For all aeroelastic analyses, the selected mass configuration corresponds to the Maximum Take-Off Weight (MTOW), due to its significant structural deformations, representing a critical test case. The first flexible eigenmode of the final model appears at 3.17 Hz. This frequency does not fall in the range expected for an aircraft of similar size and weight but is comparable to a larger (and more flexible) passenger transport aircraft, reflecting the intentional tuning of the model.

Results

Trim Cases

Using the mass and stiffness matrices exported from *MSC Nastran*, the trim conditions for the Douglas DC-3 model were computed using both *Loads Kernel* and *MSC Nastran* (SOL144). Three trim cases were analyzed at a True Airspeed (TAS) of 70 m/s and Flight Level FL000: horizontal level flight ($n_z = 1$), push-down maneuver ($n_z = -1$), and pull-up maneuver ($n_z = 2.5$), based on CS-25 certification specifications [12]. Trim results showed close agreement between both tools, with minor differences due to modeling approaches. *Loads Kernel* uses a modal approach requiring convergence, with 71 eigenmodes found sufficient. Additionally, *MSC Nastran* assumes no elastic deformation at the wing root, while *Loads Kernel* allows it, complicating direct comparisons in the flexible case. Aeroelastic effects were significant: In horizontal level flight, *Loads Kernel* showed a 26.6% increase in trim angle of attack due to flexibility, and a 5.22% reduction in lift coefficient. Fig. 4 illustrates the elastic deformation of the wing for each trim case. The maximum vertical displacement reached 1.55 m at the wing tip during the pull-up maneuver, remaining within linear elasticity limits. The elastic twist varied across the span, with a maximum of -1.98º at the tip, affecting lift distribution and overall performance.

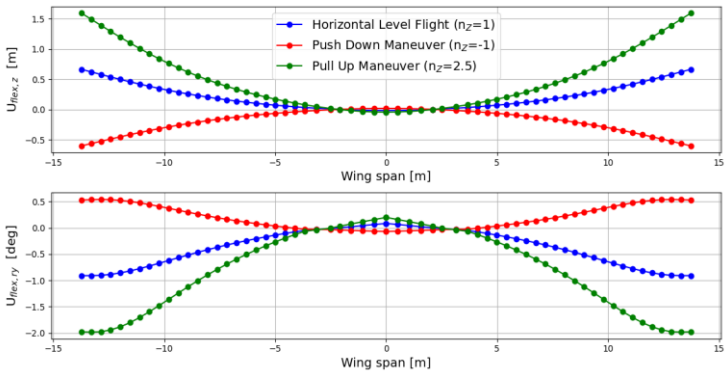

Figure 4: Loads Kernel elastic deformation of the wing at True Airspeed (TAS) of 70 m/s, Flight Level FL000, M3 for the final modified aeroelastic model.

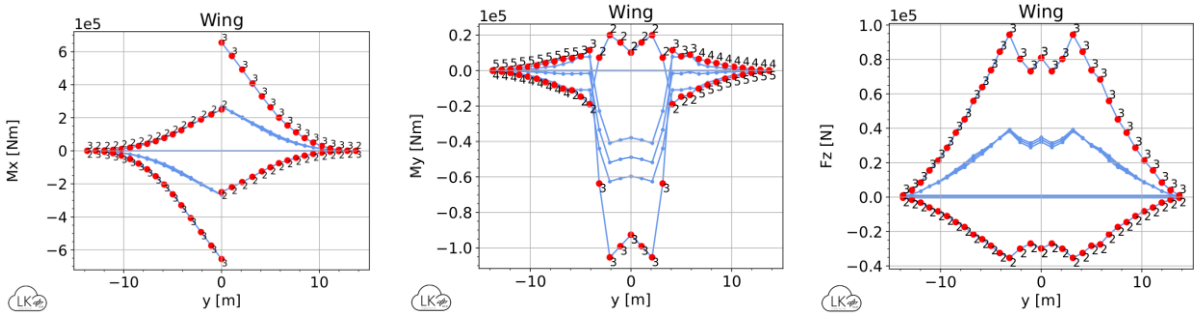
Maneuver Loads

Maneuver loads were computed using *Loads Kernel*, considering critical cases for structural sizing. The flight conditions are the same as those used in trim cases. The maneuvers analyzed include: (1) horizontal level flight ($n_z = 1$), (2) push-down ($n_z = -1$), (3) pull-up ($n_z = 2.5$), and (4) and (5) roll maneuvers. Although CS-25 Amendment 28 [12] defines a roll rate of 5.45º/s, a more representative rate of 20º/s over 3 seconds was applied. Section loads were derived from integrated nodal loads at 16 monitoring stations per wing. The quantities of interest are bending moment M_x, torsional moment M_y, and shear force F_z, based on the coordinate system defined in Fig. 3. Given the validated agreement with *MSC Nastran*, only *Loads Kernel* results are presented. Observing the 1-D Envelopes (Fig. 5), maneuver (3) produced the highest negative bending moment at the wing root, while maneuver (2) induced the highest positive moment. Torsional moment M_y showed a change in critical load case near the wing kink, influenced by elastic twist deformation (Fig. 4). Maneuvers (4) and (5) contributed significantly to torsional loads in the outboard wing sections. Shear force F_z followed a similar trend to M_x, with peak values occurring near the wing root.



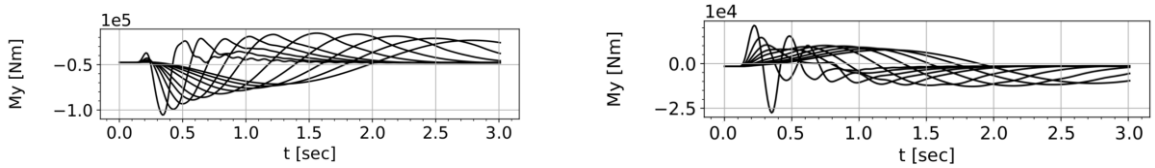


Figure 5: 1-D envelope of bending moment M_x, torsional moment M_y and shear force F_z.

Gust Loads

Gust loads were analyzed using the (1-cos) Discrete Gust Model implemented in *Loads Kernel*, under the same flight conditions as the maneuver loads. Gust profiles at sea level were defined according to CS-25.341 [12], covering the required certification spectrum. One-dimensional and two-dimensional load envelopes were computed similarly to maneuver loads, with focus placed on the time-domain response. The bending moment M_x over time showed similar positive and negative peak magnitudes, with the highest peak occurring for a gust gradient of H = 23 m, deviating from empirical predictions that suggest H = 44 m. The shear force F_z followed the same trend as M_x. The torsional moment M_y (Fig. 6) exhibited larger negative peaks, with the highest arising from H = 9 m. Oscillations observed at the wing kink for this gust gradient suggest

Materials Research Proceedings 69 (2026) 352-357 https://doi.org/10.21741/9781644904251-63

excitation of an eigenmode near 3.3 Hz, close to the first symmetric wing bending mode (3.17 Hz). This behavior is attributed to low torsional stiffness and the aft location of wing mass points relative to the LRA, resulting in strong bending-torsion coupling. Further simulations revealed coupling between gusts and the short-period flight mechanics mode due to high static margin. Reducing the static margin to approximately 10% modified the moment and force responses, leading to distinct positive and negative peak magnitudes and shifting the highest peak to a gust gradient between H = 37 m and H = 51 m, aligning with empirical expectations.

(a) Wing root. (b) Wing kink.

Figure 6: Torsional moment M_y over time for different gust gradients.

Flutter Check

Flutter check was performed using both *Loads Kernel* and *MSC Nastran* (SOL145), applying the pk-method at flight level FL000. Both tools identified the first unstable mode as the pure symmetrical torsion mode, with flutter speeds of 195 m/s in *Loads Kernel* and 203 m/s in *MSC Nastran*. A second mode became unstable at 262 m/s and 256 m/s, respectively. These flutter speeds are outside the flight envelope (Never exceed speed V_{NE} = 119.72 m/s) but remain within the subsonic regime (Ma < 0.6), as intended.

Conclusion and Outlook

This work develops the Douglas DC-3 aeroelastic model, bridging the identified knowledge gap with a comprehensive and open-source platform for demonstration and testing. The model, which balances complexity and simplicity, underscores the importance of aeroelasticity in aircraft design and stability. It captures key phenomena such as wing bending, torsion, and flutter, and was validated through trim, maneuver, gust, and flutter analyses using both *Loads Kernel* and *MSC Nastran*, showing consistent results across tools.

Keywords: Rotorcraft Stability, Ground Resonance, Linear Time-Periodic Systems, Floquet Method, LTI Harmonic Decomposition

Abstract. Ground resonance is a rotorcraft instability that involves an interaction between the rotor and its support, consisting of the fuselage and the landing apparatus. In cases where the rotor lacks symmetry, the equations of motion are periodic. This paper compares the classic time-periodic Floquet approach to investigate stability with the truncated linear time-invariant harmonic decomposition. Then, various cases are presented dealing with variations in some basic rotor characteristics, such as the number of blades. These findings show the capacity of the decomposition to represent time-periodic modes and present a criterion for the optimal application of this decomposition, which is extremely advantageous because it leads to a linear model for further analyses.

Introduction

Ground resonance is an instability caused by the coupling between structural vibrations and the periodic inertia forces originating from the lead-lag degrees of freedom of helicopter blades. This phenomenon is avoided through dampers connecting each blade with the rotor mast (or with another blade for interblade configurations). This problem was first studied by Coleman and Feingold [1], then the analysis was generalised by Hammond [2] for cases where the formulation cannot be reduced to a linear time-invariant form, typically if nonsymmetric behaviour is analysed, i.e. the failure of a single lag damper, take-off or landing scenarios involving wind or uneven surfaces. As periodic coefficients appear in the equations, modal analysis is more complex, especially in the context of preliminary design or nonlinear stability.

The following sections explain briefly the classic Floquet method and the novel harmonic decomposition. After that, a succinct overview of the rotor model is provided, with a focus on multiblade coordinates. Subsequently, results are shown for a four-bladed rotor with one inoperative damper, followed by a discussion of rotors with more failed dampers, different damper attachment and a changed number of blades. Conclusively, the relationship between the number of rotor blades, multiblade coordinates and modal participation is highlighted to delineate a reasonable criterion to apply the harmonic decomposition.

Modal analysis of periodic systems and linear time-invariant formulation

Floquet analysis for linear time-periodic systems. The Floquet approach, as formulated by Peters et al. [3], enables the stability analysis of Linear Time-Periodic (LTP) systems. Let a LTP system be defined as $d\{x(t)\}/dt = [A(t)]\{x(t)\}$, with $[A(t)] = [A(t+T)]$, i.e. periodic of period T. If the transition matrix $[\Phi(t)]$ is defined as $\{x(t)\} = [\Phi(t)]\{x(0\}$, then the stability of the system may be discerned from the eigenvalues of $[\Phi(T)]$, the *characteristic multipliers* Λ, or from the *characteristic exponents* $\eta = 1/T\ log(\Lambda) = \lambda + i\omega$. ω is not unique (the complex logarithm is multi-valued), as any integer multiple of $\Omega = 2\pi/T$ may be added without loss of meaning of the solution. Nonetheless, LTP stability is based on λ or $|\Lambda|$, which are uniquely defined. In particular, the system is unstable if at least one $\lambda > 0$.

LTI Harmonic decomposition. Lopez and Prasad [4] propose a linear time-invariant *Harmonic Decomposition* (HD) of an LTP system (where $\psi = \Omega t$), with the state vector expanded as:

$$\{x\} = \{x^0\} + \sum_{n=1}^{N_H} \quad \{x^{nc}\} cos(n\psi) + \{x^{ns}\} sin(n\psi) \tag{1}$$

N_H is arbitrary and must be chosen properly, since $N_H \to \infty$ causes the HD modes to tend exactly to the LTP modes, whereas truncation to a finite number of harmonics leads to approximation.

A possible criterion for minimum N_H is based on the modal participation of the different harmonics to states and modes.

After differentiating in time Eq. (1) and substituting it in the system equations, integration is performed over one revolution for the average term x^0; whereas the system equations are multiplied by $cos(j\psi)$ or $sin(j\psi)$ with $j = 1, \ldots, N_H$ and integrated over one rev to obtain the equations for x^{jc} and x^{js}. This formulation is computationally efficient, as the integration of the matrix terms may be substituted with the Fourier series expansion of $[A]$. The eigenvalues of the system are *equivalent to the Floquet exponents of the LTP system* ([4]).

Modal participation. After presenting the HD, modal participation [3,4] is introduced to provide an in-depth assessment of the harmonic content of modes. The modal participation of the n-th harmonic to the j-th state and k-th mode is defined as:

$$\phi_{j,k,n} = |c_{j,k,n}| / \sum_l \quad |c_{j,k,l}|, \quad -N_H \leq l \leq N_H \tag{2}$$

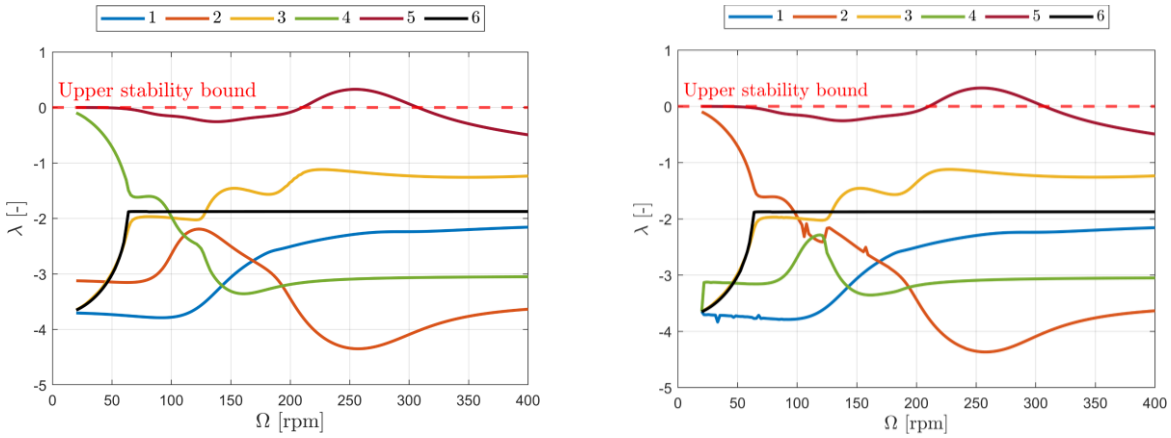
where $c_{j,k,n}$ is the n-th harmonic coefficient of the Fourier series expansion of $V_{j,k}(t)$, the j-th state of the k-th LTP eigenvector.

Given the equivalence of the LTI HD formulation to the LTP problem, the k-th LTI HD eigenvector contains the Fourier coefficients directly and can be used alternatively to compute the modal participation. The addition of integer multiples of Ω to the imaginary part of η, or equivalently the choice of the modes associated with higher harmonics in the LTI HD, does not change the harmonic content of the modes, rather their numbering, i.e. the value of n is shifted.

Ground resonance model and multiblade coordinates

The rotor model is originally from [2]. The j-th blade is linked to a rigid arm with a hinge, which allows a lag motion ζ_j. All blades constitute the rotor, spinning with a constant angular speed Ω. The arm is connected to the rotor mast and the structure of the rotorcraft, referred to as the "hub", whose dynamics is represented through two damped harmonic oscillators. This simple model encapsulates the dynamic interactions causing ground resonance. This system is unstable and requires additional dampers mounted between each blade and the rotor head (Hub-to-Blade or H2B) or between adjacent blades (Blade-to-Blade or B2B). The full derivation of all model equations, with both damper connections, is discussed in Bassi [5].

Notably, periodic coefficients, linking the hub equations to the blade ones, emerge in the system matrices whenever asymmetry is present. Unless the hub is symmetric, and all blades and dampers are equal, they cannot be deleted. Moreover, as the equations of the blades are in a rotating frame, while the hub ones are in a fixed frame, they may all be written in a fixed frame through multiblade coordinates (MBC). The j-th lag angle ζ_j is expressed as the sum of collective and cyclic coordinates:



$$\zeta_j = Z_0 + Z_d(-1)^j + \sum_{n=1}^{N*} \quad Z_{nc} cos(n\psi_j) + Z_{ns} sin(n\psi_j) \tag{3}$$

Materials Research Proceedings 69 (2026) 358-361 https://doi.org/10.21741/9781644904251-64

with $\psi_j = \Omega t + (2\pi)/N_b(j-1), j = 1,\ldots,N_b$, and $N^* = (N_b - 1)/2$ for odd N_b (Z_d is absent), while $N^* = N_b/2 - 1$ for even N_b.

Stability of rotors and modal participation

Four-bladed rotor stability. The results of Fig. 1 deal with the hub-to-blade rotor with four blades, first presented in [2]. One of the blade dampers is inactive, so periodic coefficients appear. The time-periodic equations are harmonically decomposed up to the first harmonic, i..e $N_H = 1$ in Eq. (1). The system is correctly predicted to be unstable. The two approaches provide the same modes as in [2], except at low RPM, where the continuation algorithm tracks differently.

(a) HD modes *(b) Floquet modes*

Figure 1: Comparison of modes, 4 blades, H2B dampers

Modal participation in different rotors. Modal participation is computed in both configurations, then with a different number of inoperative dampers, and finally with different numbers of bladesN_b. For LTP modes, the principal logarithm is employed, whereas the modes in Fig. 1 are used in the HD case, thus achieving the same numbering for the harmonics.

The results for the 4-bladed rotor are also achieved with the two damper configurations, as well as when two adjacent or opposite dampers fail. Therefore, damper attachment and functionality do not affect modal participation. Regarding the variation of N_b, the harmonics with the highest modal participation in the unstable mode are reported in Table 1. Notably, all other modes never have harmonics higher than those in the table. To draw a link with the number of sinusoidal terms in the multiblade coordinates, the variable N^* from Eq. 2 is reported for each N_b, alongside the minimum N_H required to have a good approximation as in Fig. 1.

The conclusion is that the harmonic decomposition must contain at least as many harmonics as the cyclic terms in the MBC to approximate LTP modes.

Materials Research Proceedings 69 (2026) 358-361 https://doi.org/10.21741/9781644904251-64

Table 1: Modal participation to unstable mode

N_b	3 or 4		5 or 6		7 or 8	
N^*	*1*		*2*		*3*	
min N_H	*1*		*2*		*3*	
States	Z_{1c}, Z_{1s}, x_H, y_H	Z_0, Z_d	Z_{2c}, Z_{2s}	Other	Z_{3c}, Z_{3s}	Other
Harm. with max $\phi_{j,k,n}$	*+1/-1*	0	*+2/-2*	As $N_b = 3,4$	*+3/-3*	As $N_b =$ 3,4,5,6

Conclusion

The harmonic decomposition has been presented alongside its time-periodic counterpart, the Floquet method. The first provides an excellent approximation of modal damping if the proper number of harmonic terms has been employed, which in turn is determined from the number of cyclic coordinates in the MBC. In conclusion, the HD successfully and reliably approximates LTP modes, providing an ever-useful linear time-invariant representation.

Keywords: Whirl Flutter, Experimental Modal Analysis (EMA), Operational Modal Analysis (OMA), Aeroelasticity

Abstract. Whirl flutter is a critical aeroelastic instability arising from the coupling of aerodynamic, structural, and gyroscopic effects in turboprop propulsion systems. This work investigates the phenomenon through analytical, numerical, and experimental approaches using a Whirl Flutter Small-Scale Demonstrator (WFSD). The demonstrator reproduces the dynamic behaviour of a turboprop configuration with two degrees of freedom, namely pitch and yaw. Analytical models based on strip theory, numerical simulations performed in MSC NASTRAN, and wind tunnel tests were used to evaluate natural frequencies and aeroelastic stability. The results show a strong correlation among the three methodologies, validating the modelling framework and providing reliable data to support the design of safer and more efficient propeller-driven systems.

Introduction

Whirl flutter is a complex and critical aeroelastic instability that arises from the dynamic interaction between unstable aerodynamic forces, structural rigidities, and gyroscopic inertial effects in engine-propeller systems elastically mounted on aircraft [1][2]. Its understanding and mitigation have historically been of paramount importance, especially after significant accidents involving turboprop aircraft in the 1960s [1][3][4][5]. To ensure the safety and reliability of modern propulsion systems, a thorough knowledge of this phenomenon is indispensable. This study aims to address this challenge through a comprehensive multidisciplinary survey, which harmonises and validates the results obtained from analytical analyses, numerical simulations, and experimental tests. At the heart of the research is the Whirl Flutter Small-Scale Demonstrator (WFSD)(Fig.1), a small-scale physical demonstrator designed to accurately replicate the dynamic and aeroelastic behaviour of a turboprop propulsion system under critical flight conditions. The model is based on a two-degree-of-freedom (2DOF) configuration with a rigid propeller, which includes pitch and yaw freedoms, elastically constrained by a spring system [6]. The design of the demonstrator considers crucial details such as materials and spring specifications to ensure that natural frequencies and vibration modes are consistent with those of a full-scale system [6]. During the tests, the stiffness of the springs, and thus their tension, was varied using a position variator. Configurations corresponding to positions 1 and 14 were tested, this means the two ends of the demonstrator's stay.

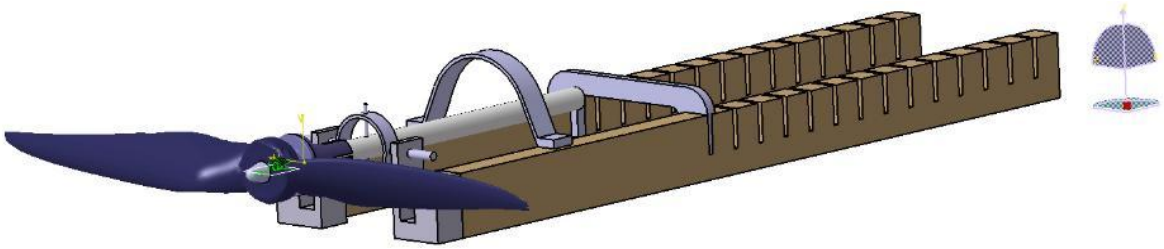

Figure 1 - Whirl Flutter Small-Scale Demonstrator

Methodology

The study combines analytical, numerical, and experimental methods to capture the essential features of the whirl flutter phenomenon and validate the results across the different approaches. The analytical investigation starts from a 2DOF model and employs strip theory to predict the natural frequencies and vibration modes of the system. This part of the study examines the influence of key structural and aerodynamic parameters for a more accurate representation of propeller performance [4]. In parallel, an in-depth numerical analysis is conducted using a finite element model (FEM) for flutter analysis in NASTRAN (SOL 145) [7]. This implementation builds upon the work of Rodden and Rose, who developed a preprocessor to include aerodynamic and gyroscopic forces of the propeller and nacelle in flutter analysis. Their approach enables the modelling of the propeller in Nastran as a point mass using the CONM2 card, with torsional springs defined on the Y and Z axes via the CELAS2 cards, and structural damping on the propeller attachment using the CDAMP1 and PDAMP cards. The model accounts for the flexibility of the shaft and the real distribution of the masses, which are crucial for a faithful representation of the system. Simulations are performed at various speeds and use the FLUTTER PK option to carry out the flutter analysis using the P-K method. A key objective is the generation of Campbell diagrams, enabling the analysis of the behaviour of natural whirl frequencies (backward and forward) as a function of the propeller's rotational speed. These models also allow the extraction of stiffness and aerodynamic damping matrices for different flight conditions.

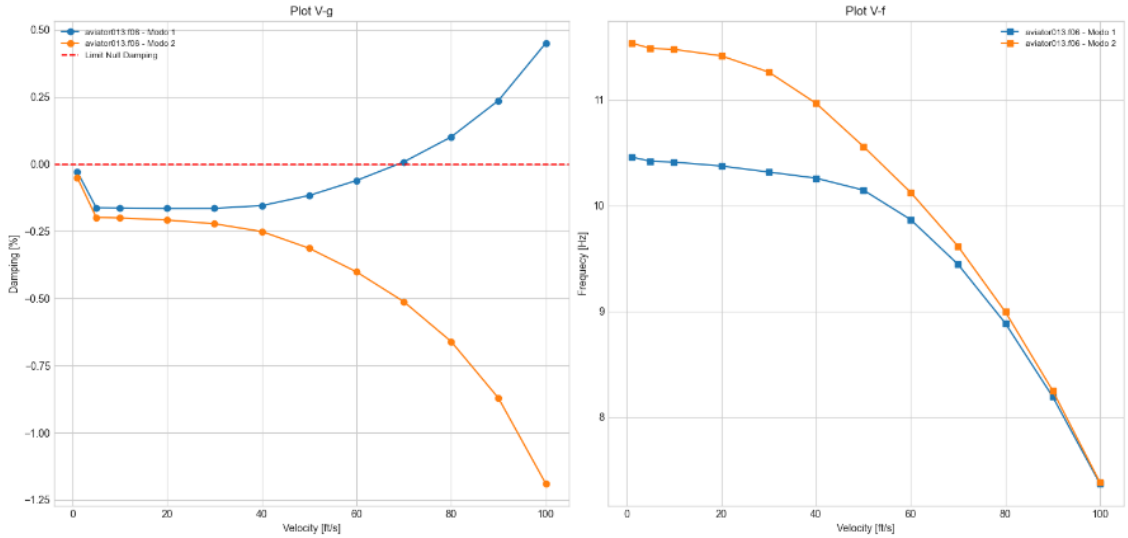

Figure 2 – VGF plot of the Model

The experimental phase is divided into two distinct phases. Initially, the tests are performed via an Experimental Modal Analysis (EMA) on the fixed-helix demonstrator. EMA was carried out in still air using an instrumented hammer to excite the structure. Accelerometers placed at selected locations on the nacelle and propeller hub measured the response. The analysis provided the natural frequencies and mode shapes of the demonstrator, allowing validation of the inertial and elastic

Materials Research Proceedings 69 (2026) 362-365 https://doi.org/10.21741/9781644904251-65

characteristics of the model. Operational Modal Analysis (OMA) was subsequently conducted in an open-circuit wind tunnel. During these tests, the stiffness configuration (positions 1 and 14), airflow velocity, and propeller rotational speed were systematically varied. The demonstrator was mounted on an aluminium support frame designed to minimise mechanical interference with the system dynamics. These tests enabled the identification of the whirl modes and the experimental assessment of aeroelastic stability.

Figure 3 – Test setup

Results

Table 1 presents a comparison between numerical and experimental results. The measured natural frequencies show excellent agreement with the FEM predictions, with deviations below 1%. This confirms the accuracy and reliability of the developed models.

Table 1 – Results of Numerical- Experimental Comparison.

	Flutter Velocity [ft/s]	Pitch Freq. [Hz]	Yaw Freq. [Hz]	Err %
Numerical	68.4	9.71	9.52	1.03
Experimental	68.0	9.61	9.61	0.95

The Campbell diagrams derived from the numerical simulations effectively captured the evolution of the forward and backward whirl modes with increasing propeller rotational speed. The backward whirl frequency decreased with speed, while the forward mode increased, approaching the rotational frequency line at higher RPM. Experimental results confirmed these trends. Increasing the spring stiffness (from position 1 to 14) caused an upward shift in both pitch and yaw natural frequencies and delayed the approach to the whirl-flutter boundary. The measured damping behaviour was consistent with theoretical expectations, showing a stabilising effect as stiffness increased. Overall, the analytical, numerical, and experimental results demonstrated strong consistency. The validated FEM and analytical models accurately reproduced the system

dynamics, confirming that the WFSD successfully emulates the aeroelastic coupling typical of turboprop configurations.

Conclusion

The present work provided an integrated analytical, numerical, and experimental investigation of whirl flutter on a small-scale demonstrator. The WFSD has demonstrated to be a useful tool for simulating the coupled aeroelastic behaviour of turboprop propulsion systems. The excellent agreement between FEM predictions and wind tunnel measurements validates the adopted modelling approach and demonstrates the robustness of the experimental methodology. These results represent a significant step toward the reliable prediction and control of whirl flutter phenomena in propeller-driven aircraft. Future developments will focus on refining the aerodynamic modelling, incorporating nonlinear effects, and expanding the test matrix to include higher rotational speeds and different propeller geometries and configurations.

Keywords: Flutter Suppression System, Double Ailerons Wing, Adaptive Control, Fault Tolerance

Abstract. This work presents a fault-tolerance analysis of an adaptive control scheme for flutter suppression using multiple control surfaces. The proposed architecture is designed to exploit the distributed actuation capabilities of modern wings to enhance performance and reliability in realistic flight conditions. By employing an adaptive control technique, the system continuously adjusts to variations in flight dynamics without requiring prior knowledge of the complete aeroelastic model. Practical challenges, such as actuator faults and external disturbances, are explicitly addressed, contributing to the development of more robust and fault-tolerant flutter suppression strategies. The methodology is demonstrated on a representative system modeled using a low-order aeroelastic beam formulation based on Euler–Bernoulli beam theory and strip theory aerodynamics, and is suitable for extension to higher-fidelity models.

Introduction

The aviation industry is moving towards lightweight, high-aspect-ratio wing designs to improve fuel efficiency and reduce CO_2 emissions. While slender wing structures offer aerodynamic advantages, they are also more susceptible to aeroelastic instabilities such as flutter, posing significant limitations on their operational envelope. Adaptive control strategies have attracted growing interest due to their capability to manage the highly dynamic, speed-dependent behavior of aeroelastic systems [1]. These methods offer robustness to modeling uncertainties and flight condition variations, but so far, their application has primarily been restricted to low-order aeroelastic models. Furthermore, only a limited number of studies have investigated the integration of multiple control surfaces in adaptive flutter suppression architectures [2]. This work contributes in this framework by presenting a fault-tolerance analysis of an adaptive control scheme for flutter suppression using multiple control surfaces. The architecture is designed to exploit the distributed actuation potential of modern wings, with a focus on improving performance and reliability in realistic flight scenarios. Relying on adaptive control techniques, the system dynamically adjusts to changes in flight conditions and structural properties without requiring full knowledge of the aeroelastic model in advance. Additionally, the proposed approach takes into account practical considerations such as actuator faults and external disturbances, contributing to the development of more fault-tolerant and robust flutter suppression systems. The methodology is suitable for application to higher-fidelity aeroelastic models, moving closer to implementation on actual aircraft configurations.

Materials and method

The aeroelastic plant, representing a modified Goland's wing [3] equipped with double aileron, is modeled exploiting a low order aeroelastic beam formulation [4] based on Euler-Bernoulli beam

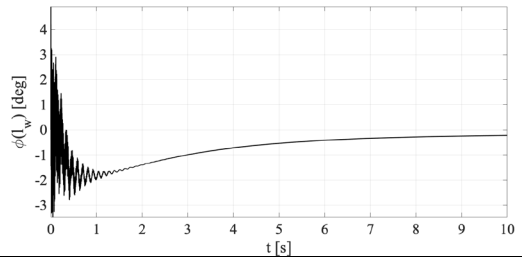
Materials Research Proceedings 69 (2026) 366-369 https://doi.org/10.21741/9781644904251-66

theory and strip theory aerodynamics which allows to cast the aeroelastic equations in the following state space form

$$\begin{cases} \dot{X} = \mathrm{A}X + \mathrm{B}u + \mathrm{B}^{g}w_{g} \\ Y = \mathrm{C}X \end{cases}. \quad (1)$$



where A is the dynamic matrix, B is the control-state matrix, B^{g} is the gust influence matrix, C is assumed as an identity matrix in the hypothesis of ideal sensors that directly measure the structural displacements of interest, the control input vector u collects the ailerons commanded deflections, and w_g is the gust disturbance [5]. Loss of aileron effectiveness is taken into account by means of an effectiveness factor α_{f} that multiplies the transfer functions related to eq. 1 linking the inboard or outboard aileron deflection with the structural displacements. The Adaptive control scheme generates the control input by processing the wing tip torsion measurement $\phi(\mathrm{l_w})$, which is augmented with the output of a parallel feedforward compensator needed to fulfill the passivity requirements of the adaptive controller [6,7]. Specifically, the augmented plant meets the passivity requirements for velocity values below $U_f^{CL} = 190.6m/s$, which represents the ideal flutter boundary of the closed loop system.

The adaptive controller invariant gains were tuned by means of a Population Decline Swarm Optimization $\mathrm{P_DSO}$ algorithm [8]. The objective function was the Integral of Time Absolute Error ITAE of the wing tip torsion angle, which was computed considering the plant at the open loop flutter speed $U_f = 109.5m/s$ subjected to a pulse disturbance on the wing tip torsion rate of amplitude 100 rad/s and width 0.001 s. The optimized adaptive controller was then tested in a flight scenario involving a 1-cosine gust disturbance and loss of actuator effectiveness considering the wing flying at U_f^{CL}. The obtained results in terms of ITAE, maximum transverse displacement at the tip $w(l_w)$, maximum inboard aileron deflection δ^{in}, and maximum outboard aileron deflection δ^{out} are summarized in Table 1.

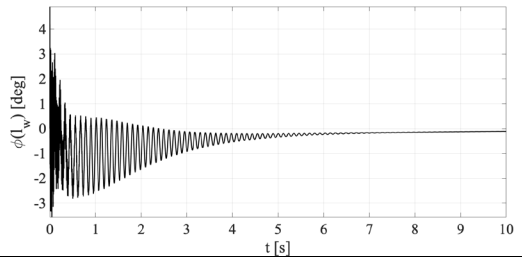


Table 1: Fault tolerance analysis results

Case	α_f^{in}	α_f^{out}	ITAE [rad-s]	Max$[w(l_w)]$ [m]	Max(δ^{in}) [deg]	Max(δ^{out}) [deg]
1	1.0	1.0	23.6	0.060	20	5.8
2	0.5	1.0	12.6	0.067	20	6.7
3	1.0	0.5	59.2	0.090	20	14.2
4	0.5	0.5	unstable	-	-	-
5*	0.0	1.0	245.0	0.200	52.3	40.0
6	1.0	0.0	unstable	-	-	-

The system maintains stable and acceptable performance when the inner aileron experience 50% loss of effectiveness. In this case, the reduction in ITAE observed between the first and second cases is attributed to the oscillatory nature of the response in the second scenario, as shown in Figure 1. Although the system exhibits increased oscillations, the error tends to decay more rapidly over time, resulting in a lower accumulated time-weighted error. In contrast, the first case presents a smoother, more damped response, but with a sustained deviation from the desired setpoint, leading to a higher ITAE.

(a) Fault-free scenario

(b) Inner aileron partial loss $\alpha_f^{in} = 0.5$

Figure 1: Wing tip torsion displacement

A reduction in the effectiveness of the outer aileron significantly degrades system performance, as indicated by the increase in ITAE and tip deflection. Simultaneous degradation of both ailerons and complete failure of the outer one lead to instability, demonstrating the key role of the outer control surface. It is worth noting that, in the case of complete failure of the inner aileron the system exhibits poor performance with large control surface deflections, but the system is still able to damp out the vibrations of the linear aeroelastic plant.

Conclusions

This work investigated the flutter suppression capabilities of a simple adaptive control strategy implemented on a wing configuration with double ailerons. The fault tolerance analysis demonstrated that the flutter suppression system exhibits greater robustness to partial loss of effectiveness in the inner ailerons than in the outer ones. While moderate inner actuator degradation may even improve the ITAE index due to a more oscillatory yet convergent response, outer actuator degradation significantly degrades performance and leads to larger wing-tip deflections. Complete or simultaneous failures ultimately result in instability, highlighting the critical importance of actuator redundancy. These findings emphasize that maintaining at least partial availability of both actuator groups is essential to ensure closed-loop stability and acceptable performance in flutter suppression.

Keywords: Unsteady Aerodynamics, Aeroelasticity, State-Space, Lifting-Line Theory, Morphing Wings, Paper Flutter, Flag Flutter, Finite Element Method

Abstract. This paper presents a state-space formulation for the aeroelastic stability analysis of deformable-airfoil wings. The proposed approach couples the wing structural dynamics modeled as a cantilever plate (through an FEM approach) with aerodynamic loads computed through an Unsteady Lifting-Line Theory (ULLT), which evaluates the unsteady sectional loads using the Küssner-Schwarz and accounts for wake effects through the Biot–Savart law. The corresponding bound circulation is obtained via the Kutta–Joukowski theorem extended to unsteady flows. The distributed aerodynamic loads are projected onto the shape functions introduced in a Galërkin solution approach, thus yielding an aerodynamic operator expressed through transcendental transfer functions, which is then approximated into a rational state-space form. This enables straightforward aeroelastic stability assessment through eigenvalue analysis and provides a framework suitable for control design. The model's accuracy is validated using the paper flutter problem, whose aeroelastic behavior is representative of deformable-airfoil wings.

Introduction

Engineers have traditionally designed aircraft to perform optimally under specific conditions, but this approach has become restrictive as aviation technology advances. Inspired by birds and insects, which naturally change wing shape for both efficient flight and agile maneuvering, researchers have increasingly explored the concept of morphing aircraft, which are capable of real-time shape adaptation to improve performance across multiple flight conditions. While morphing is not new, as seen in the Wright Brothers' wing-warping system and modern high-lift devices, recent research has formalized morphing into categories such as planform, out-of-plane, and airfoil morphing, with camber morphing being the most widely studied [1,2]. Numerous designs, including compliant and composite-based morphing airfoils, have been developed and modeled to optimize aerodynamic efficiency and stability. Aeroelastic modeling has also played a key role in analyzing and optimizing these systems for stability and performance. Interestingly, similar aeroelastic phenomena appear in other fields as well, such as medical research on snoring, where the soft palate behaves like a flexible plate, and industrial challenges like paper or flag flutter.

The present paper aims to develop a state-space formulation for studying the aeroelastic stability of deformable-airfoil wings or camber-morphing wings, a subcase of the more general morphing wings category. Throughout the years, various models have been proposed to evaluate the aerodynamic loads, from high-fidelity CFD approaches to low-fidelity

analytical formulations. In the present paper, a novel aeroelastic tool is proposed, obtained by coupling the structural dynamics model with the aerodynamic loads evaluated by an Unsteady Lifting-Line Theory (ULLT), developed for the unsteady aerodynamics of camber morphing wings. The aerodynamic three-dimensional solver recently presented by the authors [3,4,5,6] is based on the analytical Küssner-Schwarz theory for the evaluation of the sectional unsteady aerodynamic loads, coupled with the application of the Biot-Savart law for determining the wake inflow due to the trailed vorticity. The extension to unsteady aerodynamics of the Kutta-Joukowski theorem is also applied to determine the sectional bound circulation from the knowledge of the evolution of the sectional circulatory lift [7]. The generalized aerodynamic loads forcing the structural dynamics are obtained by projections of the airfoil distributed loads onto suitable shape functions introduced in the Galërkin solution approach. These are related to the corresponding Lagrangian coordinates through transcendental transfer functions of the reduced frequency, collected in the aerodynamic matrix. Thus, the rational matrix approximation of the latter is applied in order to describe the aerodynamic operator in a state-space form, from which the state-space aeroelastic model is readily determined. This state-space aeroelastic formulation is very convenient since it allows the study of the aeroelastic stability through eigenproblem solution and can be straightforwardly applied for control purposes. The accuracy of the overall aeroelastic model will be assessed by comparison with experimental/numerical data regarding the specific test case of paper flutter (also known as flag flutter), an industrial problem that limits the speed of printing machines, which is widely documented in the literature from both numerical and experimental perspectives (see for example [8,9]) and whose aeroelastic behavior is closely related to the ones of deformable-airfoil wings.

Observing that literature results on paper flutter are typically related to one-dimensional approximation of the structural dynamics coupled with a two-dimensional description of the aerodynamic loads account for only shed wake vorticity, the numerical investigation examines the effects on the aeroelastic simulation given by including the wake trailed vorticity and modeling the structure as a flat plate through an FEM tool.

Aeroelastic Model based on the ULLT approach

In this work, the aeroelastic operator for morphing wings is derived by applying a frequency-domain Unsteady Lifting Line Theory solver, ULLT, suitable for the analysis of unsteady aerodynamics of morphing wings with deformable camber. The model, recently presented in the work [5] as an extension of the previously published ULLT for non-morphing wings [10], is based on the evaluation of the pressure distribution along the whole wing through the analytical Küssner-Schwarz theory for unsteady flows [11,12], which is then integrated to obtain the generalized loads as projections onto the shape functions used to express the wing deformation in a Galërkin approach. The Küssner-Schwarz theory is the perfect choice for the aerodynamic study of camber morphing wings, since it is a linear aerodynamic theory, for incompressible, potential flows providing the airfoil pressure loads generated by an arbitrary distribution of downwash, thus representing the extension of the Theodorsen theory to deformable camber airfoils. While the shed vorticity is already analytically included in the Küssner-Schwarz theory (through the well-known Theodorsen function [13]), the Biot-Savart law is used to determine the wake trailed vorticity effects on the sectional downwash appearing in the Küssner-Schwarz theory. The wake vorticity released by the lifting body is determined from the relation between the sectional bound circulation and the sectional circulatory lift provided by the extension of the Kutta-Joukowski theorem to unsteady linear aerodynamics presented in [7], which closes the loop of the aerodynamic system.

This aerodynamic solution approach yields the following relation between the M generalized aerodynamic forces, **f**, and the M Lagrangian coordinates, **q**, of the structural dynamics problem

Materials Research Proceedings 69 (2026) 370-374 https://doi.org/10.21741/9781644904251-67

$$\tilde{\mathbf{f}} = \mathbf{E}(\mathrm{k})\,\tilde{\mathbf{q}} \tag{1}$$

where k is the reduced frequency and $\mathbf{E}$ is the transcendental [M × M] aerodynamic matrix, that collects the aerodynamic frequency response functions (see [5] and [10] for details).

The presence of the transcendental contributions comes from three sources: *i*) the exponential contribution due to the delays appearing in the Biot-Savart law used to evaluate the downwash generated by the wake trailed vorticity (the vorticity at a given wake point corresponds to the vorticity released by the trailing edge when passing at that point), *ii*) the Theodorsen lift deficiency function used to evaluate the coefficients a_n of the Küssner-Schwarz theory (see [11, 12] for more details), and *iii*) the frequency response function, G(k), of the unsteady Kutta-Joukowski theorem (see [7]). This implies that, in this form, the aerodynamic matrix is unsuitable for aeroelastic stability analyses and control applications.

To overcome this difficulty, it is convenient to apply the following rational-matrix approximation of the aerodynamic matrix along the imaginary axis of the complex plane

$$\mathrm{E(k)} \cong (\mathrm{ik})^2\mathrm{A}_2 + \mathrm{ikA}_1 + \mathrm{A}_0 + \mathrm{Q(ikI - A)^{-1}R} \tag{2}$$

where $\mathbf{A}_2$, $\mathbf{A}_1$ and $\mathbf{A}_0$ are [M × M] matrices, $\mathbf{A}$ is a diagonal [N_p × N_p] matrix, where N_p is the number of aerodynamic poles that can be arbitrarily increased to better approximate the aerodynamic transfer functions, whereas $\mathbf{Q}$ is a [M × N_p] matrix and $\mathbf{R}$ is a [N_p × M] matrix. These constant-coefficient matrices can be determined by a least-square approximation technique [14,15].

Thus, the combination of Eq. (2) with (1), followed by the transformation into the time domain yields, for $\tau = t\,V/b$ (being t the dimensional time, V the velocity and b the semi-chord),

$$\begin{cases} \mathbf{f}(\tau) = \mathbf{A_2}\,\ddot{\mathbf{q}} + \mathbf{A_1}\,\dot{\mathbf{q}} + \mathbf{A_0}\,\mathbf{q} + \mathbf{Q}\,\mathbf{r} \\ \dot{\mathbf{r}} = \mathbf{A}\,\mathbf{r} + \mathbf{R}\,\mathbf{q} \end{cases} \tag{3}$$

where $\mathbf{r}$ denotes the vector of the N_p additional aerodynamic states introduced by the rational contribution in Eq. (2).

Equation (3) represents the state-space model of the wing generalized aerodynamic loads derived from the frequency-domain ULLT solver, suitable for aeroelastic stability analyses and control purposes once coupled with a structural dynamics operator. Previous analyses were accomplished by approximating the lifting body as a semi-infinite thin plate (namely, a cantilever beam with the inclusion of the Poisson ratio) [3]. In the present work, a complete cantilever plate is considered in order to better simulate the phenomenon of the paper flutter. To this aim, mass and stiffness matrices relative to the cantilever plate, respectively $\mathbf{M}$ and $\mathbf{K}$, are determined by a Finite Element Method (FEM) approach (specifically, the commercial software Inventor Nastran). The corresponding eigenvectors are applied to determine the approximated natural modes of vibration of the structure, which, in turn, are used as the shape functions of the Galërkin approach. The complete aeroelastic system defined in a state-space form reads

$$\begin{cases} \mathbf{M}\,\ddot{\mathbf{q}} + \mathbf{K}\,\dot{\mathbf{q}} = \mathbf{A_2}\,\ddot{\mathbf{q}} + \mathbf{A_1}\,\dot{\mathbf{q}} + \mathbf{A_0}\,\mathbf{q} + \mathbf{Q}\,\mathbf{r} \\ \dot{\mathbf{r}} = \mathbf{A}\,\mathbf{r} + \mathbf{R}\,\mathbf{q} \end{cases} \tag{4}$$

from which the velocity and frequency of flutter are determined through a standard eigen- value analysis.

Numerical Investigations

The numerical results presented in this section are obtained by three different applications of the aeroelastic model, whose accuracy is assessed by comparison with the experimental benchmark of Huang [8]. It considers a thin rectangular aluminum plate, with a span length

Materials Research Proceedings 69 (2026) 370-374 https://doi.org/10.21741/9781644904251-67

of 6 cm and four different values of the chord: 4, 6, 8, 10 cm. Along with the complete ULLT aerodynamic model coupled with the plate structural operator, a simplified version of it, not including the trailed vorticity effects, is considered. This last model consists of a strip-theory (S-T) approach based on the Küssner-Schwarz theory, and it is coupled with both the beam-like and plate modeling of the structure, in order to evaluate the resulting prediction discrepancies.

The results, for both the flutter velocity and frequency, are shown in Fig. 1. First, note the excellent accuracy of flutter frequency predicted by all the aeroelastic models considered, resulting from the comparison with the experimental. On the other hand, the flutter velocity prediction is less accurate, with a slightly better accuracy of the ULLT with respect to the S-T. This means that, although the trailed vorticity effect has an important role in the aerodynamic model, other phenomena not captured by the ULLT model could have a more significant influence on the aeroelastic stability.

The slight difference between the results obtained by beam and plate structural modeling is also noticeable. The correlation between the flutter frequencies of the analyzed configurations and their natural vibration frequencies shows that the critical frequency practically corresponds to the frequency of vibration of the second natural vibration mode of the beam model. This confirms the validity of the aeroelastic tool based on the simpler description of the structural dynamics operator. The analyses indicate that flutter instability primarily occurs in symmetric bending vibration modes, for which aerodynamic forces are uniformly distributed along the direction orthogonal to the undisturbed flow, coupling between aerodynamic forces and structural deformations is stronger, and more efficient energy transfer and accumulation until the flutter threshold occurs. In contrast, antisymmetric modes experience partial force cancellation, reducing energy transfer and delaying instability.

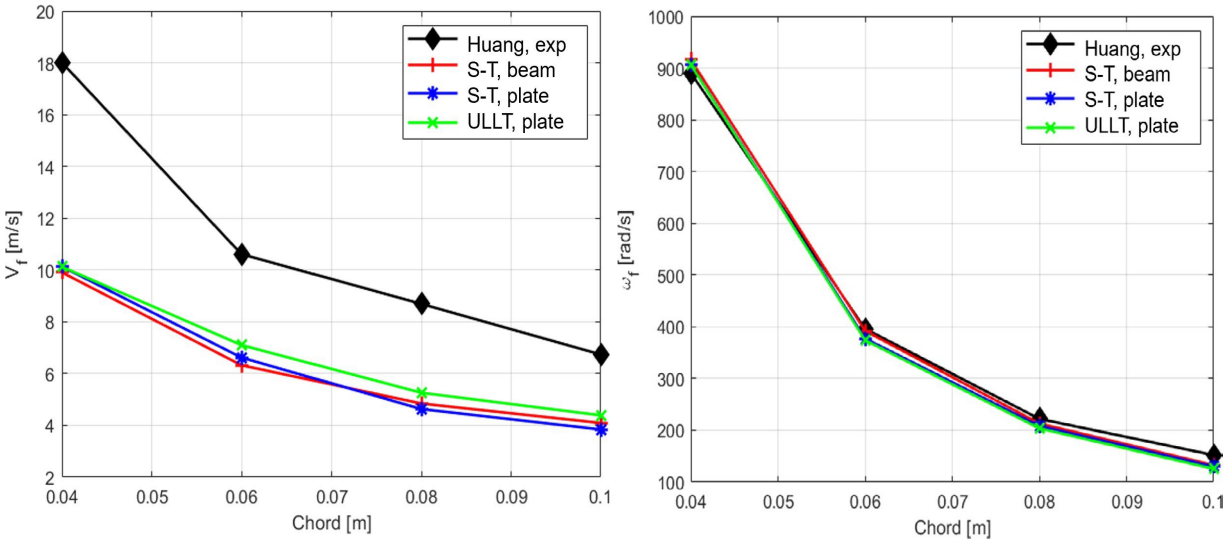

Figure 1: Velocity and frequency of flutter as functions of the chord length. Comparison between strip-theory results for both beam and plate models, ULLT results including the trailed vorticity, and the experimental data by Huang [8].

Conclusions

A state-space formulation for the aeroelastic stability analysis of deformable-airfoil wings has been presented. It relies on a ULLT aerodynamic solver based on the Küssner-Schwarz theory for the evaluation of the sectional aerodynamic loads, on the unsteady Kutta–Joukowski theorem for the definition of the bound circulation from the circulatory lift, and on the Biot–Savart law for the inclusion of the wake trailed vorticity effects. Considering a paper flutter problem, the comparison of the outcomes of the present model with experimental data from

the literature showed very good accuracy in terms of flutter frequency prediction. Less accurate is the prediction of the flutter velocity. The effect of the trailed vorticity seems to be marginal for the examined problem, and, at the same time, the prediction accuracy seems to be scarcely affected by the improvement of the structural operator (from beam-like to plate modeling), since the identified flutter mode is close to the second mode of vibration of the cantilever beam.

Abstract. This work presents a methodology for the aeroelastic analysis of a highly de- formable wing in compressible flow. The aim is to define a design tool for innovative, highly deformable aeronautical configurations, in which nonlinearities in the structural operator and the effects of body and wake deformation in the compressible-flow aerodynamic operator are significant and play a crucial role in simulating the aeroelastic behavior.

Introduction

Recent advances in aeronautical engineering have increasingly focused on novel structural concepts featuring highly flexible lifting surfaces, for which significant geometric deformations occur during flight due to aerodynamic and structural interactions. These solutions, often adopted to improve aerodynamic efficiency and adaptability to varying operational conditions, introduce new design challenges. In particular, the interaction between aerodynamic forces and the significant elastic response of the structure makes aeroelasticity crucial, especially when assessing flutter and dynamic stability conditions. The aeroelastic analysis is of paramount importance to ensure the safety and good performance of novel aircraft configurations, requiring advanced predictive models and a deep understanding of fluid-structure coupling mechanisms [1, 2].

Aeroelastic analyses can be accomplished through experimental campaigns [3] or by employing theoretical-numerical models [4]. While experiments provide direct and tangible data, they often demand substantial resources and offer limited flexibility. Theoretical-numerical models, on the other hand, allow for the exploration of a wide range of operating conditions and structural configurations, offering predictive tools that are valuable during the design and optimization phases, although necessarily affected by a given degree of approximation. This work presents the development and application of a theoretical-numerical model for the aeroelastic analysis of a flexible wing, with the aim of identifying aeroelastic response and flutter conditions.

The aeroelastic model is obtained by coupling a geometrically nonlinear structural dynamics model for a bending-torsion beam [5] with the aerodynamic loads evaluated using a free-wake panel method solver. This solver is based on a novel boundary integral formulation for the solution of compressible potential flows around deforming lifting bodies, recently introduced by the authors [6]. It pays particular attention to the inclusion of body deformation and free-wake description, since these factors strongly affect the aerodynamic loads prediction and therefore the aeroelastic response. The aeroelastic coupling is based on a Galerkin approach and solved via a time-marching method, since the wing structural model and the free wake formulation introduce structural and aerodynamic nonlinearities that cannot be treated in the frequency domain.

The first section presents the aeroelastic model, whereas the second discusses the numerical investigation, which aims to validate the developed aeroelastic solver against literature results, and

to assess the impact of including deformations and compressible aerodynamic effects on the wing aeroelastic response.

Aeroelastic model

This section presents the methodology used to develop the aeroelastic model for flexible wings subjected to moderate bending (in-plane and out-of-plane) and torsion displacements. The wing is modeled as a straight, slender, homogeneous, and isotropic beam undergoing moderate displacements, with geometric and mechanical properties that vary along its span. The aerodynamic forces are evaluated using a compressible potential-flow model.

Structural dynamics model. To derive the structural dynamic model of the wing, the space-time partial differential equations presented in Ref. [5] are considered, referring to the case of a bi-directional bending and torsion beam, namely a beam subject to in-plane bending, out-of-plane bending, and torsion about the elastic axis.

For the solution procedure, spatial integration of the structural-aerodynamic coupled model is performed using the Galerkin method, with shape functions corresponding to the natural modes of vibration of the uncoupled linear bending and torsional uniform beam models, with clamped-free boundary conditions. The method allows the transformation of the system of space-time partial differential equations into a set of ordinary differential equations in time

$$\mathbf{M}\,\ddot{\mathbf{x}}(t) + \mathbf{K}\big(\mathbf{x}(t)\big)\mathbf{x}(t) = \mathbf{f}(t) \tag{1}$$

where $\mathbf{M}$ is the mass matrix, $\mathbf{x}$ is the vector of the Lagrangian coordinates (time-variant coefficients of the linear combination of shape functions providing the beam bending and torsion displacements) and $\mathbf{K}\big(\mathbf{x}(\mathrm{t})\big) = \mathbf{K_L} + \mathbf{K_{NL}}(\mathbf{x}(\mathrm{t}))$ is the stiffness matrix, which is linear combination of a linear stiffness matrix $\mathbf{K_L}$ and a non linear contribution $\mathbf{K_{NL}}$. In addition, $\mathbf{f}$ is the vector collecting the generalized aerodynamic forces.

Aerodynamic model. The generalized aerodynamic forces are obtained by solving a compressible potential-flow problem around lifting bodies.

To perform an accurate simulation taking into account wing deformation and wake vorticity evolution, the boundary integral equation formulation proposed in Ref. [6] is adopted, with the wake contribution expressed in terms of the material wake description proposed in that work. The formulation includes kinematic and geometric terms that account for the deformation of the boundary surfaces, making it particularly suitable for aeroelastic analyses, where both the lifting body and the wake can deform.

The velocity potential is solved using a zero-order panel method, which yields the following solution of the problem

$$\phi_k = B_{kn}\,\psi_n + C_{kn}\,\phi_n + D_{kn}\dot{\phi}_n + F_{km}\Delta\phi_m \tag{2}$$

where ϕ_k and ϕ_n represent the velocity potential at the receiving points and at the panel centroids, respectively, ψ_n denotes the normalwash at the panel centroids as determined from the imposition of the impermeability boundary condition, while $\Delta\phi_m$ are velocity potential discontinuities evaluated at the centroids of the wake panels. The influence coefficients B_{kn}, C_{kn}, D_{kn} refer to the lifting body, while F_{km} corresponds to the wake contributions.

The computed velocity potential distribution over the body is then used to derive the generalized aerodynamic forces, $\mathbf{f}$, via the application of the unsteady, non-linear, Bernoulli theorem.

Numerical results

This section presents the numerical results obtained by using the aeroelastic model in Eq.

(1). The main objective of the numerical investigation is the assessment of the influence of the effects of the inclusion of body and wake deformations in the aeroelastic formulation in terms of

Materials Research Proceedings 69 (2026) 375-379 https://doi.org/10.21741/9781644904251-68

predicted aeroelastic stability boundaries. This is accomplished by comparisons with the results given by aeroelastic stability analysis based on the compressible-flow velocity potential formulation valid for undeformed wing surfaces presented in [7]. Moreover, the comparison with the results of the aeroelastic stability analysis performed by using an incompressible-flow model is also presented.

The aeroelastic model presented in Eq. (1) is non-linear, and thus, to evaluate the flutter stability, a time-marching scheme is used.

The numerical investigation deals with the Goland's wing model [8]. It is important to note that the structural dynamics model of Goland's wing is linear (with in-plane bending displacement neglected), but, however, the deformation of the wing is taken into account along with the wake surface deformation, and thus a time-marching scheme is requested.

Table 1 presents a comparison between the flutter speeds reported in the literature and those obtained by using the present model (PM). The comparison is carried out both under the assumption of a rigid-body aerodynamic formulation (Rig.), as described in [7], where the deformation is considered only in the definition of the impermeability boundary condition (rigid body and fixed flat wake are considered), and under the assumption of deformable surfaces by employing the aerodynamic formulation given in Eq. (2), in which the influence aerodynamic coefficients are time-dependent (due to the deformation of body and wake).

The results show excellent agreement between the data reported in the literature and those obtained by using the aeroelastic model developed in this work.

It is worth noting that the predictions based on the incompressible flow assumption tend to be more conservative than those considering flow compressibility. The flutter phenomenon depends, of course, on the dynamics of the aerodynamic loads, and particularly to their phase shift with respect to the dynamic response of the structure. Although the amplitude of the aerodynamic loads is typically higher in the compressible-flow case compared to the incompressible-flow one, the presence of a transmission delay contributes to postponing the onset of the aeroelastic instability.

Figure 1 shows the aeroelastic stability limit as a function of the altitude. Changing altitude affects both air density and speed of sound, thereby modifying the magnitude of the unsteady aerodynamic loads as well as the transmission delay. The aim is to investigate how compressibility affects the stability boundary.

The formulation based on compressible flow, except at very high altitudes, yields less conservative predictions compared to the incompressible case. Furthermore, the formulation accounting for surface deformations anticipates the onset of instability. This is due to the geometric deformation of the body and wake, which alters the vorticity distribution in the flow field, and thus the magnitude and phase of the aerodynamic loads.

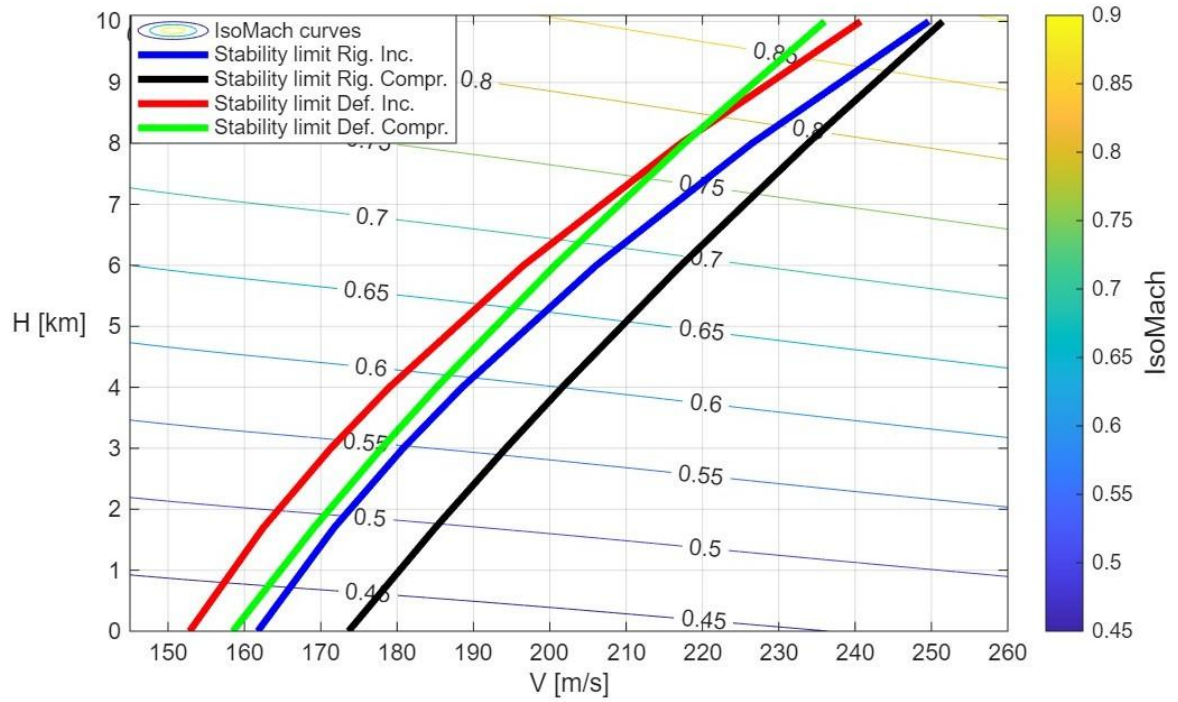

Figure 1: Flutter stability limit .vs. altitude

Conclusions

In this work, a non-linear model for the aeroelastic analysis of highly deformable wings has been presented.

The wing structural dynamics has been modeled using an equivalent bending-torsion beam representation, with clamped-free boundary conditions. Aerodynamic forces have been described through a panel method for the solution of compressible potential flows around lifting bodies, able to account for significant wing deformations and the evolution of the wake sur- face due to the self-induced velocity field.

The main objective of the numerical investigation has been the assessment of the influence of wing and wake deformations on the predicted aerodynamic loads and thus on the wing aeroelastic response. Specifically, the aeroelastic outcomes from the panel method, including wing and wake deformations (free-wake analysis), are compared with those deriving from the panel method that considers wing deformations only in terms of their effect on the impermeability boundary conditions. This comparison has revealed a difference of approximately 10% between the aeroelastic stability boundaries given by the two models analyzed. It is important to highlight that the deformable model generally predicts a lower flutter speed, thus showing that the simpler model does not provide conservative stability predictions. Furthermore, the aeroelastic results of the incompressible flow model have been considered. They show that although the compressible model generates aerodynamic loads with higher amplitudes, aeroelastic instability occurs at higher speeds compared to those of the incompressible case. This behavior is attributed to the transmission delays inherent in the compressible model, which introduce a phase shift between the aerodynamic loads and the dynamic response, postponing the onset of flutter instability.

Keywords: Propeller-driven Vibration Testing, Modal Analysis, Flexible Wings, Operational Modal Analysis, Experimental Structural Dynamics

Abstract. This study details the development and initial validation of a newly introduced modal testing method, called Propeller-Driven Vibration Testing (PVT), designed for validating aircraft wing dynamics. Ground vibration testing (GVT) is crucial for aircraft certification, but it is often costly and time-consuming. By utilising the operational modal analysis (OMA) principle, PVT leverages the forces generated by an aircraft propeller running to excite the wing structure, potentially streamlining the GVT process. The research specifically examines a flexible wing model spar, constructed from Aluminium 7075-T6, excited by varying propeller speeds. Seven distinct vibration tests were conducted, including a baseline case without propeller rotation and numerous configurations with the propeller spinning at different throttle settings. Results demonstrate the feasibility of PVT in assessing dynamic characteristics, indicating that this method could significantly reduce the duration and resources needed for traditional GVT, thereby optimising the certification timeline for future electrical regional aircraft designs.

Introduction

Ground vibration testing (GVT) is a pivotal part of the aircraft certification process [1]. As such, complex and lengthy testing campaigns are usually needed, lasting weeks and involving intricate setups [2]. These make GVT expensive and time-consuming. In addition, recent advances in materials and aircraft design have highlighted that this process cannot always be considered fully linear. Nonlinearities arise from the interaction of subparts and geometrical effects [3]. Nevertheless, these are not considered in this work, as in typical operational scenarios, civil aircraft operate in the linear regime.

For these reasons, a series of approaches have been proposed to increase the efficiency of the GVT process. In particular, the Taxi Vibration Testing (TVT) [4] has received some attention over the last 20 years. The procedure proposed in TVT is to use the aircraft taxing on a taxiway or runway, uneven by definition, as a source of input for the excitation of an aircraft during a dynamic test. Within TVT, two approaches are sought: the (i) towing-based, as shown in [5], and the (ii) active taxing, through the aircraft own propulsion. A demonstrator-scale example of the latter is shown in [6].

The idea behind the PVT is that, with the race towards electric regional aircraft, it can serve as an additional tool for the dynamic validation of the aircraft system, freeing pressure, time, and money from the GVT. This would allow practitioners to streamline the verification process for certification, as it is foreseen to shorten the dynamic testing campaign.

In this work, the concept of PVT is preliminarily validated on the flexible wing model spar from the Experimental Flight Dynamics Testing for Highly Flexible Aircraft project at the University of Bristol [7]. First, the wing spar is tested with the propeller off to define a baseline case. Then,

Materials Research Proceedings 69 (2026) 380-383 https://doi.org/10.21741/9781644904251-69

the test is carried out with a series of different input voltages, resulting in different Revolutions per Minute (RPMs). Finally, a propeller voltage sweep is conducted.

In the following sections, the experimental setup and specimen are described, followed by the introduction and discussion of the results.

Materials and Methods

The wing spar considered in this work spans 80 cm (out of the 7 cm constrained end) and has a constant thickness of 2.3 mm. The specimen is made out of Aluminium 7075-T6, thus yielding typical Aluminium properties for density, Young's modulus, shear modulus, and Poisson's ratio. The spar planform is characterised by four distinct sections, shown in Figure 1 alongside their dimensions.

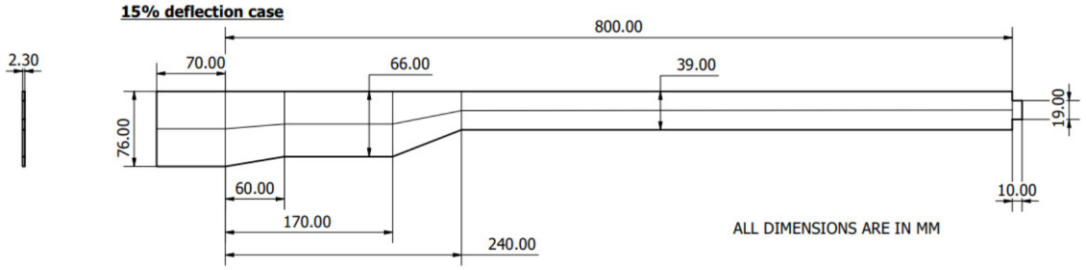

Figure 1 Flexible wing spar geometry (retrieved from [7]).

The constrained root is secured to a wall mount, providing the spar a cantilever beam-like setup. Furthermore, the spar is fitted with an in-house designed and manufactured motor bracket, positioned at 32 cm from the tip. The bracket is 3D printed using a carbon-reinforced nylon filament. A TMOTOR AS2317 electric motor, with a two-blade 8-inch propeller, is attached to the bracket. The motor is driven by a Favourite FVT 50A BLHeli_32 electronic speed control unit, connected to a lithium polymer 3S LiPo battery and to a receiver. This is, in turn, linked to a radio controller. The spar-bracket-motor assembly is instrumented with seven mono-axial accelerometers, five of which have a nominal sensitivity of approximately 100 mVg^{-1} and the remaining two have a sensitivity of 10 mVg^{-1}. The latter are placed in the accelerometer row at the spar tip. The accelerometers and motor bracket location are shown in Figure 2.

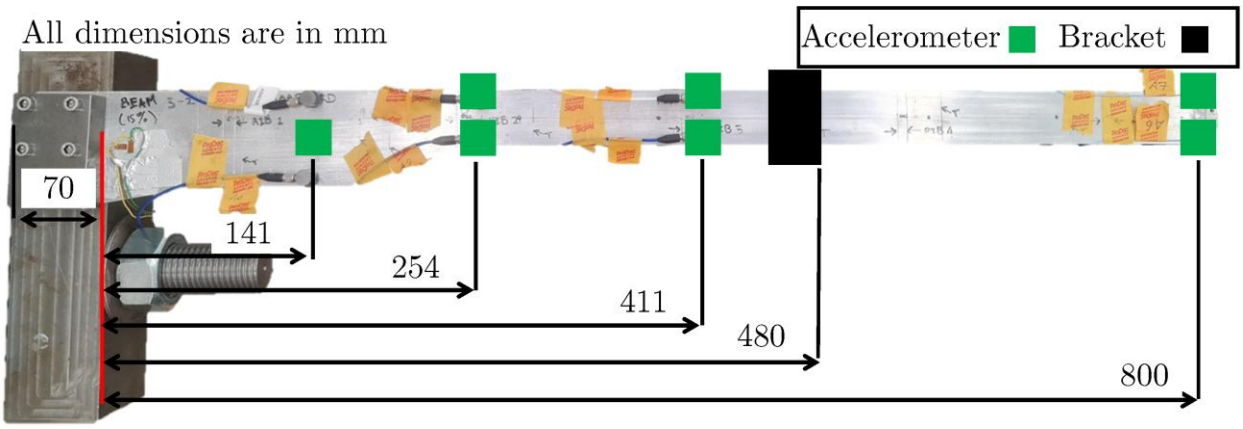

Figure 2 Experimental setup. Any distortion in the image is due to camera lens effects only.

Seven different vibration tests were carried out on the spar-bracket-motor-propeller assembly. One with the motor not spinning (i), while, in the remaining cases, the motor spins at five different fixed rates (25, 37.5, 50, 62.5, 75% throttle - cases ii-vi respectively). A final case was conducted

Materials Research Proceedings 69 (2026) 380-383 https://doi.org/10.21741/9781644904251-69

for an up-and-down sweep, where the throttle position is varied, ideally, linearly between 12.5 and 77.5% (vii).

In test (i), the assembly is excited with two impulses delivered with two subsequent hammer hits, such that the second hammer hit happens after the free-decay response of the first is fully damped. Only the seven output signals of the accelerometers labelled in Figure 2 are recorded at any time. The motor-off test lasts roughly $T_d \approx 120$ s, while in tests ii-vi $T_d \approx 300$ s. The sweep up and down test lasts approximately 600 s. All tests are sampled at a frequency $f_s = 1066$ Hz.

Results

The results from the seven tests are presented in Figure 3, which shows the Average Normalised Power Spectral Density (ANPSD) of the seven channels for each test for clarity.

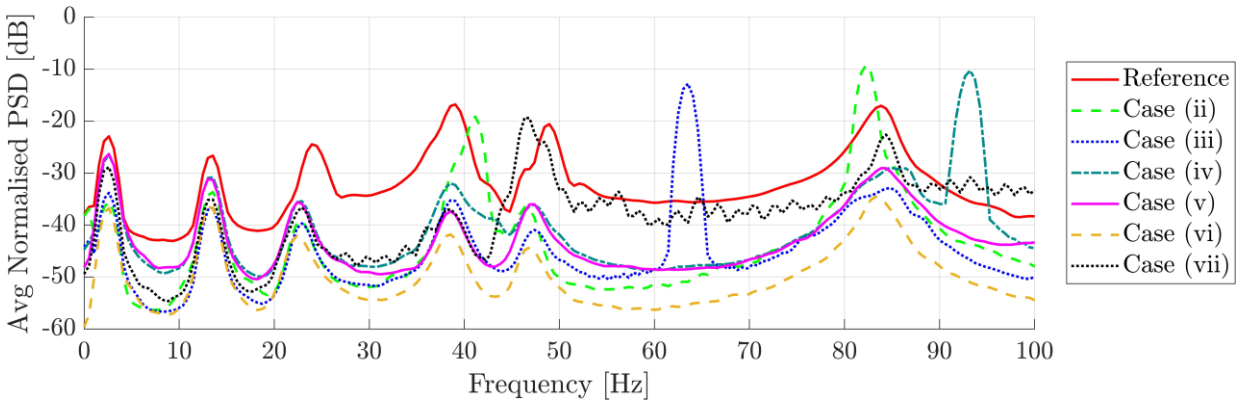

Figure 3 ANPSD of all cases tested via impulse testing and PVT.

The impulse test with the engine off and the propeller stationary, shown in Figure 3 (red), serves as the reference. As shown, all test conditions exhibit ANPSD peaks consistent with those of the reference case. Therefore, the same modes are observed irrespective of the test configuration, supporting the suitability of PVT for the modal analysis of flexible wings. However, some limitations remain. For throttle settings of 50% or less, the harmonics of the spinning propeller interfere with the measurements, which are visible at approximately 42, 63, 84, and 94 Hz in cases ii–iv. By contrast, for higher throttle settings, the dominant harmonics lie above 100 Hz, outside the frequency range analysed.

Since propeller harmonics are not always known *a priori*, case vii employs an up-down sinusoidal sweep in PVT to avoid harmonic overlap. This strategy is effective, although it yields a noisier PSD estimate than the fixed-throttle tests. This might be attributed to the fact that the sweep had to be carried out *manually*, without the aid of an external controller to regulate its rate.

Conclusions and Future Work

In this work, the viability of a new vibration testing technique applied to aeronautical components, namely Propeller-driven Vibration Testing (PVT), is proposed. The proposed method aims at using the aircraft or wing propeller as a source of excitation for the system modal analysis. The PVT is preliminary validated on a flexible wing spar equipped with an electrical motor driving a propeller. Method challenges have been identified in the propeller harmonics, which can be mitigated by using higher motor throttle settings, which push the harmonics to higher frequencies, or by implementing a throttle sweep strategy. Thus, proving the PVT as a viable vibration testing technique.

Future work includes extracting modal parameters, including mode shapes, from the response data. Furthermore, it involves the setup of a test bench with a fully controllable and verifiable throttle sweep rate, running the test on a flexible wing, including its skin, to study the effects of

aerodynamics on the PVT, and then transitioning to a full small form factor aircraft, such as a small unmanned aerial vehicle.

Aknowledgements
The authors thank Prof Mark H. Lowenberg from the School of Civil, Aerospace and Design Engineering at the University of Bristol for kindly allowing the use of the wing spar, which was designed and manufactured within the EPSRC Experimental Flight Dynamics Testing for Highly Flexible Aircraft project grant ref. EP/T018739/1. Furthermore, the first author is supported by the grants for research activity of young PhD holders, part of the Universidad Carlos III de Madrid Own Research Program (TOMA - Tangential interpolation for Operational Modal Analysis project).

Keywords: Ventilated Brake Disc, Radial Vane, BCC Lattice, WBCC Lattice, Thermalmechanical Analysis

Abstract Brake discs are critical components during a vehicle's braking phase. To dissipate the heat generated, ventilated discs are commonly employed. Among these, radial vane configurations are widely adopted due to their effective cooling performance and relatively simple manufacturability. This work presents a preliminary comparison between a conventional radial vane disc and lattice cores ventilated disc. Specifically, a coupled steady-state thermal-mechanical analysis is conducted to assess the radial and circumferential temperature distributions, as well as the thermal stresses, during a hard braking event. The steadystate assumption is adopted as a first approximation to evaluate the thermo-mechanical behaviour of the two configurations. The results show that the lattice core disc has a lower maximum temperature and a more uniform thermal distribution, suggesting an improved heat dissipation capability compared with the conventional design.

Introduction

Brake discs are critical components during a vehicle's braking phase. Friction between the pads and the disc slows the vehicle and converts kinetic (and, where relevant, potential) energy into heat. A large fraction of this energy, up to 90%, is absorbed by the disc and must be appropriately dissipated to avoid local overheating, which can lead to wear, oxidation, and thermal fatigue [1–4]. To better dissipate heat, ventilated discs with radial or curved vanes are widely used for their superior cooling performance. During rotation, air is drawn into the disc by centrifugal forces and guided through the vanes, promoting forced convection and improving thermal dissipation [5,6].

Recently, lattice structures have gained increased attention in various engineering fields due to their tunable thermo-mechanical properties at low mass [7–10]. Among these, BodyCentred Cubic (BCC) lattices are a common choice, as they are easy to manufacture, can be designed for specific stiffness, and provide a high surface-area-to-mass ratio.

This work compares three brake disc designs: a conventional radially-ventilated disc, a disc with a Body-Centred Cubic (BCC) lattice core, and a novel lattice configuration featuring BCC unit cells with curved struts referred to as Waved Body-Centred Cubic (WBCC) [11]. To isolate geometric effects, the different designs have the same core mass. Given the geometric complexity of the lattice structures, a preliminary steady-state, coupled thermomechanical analysis is conducted. Although simplified, this approach enables a direct comparison of heat-dissipation and structural behaviour under identical loads and boundary conditions.

The study evaluates the discs' effectiveness by examining temperature and stress fields along the radial, circumferential, and through-thickness directions.

Materials Research Proceedings 69 (2026) 384-389 https://doi.org/10.21741/9781644904251-70

Steady-state thermo-mechanical model

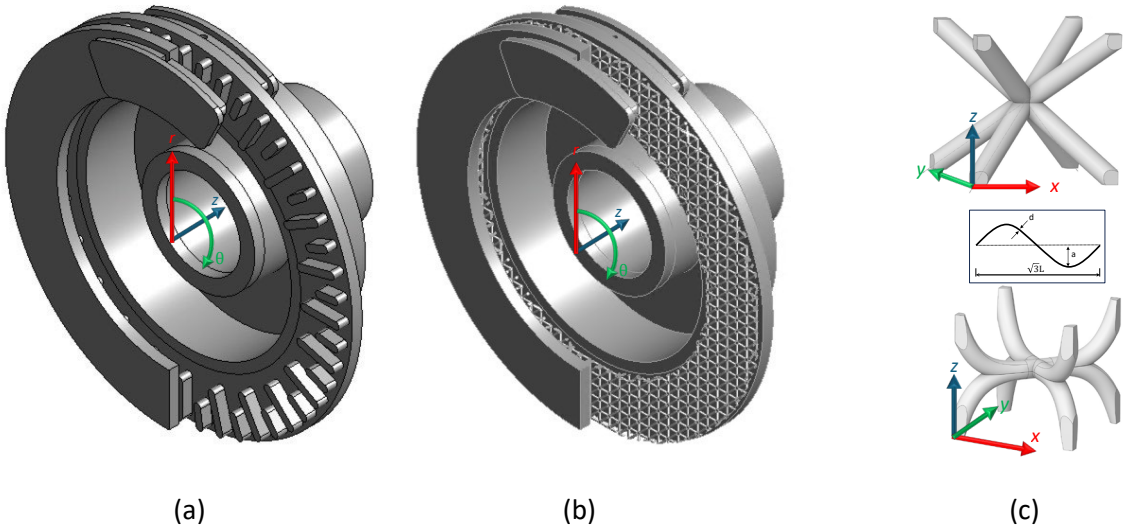
The transient energy equation $\rho c_p \frac{\partial T}{\partial t} = \nabla \cdot (k \nabla T)$ derived from the Fourier's law for a steady-state analysis simplifies to:

$$\nabla \cdot (k \nabla T) = 0 \tag{1}$$

In this study, both internal heat generation and radiation effects are neglected. However, the frictional heating at the pad-disc interface and the convective dissipation to the surrounding air must be accounted for. The local frictional heat flux at the interface is:

$$q''_{fric}(r) = \eta \mu p(r) V(r), \quad \text{with} \quad V(r) = \omega r \tag{2}$$

where η is the the heat-partition ratio into the disc, μ is the friction coefficient between the pad and the disc, p is the normal pressure applied to the pads, $V(r)$ is the sliding velocity retrieved from the angular velocity ω and the radius r of the disc.



Defining h as the convective heat coefficient, the convective heating flux is:

$$q''_{conv} = h(r)(T - T_\infty) \tag{3}$$

Keeping μ, p, ω, h constant, the study simulates a constant friction power, pressure on the pads, angular velocity, and convective exchanges to isolate the effect of core geometry on temperatures and stresses.

Geometry and numerical model

The analyses were performed on a ventilated brake disc featuring three different cores designs: a conventional radial vane core, a BCC lattice core, and a Waved Body-Centred Cubic lattice core. The three configurations, reported in Figure 1, are characterised by the same mass to have a direct comparison of their thermo-structural performance. The WBCC structure is derived from the BCC cell by introducing sinusoidally curved struts with a wave amplitude of $a = 1.5$ mm. Unlike the BCC lattice, which is intrinsically isotropic, the WBCC cell exhibits directional dependence. In this study, only the WBCC configuration with its z-axis aligned with the disc thickness direction is considered.

(a) (b) (c)

Figure 1: Brake disc model (top half disc hidden for clarity). (a) Radial vane, (b) Lattice core and (c) BCC and WBCC unit cell detail

Materials Research Proceedings 69 (2026) 384-389 https://doi.org/10.21741/9781644904251-70

The simulations were conducted using ANSYS Workbench 2022 R1.

Gray cast iron, commonly used in automotive applications, was assigned to the disc, while the brake pads are assumed as an elastomer and modelled with a linear elastic material. The material properties are reported in Table 1.

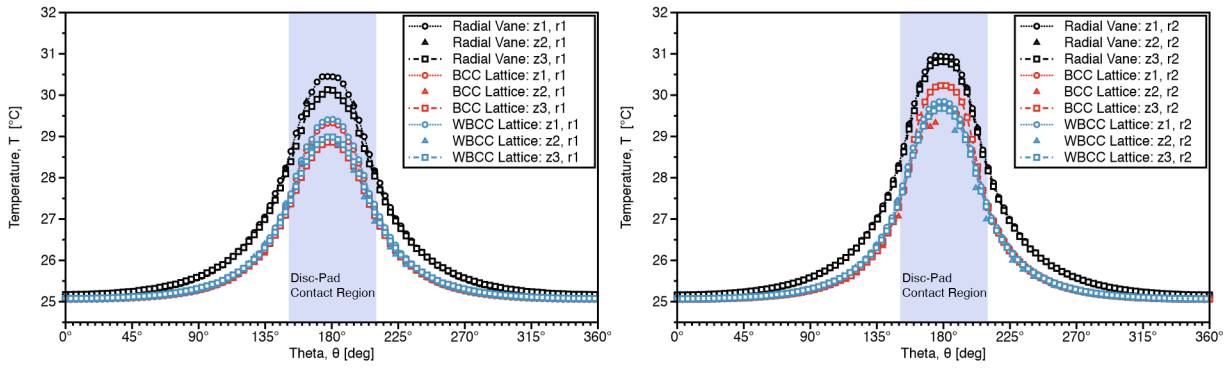


Table 1: Material properties

Property	Brake Disc and Core	Brake Pads
Density, ρ [kg/m^3]	7200	2045
Young's Modulus, E [GPa]	110	0.8
Poisson's Ratio, v [-]	0.28	0.34
Thermal Conductivity, k [W/(m °C)]	53	0.84
Specific heat constant pressure, c_p [J/(kg °C)]	586	1000
Convective heat transfer coefficient, h [W/(m^2 °C)]	50	50

A constant angular velocity of 55 rad/s was applied to the disc, while a force of 50,000 N was applied to each brake pad. The frictional contact between the pads and the disc was defined with a coefficient of $\mu = 0.25$. Through an APDL script, the heat-partition ratio η was set to 0.9. To evaluate heat dissipation, a convective heat transfer coefficient of 50 W/(m^2 °C) was applied to all external and internal surfaces of the disc and pads models. This simplified approach, using a uniform coefficient, allows for a direct comparison of the core architectures by isolating the effects of internal thermal conduction and surface area. Ambient temperature was set to 25 °C for all components.

Results and Discussion

All results are evaluated at three specific depths within the disc: on the external surfaces of the core under the inner and outer disc z_1 and z_3, and at the mid-plane of the core z_2. In addition, three radial positions are considered along the friction track: r_1, located near the inner edge of the brake pad; r_2, at the pad's mid-radius; and r_3, close to the outer edge. Finally, the distributions are assessed over the entire circumferential angle of the disc to capture the full tangential variation of temperature and stress fields. The circumferential temperature distributions are compared in Figure 2.

Materials Research Proceedings 69 (2026) 384-389 https://doi.org/10.21741/9781644904251-70

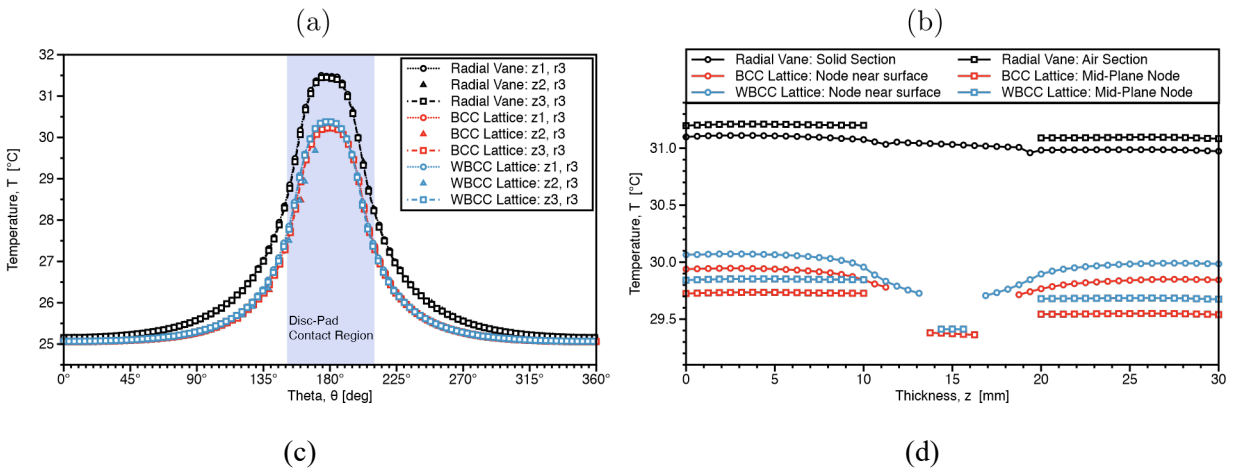

Figure 2: (a)-(c) Circumferential temperature distributions at different radial and depth locations. (d) Through-thickness temperature profiles at r_2 near $\theta \approx 180°$

All the temperature profiles in Figure 2(a)-(c) exhibit a single symmetric peak centred within the highlighted light-blue region, corresponding to the pad-disc contact area. The BCC and WBCC lattice configurations consistently show lower peak temperatures than the conventional radial-vane core, with nearly identical values to each other. Both lattice designs reduce the maximum temperature by about 6%. This trend aligns with their larger surface area, as the convective power scales with $Q_{conv} \approx \int(h, \Delta T)dA$. The lattice configurations also feature a narrower width peak, indicating a more localised heat sink due to enhanced heat extraction near the hot sector, which sharpens the thermal profile and limits circumferential diffusion. At all circumferential locations, the through-thickness temperature trends are similar across the three designs, with the surfaces (z_1, z_3) warmer than the mid-plane (z_2). Figure 2(d) illustrates this behaviour at two points near the pad centre $(r_2, \theta \approx 180°)$. In the radial-vane disc, these positions correspond to a solid vane and an adjacent ventilated channel, while in the lattice configurations they coincide with the strut junction nodes—one at the disc surfaces and the other at the core mid-plane. Consistent with the previous plots, the through-thickness profiles reveal small but systematic differences, with the radial-vane disc remaining slightly hotter than the lattice designs.

Finally the Von Mises stress map distributions on the disk-pad contact surface for the three design is shown in Figure 3(a)-(c). On the disc-pad contact face, the equivalent von Mises stresses concentrate in the hot sector beneath the pad. The radial-vane core shows the highest peak ($\approx$ 28.2 MPa), with a uniform broad distribution under the contact. The BCC lattice lowers the peak to $\approx$ 22.0 MPa (about 23% reduction compared to the radial-vane), while the WBCC has the greatest reduction with of about 35% compared to the standard configuration. In both lattice designs the high-stress zone is more confined, in accordance with the lower, sharper temperature peaks observed earlier. Away from the contact sector, the stresses remain low across all designs. Overall, the lattices mitigate peak stress on the pad-disc surface, with the WBCC providing the largest reduction.

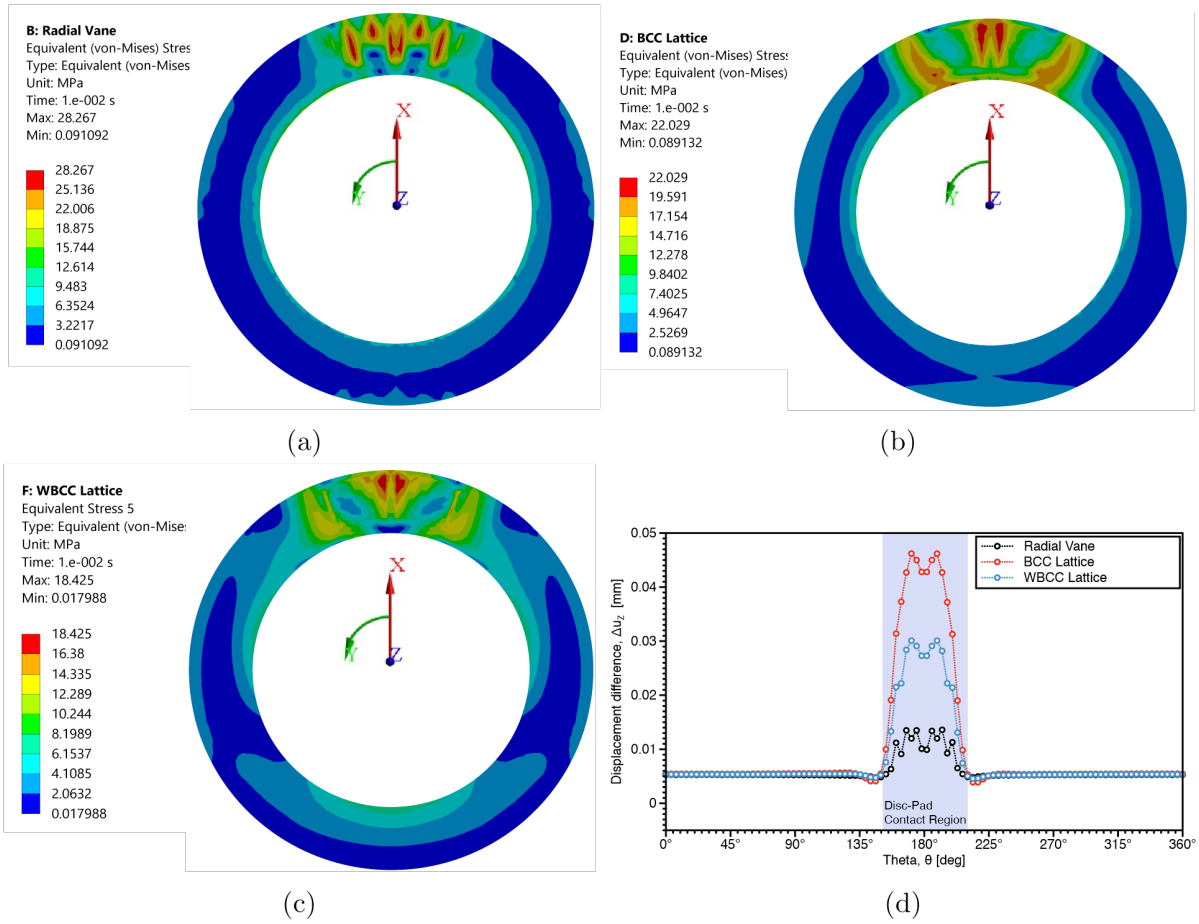

Figure 3: Circumferential equivalent (von Mises) stress distribution: (a) Radial Vane, (b) BCC Lattice, (c) WBCC lattice. (d) Core face distance difference comparison

Figure 3(d) shows the face-to-face core displacement difference, Δu_z. The BCC lattice shows the largest displacement which results in the lowest stiffness of the three configurations. The WBCC design, on the other hand, has an intermediate behaviour, while the standard radial configuration is the smallest. Overall, the radial core is approximately three time stiffer than the BCC and approximately two times stiffer than the WBCC configuration.

Conclusions

In this preliminary comparison of different cores for ventilated vane brake discs, lattice designs, particularly WBCC, improved the thermal properties by lowering peak temperatures and localizing the heat sink, though at the cost of reduced disc stiffness. Further analyses are needed to better evaluate the thermo-mechanical properties.

Trim Analysis of Highly Flexible Aircraft via a Coupled DG-VLM Framework

Elisa TESTAQUATRA[1,a], Vincenzo GULIZZI[1,b*]

[1]Department of Engineering, Università degli Studi di Palermo, Italy

[a]elisa.testaquatra@unipa.it, [b]vincenzo.gulizzi@unipa.it

Keywords: Flexible Aircraft, Hyperelasticity, Nonlinear Trim, Discontinuous Galerkin Method, Vortex Lattice Method

Abstract. An original computational framework for the trim analysis of highly-flexible aircraft is presented in this work. The framework is based on the combination of a discontinuous Galerkin (DG) method and a non-planar Vortex Lattice Method (VLM). The DG method is employed for solving three-dimensional finite-strain, whereas the non-planar VLM is employed for solving potential-flow aerodynamics of the deformed structure. The DG-VLM coupling is performed by considering the forces generated by the vortexes as energetically equivalent to body forces acting on the structure. The framework is validated by considering the finite-strain response of a cantilever beam, the finite-strain response of a highly flexible wing, and the angle of attack and elevator deflection at longitudinal trim condition of an aircraft featuring the same highly flexible wing.

Introduction

Over the past years, research on High Aspect Ratio Long Endurance (HALE) aircraft has been of particular interest, as high-aspect-ratio wings provide greater aerodynamic efficiency, reducing fuel consumption and extending endurance. However, high-aspect-ratio wings may undergo large deformations and rotations, which can significantly affect their aerodynamic characteristics. For this reason, the analysis and design of vehicles featuring such type of wings, including the aspects related to their flight mechanics performances, must be performed accounting for fluid-structure interaction effects.

Numerical methods are often necessary as analytical solutions are seldom available, especially in the regime of large deformations and rotations. Recently, several approaches have been proposed to solve the aeroelastic problems of highly flexible aircraft. Murua and Palacios [1] developed a computational framework based on a geometrically exact beam model and the Unsteady Vortex Lattice Method (UVLM). Zhang et al.[2] developed a 3D co-rotational beam framework, coupling the structural dynamics with unsteady aerodynamics. Drachinsky and Raveh [3] employed the modal rotation method to capture large deformations through spatial derivatives of mode shapes. Medeiros and Cesnik [4] proposed a reduced-order geometrically nonlinear formulation, accounting large deformation effects on both inertia and stiffness terms.

This contribution presents a novel computational framework for the aeroelastic analysis of highly flexible aircraft based on finite-strain elasticity and potential-flow aerodynamics. The framework is based on the coupling between a discontinuous Galerkin (DG) method for solving finite-strain total-Lagrangian elasticity and a non-planar Vortex Lattice Method (VLM) for solving potential flow aerodynamics. The framework is validated considering the finite-strain response of a cantilever beam and the finite-strain response of a highly flexible wing. Then, the framework is employed to study the longitudinal trim of an aircraft featuring a high-aspect-ratio wing. Numerical results are presented by comparing the computed values of angle of attack and elevator deflection at trim condition upon considering a rigid wing, an elastic wing undergoing small deformations, and an elastic wing undergoing large deformations.

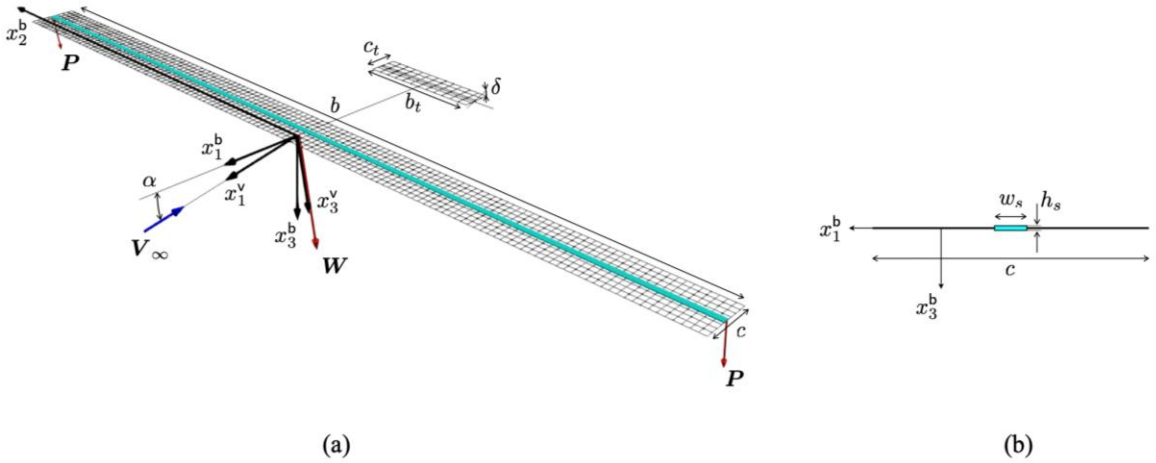

Figure 1: (a) Geometry of the flexible aircraft. (b) Load-bearing rectangular cross section of the main wing.

Problem statement

Let us consider the longitudinal behavior an aircraft modeled by a main wing and a horizontal tail, as shown in Fig.(1a). The span and the chord of the main wing are denoted by b and c, respectively, while the span and the chord of the horizontal tail are denoted by b_t and c_t, respectively. The main wing has a load-bearing rectangular cross section of density ρ_s, width w_s, and thickness h_s, that is placed at 50% of the wing's chord; see Fig.(1b). The entire horizontal tail is supposed to be a rigid movable surface that can rotate of an angle δ around an axis placed at 0.39% of its chord. The aircraft is assumed to be in horizontal flight at a speed V_∞ and angle of attack α within a fluid whose density is denoted by ρ_∞.

The flexible part of the aircraft is the load-bearing cross-section of the main wing, which is made of an isotropic material identified by Young's modulus E and Poisson's ratio v. Two different elastic behaviors are considered for the main wing cross section, namely a linear elastic behavior within the small-deformation hypothesis and a hyper-elastic behavior accounting for large deformations and rotations. In the former case, the deformation of the main wing is obtained by solving the equations of linear elasticity combined with a constitutive behavior that can be written as $\boldsymbol{\sigma} = \boldsymbol{C\varepsilon}$, where $\boldsymbol{\sigma}$ and $\boldsymbol{\varepsilon}$ are vectors collecting the stress and strain components, respectively, in Voigt notation, and $\boldsymbol{C}$ is the associated matrix of elastic coefficients for isotropic materials. On the other hand, in the hyper-elastic case, the deformation of the main wing is obtained by solving the equations of finite-strain elasticity in combination with a constitutive behavior of the form $\boldsymbol{S} = \boldsymbol{CE}$, where $\boldsymbol{S}$ and $\boldsymbol{E}$ are vectors collecting the second Piola-Kirchhoff stress components and the Green-Lagrange strain components, respectively, in Voigt notation, whereas, following the Saint Venant–Kirchhoff model, $\boldsymbol{C}$ is the same matrix of elastic coefficients employed in the small-strain case.

The loads acting on the wing structure consist of its weight, a load $\boldsymbol{P}$ placed at each tip of the wing, and the aerodynamic loads deriving from the interaction with the fluid.

DG-VLM formulation

The solution of the aeroelastic problem introduced in the preceding section is performed by combining a DG formulation for solving finite-strain elasticity and a non-planar VLM for solving potential-flow aerodynamics. In this section, the solution of finite-strain is reported, whereas the solution of the rigid and small-strain problems can be obtained as special cases.

Following Gulizzi et al.[5], it is possible to show that the DG weak form associated to the finite-strain elastic behavior of the wing structure can be stated as follows: find $\boldsymbol{\varphi}$, being $\boldsymbol{\varphi}$ the

Materials Research Proceedings 69 (2026) 390-395 https://doi.org/10.21741/9781644904251-71

approximated deformation mapping, such that $B(\boldsymbol{V},\boldsymbol{\varphi}) = F(\boldsymbol{V},\boldsymbol{b_0})\ \forall \boldsymbol{V} \in \boldsymbol{V}^{hp}$, being $\boldsymbol{V}^{hp}$ the space of discontinuous polynomial vector fields, where

$$B(\boldsymbol{V},\boldsymbol{\varphi}) \equiv \int_{\mathcal{D}^h} \frac{\partial \boldsymbol{V}^T}{\partial x_k}\frac{\partial w}{\partial \boldsymbol{F}_k} - \int_{\mathcal{J}^h}\left(\llbracket \boldsymbol{V}\rrbracket_k^T\left\{\frac{\partial w}{\partial \boldsymbol{F}_k}\right\} + \{\boldsymbol{\Pi}_k^T\}\llbracket\boldsymbol{\varphi}\rrbracket_k\right) + \int_{\mathcal{J}^h}\mu\llbracket\boldsymbol{V}\rrbracket_k^T\llbracket\boldsymbol{\varphi}\rrbracket_k + \\ - \int_{\mathfrak{B}_D^h}\left(\boldsymbol{V}^T\ \frac{\partial w}{\partial \boldsymbol{F}_k}n_k + \boldsymbol{\Pi}_k^T n_k\boldsymbol{\varphi}\right) + \int_{\mathfrak{B}_D^h}\mu\boldsymbol{V}^T\boldsymbol{\varphi} \qquad (1)$$

and

$$F(\boldsymbol{V},\boldsymbol{b}) \equiv \int_{\mathcal{D}^h}\boldsymbol{V}^T\boldsymbol{b} \qquad (2)$$

In Eq.(1), w denotes the solid strain energy function, $\boldsymbol{F}_k$ denotes the k-th column of the deformation gradient tensor, n_k is the k-th component of the unit normal of the solid boundary, while $\boldsymbol{\Pi}_k$ is a symmetrization vector and μ is a penalization parameter that are typical of DG formulations. Additionally, the integrals appearing in Eq.(1) are referred to as broken integrals and must be intended as the sum over the mesh elements of the integrals computed over each element domain and boundary. See Ref.[5] for further details.

Eventually, Eq.(2) accounts for the loads acting on the wing structure and includes those stemming from gravity, the concentrated loads at the wing tips and the aerodynamic loads, which are computed solving a non-planar VLM system where the vortexes deform with the structure [6].

Upon introducing the DG structural degrees of freedom that are collected in the vector $\boldsymbol{X}$ and the VLM degrees of freedom that collected in the vector $\boldsymbol{\Gamma}$, the final system of equations governing the aeroelastic problem can be written as

$$\begin{cases}\boldsymbol{R}_S(\boldsymbol{X},\boldsymbol{\Gamma}) = \boldsymbol{0}\\ \boldsymbol{R}_A(\boldsymbol{X},\boldsymbol{\Gamma}) = \boldsymbol{0}\end{cases} \qquad (3)$$

where $\boldsymbol{R}_S(\boldsymbol{X},\boldsymbol{\Gamma})$ denotes the equations associated with the structural problem and $\boldsymbol{R}_A(\boldsymbol{X},\boldsymbol{\Gamma})$ denotes the equations associated with the aerodynamic problem. This system of equations is solved via a Newton-Raphson approach.

Results

In the first set of tests, an isolated half-wing with a load P placed at its tip is considered. The wing is clamped at its root and has a square cross section, i.e., $ws = hs$. Two lengths are considered, namely $b/2 = L = 10w_s$ and $b/2 = L = 100w_s$. The deformation of the structure using a kinematic model featuring a third-order approximation along the cross section and fifth-order approximation along the span. The obtained results are reported in Fig.(2) for the two lengths in terms of u_z/L versus $PL^2/(EI)$, where I is the moment of inertia of the cross section. The comparison with the results available in the literature [7,8] confirms the capability of the proposed framework to capture finite-strain bending behaviors.

Materials Research Proceedings 69 (2026) 390-395 https://doi.org/10.21741/9781644904251-71

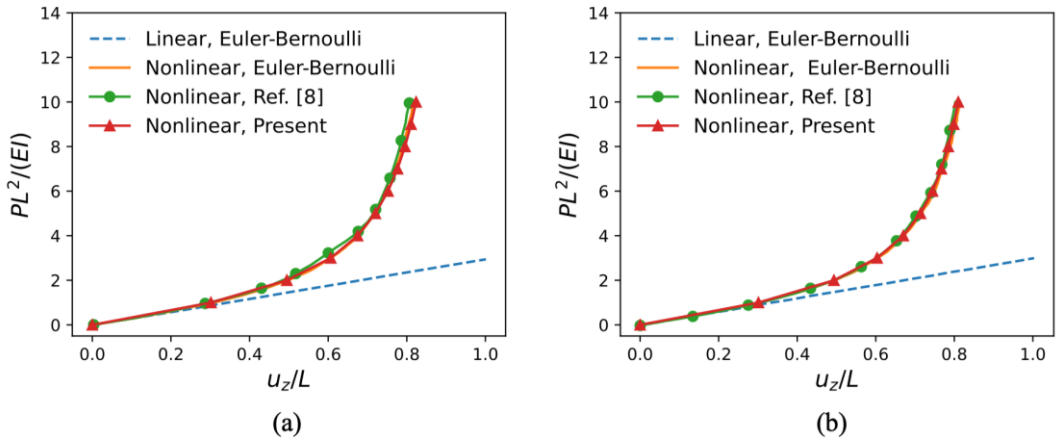

Figure 2: Vertical displacement of a cantilever beam under finite deformations due to a tip load.

In second set of tests, the developed framework is employed to compute the aeroelastic response of a half-wing clamped at its root in terms of tip displacement versus wind speed. The wing is modeled under the small-strain hypothesis and under the finite-strain hypothesis. The geometrical and material properties of the considered wing can be found in Ref.[9]. The wing tip displacement as a function of the flow speed is reported in Fig.(3) for an angle of attack of 0.4°. The results obtained using the linear model and the nonlinear model are compared with the results (both numerical and experimental) provided in Ref.[9]. As shown in figure, it is possible to notice how the linear and nonlinear models agree for low speed, while they start to provide different results for a flow speed V_∞ approximately above 31 m/s, when the geometric nonlinearities become dominant. In particular, the linear models provide a tip displacement that tends to infinity as the flow speed approaches the divergence speed. Such a divergent behavior is not present in the results obtained by the nonlinear models, which remain much closer to the experimental results, confirming that the use of a finite-strain model is essential for accurately capturing the aeroelastic behavior of a highly flexible wing.

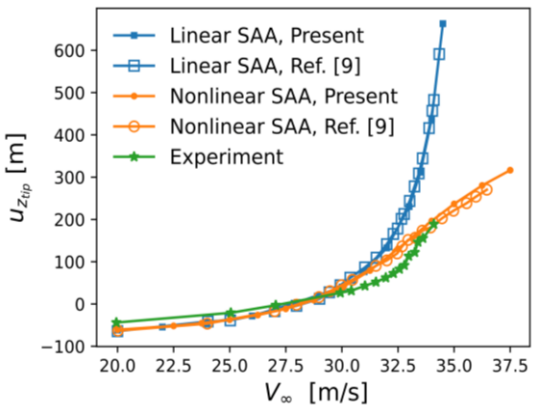

Figure 3: Wing tip displacement versus wind speed for a highly-flexible wing.

Eventually, the framework is employed to compute longitudinal trim conditions in terms of angle of attack and elevator deflection of an aircraft featuring the same highly flexible wing considered for the previous set of tests. The geometrical properties of the entire aircraft can be found in Ref.[10]. Table (1) reports the obtained values of angle of attack α and elevator deflection δ at longitudinal trim condition for $V_\infty = 25$ m/s in the cases the wing is considered rigid or highly flexible. An error of approximately 10% is observed with the results provided in the literature.

Table 1: Angle of attack α and elevator deflection δ at longitudinal trim condition for an aircraft featuring a highly-flexible wing for V_∞ = 25 m/s.

	Present		Ref.[10]	
	α [°]	δ [°]	α [°]	δ [°]
Rigid	3.77	-1.97	3.76	-1.98
Flexible	2.88	-1.99	3.22	-1.81

Conclusions

A novel computational framework for the trim analysis of highly-flexible aircraft has been presented. The novelty of the framework is the combined use of a discontinuous Galerkin method for solving finite-strain elasticity and a non-planar Vortex Lattice Method for solving potential-flow aerodynamics of the deformed structure. The capabilities of the framework have been assessed by analyzing the finite-strain bending of a cantilever beam subject to a tip load, the finite-strain aeroelastic response of an isolated wing, and the longitudinal trim of an aircraft featuring a highly-flexible wing. A satisfactory comparison between the results obtained with the present framework and the results available in the literature, which consist of both numerical and experimental results, has been observed. Currently the framework is being extended to consider different kinematic approximations, more complex internal structures and materials, and a wider range of flight conditions.

Keywords: Aeroelasticity, Limit Cycle, Panel Method, Vortex Lattice, Pazy Wing

Abstract. Predicting the non-linear aeroelastic behavior of very flexible structures and the limit cycle oscillations that often develop is a challenge. This work investigates the nonlinear aeroelastic behavior of the Pazy Wing to determine the nature of its LCOs by coupling a nonlinear structural beam model with different mid-fidelity aerodynamic methods: the vortex lattice method and the panel method. The results demonstrate that the limit cycle originates from nonlinear structural effects, rather than aerodynamic nonlinearities. While both methods successfully predict the onset of the phenomenon, this study highlights that only the panel method accurately estimates the oscillation amplitude when compared to experimental data. This underscores the fundamental role of 3D aerodynamic effects, which are underestimated by the vortex lattice. The study therefore provides clear guidance for selecting efficient models, recommending the coupling of a nonlinear structural model with 3D aerodynamics as the optimal approach for a correct assessment of LCO severity.

Introduction

Due to increasing interest in the first decade of the 21st century for HALE (High Altitude Long Endurance) aircraft handling a plurality of goals, the aerospace industry, also driven by the need for greener, lightweight, therefore more elastic vehicles, started developing flying machines characterized by extremely slender wings. Due to their elongated shape, such components are exceptionally flexible, reaching an in-flight deflection up to 25% of their semispan, thus posing new challenges in the estimation of aircraft's flutter boundaries. Moreover, it may happen that such large deflections bring the structure out of the linear deformation field, making it necessary to establish some ad hoc tools to investigate how this impacts the dynamic behavior of said component. In these kind of design, it may occur, for example, that divergent modes lead to Limit Cycle Oscillations (LCOs), a nonlinear phenomenon characterizing post-flutter structural behavior, which, depending on the cycle amplitude, may cause structural failure. An essential step in the assessment of novel nonlinear models is wind tunnel testing, allowing to gather data for computational models' validation. With this aim, the *Pazy Wing*, designed to experience deformation up to the 50% of its semi-span, was built at Technion [1]. It manifested both hard and soft flutter, and several LCOs. In particular, there is a Hump Mode region that is a speed bounded region of instability where the wing experiences LCOs. However, increasing the airspeed past this region, the wing regains stability, until it gets into an unbounded oscillation that is denominated Hard Flutter. The purpose of the present study is to evaluate if this nonlinear aeroelastic behavior can be assessed using mid-fidelity approaches. Additionally, by using these simulations, this work aimed at assessing the nature of such LCOs, trying to discriminate if they are dominated by structural or aerodynamic nonlinearities or by both. A reduced order structural model, namely a beam, was created in MBDyn [2] and loaded using three different aerodynamic models: strip theory, Vortex Lattice Method (VLM) and Panel Method (PM) [3]. In the VLM method, the lifting wing is represented by a line where at each section is associated an airfoil with certain lift, drag,

Materials Research Proceedings 69 (2026) 396-401 https://doi.org/10.21741/9781644904251-72

and moment characteristics curves, which can be linear or nonlinear. Whenever the associated vorticity changes along the line, the system will generate a vortex particle that is released in the wake. In contrast, the PM method does not relay on the characteristics of the airfoils, but represents the lift produced by the wing through local vorticity distributions on the surface represented through panels [4].

Models and Methods

The beam model, implemented in MBDyn, is composed of 16 structural dynamic nodes that lye along the y-direction. Inertia and stiffness characteristics were determined by a previous study, which started from a detailed Finite Element Method (FEM) model of the wing [5]. The MBDyn representation was validated by means of comparison of the predicted frequencies and modes with the same quantity identified in both the wind tunnel tests and the paper [5]. The results of this comparison are reported in Table 1.

Table 1: Eigenfrequencies from Wind Tunnel Test (WTT), MBDyn and UM/NAST models.

Mode	MBDyn [Hz]	WTT [Hz]	UM/NAST [Hz]
OOP1	4.22	4.17	4.22
OOP2	28.29	28.3	28.37
T1	41.46	41.3	40.72
OOP3	81.99	81.5	82.48
IP	108.57	N.A.	108.65

The first aerodynamic model used, directly implemented in MBDyn, was the strip theory, used with and without a tip loss correction [6]. Then, the coupling through DUST [3] software was performed to use the PM and the VLM, with and without nonlinear corrections.

Initially, the static deformed shape obtained, in terms of the tip torsion angle and the out-of-plane bending, was compared with the wind tunnel tests data to validate the different approaches used. Here in Figures 1-2 the results of the comparison at a single angle of attack $\alpha = 5°$. More results can be found in Ref. [7]. No significant differences were shown between the various methods adopted and the WTT data, with an exception only for the stip-theory model.

Materials Research Proceedings 69 (2026) 396-401 https://doi.org/10.21741/9781644904251-72

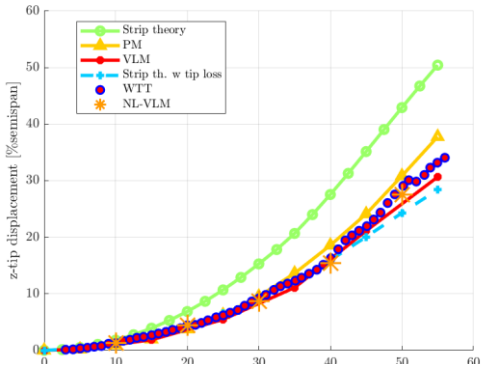

Figure 1: Out of plane tip displacement - comparisons at α = 5°.

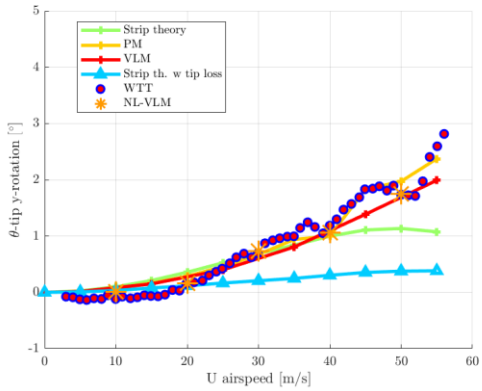

Figure 2: Tip torsional rotation - comparisons at α = 5°.

Looking at the torsion angle of the tip reported in Fig. 2, it is visible that the WTT data are also less regular than the bending ones, due to the relevant difficulties encountered during the collection of the experimental data. The VLM and PM results appeared to be more coherent with the experimental results than the strip-theory ones, especially in the high-speed range. Therefore, the strip theory model was deemed unsuitable for performing an accurate aeroelastic analysis. Thus, the following studies were deepened only through the VLM and PM aerodynamic models.

Results

All results are discussed in a comparative way among the different methods and where several cases, varying U or α, were investigated, just one will be reported here (more in [7]). Since the simulations, due to software capabilities, were all performed in time domain, the stability limits were identified by looking at oscillations in the tip vertical position, using a pseudo-experimental approach. The studies were then deepened by performing a post-processing of simulation results in the frequency domain. The nonlinear correction of the VLM was used in the determination of the Hump mode region, but, since no significant difference was displayed, nor in terms of oscillations or boundaries with respect to the simple VLM, said model was not deepened any further.

Hard flutter. Figure 3 displays a graph that shows the hard flutter onset point for both VLM and PM. The simulations were run at α = 1° and significant differences between the two results were shown. The VLM underpredicts the static deformed shape above certain speed values (see Fig. 1), leading to an increase in the estimated speed at the flutter boundary. A detailed analysis showed that the PM method predicted the hard flutter onset at 84.83 m/s. Although experimental data are not available for comparison, the individuated stability boundary is coherent with what found in other numerical studies [1], [5], [8].

Materials Research Proceedings 69 (2026) 396-401 https://doi.org/10.21741/9781644904251-72

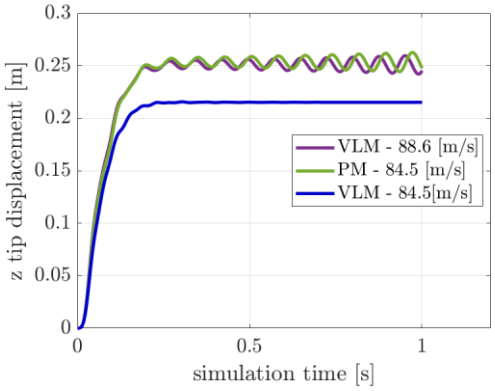

Figure 3: Hard Flutter: onset - comparison of time responded at different speeds.

Hump mode. For what concerns instead the investigation of the hump mode boundaries, similar analyses were performed.

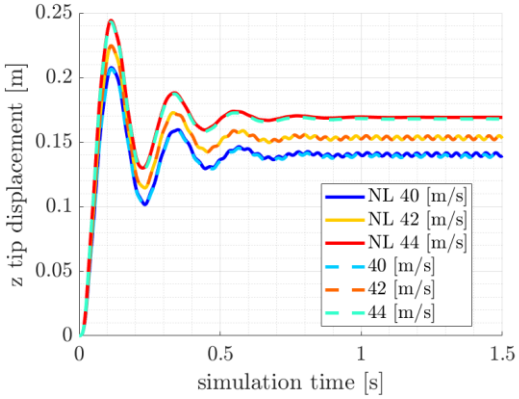

Figure 4: Hump Mode boundaries: VLM and NL-VLM comparisons α = 7°.

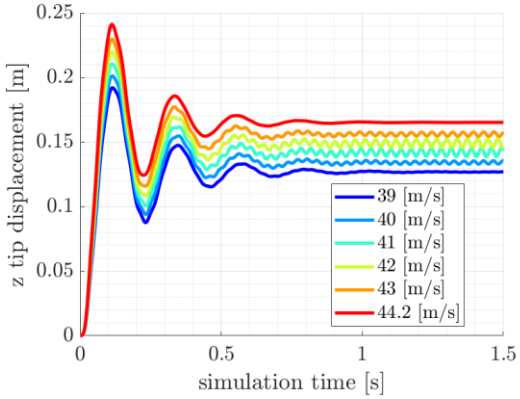

Figure 5: Hump mode boundaries: results of PM α = 7°.

Figure 4 displays the soft flutter region in the prescribed α and U, retrieved by means of the VLM with and without considering its nonlinear correction (i.e., the stall region for the lift coefficient). No significant differences are visible between the two models. Therefore, the nonlinear aerodynamic effects do not seem to play a determinant role in the individuation of the hump mode boundaries, or in the determination of the amplitudes of the oscillations. Figure 5 shows the hump mode boundaries identified at α = 7° through the PM. No significant differences are identified in terms of stability limits.

With the aim of validating the obtained results, while assessing at the same time which modes were coalescing, giving birth to the instability, a frequency study, by means of a perturbation analysis, was conducted. This investigation was carried out for a variety of velocities and angles to understand when, for different deformed shapes, the modes coalesced, leading to null damping ξ. The results of this set of analyses are summarized in Fig. 6, which shows a good agreement among the information retrieved in the frequency and time domains. Finally, the unstable regions, identified using PM and VLM are overlapped in Fig. 7, showing limited differences in the full envelope of conditions.

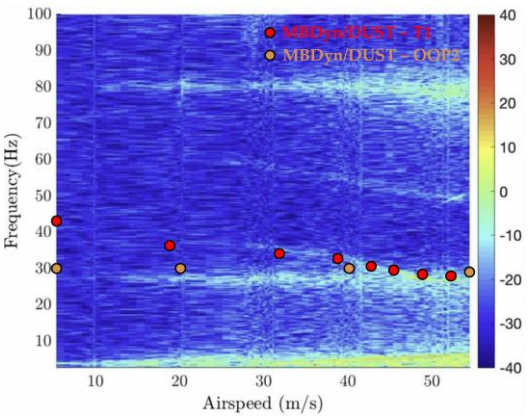

Figure 6: OOP2-T1 modes frequency oscillation at different speeds.

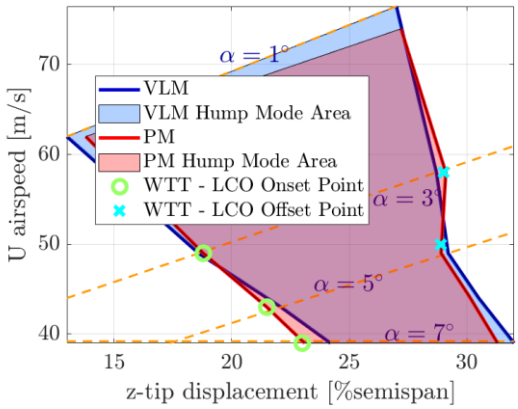

Figure 7: Hump mode area comparison.

Post-flutter behavior. With the aim of investigating the post flutter behavior, two simulations were run in the mid of the hump mode speed range, using both the PM and the VLM. Figure 8 at α = 7° shows that the PM predicts an amplitude that is closer to the experimental one.

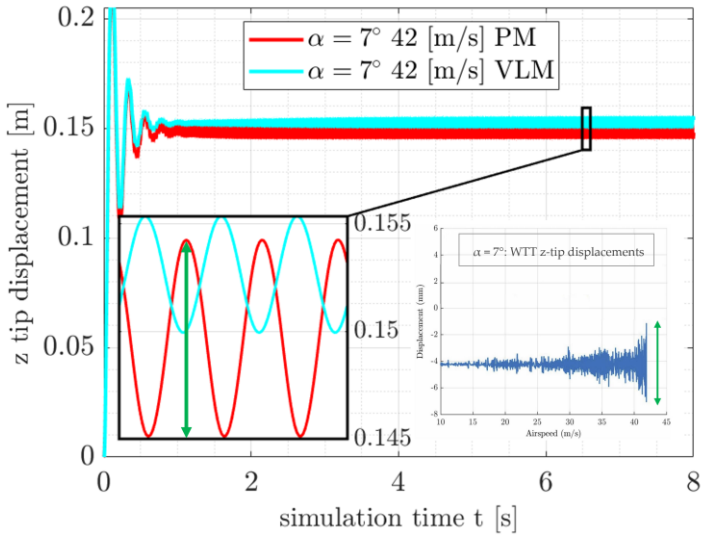

Figure 8: Post flutter wing tip oscillation at α = 7° in the hump mode range.

Also, at α = 5° the oscillations tend to stabilize into a limit cycle of about 8 mm (see [7]). In both cases a significant difference in the resulting amplitude of the LCO by VLM and PM is shown. Given the results related to vertical tip displacement with the VLM and NL-VLM models, as also reported in Fig. 4, it is clear that the amplitude of the oscillations is independent of nonlinear aerodynamic effects. Consequently, the magnitude mismatch cannot be attributed to these effects. Results from the wind tunnel tests present good agreement in terms of oscillations size with those retrieved through the PM, therefore, it is possible to say that such a difference in the amplitude of the motion can be attributed to 3D aerodynamic effects, which are correctly caught by the PM, but are not correctly detected by the VLM or its nonlinear correction, since it remains locally a bi-dimensional method.

Conclusions

This study focused on the nature of LCOs in the Pazy Wing through a comparative analysis of mid-fidelity aeroelastic models. The main conclusion is that the LCOs exhibited by the wing are primarily driven by structural nonlinearities. This finding is supported by the fact that both the VLM and the PM, when coupled with a non-linear structural model, were able to predict the onset of oscillations, regardless of the inclusion of nonlinear aerodynamic corrections. However, a critical distinction emerged in the assessment of the severity of the phenomenon. Only the Panel Method showed quantitative agreement with the experimental data regarding the oscillation amplitude. In contrast, the VLM consistently underestimated this amplitude. This discrepancy is attributed to the PM's ability to capture three-dimensional aerodynamic effects, which prove to be fundamental in determining the post-flutter response but cannot be adequately modelled by a two-dimensional approach like the VLM.

Consequently, for engineering applications requiring a reliable yet computationally efficient prediction of the aeroelastic behavior of very flexible wings, the use of nonlinear structural models paired with 3D aerodynamic methods, such as the PM, is recommended. Employing simpler models, while correctly identifying instabilities, carries the risk of underestimating the severity of the oscillations, and therefore the operational safety of the aircraft.

Keywords: Hydrogen Aircraft, Dry Wing, Aeroelasticity, Structural Sizing, Load Analysis

Abstract. Hydrogen aircraft eliminate the beneficial inertial relief provided by wing fuel storage, substantially increasing structural loads. This study quantifies the resulting penalties for a "dry wing" through detailed aeroelastic simulation and a two-stage structural sizing. A kerosene-fueled reference aircraft wing and a dry wing variant were analyzed using the FAST toolchain and NASTRAN optimization based on critical load cases. Results show that removing wing fuel increased shear forces and root bending moments by up to 48% and 25%, respectively. To satisfy all design constraints, the final optimized dry wing box required significant reinforcement, resulting in a 8.4% weight penalty. This work provides essential quantitative data and insights specific to the dry wing configuration, crucial for early-stage hydrogen-powered aircraft design.

Introduction

Climate change has become a critical concern. The aviation industry faces particular scrutiny due to its significant carbon footprint and the complexity of decarbonization. Reducing carbon emissions is now an urgent priority for aviation, especially given the long turnover times associated with aircraft fleets. Aligning with the ambitious goals set forth by the Flightpath 2050 initiative, the aviation industry aims to reduce CO_2 emissions by 75%, NO_X emissions by 90%, and the noise footprint by 60% by 2050, relative to the levels recorded in the year 2000 [1].

However, the incremental improvements in aircraft efficiency seen over recent decades will no longer be sufficient to meet future targets. Both Boeing and Airbus project that global air traffic, measured in revenue passenger kilometers, will double within the next two decades [1]. This anticipated growth in demand is expected to outweigh the emissions reductions achieved through technological advancements alone [2]. Consequently, without more transformative innovations and comprehensive systemic changes, the efficiency gains may be eclipsed by the expansion of air travel, emphasizing the need for more radical solutions.

Hydrogen-powered aircraft represent a promising solution for decarbonization. During flight, hydrogen-powered aircraft produce zero CO_2 emissions. Hydrogen can be produced through electrolysis using electricity from renewable sources. Hydrogen-powered aviation is predicted to be the most cost-effective and sustainable pathway to achieving carbon-neutral air travel in the long term [3].

However, hydrogen as a fuel presents significant challenges, particularly in terms of storage, due to its different properties compared to traditional Jet-A fuel. While liquid hydrogen has a high gravimetric energy density of 33.3 kWh/kg compared to kerosene's 12 kWh/kg [1], it requires approximately four times more volume.

The large volume requirement and geometric constraints imposed by cryogenic insulation make traditional wing fuel tanks unsuitable for hydrogen storage. External wing-mounted hydrogen tanks are not viable for commercial aircraft, as the drag penalty outweighs any mass savings from the inertial relief provided by the tanks [4]. Several studies [5–7] suggest that integrating the fuel tank into the fuselage appears to be the most viable solution for hydrogen-powered aircraft.

Materials Research Proceedings 69 (2026) 402-407 https://doi.org/10.21741/9781644904251-73

Most research on hydrogen-powered aircraft has focused on fuel storage solutions. However, publications on the structural impact of transitioning from kerosene to hydrogen remain limited. Without fuel in the wing—and thus the loss of inertial relief—aircraft designers face the challenge of heavier wing structures, particularly as future wings are likely to feature higher aspect ratios for aerodynamic efficiency.

Several research projects are currently exploring this topic. One such project is the UP Wing initiative under Clean Aviation. Méheut explored the strut-braced hydrogen dry wing concept using multidisciplinary optimization [8].

In the DLR EXACT project, long-range hydrogen aircraft are being investigated. A conceptual load analysis performed using the tool LOADzero revealed that the wings of hydrogen-powered aircraft experience 20% higher shear force and 15% greater root bending moment compared to kerosene-powered aircraft [9]. These findings highlight the necessity for more detailed investigations into the impact of fuel absence on wing structures, as the analysis relied on analytical methods.

This paper quantitatively assesses the wing weight penalties in hydrogen-powered aircraft using high-fidelity aeroelastic simulation and structural sizing.

Aircraft Models

This study uses an A320-like reference configuration developed by Bauhaus Luftfahrt (BHL). This configuration, featuring a winglet and utilizing aluminum as the primary material, was designed using the BHL in-house tool, BLADE, and adheres to the same top-level requirements as the A320. The full geometry is shown in Fig. 1.

To isolate and quantify the effects of the missing fuel mass inside of wing, a dry wing configuration is introduced. This configuration is based on the reference aircraft but converts the wing-borne kerosene fuel into an equivalent hydrogen mass that is relocated to the fuselage. Critically, the wing planform and all other parameters are kept identical to the reference model. This setup enables a focused evaluation, separating the dry wing effect from other influencing design factors.

The aeroelastic model is automatically generated using the in-house multi-fidelity toolchain, the *Flexible Aero-Structural Toolbox* (FAST). The FAST toolchain automates FEM generation (Beam and Shell) and provides versatile analysis capabilities.

Figure 1: Reference Aircraft.

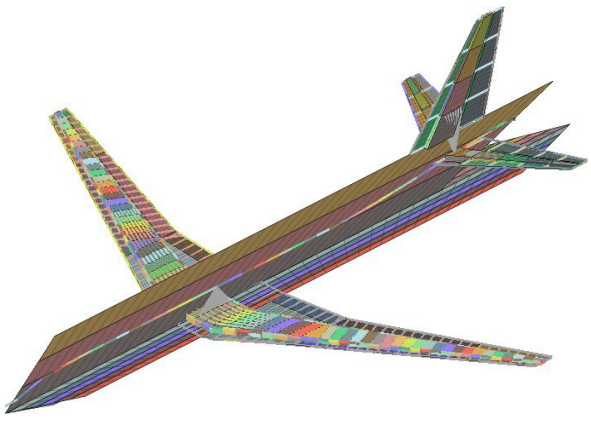

Figure 2: Aeroelastic model of reference configuration.

Given the primary focus on the wing's behavior, the wing box is modeled using shell elements, while stiffeners and stringers are represented by beam elements. To reduce computational cost and modeling effort, the fuselage structure is simplified to a rigid beam.

Materials Research Proceedings 69 (2026) 402-407 https://doi.org/10.21741/9781644904251-73

Non-structural masses (e.g., engine and landing gear) are accounted for in the model. The fuel mass is represented by concentrated mass elements: for the wet wing (reference configuration), mass is distributed along the wing span; for the dry wing configuration, this mass is placed in the fuselage.

For the aerodynamic side, a full-aircraft model based on the Doublet Lattice Method (DLM) is employed. This model covers the complete aircraft and ensures direct compatibility with the NASTRAN solver format required for the aeroelastic analysis. The resulting full aeroelastic model is illustrated in Fig. 2.

Methodology

To systematically evaluate the dry wing effect and quantify the impact of losing fuel inertial relief on the load-bearing wing box, a structural sizing analysis is required. This process necessitates the prior identification of critical design load cases.

Determining load cases for structural sizing typically requires a comprehensive analysis across the full flight envelope and all mass configurations, resulting in hundreds of simulations. However, since this study aims to assess the dry wing effect rather than conduct an exhaustive certification-level analysis, a simplified approach is adopted. Only steady maneuver loads are simulated for one representative mass configuration.

The representative mass configuration selected is the maximum take-off mass with full payload and the center of gravity positioned at 15% mean aerodynamic chord. This specific case typically represents the most demanding mass configuration with regard to steady maneuvers.

In total, 60 maneuver load cases were simulated, including 2.5g pull-up, −1g push-over, and 1.67g roll maneuvers. All cases adhere to the certification specification (CS) 25 [10] flight envelope boundaries and maneuvering load factor limits across a range of speeds and altitudes.

Following the simulation, the load results are post-processed to generate load envelopes. The most critical load cases are subsequently extracted from these envelopes and used as inputs for the structural sizing process.

Structural sizing of the wing was performed in two sequential stages using NASTRAN's SOL200 optimization module. This two-stage approach ensures a minimal-mass design that satisfies material strength, buckling, and aeroelastic stability requirements. To reduce computational effort and the number of design variables, the geometry of stiffeners and stringers was held constant and not included in the optimization. The design variables are defined as the thicknesses of the primary structural elements (spars, ribs, and skins).

Stage 1: Strength and Buckling Sizing. The objective of the first stage was to minimize the wing's structural mass subject to material strength and buckling criteria. Static analysis and linear buckling analysis were performed under the critical loads derived from the load analysis process. The optimization problem for this stage is formulated as:

$$\begin{aligned} \text{minimize} \quad & \mathrm{m}(\mathrm{t}) \\ \text{subject to} \quad & \sigma(\mathrm{t}) \leq \frac{\sigma_{\text{ultimate}}}{1.5} \\ & \lambda \geq 1.4 \end{aligned}$$

Here, t represents the thickness of the structural elements (the design variables), and the objective function $\mathrm{m}(\mathrm{t})$ is the total mass of the wing structure. The constraints limit the von Mises stress $\sigma(\mathrm{t})$ to be less than the ultimate allowable stress σ_{ultimate} divided by a safety factor of 1.5, and ensure the linear buckling factor λ is greater than or equal to 1.4. A safety factor of 1.4 was selected for the buckling analysis, a slightly less conservative value than 1.5, given that linear buckling analysis inherently provides a conservative estimate compared to nonlinear methods. The

Materials Research Proceedings 69 (2026) 402-407 https://doi.org/10.21741/9781644904251-73

optimization monitored the first 10 buckling modes to ensure both global and local criteria were satisfied.

Following the initial sizing, a comprehensive aeroelastic analysis was conducted to ensure the wing's stability and preclude hazardous phenomena such as aileron reversal, divergence, and flutter. This evaluation is essential for meeting CS-25 requirements [10], which mandate stability up to $1.15V_D$ or $1.15M_D$.

To satisfy the subsonic-only validity of NASTRAN's DLM, the simulation was performed at sea level at a Mach number of approximately 0.70. This condition was selected to achieve a high dynamic pressure, where the possibility of aeroelastic instabilities is highest.

For flutter and divergence analyses, NASTRAN's Solution 145 was employed. A non-matched point flutter analysis was performed using the PK solver with a fixed Mach number and a fixed density ratio. The analysis utilized 40 structural modes and assumed 2% structural damping, with a reduced frequency range from 0.0001 to 10.0 to cover all frequencies of interest. The extremely low end of this range was specifically intended to capture potential divergence.

For the aileron reversal check, NASTRAN's Solution 144 was used. The aileron effectiveness, η_{ail}, is defined as the negative ratio of the roll coefficient due to aileron deflection (Cl_{δ_a}) to the roll coefficient due to rolling (roll damping, Cl_p). The aileron effectiveness should remain positive.

Stage 2: Aeroelastic-Constrained Sizing. As the initial sized model demonstrated a failure in the aileron reversal check, a subsequent structural sizing optimization was performed. The objective function remained the minimization of structural weight. However, this second-stage optimization was constrained by the aileron effectiveness. The structural properties resulting from the first sizing served as the lowest bound for the design variables in this new optimization. This allowed the optimizer only to increase thicknesses to satisfy the new aeroelastic constraint while ensuring the final structural design maintained a minimal weight that satisfied all criteria.

Results

The comparison between the reference aircraft and the dry wing configuration is carried out in two main steps.

The first step compares the maximum loads on the wing structure. This provides an initial, quantitative indication of the consequences of losing fuel inertial relief, which, in the reference configuration, helps to alleviate structural stress.

Fig. 3 and 4 show the load envelopes derived from the reference model and the dry wing model. A significant increase in internal loads is observed for the dry wing: a 48% increase in shear force (F_z) and a 25% increase in bending moment (M_x) are noted.

The thickness distributions resulting from the two-stage structural sizing process are presented

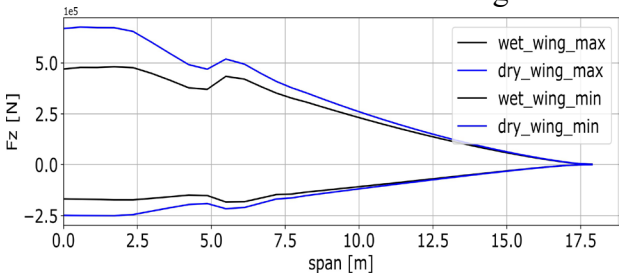

Figure 3: Comparison of shear force.

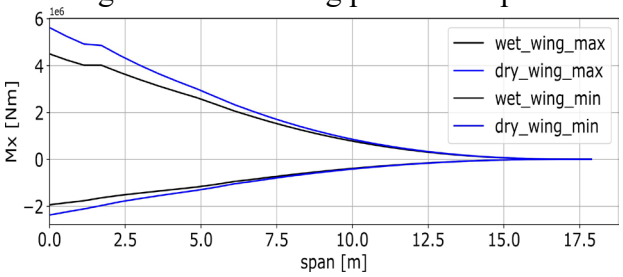

Figure 4: Comparison of bending moment.

in Fig. 5 and 6. The results show a noticeable increase in thickness for the dry wing configuration compared to the wet wing, particularly evident in the upper skin. This reinforcement is required to compensate for the missing inertial relief from the wing-borne fuel mass.

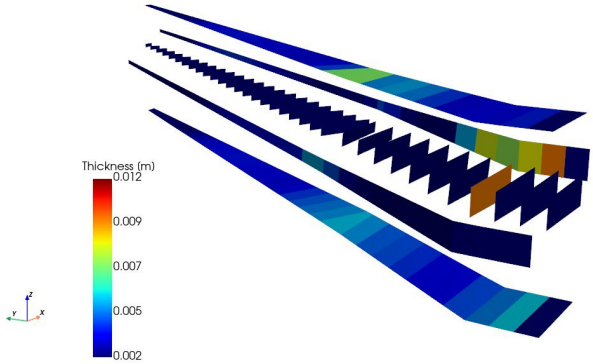

Figure 5: Thickness distribution of wet wing.

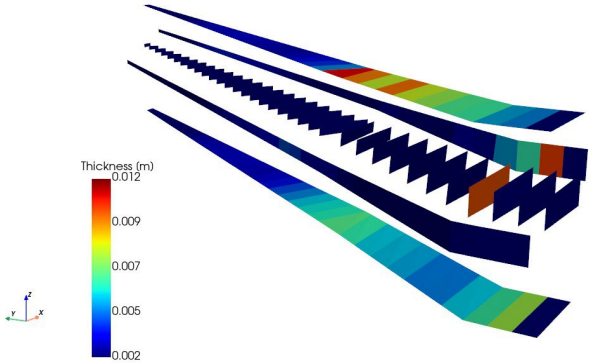

Figure 6: Thickness distribution of dry wing.

Furthermore, due to the swept wing geometry at the wing kink, stresses are not distributed evenly across the wing box. This non-uniformity results in a triangular stress redistribution area near the wing root, which necessitates a clear increase in the thickness of the skin, spars, and ribs in this specific region. Higher stresses are also concentrated toward the rear spar due to shear lag effects, which contributes to the higher required thickness in that location.

The final optimal wing box weight from the completed two-stage sizing process for the dry wing is 4373 kg, compared to 4034 kg for the wet wing.

Conclusion and Outlook

The structural and aeroelastic impact of a dry wing hydrogen concept is quantified using a two-stage optimization. Load analysis showed a significant increase in internal loads of wingbox, specifically a 48% increase in shear force and a 25% increase in bending moment over the wet wing. Structural reinforcement was required to satisfy strength, buckling, and the critical aileron reversal constraint. This resulted in a 8.4% weight penalty for the dry wing, directly quantifying the structural enforcement needed for the hydrogen concept.

Future work will focus on expanding the analysis beyond static maneuvers to include dynamic load cases, specifically incorporating gust load to identify critical load case. Furthermore, the load analysis will be refined by assessing various mass configurations across the full flight envelope. Finally, a parametric study is planned to gain crucial insights into how the wing aspect ratio influences the structural and aeroelastic performance of the dry wing concept.

Keywords: Interblade Damper, Helicopter Rotor, Ground Resonance

Abstract. This paper presents the formulation and sensitivity analysis of ground resonance stability in rotorcraft equipped with unconventional lead-lag damping configurations, including the inter-blade and the recently proposed inter-2-blade arrangements. The developed framework enables consistent linearization of the coupled rotor-airframe system and supports comparison of the stability performance of conventional and novel damper configurations.

Introduction

Ground Resonance (GR) is a dynamic instability typical of helicopters, caused by the adverse coupling between the cyclic lead-lag motion of the blades and the motion of the airframe acting as a flexible support. It arises when the frequency of the slow first-order cyclic lead-lag mode approaches that of either the longitudinal (pitch) or lateral (roll) airframe motion [1].

Helicopter rotors are commonly equipped with damping devices to prevent such instability. The most conventional configuration employs dampers directly connecting each blade to the hub (BTH). Alternative arrangements connect the blades in different ways, often bypassing the hub. Among these, the "inter-blade" (IB) configuration couples adjacent blades, while the "inter-2-blade" (I2B) configuration connects non-adjacent blades [2, 3]. These concepts offer potential advantages partly explored in earlier studies.

The objectives of this work are:

- to develop a framework describing the exact kinematics of damper activation as a function of blade motion,
- to couple the consistently linearized damper-blade kinematics with industry-grade rotorcraft aeroelastic solvers,
- to formulate a consistent sensitivity analysis of the GR eigensolution,
- to assess the stability performance of the three configurations (BTH, IB, I2B), including selected damper-failure conditions.

The GR problem is analyzed by linearizing about steady reference equilibrium conditions.
The kinematics are derived by consistently linearizing a geometrically exact multibody model. For the nominal isotropic rotor, the system obtained through the multiblade coordinate transformation is linear and time-invariant and is treated using standard eigenanalysis.

Blade Lag Dynamics. Following Coleman's formulation [1], the linearized lead-lag dynamics of the *m*th blade in a rotor with three or more blades is expressed as

$$I_\xi \ddot{\xi}^{(m)} + \left(eS_\xi \Omega^2 + k_\xi\right) \xi^{(m)} = \tau_{\text{damper}}^{(m)} - S_\xi \ddot{y} \cos\psi_m + S_\xi \ddot{x} \sin\psi_m \qquad (1)$$

with $m = 1..N_b$, and the damping torques are

Content from this work may be used under the terms of the Creative Commons Attribution 3.0 license. Any further distribution of this work must maintain attribution to the author(s) and the title of the work, journal citation and DOI. Published under license by Materials Research Forum LLC.

$$\tau_{\text{damper}}^{(m)} = -c_\xi \begin{cases} \dot{\xi}^{(m)} & \text{BTH} \\ 2\dot{\xi}^{(m)} - \dot{\xi}^{(m-1)} - \dot{\xi}^{(m+1)} & \text{IB} \\ 2\dot{\xi}^{(m)} - \dot{\xi}^{(m-2)} - \dot{\xi}^{(m+2)} & \text{I2B} \end{cases} \tag{2}$$

Equation (1) is azimuth-dependent because the forcing terms associated with the airframe roll and pitch through the corresponding lateral and longitudinal accelerations depend on the blade azimuth $\psi_m = \psi + 2\pi\, m/N_b$.

Multiblade Coordinates. For identical, equally spaced blades (isotropic rotor), introducing the multiblade (Coleman) transformation eliminates azimuth dependence:

$$\xi^{(m)} = \xi_0 + \sum_{n=1}^{\text{fix}((N_b-1)/2)} [\cos(n\psi_m)\xi_{nc} + \sin(n\psi_m)\xi_{ns}] + (-1)^m \xi_{N_b/2} \tag{3}$$

The last term applies only to even N_b. The transformation can be written compactly as

$$\boldsymbol{\xi}_b = \mathbf{T}(\psi)\boldsymbol{\xi} \qquad \dot{\boldsymbol{\xi}}_b = \dot{\mathbf{T}}(\psi)\boldsymbol{\xi} + \mathbf{T}(\psi)\dot{\boldsymbol{\xi}} \qquad \ddot{\boldsymbol{\xi}}_b = \ddot{\mathbf{T}}(\psi)\boldsymbol{\xi} + 2\dot{\mathbf{T}}(\psi)\dot{\boldsymbol{\xi}} + \mathbf{T}(\psi)\ddot{\boldsymbol{\xi}} \tag{4}$$

Here, $\boldsymbol{\xi}$ denotes the multiblade coordinates, $\boldsymbol{\xi}_b$ the individual blade coordinates, and $\mathbf{T}(\psi)$ the azimuth-dependent transformation matrix.

Coupled Rotor-Airframe Equations. After algebraic manipulation, the coupled rotor-airframe equations can be expressed as

$$\begin{bmatrix} N_bI_\xi/2 & 0 & 0 & N_bS_\xi/2 \\ 0 & N_bI_\xi/2 & -N_bS_\xi/2 & 0 \\ 0 & -N_bS_\xi/2 & M_x + N_bM_b & 0 \\ N_bS_\xi/2 & 0 & 0 & M_y + N_bM_b \end{bmatrix} \begin{Bmatrix} \ddot{\xi}_{1c} \\ \ddot{\xi}_{1s} \\ \ddot{x} \\ \ddot{y} \end{Bmatrix}$$

$$+ \begin{bmatrix} N_b\Xi_\clubsuit c_\xi/2 & N_bI_\xi\Omega & 0 & 0 \\ -N_bI_\xi\Omega & N_b\Xi_\clubsuit c_\xi/2 & 0 & 0 \\ 0 & 0 & C_x & 0 \\ 0 & 0 & 0 & C_y \end{bmatrix} \begin{Bmatrix} \dot{\xi}_{1c} \\ \dot{\xi}_{1s} \\ \dot{x} \\ \dot{y} \end{Bmatrix}$$

$$+ \begin{bmatrix} N_b\left[\Xi_\clubsuit k_\xi + (eS_\xi - I_\xi)\,\Omega^2\right]/2 & N_b\Xi_\clubsuit c_\xi\Omega/2 & 0 & 0 \\ -N_b\Xi_\clubsuit c_\xi\Omega/2 & N_b\left[\Xi_\clubsuit k_\xi + (eS_\xi - I_\xi)\,\Omega^2\right]/2 & 0 & 0 \\ 0 & 0 & K_x & 0 \\ 0 & 0 & 0 & K_y \end{bmatrix} \begin{Bmatrix} \xi_{1c} \\ \xi_{1s} \\ x \\ y \end{Bmatrix} = \begin{Bmatrix} 0 \\ 0 \\ 0 \\ 0 \end{Bmatrix} \tag{5}$$

with $\Xi_{\text{BTH}} = 1$, $\Xi_{\text{IB}} = 2(1 - \cos(2\pi/N_b))$, and $\Xi_{\text{I2B}} = 2(1 - \cos(4\pi/N_b))$, the latter two for ideal damping, i.e., directly proportional to the respective combinations of blade rotation.

The remaining multiblade coordinates remain decoupled from the airframe and are not discussed here. In the IB and I2B configurations, the collective motion receives no damping, and higher-order cyclic or reactionless I2B equations experience reduced damping compared with IB and BTH [3].

Damper Activation Kinematics. In practical designs, the damper activation depends on the relative motion of the blades through nonlinear kinematic relationships. Let $\varphi^{(m)}$ denote the activation of the mth damper (relative rotation or displacement),

$$\boldsymbol{\phi}^{(m)}\left(\mathbf{x}^{(m)}, \boldsymbol{\xi}_b\right) = \mathbf{0} \tag{6}$$

that represents the scleronomic constraint equations, where $\mathbf{x}^{(m)}$ collects the internal coordinates of the damper, with $\varphi^{(m)} = \varphi^{(m)}(\mathbf{x}^{(m)})$ (without excessive loss of generality, $\varphi^{(m)}$ can directly be an element of $\mathbf{x}^{(m)}$, or a linear combination, $\varphi^{(m)} = \mathbf{C}\,\mathbf{x}^{(m)}$; in the following, the superscript (m) will be

Materials Research Proceedings 69 (2026) 408-413 https://doi.org/10.21741/9781644904251-74

omitted for ease of notation). $\boldsymbol{\phi}$ contains as many equations as internal coordinates $\mathbf{x}$. The blade rotations, $\boldsymbol{\xi}_b$, are the independent variables. Equation (6) is solved to determine $\mathbf{x}$ as a function of $\boldsymbol{\xi}_b$, and thus determine the reference configuration of the damper system for a given reference blade lag rotation.

Linearization of Eq. (6) around the reference configuration yields

$$\Delta\mathbf{x} = -\boldsymbol{\phi}_{/\mathbf{x}}^{-1}\boldsymbol{\phi}_{/\boldsymbol{\xi}_b}\Delta\boldsymbol{\xi}_b \qquad \text{and} \qquad \Delta\varphi = -\mathbf{C}\boldsymbol{\phi}_{/\mathbf{x}}^{-1}\boldsymbol{\phi}_{/\boldsymbol{\xi}_b}\Delta\boldsymbol{\xi}_b = \boldsymbol{\Psi}\Delta\boldsymbol{\xi}_b \tag{7}$$

where submatrix $\boldsymbol{\phi}_{/\mathbf{x}}$ of the constraint Jacobian matrix is square by assumption and invertible as long as the closed kinematic chain it describes is not in a singular configuration. In the ideal BTH case, $\boldsymbol{\Psi}_i^{(m)} = \delta_{im}$, where δ_{im} is Kronecker's operator; in the ideal IB case, $\boldsymbol{\Psi}_i^{(m)} = \delta_{im}$ and $\boldsymbol{\Psi}_{i+1}^{(m)} = -\delta_{im}$; finally, in the ideal I2B case, $\boldsymbol{\Psi}_{i-1}^{(m)} = \delta_{im}$ and $\boldsymbol{\Psi}_{i+1}^{(m)} = -\delta_{im}$.

Damper Contribution to Virtual Work. The virtual work of the mth damper is

$$\delta\mathcal{W}_{\text{damper}}^{(m)} = -\delta\varphi\left(c_\varphi\Delta\dot{\varphi} + k_\varphi\Delta\varphi\right) = -\delta\boldsymbol{\xi}_b^{\mathsf{T}}\boldsymbol{\Psi}^{\mathsf{T}}\left(c_\varphi\boldsymbol{\Psi}\Delta\dot{\boldsymbol{\xi}}_b + k_\varphi\boldsymbol{\Psi}\Delta\boldsymbol{\xi}_b\right) \tag{8}$$

where c_φ and k_φ are the linearized viscous and elastic characteristics of an elastomeric damper. In the ideal case, $c_\xi \equiv c_\varphi$ and $k_\xi \equiv k_\varphi$, whereas in practical cases, the kinematics of the lag activation mechanism hidden in $\boldsymbol{\Psi}$ need to be used.

Using the same reference configuration for all blades (e.g., the same reference lead-lag angle), the kinematic problem is solved for just one damper, and the same expression of Eq. (8) for the virtual work is used for all, simply changing the indexes of the involved blade rotations in $\boldsymbol{\xi}_b$. Stacking all dampers yields

$$\delta\mathcal{W}_{\text{dampers}} = \sum_m \delta\mathcal{W}_{\text{damper}}^{(m)} = -\delta\boldsymbol{\xi}_b^{\mathsf{T}}\mathbf{B}^{\mathsf{T}}\left(c_\varphi\mathbf{B}\Delta\dot{\boldsymbol{\xi}}_b + k_\varphi\mathbf{B}\Delta\boldsymbol{\xi}_b\right) \tag{9}$$

where

$$\mathbf{B}^{\mathsf{T}} = [\boldsymbol{\Psi}^{(1)^{\mathsf{T}}}, \ldots, \boldsymbol{\Psi}^{(N_b)^{\mathsf{T}}}]$$

A kinematically and energetically consistent definition of damper activation does not alter the structure of Eq. (5), only affecting the coefficients $\Xi_\clubsuit$. It also affects the remaining rotor equations, which, however, remain decoupled from the airframe motion.

Sensitivity of Eigensolution. Equation (5) can be written as

$$\left(s^2\mathbf{M}_c + s\mathbf{C}_c + \mathbf{K}_c\right)\mathbf{z} = \mathbf{0} \tag{10}$$

where $\mathbf{z}$ is the eigenvector and s the eigenvalue.

The sensitivity of the ℓth eigenpair to a generic parameter p is obtained by differentiating Eq. (10) and the L^∞ normalization condition $\mathbf{n}^{\mathsf{T}}\mathbf{z} = 1$ ($\mathbf{n} = [0, \ldots, 1, \ldots 0]^{\mathsf{T}}$) with respect to p, i.e.,

$$\begin{bmatrix} \left(s_\ell^2\mathbf{M}_c + s_\ell\mathbf{C}_c + \mathbf{K}_c\right) & \left(2s_\ell\mathbf{M}_c + \mathbf{C}_c\right)\mathbf{z}_\ell \\ \mathbf{n}^{\mathsf{T}} & \end{bmatrix} \begin{Bmatrix} \mathbf{z}_{\ell/p} \\ s_{\ell/p} \end{Bmatrix} = \begin{Bmatrix} -\left(s_\ell^2\mathbf{M}_{c/p} + s_\ell\mathbf{C}_{c/p} + \mathbf{K}_{c/p}\right)\mathbf{z}_\ell \\ 0 \end{Bmatrix} \tag{11}$$

If the damper kinematics depend on p, the corresponding derivatives include

$$\Delta\varphi_{/p} = -\mathbf{C}\boldsymbol{\phi}_{/\mathbf{x}}^{-1}\left(\boldsymbol{\phi}_{/\boldsymbol{\xi}_b p} - \boldsymbol{\phi}_{/\mathbf{x}p}\boldsymbol{\phi}_{/\mathbf{x}}^{-1}\boldsymbol{\phi}_{/\boldsymbol{\xi}_b}\right)\Delta\boldsymbol{\xi}_b = \boldsymbol{\Psi}_{/p}\Delta\boldsymbol{\xi}_b \tag{12}$$

while for parameters directly affecting system matrices, the computation is straightforward.

Damper Failure. If one or more dampers fail, the problem becomes time-periodic. Its stability can be studied using the Floquet-Lyapunov method [4], and its sensitivity can be derived following the procedure in [5].

Results

Realistic IB and I2B layouts, adapted from existing designs, are shown in Fig. 1. In the IB configuration (left), a rotational damper is attached to blade m and linked to blade $m + 1$ through

Materials Research Proceedings 69 (2026) 408-413 https://doi.org/10.21741/9781644904251-74

a rigid connection. The model is treated as two-dimensional for clarity, but has also been implemented in 3D. Each sub-assembly consists of a blade, a damper, and a connecting link between the damper and the preceding blade, for a total of three bodies and nine DoF, eight of which are eliminated by the four hinges, leaving one DoF, the blade rotation. Each closed loop consists of four bodies and 12 DoF, 10 of which are eliminated by the five hinges, corresponding to a five-bar mechanism. Prescribing the rotations of the blades makes the problem kinematically determined. Using data from [6], the transmission ratio is $\boldsymbol{\Psi}(m, m+1) = [-1.5045, 0.6320]$, which differs notably from the ideal $[-1, 1]$.

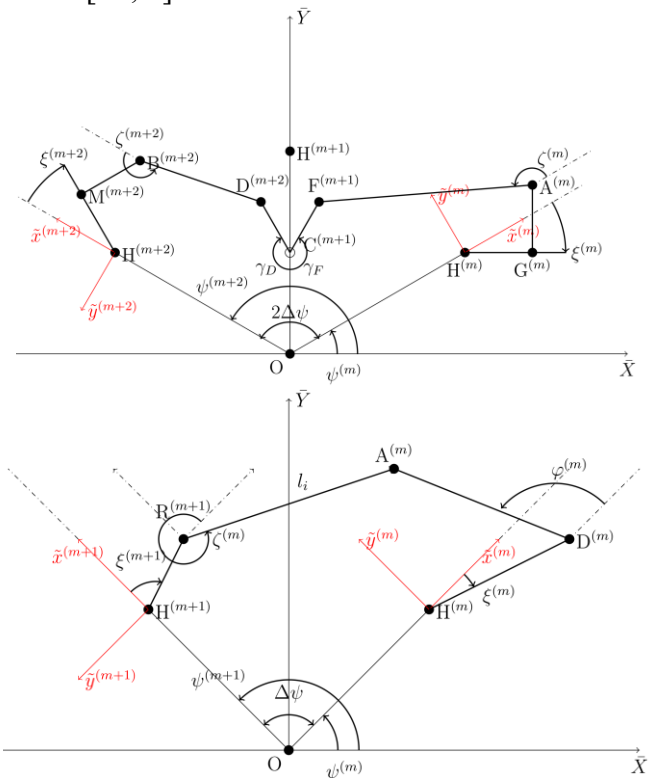

Figure 1: Realistic configurations: inter-blade (left) and inter-2-blade (right).

Figure 2 presents the coupled rotor-airframe eigensolution for the IB configuration. The top-left panel shows the real parts of all eigenvalues; the top-right highlights the critical mode (real and imaginary parts), the slow cyclic eigenvalue, which becomes unstable slightly above $\Omega_{100\%}$. The bottom panels show its sensitivity to the stiffnesses (left) and dampings (right) of the damper and the link's elastomeric bearings.

Using sensitivity analysis, equivalent BTH and I2B models were tuned by continuation. The equivalent BTH configuration was matched by adjusting k_ξ and c_ξ to reproduce the same slow cyclic eigenvalue as the IB case at $\Omega_{100\%}$. The equivalent I2B model was tuned by adjusting also other kinematic parameters to match the slow cyclic and also the collective eigenvalue, which is undamped in the ideal IB and I2B cases.

Figure 3 compares the real parts of the eigenvalues for the IB (left), I2B tuned for slow cyclic (center), and I2B tuned for both slow cyclic and collective modes (right) at $\Omega_{100\%}$. The results demonstrate strong similarity and comparable GR stability among the configurations.

Finally, results obtained with a detailed rotor and airframe aeroelastic model implemented in MASST [7], a general-purpose rotorcraft aeroelasticity tool, confirm the observed trends.

Investigation of Lift-offset Effect on Performance and Vibratory Loads of a Rigid Coaxial Rotor

Jae-Hee HWANG[1,a *], and Jae-Sang PARK[1,b]

[1]Chungnam National University, Republic of Korea

[a]ghkdnonon7@gmail.com, [b]aerotor@cnu.ac.kr

Keywords: Rigid Coaxial Rotor, Lift-Offset, Aerodynamic Performance, Hub Vibratory Loads, Pitch-Link Vibratory Loads

Abstract. This study investigates the hub and pitch-link vibratory loads of a generic lift-offset coaxial rotor, using the comprehensive rotorcraft analysis code, CAMRAD II. The analysis results indicate that increasing the lift-offset leads to a reduction in the hub vibratory load (VI) and pitch-link vibratory loads at 250 knots. Furthermore, the rotor aerodynamic performance improves with increasing lift-offset.

Introduction

In recent years, the rotorcraft community has actively pursued the development of rotorcraft with enhanced high-speed and long-range flight capabilities. Lift-offset compound helicopters adopt the Advancing Blade Concept (ABC) to achieve superior high-speed performance. However, the lift-offset coaxial rotor (or rigid coaxial rotor) requires short inter-rotor spacing between the upper and lower rotors, demanding highly stiff blades that generate significant vibrations in high speed flights. The airframe vibrations from the rotor hub vibratory loads cause various problems, such as limited maximum flight speed, increased mechanical fatigue, and passenger discomfort. In addition, the severe pitch-link vibratory loads should be investigated since the pitch-link is an important component of a rotor control system to control blade pitch motions. The analysis examines the effects of pitch-link stiffness on rotor aerodynamic performance, hub vibratory loads, and pitch-link forces at various flight speeds, and investigates the influence of lift-offset on them at a flight speed of 250 knots.

Analytical Methods

The modeling and analysis are conducted based on the authors' previous studies [1, 2], in which the modeling and analysis of the lift-offset rotor were validated against wind tunnel test results. This study employs the generic lift-offset coaxial rotor developed in the authors' previous work [3] which is similar to the SB>1 Defiant rigid coaxial rotor (Figure 1). CAMRAD II is utilized for the rotor aeromechanics modeling and analyses. Blade structural dynamics is modeled using eight nonlinear beam elements per blade. The rotor control system, including pitch-links, pitch-horns, and swashplates, is also incorporated into the model. For unsteady rotor aerodynamics, 25 aerodynamic panels for a blade are employed, based on the second-order lifting-line theory and an airfoil table lookup. Furthermore, a general free-wake model is applied to account for the aerodynamic interference between the upper and lower rotors. With six pitch control angles (θ_0^U, θ_{1C}^U, θ_{1S}^U, θ_0^L, θ_{1C}^L, θ_{1S}^L), the rotor is trimmed to match the assumed rotor thrust, hub roll moments prescribed using an assumed lift-offset value, zero hub pitch moments, and zero torque of a coaxial rotor.

The analysis examines the effects of pitch-link stiffness values (K_{pl}) and lift-offsets on rotor aerodynamic performance, hub vibratory loads, and half peak-to-peak pitch-link forces.

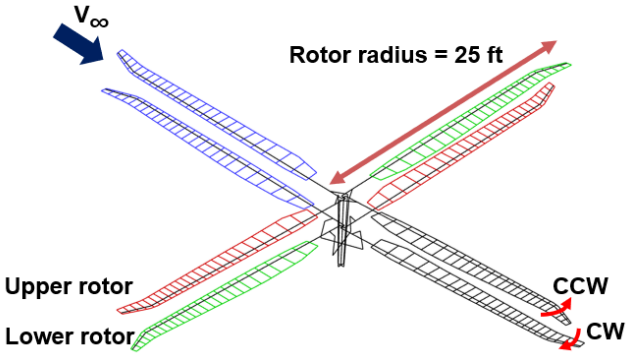

Figure 1. CAMRAD II model for lift-offset coaxial rotor

Results

Fan plot

The natural frequencies of a rotating blade are analyzed in terms of the rotor rotational speed to investigate the structural dynamics of the present lift-offset rotor with different pitch-link stiffness values. As seen in the figure, the first torsion mode (1T) frequency decreases as the pitch-link stiffness (K_{pl}) decreases; however, due to the extremely high blade stiffness (rigid blades), it still exhibits high natural frequency values exceeding 10P (where 1P = 1/rev is a nondimensional rotor speed).

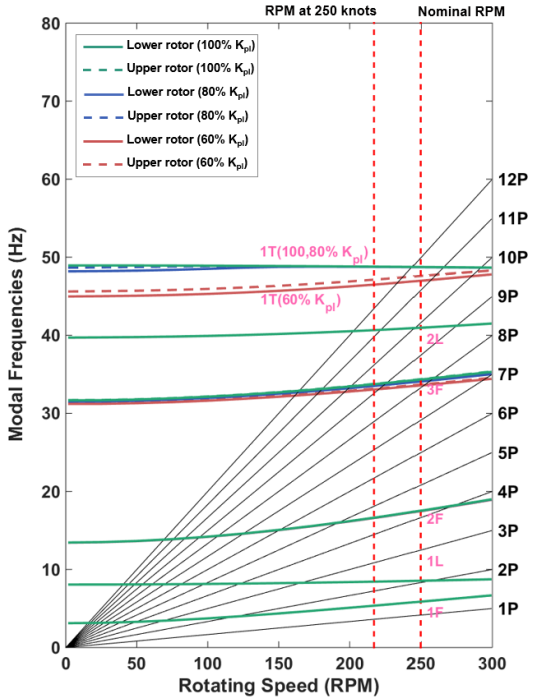

Figure 2. Natural frequencies of a rotating blade for the lift-offset coaxial rotor (in vacuum)

Analysis with various pitch-link stiffness values

As the pitch-link stiffness (K_{pl}) decreases, the rotor aerodynamic performance (rotor effective lift-to-drag ratio, L/D_e) in forward flight is not altered significantly (Figure 3); however, the hub vibratory loads (Vibration Index, VI) and pitch-link forces (1/2 peak-to-peak forces) increase (Figure 4).

Materials Research Proceedings 69 (2026) 414-417 https://doi.org/10.21741/9781644904251-75

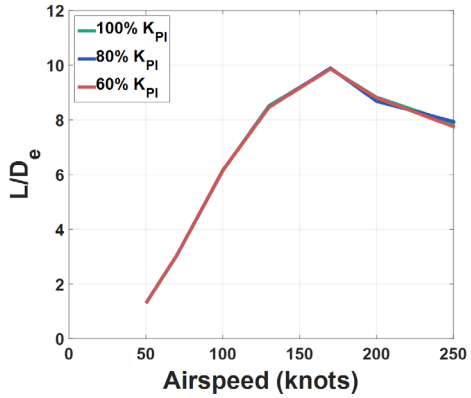

Figure 3. Aerodynamic performance with different pitch-link stiffness values; rotor effective lift-to-drag-ratios (L/D_e)

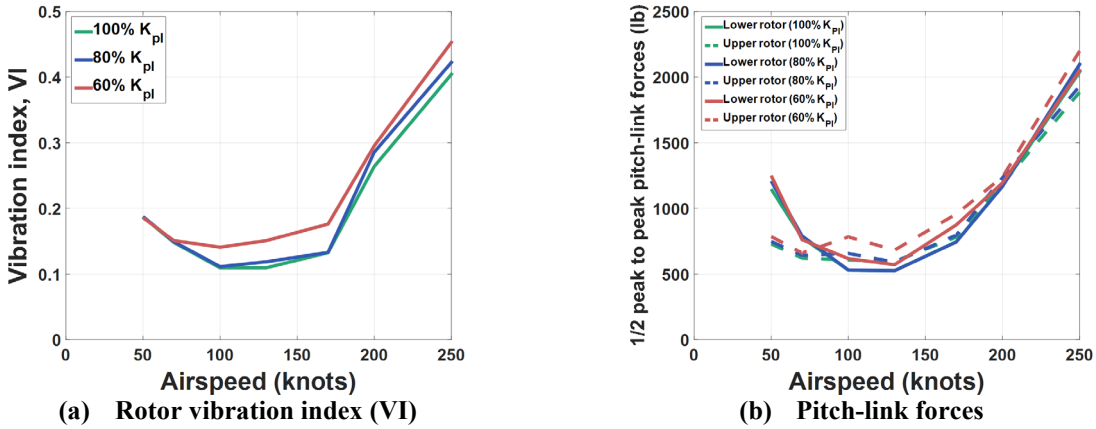

Figure 4. Hub vibratory loads and pitch-link forces with different pitch-link stiffness values

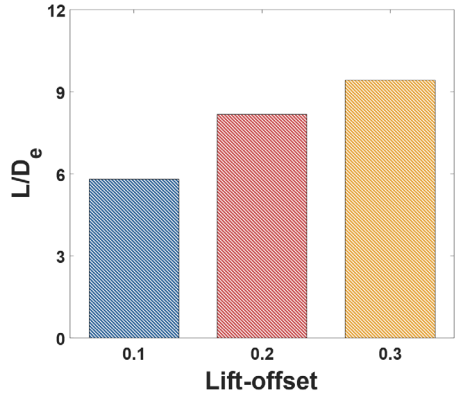
Analysis with various lift-offset values

Forward flight performance and vibratory loads of the lift-offset coaxial rotor are investigated in Figures 5 and 6 at a flight speed of 250 knots. In these examples the baseline pitch-link stiffness (100% K_{pl}) and various lift-offset values of 0.1, 0.2, and 0.3 are considered to analyze the effect of lift-offset. Figure 5 illustrates the variations of the rotor effective lift-to-drag ratio (L/D_e) in terms of the lift-offset value. As the lift-offset increases, the L/D_e is observed to increase; therefore, the aerodynamic performance is improved. Furthermore, the hub vibratory load (VI) and pitch-link force both decrease as the lift-offset increases, as shown in Figure 6.



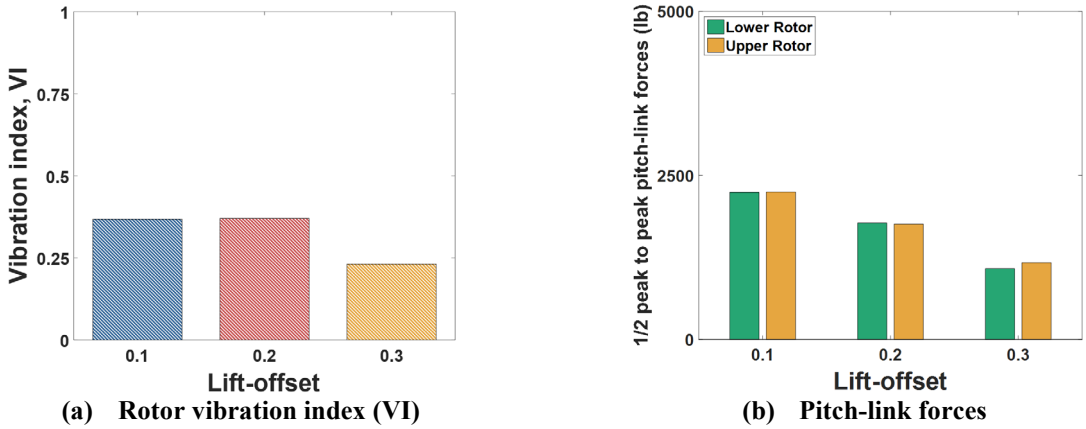


Figure 5. Aerodynamic performance with different lift-offset values at 250 knots; rotor effective lift-to-drag-ratios (L/D_e)

(a) Rotor vibration index (VI) **(b) Pitch-link forces**

Figure 6. Hub vibratory loads and pitch-link forces with different lift-offset values at 250 knots

Conclusions

In this work, the performance and vibratory loads of a generic lift-offset coaxial rotor were investigated with various pitch-link stiffness and lift-offset values. This study utilized the rotorcraft comprehensive analysis code, CAMRAD II, to investigate the performance, hub vibratory loads, and pitch-link forces for the lift-offset coaxial rotor. The rotor aerodynamic performance in forward flight remained unchanged with varying pitch-link stiffnesses (100%, 80%, and 60% K_{pl}); however, hub vibratory loads and pitch-link forces both increased when using lower pitch-link stiffness. Furthermore, at 250 knots, a higher lift-offset value improved aerodynamic performance and decreased hub vibratory loads and pitch-link forces of the lift-offset coaxial rotor.

Abstract. High-fidelity modeling of unsteady aerodynamic phenomena is critical for the development of next-generation rotor blades and morphing airfoils. This study examines the unsteady flow over four representative 3D morphing NACA 13112 airfoil sections, each associated with a blade of the IAR 330 PUMA main rotor and pitching about an axis located at 25% of the chord. Simulations conducted at Mach 0.38 replicate hover conditions and capture the dominant unsteady mechanisms governing dynamic stall. Wind-tunnel measurements were used exclusively to validate the baseline airfoil section, confirming the accuracy of the numerical predictions. Two morphing strategies were investigated. The first employed pre-morphed CAD geometries generated in CATIA for trailing-edge flap (TEF) deflections ranging from −20° to +20°, using a fixed flap-chord fraction of 0.75c. The second implemented dynamic morphing via compiled user-defined functions (UDFs) in conjunction with CATIA-generated bodies corresponding to various flap-chord lengths. The angle of attack followed a sinusoidal variation between −3° and +18°, while a dedicated UDF imposed TEF rotation within the same deflection range. The flap motion was applied in antiphase to the pitching cycle, and a dynamic mesh continuously updated the geometry, enabling a realistic representation of unsteady morphing effects across all blade sections. For static validation, unstructured O-grid and C-grid meshes were generated and compared against wind-tunnel data. For dynamic simulations, an unstructured mesh featuring a fixed outer domain and a rotating inner rotor domain was employed to resolve cyclic pitching, flap motion, and rotor-induced flow interactions. The numerical setup used a Moving Reference Frame at 265 rpm and a sliding-mesh interface to capture relative domain motion. Parametric studies demonstrate that TEF amplitude and flap-chord fraction have a significant impact on the unsteady aerodynamic response. Dynamic morphing effectively delays stall, reduces unsteady loads, and enhances aerodynamic damping, highlighting its potential for improving the stability and performance of future rotor systems.

Introduction

Aerodynamic research plays a crucial role in understanding and optimizing the performance of lifting surfaces, encompassing both fixed wings and rotary blades. Such analyses form the

Materials Research Proceedings 69 (2026) 418-423 https://doi.org/10.21741/9781644904251-76

foundation for validating aerodynamic theories and for designing engineering solutions that improve safety, structural integrity and efficiency under various flight regimes. Experimental campaigns, notably those involving the ONERA M6 wing, have yielded comprehensive insights into transonic flow phenomena over swept wings and remain essential benchmarks for the validation of computational fluid dynamics (CFD) models [1–3].

Wind tunnel experimentation continues to serve as a cornerstone in aerodynamic performance assessment. However, confined test sections inherently introduce boundary effects and wall interference, which can distort flow characteristics and alter pressure distributions. Computational analysis has therefore become an essential complementary approach, offering the capability to resolve complex and unsteady flow structures with both flexibility and accuracy. Early numerical investigations on the NACA 0012 and S809 airfoils have demonstrated the strong influence of Reynolds number, reduced frequency, and pitch-axis position on vortex evolution, as well as on the corresponding lift and moment coefficients [4,5].

Dynamic stall represents a critical aerodynamic phenomenon in rotorcraft operation, arising when the angle of attack on the retreating blade exceeds the static stall threshold. This unsteady process induces the formation of leading-edge vortices that cause abrupt variations in lift, drag, and pitching moment, often resulting in significant vibration, structural loading, and potential aeroelastic instabilities. Extensive experimental and computational investigations have examined dynamic stall on pitching airfoils, finite wings, and rotating blades, emphasizing the combined influence of blade–vortex interactions, rotational acceleration, and three-dimensional flow development on the overall aerodynamic response.

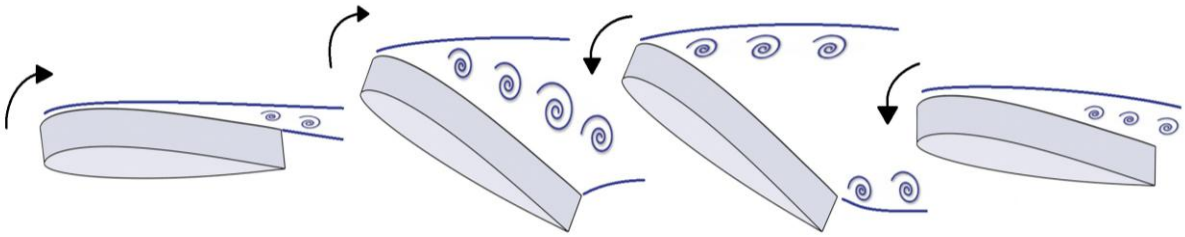

Fig. 1. Dynamic stall stages

The present work investigates the unsteady aerodynamics of three-dimensional morphing NACA 13112 airfoil sections representative of the IAR 330 PUMA main rotor. Wind-tunnel measurements were employed to validate the baseline geometry and establish the reliability of the numerical approach. Following this validation, CFD simulations were carried out to examine both pre-morphed and dynamically morphed configurations. The study focuses on how variations in flap-chord fraction and trailing-edge flap deflection influence lift and drag, with the broader aim of evaluating their effects on aerodynamic performance and dynamic stall behavior under rotor-relevant operating conditions.

Methodology

The baseline NACA 13112 geometry was generated in CATIA from discrete coordinate data. A 1:5-scale model derived from this geometry was CNC-machined for wind-tunnel testing and subsequently used to validate the steady-state CFD results, while the dynamic morphing geometries were likewise constructed in CATIA for the transient simulations.

Steady-State Analysis. To analyze the influence of grid topology on steady-state CFD accuracy, two unstructured mesh strategies were developed. The O-grid topology wraps the mesh concentrically around the airfoil, providing excellent orthogonality near the wall and facilitating accurate resolution of the viscous sublayer and boundary layer. In contrast, the C-grid topology

features an open downstream region that allows the mesh to extend naturally past the trailing edge, improving wake resolution and enabling more accurate capture of trailing-edge vortices.

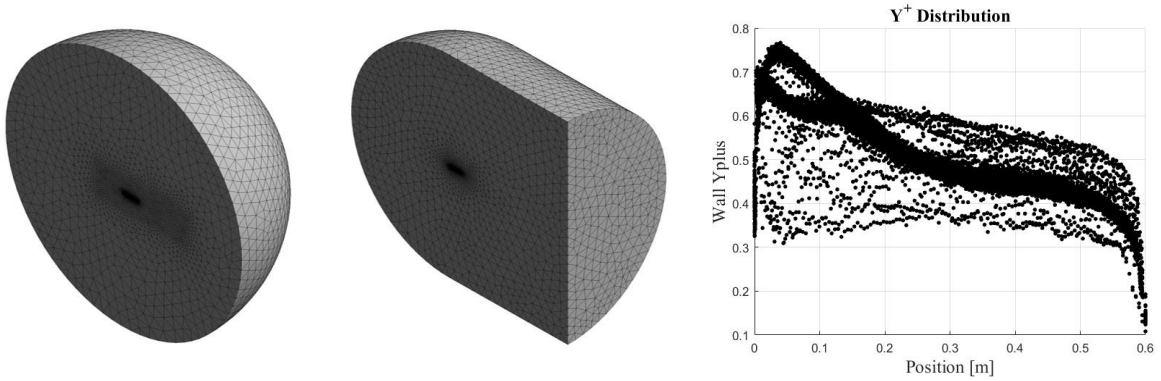

Fig. 2. Unstructured mesh with boundary-layer inflation corresponding to $y^+ \approx 1$, including C-grid and O-grid blocks around the airfoil.

The turbulence model adopted was the Spalart–Allmaras (S–A) one-equation model. Regarding physical models, compressibility effects were introduced using the ideal gas law, while viscosity variations were accounted for through Sutherland's law.

Dynamic Analysis. The mesh comprises a fully unstructured background grid combined with refined cylindrical sub-domains around the four blade sections. Each section includes multiple inflation layers to accurately resolve near-wall gradients and capture the unsteady boundary-layer behavior during dynamic pitching motion. This mesh strategy ensures numerical stability and sufficient spatial resolution for transient flow separation, dynamic stall development, and vortex convection.

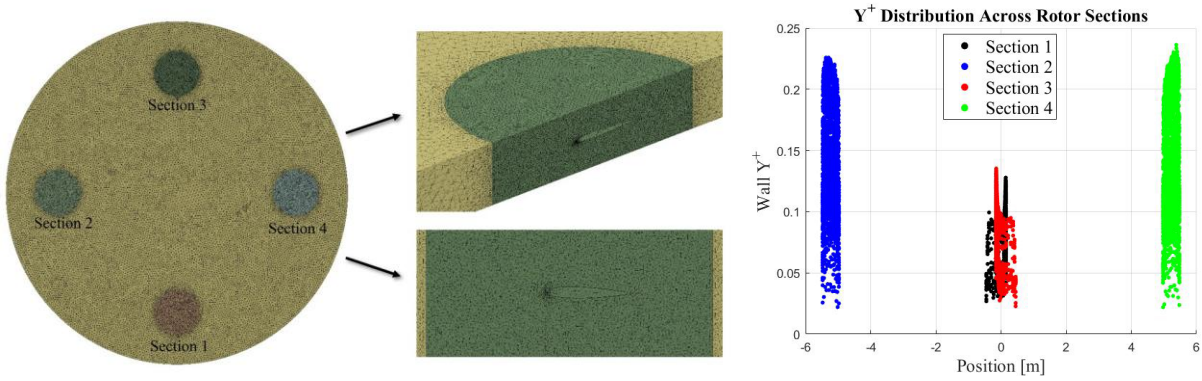

Fig. 3. Unstructured computational mesh with boundary-layer inflation corresponding to $y^+ \approx 1$ used in the transient CFD simulations.

A transient CFD analysis was conducted employing the SST k–ω turbulence model. Four airfoil sections, positioned at a radial distance of 4975 mm from the rotor hub, were examined under operating conditions corresponding to a rotor speed of 265 rpm. Each section featured a chord length of 600 mm and a span of 500 mm, matching the geometric characteristics used in the experimental model.

Materials Research Proceedings 69 (2026) 418-423 https://doi.org/10.21741/9781644904251-76

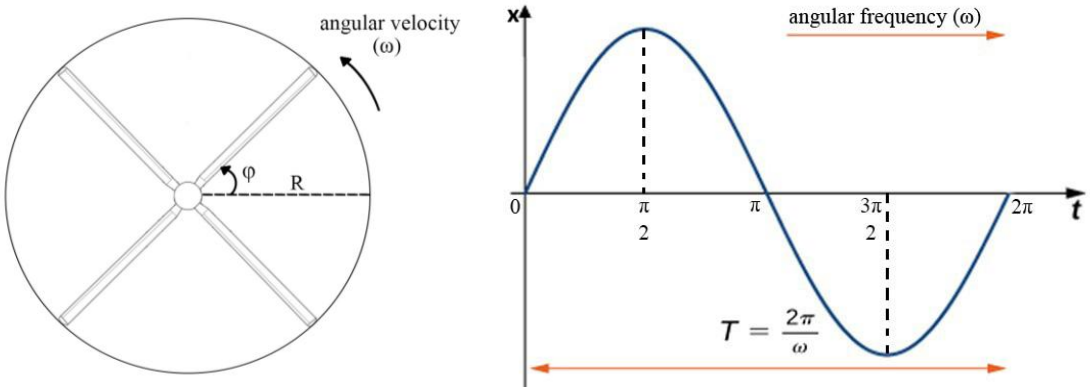

Fig. 4. Circular motion; Simple harmonic motion.

Results and discussion

Steady-State Results. The results indicate that the choice of grid topology has a significant influence on the prediction of lift and drag in the vicinity of stall. The C-grid mesh provides a smoother resolution of the suction-side flow curvature and consequently captures flow separation earlier, producing aerodynamic trends that align more closely with the experimental measurements, particularly in the post-stall regime. In contrast, the O-grid mesh, although accurate at low angles of attack, slightly underpredicts the drag increase and delays the onset of stall compared with both the C-grid results and the experimental data.

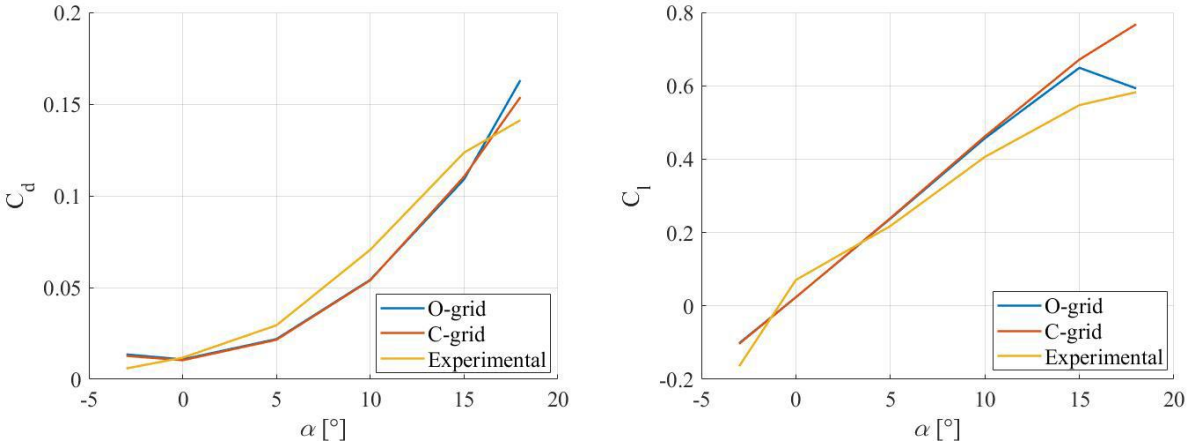

Fig. 5. Grid topology influence on aerodynamic coefficients with experimental validation.

The CFD results were validated against experimental data obtained from wind-tunnel tests conducted on the CNC-machined aluminum airfoil model. The comparison of aerodynamic coefficients showed a consistently good agreement between the numerical predictions and the measurements, confirming the reliability of the computational approach across the stall regime.

Dynamic Results. The transient CFD results in Fig. 6 illustrate the evolution of lift and drag during the first rotor revolution for the morphed airfoil sections subjected to different flap deflection angles β. The aerodynamic response exhibits periodic oscillations driven by the time-varying angle of attack and unsteady rotor-induced loading, with each section showing a distinct phase shift. The curves display key signatures of dynamic stall, including a delayed stall onset and pronounced overshoots in lift and drag as the leading-edge vortex develops and convects downstream. During the downstroke, the delayed load recovery generates the characteristic hysteresis loops in Cl and Cd, highlighting the strong unsteady aerodynamic effects acting on the morphing configurations.

Materials Research Proceedings 69 (2026) 418-423 https://doi.org/10.21741/9781644904251-76

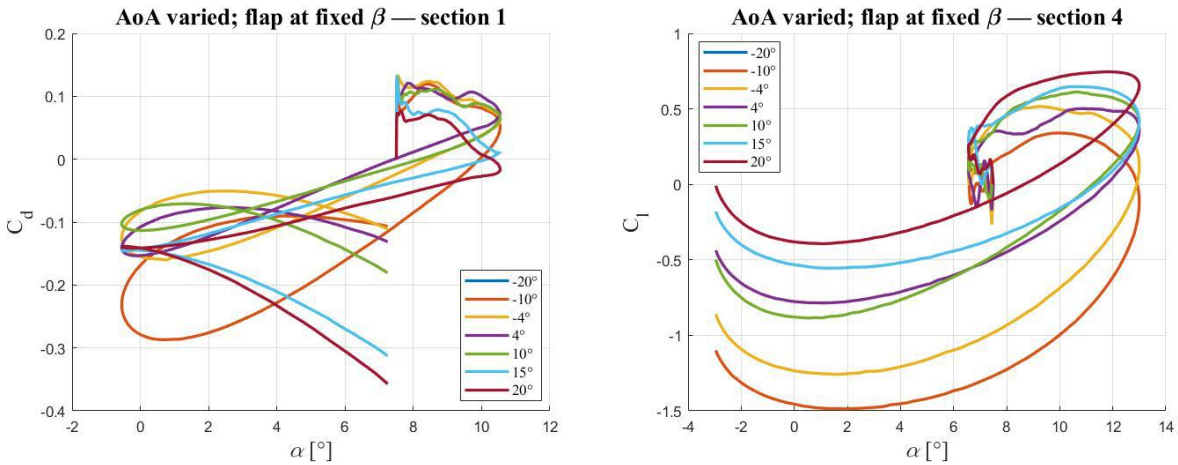

Fig. 6. Aerodynamic coefficients obtained during the first rotor revolution, highlighting the variation with angle of attack (α).

The aerodynamic loops obtained during the third rotor revolution exhibit increased distortion as the flap deflection β varies, reflecting stronger nonlinear behavior and enlarged hysteresis cycles. In this configuration, both the angle of attack and the flap motion vary sinusoidally, with the flap operating in antiphase relative to the airfoil pitching motion. Larger flap amplitudes amplify the peak aerodynamic loads and shift the stall onset, whereas smaller amplitudes produce tighter loops with smoother recovery. These trends underline the high sensitivity of the dynamic stall process to active trailing-edge morphing. As the rotor motion reaches a mature state, the signals show sharper oscillations and more pronounced extrema—particularly for higher β values—indicating the intensified unsteady vortex dynamics governing the flow.

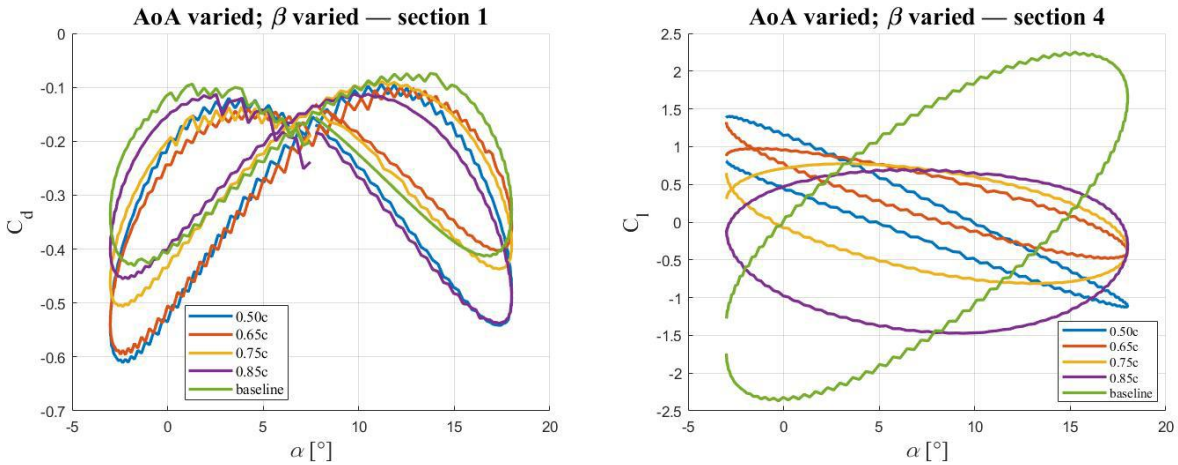

Fig. 7. Aerodynamic coefficients obtained during the third rotor revolution, highlighting the variation with angle of attack (α).

The time histories in Fig. 8 clearly reflect the sinusoidal kinematics imposed by the UDF, which become fully established by the third rotor revolution. The periodic variation of angle of attack and the antiphase flap motion produce smooth, repeatable oscillations in both lift and drag. Differences between flap-chord ratios are evident through the modulation of amplitude and waveform shape, showing how the imposed morphing law directly governs the temporal aerodynamic response.

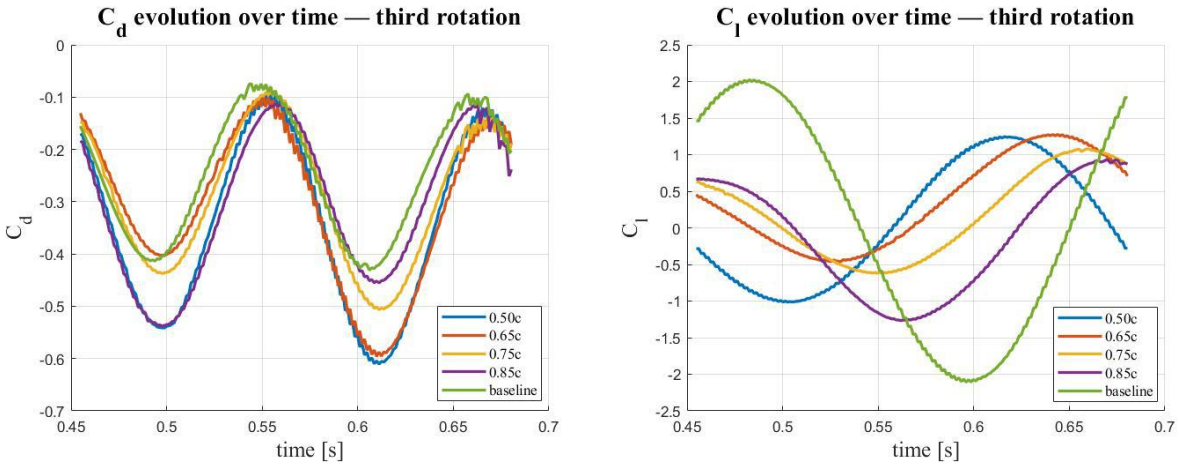

Fig. 8. Aerodynamic coefficients during the third rotor revolution: drag coefficient (Cd) for blade section 1 and lift coefficient (Cl) for blade section 4.

Conclusions

The CFD methodology showed good agreement with wind-tunnel measurements, confirming its capability to accurately predict the aerodynamic behavior of the NACA 13112 sections across pre-stall and post-stall regimes.

The sinusoidal pitch–flap kinematics imposed by the UDF, with the flap operating in antiphase to the airfoil, generated stable and repeatable unsteady responses by the third rotor rotation, clearly governing the temporal evolution of lift and drag.

Variations in flap-chord fraction and deflection angle β strongly influenced the dynamic stall characteristics, affecting stall onset, peak loads, and the extent of hysteresis across all sections.

Among the tested morphing configurations, the 0.75c flap-chord ratio yielded the highest lift-to-drag efficiency, particularly at mid-range angles of attack in the pre-stall regime.

The combined experimental and CFD investigations demonstrated a coherent and validated framework for assessing trailing-edge morphing on helicopter rotor blade sections, supporting its potential for enhancing rotorcraft aerodynamic performance.

A Survey of Advanced Air Mobility Use Cases and Implementation Challenges in Japan: A Systems Approach Perspective

Yusuke Mihara[1,a *]

[1]Shizuoka Institute of Science and Technology, Shizuoka, Japan

[a]mihara.yusuke@sist.ac.jp

Keywords: Advanced Air Mobility, System Design, Holistic Systems Approach, Use Case Analysis

Abstract. Advanced Air Mobility (AAM) is envisioned as a new form of aerial transportation designed to move people efficiently at low altitudes. The goal of AAM is to democratize access to air travel. Nevertheless, its realization depends not solely on vehicle technology but on a holistic systems approach that integrates vehicles, infrastructure, and operations. This paper discusses representative AAM use cases in Japan, focusing on air taxis and medical emergency transport, and identifies current issues toward establishing a holistic system design.

1. Introduction

Advanced Air Mobility (AAM) is envisioned as a new form of aerial mobility designed to transport people efficiently through the air [1]. Its key features include electrification, automation, and vertical take-off and landing (VTOL) capability [2]. The goal of AAM is to democratize air travel in lower altitudes. In Japan, AAM is referred to as "flying cars" due to its envisioned role in everyday transport and its potential market scale comparable to the automotive industry [3].

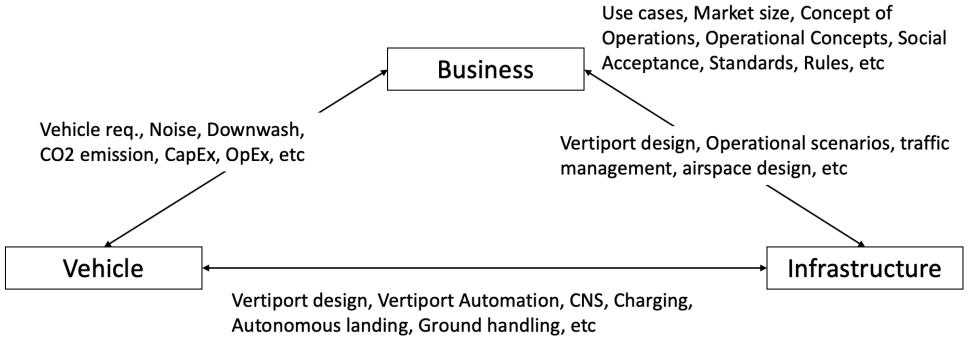

Fig.1. Socio-Technical System Design of AAM

Implementing AAM in society requires more than combining technologies such as batteries, automation, and sensors. It demands a holistic system design that includes vehicles, supporting infrastructure, and their operational use cases. Fig.1 shows that an AAM system is decomposed into vehicle, infrastructure, and business. The AAM system exhibits the interdependent relationships among Vehicle, Infrastructure, and Business in the AAM ecosystem, where each domain influences the others through technical, operational, and economic parameters such as requirements, design, operational concepts, and regulatory frameworks. Moreover, AAM must coexist with UAVs, VFR vehicles like helicopters, and IFR aircraft, making it a component within a larger system of systems (SoS). Thus, a systems approach is essential to understand and implement AAM effectively.

The AAM concept gained momentum following the 2016 Uber Elevate white paper [4], with most developments focused on realizing urban air taxis. A systems approach has been applied in

Content from this work may be used under the terms of the Creative Commons Attribution 3.0 license. Any further distribution of this work must maintain attribution to the author(s) and the title of the work, journal citation and DOI. Published under license by Materials Research Forum LLC.

Materials Research Proceedings 69 (2026) 425-430 https://doi.org/10.21741/9781644904251-77

the U.S. and Germany to evaluate the feasibility of UAM operational concepts [5,6,7]. However, these studies mainly target air taxi use cases.

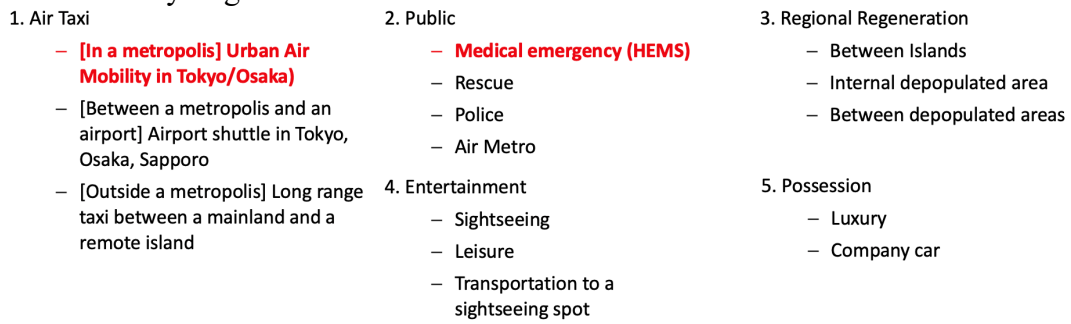

Fig.2. Potential AAM Use Cases (Applications) in Japan

This paper discusses air taxis and medical emergency application of representative AAM use cases, with the purpose of identifying conventional challenges. While AAM applications range from air taxis and rural mobility to public services and tourism, written in Fig. 2, this paper focuses on two representative cases: air taxi and medical emergency transport due to their high potential. Each case is analysed in terms of stakeholders, operational areas, routes, concepts of operation, and current transportation issues. A holistic framework is used to map use case challenges across technological, social, economic, and environmental dimensions.

2. Advanced Air Mobility

Although the term “Flying Car” is widely used in Japan, its definition can be interpreted from four perspectives, as shown in Fig.3 [3]. First, it refers to eVTOLs—the mainstream design type—but can also include hybrid or short takeoff and landing (STOL) models that fall outside this category [8]. Second, it can be defined from the purpose perspective—as an air mobility system enabling point-to-point transportation. However, Japan’s limited land area restricts the number of available takeoff and landing sites, necessitating the use of existing heliports or the construction of new vertiports. Third, it can describe roadable aircraft, combining both automotive and aeronautical functionalities, as seen in designs like PAL-V, Klein Vision, and Terrafugia. Yet, these models often rely on internal combustion engines and tend to be larger than eVTOLs, making them less dominant. Fourth, it can be framed as Urban Air Mobility (UAM), emphasizing the use case of air taxis in metropolitan areas. Nevertheless, the applications of AAM (or flying cars) are not limited to intra-urban air taxi services alone. In summary, AAM—often termed the “flying car” in Japan—can be broadly understood as an emerging form of air mobility that seeks to realize an aerial transportation economy operating within the low-altitude range of approximately 150 to 1,000 meters.

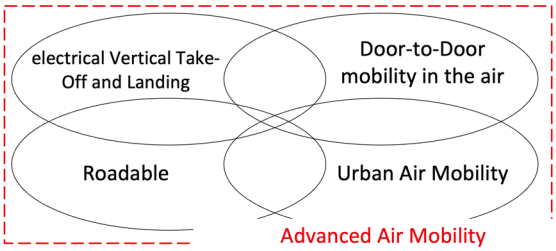

Fig. 3. A Definition of Advanced Air Mobility

3. Potential Use Cases

3.1 Air Taxi

Air taxi use cases can be classified into three categories. In the Uber Elevate White Paper, the feasibility of air taxi operations within Los Angeles was analyzed based on large-scale mobility

data [4]. Air taxis can be categorized into intra-urban, inter-urban, and extra-urban operations. This paper discusses only an intra-urban operation.

Within urban areas, existing transportation modes include trains, subways, buses, and conventional taxis. Indeed, in major metropolitan areas such as Tokyo, road congestion significantly affects travel time reliability. Most citizens rely on public transportation for commuting or daily travel, and long-distance, high-fare trips are relatively uncommon in such cities. In Tokyo, these typically occur only when individuals miss the last train at night. Analysis of operational data from Tokyo's taxi network indicates that trips costing over 5,000 yen and lasting more than 30 minutes account for approximately 7–12% of all rides [9]. Assuming that 3–5% of these customers switch to AAM, the estimated intra-Tokyo demand for air taxi services would be roughly 60–100 trips per day [4].

However, there are substantial challenges in establishing takeoff and landing sites in dense urban environments like Tokyo. Currently, there are only six public and private heliports within the city [10]. Japan's high-rise buildings, which maximize limited land by expanding office and residential spaces vertically, often include emergency landing pads or rescue areas [11]. Buildings exceeding 100 meters in height are required to allow helicopter landings during emergencies such as fires, while those between 31 and 100 meters are recommended to include hovering-based rescue spaces. Given the expected weight of AAM vehicles, such infrastructure may offer limited takeoff and landing potential [9]. Nonetheless, converting existing emergency heliports directly into operational vertiports would be challenging due to issues such as access routes, landing area dimensions, and approach angles. Any plan to enable AAM operations on rooftops would therefore require redevelopment projects that explicitly incorporate vertiport functionality from the design stage.

The size constraints of potential vertiports also influence aircraft configuration. For example, compact multi-rotor type designs such as EHang's coaxial-rotor systems are advantageous for small footprints but are limited in speed. In contrast, winged configurations—such as vectored-thrust or lift-plus-cruise types—achieve higher cruising speeds but require larger landing areas. Conventional helicopters remain costly both in terms of acquisition and operation [12]. While airworthiness certification is essential for ensuring safety, the economic feasibility of air taxi operations ultimately depends on reducing vehicle costs and improving battery performance.

Airspace design also presents critical challenges. Since March 2020, a new south-wind landing route for Tokyo International Airport (Haneda) has been in use, operating daily between 3 p.m. and 7 p.m. This route passes over central Saitama Prefecture (3,000–5,000 ft) and central Tokyo (3,000–4,500 ft) before reaching Haneda [13]. Consequently, the available airspace for urban flight operations has become more restricted. Furthermore, areas such as the Imperial Palace and the National Diet Building are politically sensitive and likely to be no-fly zones. The establishment of dedicated UAM corridors in the 150–1,000 m altitude range could enable AAM to operate within exclusive airspace. Nevertheless, with existing air traffic around Haneda's southbound route, any air taxi service must address not only safety but also aesthetic and privacy concerns. Building social consensus among AAM stakeholders and urban residents is thus indispensable.

3.2 Helicopter Emergency Medical Service (HEMS)

In Japan, a helicopter emergency medical service (HEMS), commonly known as the Doctor-Heli, has been in operation since 2001. The program was initiated in response to the lack of sufficient aerial medical transport capabilities revealed during the 1995 Great Hanshin-Awaji Earthquake. As of today, 57 aircraft operate across Japan's 47 prefectures, providing rapid transport of physicians to emergency scenes. Each helicopter is equipped with essential medical instruments and pharmaceuticals required for initial treatment. In 2022 alone, the Doctor-Heli system recorded 29,245 operational missions [14,15].

When an emergency occurs, the system is activated through a request from a local fire department command center following a 119 emergency call. A helicopter carrying both a flight physician and a flight nurse is dispatched from a base hospital. Simultaneously, local fire units transport the patient by ambulance to a designated rendezvous point, where the helicopter lands to either transfer medical staff or transport the patient directly to the hospital [14].

Public emergency ambulance services in Japan are free of charge, and the same applies to Doctor-Heli operations. However, each aircraft incurs an annual operational cost of approximately 250 million yen—including lease fees, pilot salaries, fuel, maintenance, and insurance. The average cost per sortie is estimated at 460,000 yen [14]. Due to these high operational expenses, the sustainability of the program is dependent on government subsidies, and its long-term viability remains uncertain.

Recently, discussions have emerged regarding the use of electric AAM (Advanced Air Mobility) vehicles as a complementary solution to Doctor-Heli operations. Strong requests from flight physicians, along with the public nature of the service, have facilitated social acceptance, especially regarding noise concerns. The primary objective of the Doctor-Heli is to minimize the time to first contact between medical staff and patients. In the initial stage of AAM implementation, a two-seat configuration—carrying a pilot and a physician—could be deployed, with patient transport handled by ground ambulances.

Operational data analyses indicate that compact, low-cost vehicles with a range of approximately 50 km and a maximum speed of 150 km/h are desirable [16]. Based on cost modeling from existing aircraft and operational cost structures, a fixed-wing configuration could achieve a unit cost around 100 million yen and a direct operating cost (DOC) of approximately 50,000 yen per flight hour [16]. However, these estimates assume economies of scale at a production level exceeding 100 units per year and the use of existing lithium-ion batteries; current market prices are several times higher. Thus, both battery performance improvement and reductions in capital (CapEx) and operating expenditures (OpEx) are essential for AAM to contribute effectively to the sustainability of HEMS operations.

Doctor-Heli helicopters typically meet patients at rendezvous points—designated open spaces such as riverbanks, parks, or school grounds. The MD902, a helicopter known for its low vibration, is commonly used for this purpose in Japan. With a maximum takeoff weight of approximately 2.8 tons, its relatively high disk loading produces considerable rotor downwash, generating dust and debris that can affect nearby residents [16]. Firefighters often spray water on the ground prior to landing to mitigate this effect. In contrast, a two-seat AAM vehicle would likely have a maximum takeoff weight below 2 tons, potentially improving social acceptability due to reduced downwash and noise [16]. In fact, Joby Aviation's demonstration flight planned for the 2025 Osaka Expo aims to showcase the quiet operation of electric eVTOLs, which emit no engine noise. Moreover, the required landing area is another critical issue. If AAMs can operate from smaller landing zones, the number of feasible rendezvous points will increase, reducing the time needed to reach patients. However, even compact eVTOLs—whether fixed-wing or multi-rotor configurations—are not necessarily smaller than helicopters. Among current designs, multi-rotor types such as EHang's coaxial-rotor eVTOL could potentially land in spaces as small as a supermarket or convenience store parking lot [17]. Such capability would substantially expand the network of accessible emergency landing sites, enhancing response time and system efficiency for future medical AAM operations.

4. Discussion

4.1 Use Case Challenges

Although AAM is often envisioned around the high-profile air taxi concept in megacities, focusing exclusively on dense metropolitan areas or congested airports may hinder near-term feasibility.

The development of AAM should therefore begin with simpler, regionally adaptable use cases where airspace and public acceptance barriers are lower—such as emergency medical services, logistics, or island and rural mobility. These applications can serve as testbeds for regulatory learning and operational validation.

4.2 Vehicle Challenges

From a technological perspective, three issues dominate AAM vehicle development. First, energy storage remains a major bottleneck. While lithium-ion batteries have enabled early eVTOL prototypes, their energy density is insufficient for longer missions. Even with anticipated progress in solid-state batteries, range and endurance remain uncertain, particularly under Japan's humid climate and safety regulations. Second, vehicle cost—both in acquisition (CapEx) and operation (OpEx)—must be significantly reduced to achieve business viability. Economies of scale will take time to emerge; therefore, lightweight materials, modular manufacturing, and shared-use business models are essential. Third, automation technologies such as autonomous or supervised takeoff and landing must mature to reduce pilot workload, minimize human error, and enable scalable operations. Safety certification of such autonomy functions will require new standards that balance aviation-grade reliability with automotive-level cost efficiency.

4.3 Infrastructure Challenges

Infrastructure constraints represent another major barrier to AAM implementation. First, airspace management must evolve from traditional VFR/IFR to include Digital Flight Rules (DFR) and defined low-altitude corridors that ensure safe coexistence with helicopters, drones, and conventional aircraft. Japan's complex airspace, particularly around Tokyo and Haneda Airport, already imposes strict altitude and routing limits that restrict UAM operations. Second, vertiport availability remains limited. Current heliports and emergency rooftop pads are insufficient for regular AAM use, as they lack proper approach paths, passenger access routes, and safety clearances. Future urban development must therefore incorporate vertiport-ready building designs. Third, social acceptance will depend on noise mitigation and visual integration with urban environments. Although electric propulsion reduces acoustic signatures, community-level engagement will be necessary to establish operational trust and regulatory approval.

5. Conclusion

This study examined two representative use cases of Advanced Air Mobility (AAM) in Japan through a systems approach perspective. The analysis demonstrated that AAM is not merely a new aviation technology but rather a system of systems that integrates vehicles, infrastructure, operations, regulations, and social acceptance in a highly interdependent manner.

For future research, a quantitative evaluation framework should be established that links the sequence of use case definition → technical specifications → adoption probability modeling → estimation of economic impacts. Such a systems-based framework would enable multi-dimensional assessment of AAM feasibility under regional conditions and support decision-making for both technology development and policy design.

Keywords: Fire Fighting, System Integration, Aircraft Capability Enhancing, Virtual Modelling, Computational Fluid Dynamics, Flight Testing Optimization

Abstract. The C-27J Fire Fighting program was born from the growing need in the fight against forest fires for a fixed-wing platform that is complementary to the Canadair fleet (CL-415) in a national and international context. It aims to create a firefighting version of the C-27J transport aircraft through the integration of an additional module and the related certification and industrialization, enhancing its multi-role capability. The work aims at presenting the modelling, simulation and testing activity performed in 2024 through the integration of a prototypical System on C-27J. The analytical approach developed and validated during this phase will be used to support the development of the first series unit of the System, where issues in terms of Centre of Gravity excursion will be more important because of the increase in payload.

Introduction

During 2024, the development activity related to the integration of a pressurized Fire Fighting System on the Leonardo C-27J® cargo aircraft in order to increase its multi-role capability was completed.

This activity consisted of the design, manufacturing and testing of a System suitable for market needs in terms of capabilities, performances and costs. System integration on C-27J did not require A/C modification (only control panel installation in central console and connections with A/C power supply are required).

The first chapter of this project (called POC = Proof Of Concept) regarded a feasibility phase, performed with a prototypical System, aimed at investigating the main aspects related to the integration of such a System on the C-27J and the verification of target performances. During this phase, particular attention and efforts have been devoted to the following aspects:

- Controllability and Handling Qualities (HQ) of the aircraft in the presence of the asymmetric thrust (up to 50 kN) generated by the System during the pressurized drop
- Verification of the aircraft's Centre of Gravity (CoG) under all operational conditions on the ground and in flight in the presence of the sloshing phenomena of the retardant fluid contained in the System tank (payload of 5500 liters).

Particular attention was paid to the verification of the CoG as preliminary assessments highlighted the risk of exceedance from the flight envelope due to the possible transfer of fluid from the discharge duct to the tank under intermediate fill conditions.

Materials Research Proceedings 69 (2026) 431-435 https://doi.org/10.21741/9781644904251-78

System Modelling

HQ and CoG aspects were predicted during the development phase through modelling and simulation:

- Geometric modelling of the fluid volume using CAD software "CATIA V5" for static centering analysis with respect to the aircraft Weight & Balance (W&B) envelope
- Study of sloshing phenomena and design solutions for their containment (baffles for fluid oscillations damping in the tank and check-valve between the discharge pipe and tank to inhibit pouring occurrence) through fluid dynamics simulations with CFD software "STAR CCM+" (see Fig. 1)
- Development of an algorithm in MATLAB Simulink for the Flight Engineering Simulator able to reproduce the behavior of the liquid in the tank.

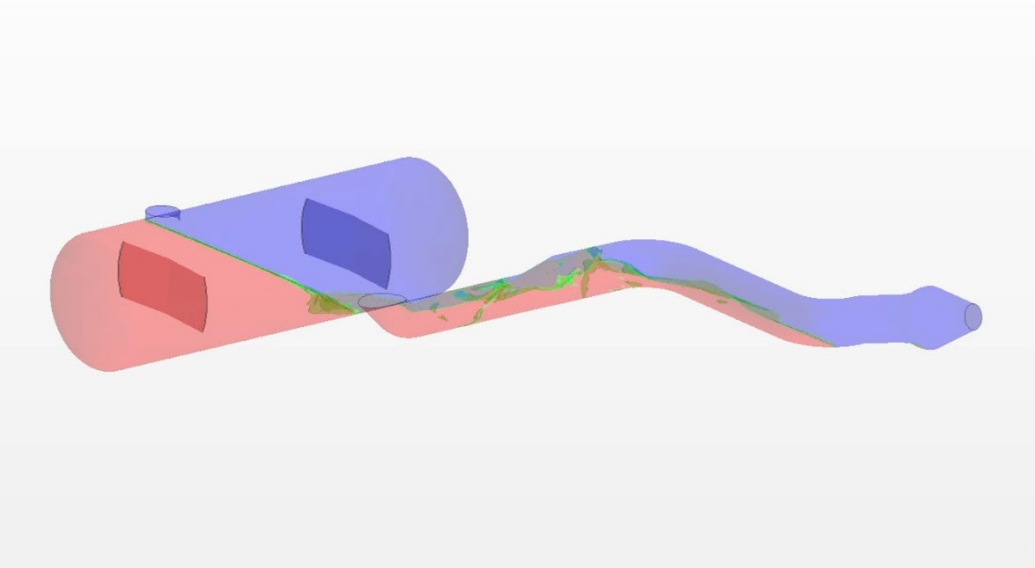

Figure 1: System at a representative instant during sloshing simulation

CFD simulations were carried out in order to reproduce the liquid transfer phenomena from the discharge pipe to the tank that static analyses are unable to capture. The results of these simulations were used to calibrate the constants of the pendulum equation on which the virtual digital model of the System is based:

$$m_{tank} \cdot \ddot{\theta} + c \cdot \dot{\theta} + k \cdot \theta = \frac{m_{tank} \cdot g}{l} \cdot \left(\frac{n_X}{n_Z} \cdot \cos\theta + \sin\theta \right) \quad (1)$$

Where:

- n_X, n_Y and n_Z are the load factors along X, Y and Z axis respectively (input parameters);
- $g = 9.81 \ \frac{m}{s^2}$ is the gravitational acceleration;
- m_{tank} indicate the liquid mass contained in the tank (output parameter);
- c, k and l are the damping, the stiffness and the length associated to the pendolum model;
- $\dot{\theta}$ and $\ddot{\theta}$ are respectively the angular speed and the acceleration of the apparent pitch angle $\theta = \tan^{-1}\left(\frac{n_X}{n_Z}\right)$ experienced by the aircraft.

Eq. 1 obtains the longitudinal CoG coordinate of the tank:

$$X_{tank} = l \cdot \cos\theta \quad (2)$$

Materials Research Proceedings 69 (2026) 431-435 https://doi.org/10.21741/9781644904251-78

The performed analyses allowed to:

- Discard the hypothesis of introducing a check-valve (which would have negatively affected System performance and aircraft safety)
- Support the clearance issuance and the Permit to Fly (PtF) request.

Next, an incremental approach was defined to safely perform the flight activity starting from a full-fill condition, validating the analysis results and progressively reducing the quantity through the following process:

1. Conduction of braking taxi tests up to the Rejected Take-Off (RTO) condition with tank in intermediate fill conditions for model validation
2. Execution of flight test with tank in full condition
3. CFD model validation using data acquired during the test like accelerations and tank liquid level measurements (see Fig. 2)
4. Prediction of the results of the next flight with reduced quantity in terms of dynamic behavior of the liquid and CoG displacement
5. Verification of absence of CoG exceedances with respect to the flight envelope
6. Repetition of steps 2-5 with progressively reduced quantities.

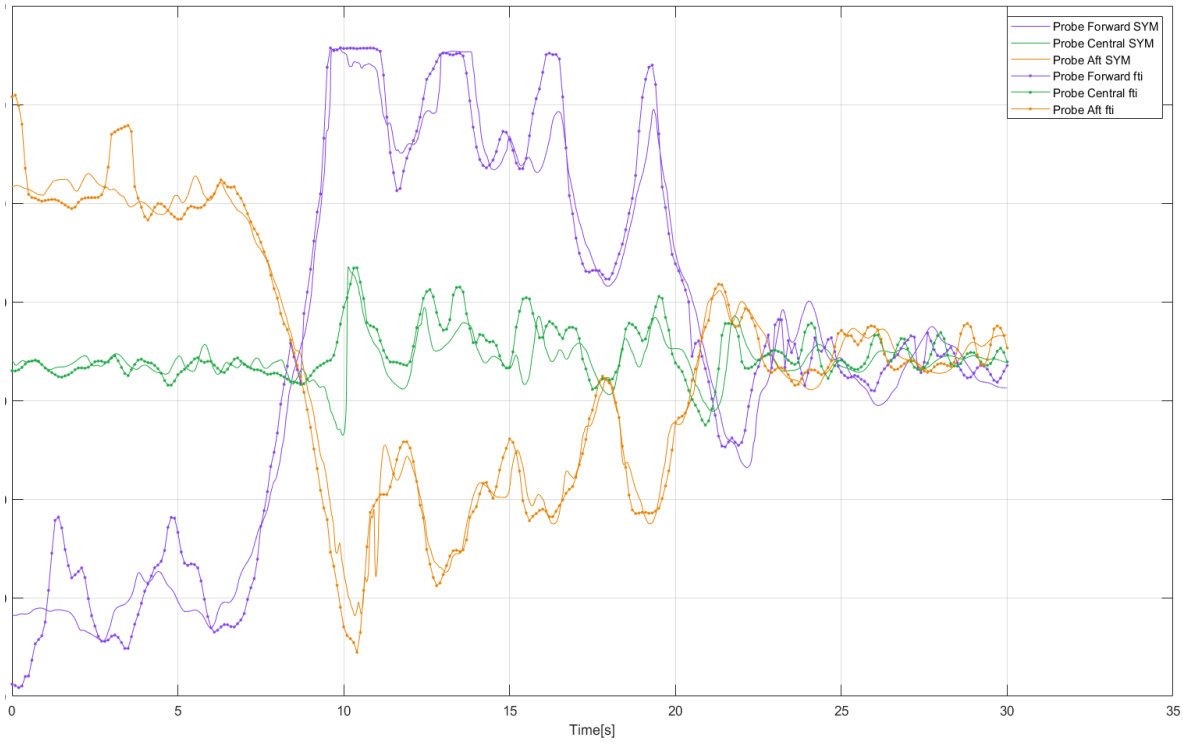

Figure 2: Comparison between measures of tank probes acquired during a test and results of CFD simulation

The results of the experimental campaign made it possible to remove the full tank limitation and validate the virtual model of the System, which demonstrated high reliability in predicting the dynamic behavior of the liquid and the performance of the System.

The analytical approach developed and validated during the PoC phase will be used to support the development of the first series unit of the System (called System Version 1 = SV1), where issues in terms of CoG will be more important as a result of the increase in payload up to 7500 liters.

Materials Research Proceedings 69 (2026) 431-435 https://doi.org/10.21741/9781644904251-78

Performance Measurement

From the performance point of view, it was verified during the testing phase by conducting ground and flight tests:

- Ground functional tests on the aircraft under all operational and emergency conditions
- In-flight functional tests with water and retardant under all operational and emergency conditions at a safe altitude
- Flight tests with water and retardant (see Figure 3) to measure performance in terms of Ground Pattern Coverage (GPC 1 = 1 gallon/100 squared feets) at 60-100 feets above the ground
- Flight testing by performing maneuvered drops under conditions similar to those experienced in an operational scenario based on what the Fire Fighting end-users reported during the demo campaigns.

Figure 3: C-27J Fire Fighter dropping retardant on the test range

System performance was measured using dedicated Flight Test Instrumentation (FTI) improving existing methods ([1], [2]). It consisted of 400 smart cups arranged to form a grid, of which they constitute the nodes, that maps the surface affected by the drop. The units are connected via radio to a master unit, which allows measurement management, data collection and system diagnostic. The master unit provides in output a coverage report with values expressed in GPC.

During this activity, it was necessary to demonstrate the achievement of GPC 6 performance, which guarantees the effectiveness of the Fire Fighting System against medium and heavy smash fires [3]. According to the criteria defined by the Interagency Airtanker Board [4], with a payload of 5500 liters the GPC 6 target is achieved when a minimum length of line of 140 ft is produced on ground. This result was successfully achieved and overcome during the experimental campaign (see Fig. 4).

Materials Research Proceedings 69 (2026) 431-435 https://doi.org/10.21741/9781644904251-78

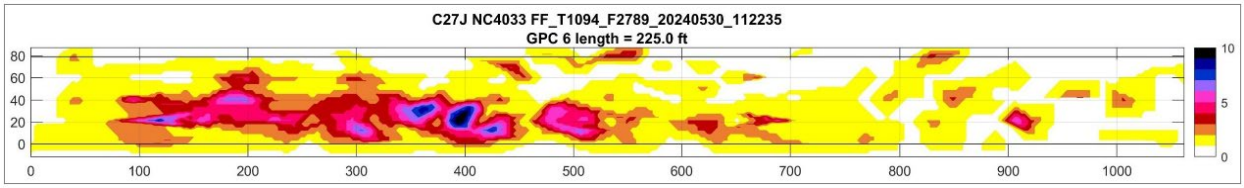

Figure 4: GPC footprint measured with dedicated FTI after a drop on test range (flight direction from right to left)

Conclusions and Next Steps

During 2024, the development activity related to the integration of a prototypical Fire Fighting System on C-27J in order to increase its multi-role capability was completed. HQ and CoG aspects were predicted through modelling and simulation. The virtual model of the System, calibrated with CFD simulations and implemented at the Flight Engineering Simulator, was validated via flight tests and allowed to gradually remove liquid filling limitation. In addition, System performance was successfully verified, using dedicated FTI improving existing methods. The analytical approach developed and validated during this phase will be used to support the development of the first series unit of the System, where issues in terms of CoG excursion will be more important because of the increase in payload.

Keywords: Multidisciplinary Design Optimization (MDO), Plug and Play Architecture, Design of Experiments (DOE), Initial Design Point (IDP), Radar Cross Section (RCS)

Abstract. An automated Multidisciplinary Design Optimization (MDO) process has been developed to support the conceptual design of uncrewed combat aircraft. This methodology integrates low-fidelity simulations to enable fast design space exploration, facilitating informed trade-offs between key engineering disciplines such as aerodynamics, weight estimation, and propulsion. It was chosen as the validation exercise a typical aircraft configuration for Loyal Wingman class, also in view to explore the design space of baseline configuration reflecting platform as Kratos XQ-58A, Boeing MQ-28, and others, Among the investigated layouts, the V-tail merged as a promising layout, offering maneuverability, scalable payload capacity, and low radar observability.The process architecture foresees to start with the parametric CAD modeling of a conceptual configuration (e.g., V-tail). Geometry is automatically generated through scripting based on modifiable input variables, ensuring real-time synchronization with analytical modules. This tight integration allows for continuous geometry control and significantly reduces iteration time. The overall architecture is modular: each block (aerodynamics, weights, propulsion, etc.) is independent and replaceable, allowing seamless updates or substitutions without disrupting the full system. The workflow can incorporate commercial tools, open-source software, or in-house developments. A key advantage lies in the system's ability to perform multi-objective optimization via automated Design of Experiments (DoE). Results are evaluated using performance indicators (KPIs), enabling the identification of an optimized baseline configuration consistent with project constraints. Compared to traditional approaches, this solution offers: wide design space exploration in short timeframes, minimal computational requirements (workstation-executable), immediate readiness for configurational multi-objective trade-off analysis and sensitivity mapping. The workflow is structured to feed into high-fidelity design phases, ensuring continuity between conceptual and preliminary design while reducing data loss and transition time.

1. Introduction

The current aerospace landscape is witnessing a paradigmatic shift toward unmanned combat aircraft as autonomous systems capable of operating in high-threat environments. This transformation requires innovative design methodologies that can rapidly explore vast design spaces to identify the most performing configurations that comply with customer goals. The V-tail configuration has emerged as a particularly promising architecture, offering several distinctive advantages: examples include avionics and armament payload capacity (internal and external), and a predisposition to medium-high maneuverability with a two surfaces only as empennages. This aspect introduces benefits also from the low observability standpoint: V-tail configurations present canted flat surfaces, contributing to radar cross section reduction across the waterline when appropriately optimized.

Materials Research Proceedings 69 (2026) 436-441 https://doi.org/10.21741/9781644904251-79

This work presents a comprehensive multidisciplinary workflow specifically adapted for conceptual design, incorporating a modular architecture that enables plug-and-play integration of multidisciplinary analysis modules. The framework is based on the necessity of rapid design space exploration, integration of stealth considerations from conceptual phases, and transition from low-fidelity conceptual models to high-fidelity detailed analyses.

2. Methodology and Architecture of the Workflow

2.1 Adaptation of the Low-Fidelity Workflow for Specific Configurations

The developed process begins with the reconstruction of a conceptual model geometry, which serves as a baseline. This geometry is then parametrized using a set of geometric relationships that define each aircraft component (e.g., fuselage, wing, V-tail) based on a set of input variables. These formulas automatically update the geometry whenever parameters are modified. This approach ensures that the parameters of each design are immediately available to the analytical and numerical modules within the workflow, which directly derive the inputs generated by the parametric script.

Therefore, the model geometry automatically updates based on changes in design parameters. The availability of a framework with seamless integration of typical Preliminary Design models reduces iteration times and improves design flexibility.

2.2 Plug-and-Play Modular Architecture with RCS Integration

A distinctive feature of the proposed workflow resides in its plug-and-play modular architecture, conceived to enable rapid reconfiguration of disciplinary blocks without compromising the overall process integrity. The baseline chain can be modified through standardized input-output interfaces. Each block is interchangeable, allowing adaptation of the process fidelity level according to design requirements. A typical workflow in shown in *Figure 1*.

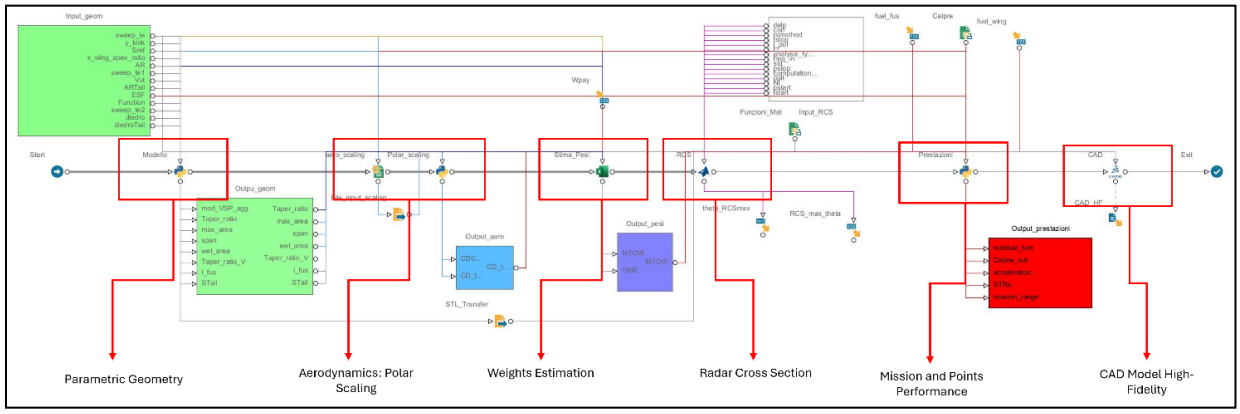

Figure 1 Multidisciplinary Workflow to Define a Design Envelope

For example, the aerodynamic block based on parametric scaling of baseline performance can be replaced with a VLM or panel method (*VSPAERO* or *FlightStream*), directly calculating the characteristics of each geometry instead of relying on a baseline scaled according to handbook methods.

The innovation of this integrated process does not reside in the individual solvers employed, but in the possibility of increasing or reducing fidelity on demand. By defining a priori the necessary inputs and outputs of each module (coherent variable names, uniform units of measurement, shared reference systems), it is possible to integrate new software into the workflow without having to redesign the global architecture. The algorithm is prone to reuse and scalability to different aircraft classes, following appropriate geometry parametrization.

Materials Research Proceedings 69 (2026) 436-441 https://doi.org/10.21741/9781644904251-79

The integration of RCS as a native discipline further expands the capabilities of conceptual design. Unlike traditional workflows, where stealth considerations are often deferred to subsequent phases with consequent design compromises, in this case RCS is treated as an interchangeable module. Based on the design stage, it can be evaluated with rapid physical-optics tools (e.g., *PoFACETS*) or with high-fidelity commercial codes.

2.3 Geometric Continuity from Low to High Fidelity

An aspect of the developed framework is the implementation of a parametric bridge to the *CATIA* CAD environment, which ensures geometric continuity from low-fidelity conceptual models to high-fidelity detailed design phases.

The CAD model in *CATIA* is parametrized upstream without resorting to scripts, but rather by applying the same parameter definition methodology used in the low-fidelity *OpenVSP* model. In this way, variables such as reference surface, aspect ratio, leading edge sweep, or tail configurations are defined in a coherent and unambiguous manner, ensuring alignment between geometries of different fidelity.

This bridge proves particularly useful in two cases:

- when it is desired to rapidly verify a design point already identified in the conceptual phase, transferring it without manual reconstructions toward the high-fidelity domain.
- when it is desired to integrate processes of different fidelity, for example using the parametric CAD geometry as input for commercial asymptotic RCS analysis codes, to evaluate low observability at low frequencies with greater accuracy.

In this way, the entire flow allows seamless transition from rapid conceptual generation to detailed engineering validation (CFD, FEM, RCS), maintaining geometric coherence, parameter traceability, and drastically reducing times and risks of manual reconstruction.

3. Loyal Wingman V-Tail Case Study

The developed workflow was applied to a Loyal Wingman case study with a V-tail configuration (as shown in *Figure 2*) for rapid definition of the design envelope.

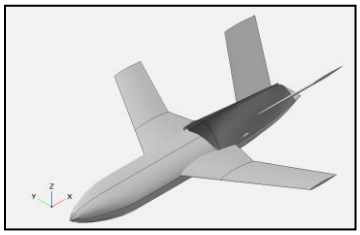

Figure 2 OpenVSP model of the Loyal Wingman

3.1 Process Timeline and Phases

One of the primary strengths of the developed process lies in its time efficiency, enabling complete execution on a single workstation. This is possible because the low-fidelity modules do not require extensive computational resources. The time constraint is critical during conceptual phases, where fast turnaround times are key factors for rapid iterations with stakeholders and support requirement definition. The algorithm employed by the workflow is outlined below:

- Parametrization and Input Preparation: this phase begins with a OpenVSP model configuration representing the conceptual layout (V-tail, flying wing, etc.), in which the geometric configuration (wing, fuselage, tail) is parametrized and the baseline reference datasets (aerodynamics, propulsion, weight) are established.
- DOE Generation and Initial Design Space Exploration: after completing the parametric definition, a Design of Experiments (DOE) is automatically generated based on

Materials Research Proceedings 69 (2026) 436-441 https://doi.org/10.21741/9781644904251-79

predefined criteria (e.g., Uniform Latin Hypercube, Full Factorial, etc.). Each DOE point is processed through the computational chain, yielding key performance indicators (KPIs).

- Design Space Evaluation with Performance Constraints for Design Zone Definition.

The IDP definition workflow including preparation typically requires two weeks. In the Loyal Wingman case *OpenVSP* model development takes 3 days, parameterization 2 days, dataset assembly 2 days and initial data analysis with baseline verification 7 days, followed by a full factorial DOE of at least 100 designs to secure design-zone accuracy.

These durations assume an existing parametric CATIA model which yields a forty-percent reduction in total timeline compared to development from scratch, since geometric logic and formulas are already available. The process duration remains largely invariant across aircraft configurations because low-fidelity methods rely on statistical and analytical techniques rather than iterative solvers; only the drag-polar extent varies for supersonic cruise, which demands a greater computation time.

3.2 Results

The design space exploration was conducted through a Design of Experiments (DOE) employing a full-factorial algorithm for the geometric input parameters that most significantly influence point performance. Two key variables were identified: the reference wing area, varied within a range of –30% to +40% relative to the baseline, and the Engine Scale Factor (ESF), varied by ±20%. The results are visualized in *Figure 3* using contours on thrust to weight ratio and wing loading graphs. The point performance metrics evaluated for this aircraft are mission range, sustained turn ratio, and ceiling.

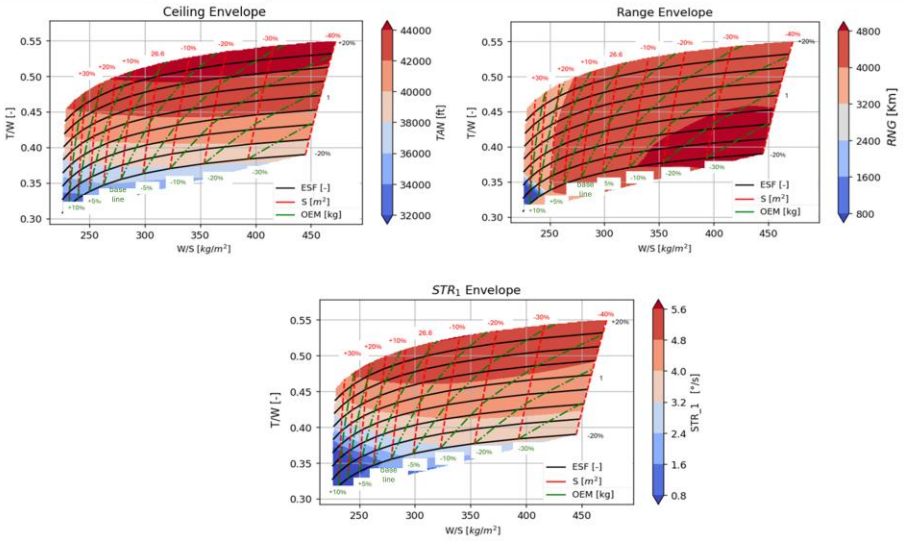

Figure 3 Point performance contours in correlation with input variables

Each design envelope represents a specific aircraft performance contour. Varying the wing area and ESF values allows visualization of trade-offs among different performance metrics. For example, a higher ESF improves sustained turn ratio and turn ceiling but penalizes mission range due to increased engine fuel consumption and weight penalty. *Figure 4* illustrates the radar cross-section analysis results. The employed methodology yields robust insights into shaping behavior trends, supplying critical guidance for directing design choices toward geometries that optimize stealth performance.

Materials Research Proceedings 69 (2026) 436-441 https://doi.org/10.21741/9781644904251-79

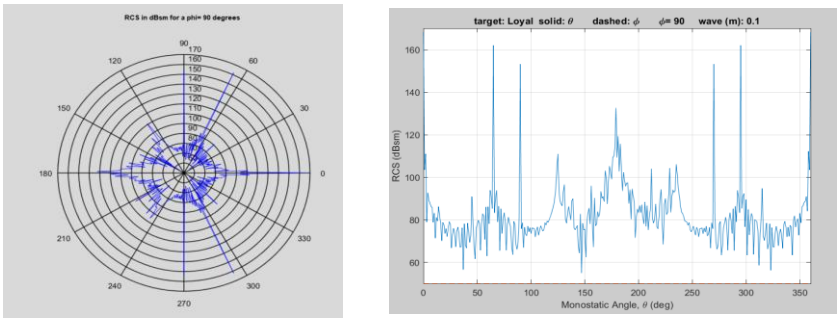

Figure 4 RCS signal of one of the generated DOE points.

Finally, the analysis identifies a design zone, shown in green in Figure 55, that satisfies all constraints. This zone therefore constitutes the design space in which ceiling, range, and sustained turn ratio meet or exceed baseline values, and RCS does not exceed the baseline maximum.

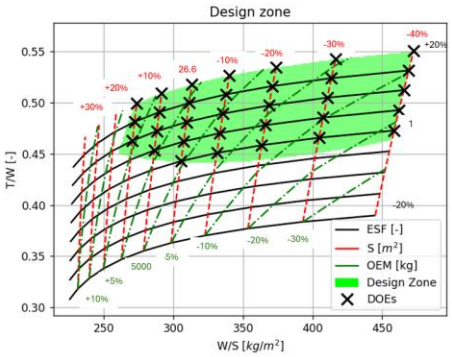

Figure 5 Final design region with overlay of data points generated through Design of Experiments (DOE)

4. Conclusion

The automated workflow represents a conceptual design methodology, addressing key challenges in defining the design space. The integration of a plug-and-play modular architecture with RCS analysis and CAD integration enables rapid exploration of the design space. The introduction of:

- A modular architecture of interchangeable blocks that clearly separates interfaces and methods, allowing rapid substitution.
- Parametric integration of preliminary RCS evaluation already from the conceptual phases, eliminating traditional discontinuities between aerodynamic design and stealth considerations. The main purpose of this assessment is to understand the criticalities of the geometrical configuration, rather than the absolute value of RCS (which would require more in-depth definitions of local geometries, like steps and gaps, and the application of RAM materials and coatings).
- A methodological bridge between low and high fidelity via CAD integration, which removes geometric inconsistencies and reduces validation times between different analysis methods for each discipline.
- A process for defining the design envelope within two weeks.

The workflow establishes a foundation for integrated design methodologies, providing the aerospace industry the tools required to address increasingly complex design challenges. The primary value lies not in the single final configuration, but in the ability to generate a design

envelope rapidly while maintaining continuity toward advanced simulations, and ensuring traceability, reusability, and accuracy throughout the entire development process.

Keywords: Environmental Performance Improvement, Roadmaps, Aircraft Technologies, Aircraft Concepts

Abstract. A systematic review of the most promising technologies and aircraft concepts for reaching climate-neutral aviation is presented, based on a technology scouting for classification and benchmarking of their environmental performance. In a first step, a heuristic approach is used to analyse existing technology roadmaps on reducing environmental impact. The main levers commonly identified are technology advancements, operational measures, sustainable aviation fuel and demand management. The aircraft technologies from the aviation roadmaps are classified in a technology taxonomy in the categories aerodynamics, structural, systems and propulsion technologies and the entry-into-service is visualised in technology roadmaps. In a second step, an overview and categorisation of recent developments in advanced and disruptive (regional, short/medium and long-range) aircraft concepts is compiled. Environmental performance improvements can reach up to 40-50% (kerosene fuel burn and CO_2) and 70% (NO_X) compared to older reference aircraft, with reductions dependent on reference aircraft age. Hydrogen combustion offers zero CO_2 while hydrogen fuel cells offer zero CO_2 and NO_X emissions. Different architectures are used for various ranges: Blended wing body and tube and wing (long-range), tube and wing (regional), and box-wing, double-bubble, strut-braced wing and tube and wing (short/medium range). While it is not possible to attribute a single reduction potential to a single technology feature, the most promising fuels are kerosene (conventionally, or in combination with batteries or fuel cells), sustainable aviation fuel and hydrogen. From the propulsion concepts, innovative turbofans (e.g. ultra-high bypass ratio turbofans) and innovative engines (e.g. hybrid-electric fans) had large improvements. In the field of aerodynamics, most applied technologies are high aspect ratio wings, riblets and laminar flow control, furthermore most concepts applied composite materials. For some aircraft concepts the climate impact was measured using climate metrics like ATR100 or GWP100, revealing trade-offs between fuel burn and climate impact or NO_X emissions.

Introduction

The aviation sector moves towards climate neutral aviation, with the goal of reaching Net Zero CO_2 emissions in 2050 [1, 2, 3]. Therefore, technological advancements are needed to reduce fuel burn and the resulting emissions. In Europe, Clean Aviation will contribute to Europe's climate neutrality by developing and implementing aircraft new technologies [4]. The concepts of a hybrid electric regional aircraft and short/medium range aircraft, both with a tube and wing architecture, have the overall target of a 30% CO_2 emission reduction compared to an aircraft with 2020 state-

Materials Research Proceedings 69 (2026) 442-447 https://doi.org/10.21741/9781644904251-80

of-the-art technology. A hydrogen-powered aircraft, either with H_2 direct combustion or a fuel cell-powertrain, would lead to 100% in-flight CO_2 reductions. The objective of the Clean Aviation project CLAIM is to translate these goals into tangible (climate) metrics and recommend an assessment methodology. As an input for a performance assessment of Clean Aviation-like aircraft concepts, a technology scouting has been performed to classify and benchmark technologies and aircraft concepts in terms of environmental performance, providing guidance for future research and deployment efforts.

In this paper the most promising aircraft technologies for emission savings are investigated by reviewing recent technology roadmaps [5]. Additionally, it compares the potential of sized aircraft concepts with different architectures and utilised technologies on an aircraft basis and linking the improvement potential to the utilised technologies [6].

Methods

A literature research was conducted to identify key trends and developments in aircraft technologies. The scouting of technology roadmaps comprised roadmaps, aviation strategies, pathways and projections from international authorities, government agencies and (non-) governmental associations. The roadmaps[1] and the mentioned technologies are classified along a defined taxonomy, to enable a fast analysis and comparison. The categories are: aerodynamics, propulsion, systems, structural, architecture/concepts, air traffic management (ATM) and (Aero) Acoustics. Information is collected on the entry-into service, interdependencies, technology readiness level (TRL), market segment, estimated market penetration and considered benefits. The results are saved in a technology database which enables the analysis and comparison of the different technologies, the identification of more progressive and conservative sources, key technologies and technology groups.

In a second step, a structured literature review on advanced and disruptive aircraft concepts was performed, considering research programs, research papers and commercial developments.

For an aircraft concept to be included in this assessment, its environmental performance must be defined relative to a reference aircraft. This can be determined through indicators such as fuel burn reduction, CO_2 or NO_X emissions, or an overall climate impact evaluated using dedicated climate metrics. The concepts were then categorised by study context, aircraft class, aircraft architecture, fuel/energy source, propulsion concept, aerodynamic concepts, and structural concepts. The collected data was analysed to provide insights into the potential environmental improvement of these advanced and disruptive aircraft concepts.

Results

All roadmaps recognise current challenges in aviation with the overall goal to decouple future growth from emissions and their resulting climate effects. The main levers are technology advancements, consisting of fuel efficiency increase and a shift towards zero carbon technologies, operational measures, SAF deployment and demand management. Without economic measures, net zero CO_2 emissions will not be reached within the sector by 2050. Non-CO_2 emissions are mostly only incorporated as a future goal and more mitigation measures are needed to reach net zero climate impact of aviation.

Through an in-depth analysis of the technologies, a database of 117 technologies, architectures, and concepts was established. Some technologies are specific to individual market segments, while others can be applied across multiple aircraft types. The technology references (if given) also vary from technologies from the year 2000 and technologies about to enter service or currently in service. Generally, there is an agreement on which type of future aircraft concepts are needed, however the expected entry-into-service (EIS) date varies:

- Sub-regional zero-carbon electric aircraft (EIS 2029-2030)

[1] The list of investigated roadmaps can be found in the CLAIM D3.1 report [5].

Materials Research Proceedings 69 (2026) 442-447 https://doi.org/10.21741/9781644904251-80

- Regional aircraft (hybrid electric EIS 2029-2040 or zero-carbon EIS 2036-2040)
- Narrow body aircraft (ultra-efficient EIS 2033-2040 or zero-carbon EIS 2042-2050)
- Wide body aircraft (ultra-efficient EIS 2042-2050 or zero-carbon EIS 2050)

The key technology groups are hybridisation and electrification, sustainable aviation fuel (SAF) upscaling, (liquid) hydrogen aircraft enabling technologies (direct combustion, fuel cell propulsion), ATM and operational technologies, and knowledge and research needs (especially for non-CO_2, fuel characteristics and operations).

Along with the most frequently mentioned technologies, technology roadmaps were developed. An example[2] for the group 'Propulsion Technologies' is given in Figure 1, where the new technologies are matched with the future aircraft type that they could be deployed on and an estimation of the entry-into-service (EIS) is given.

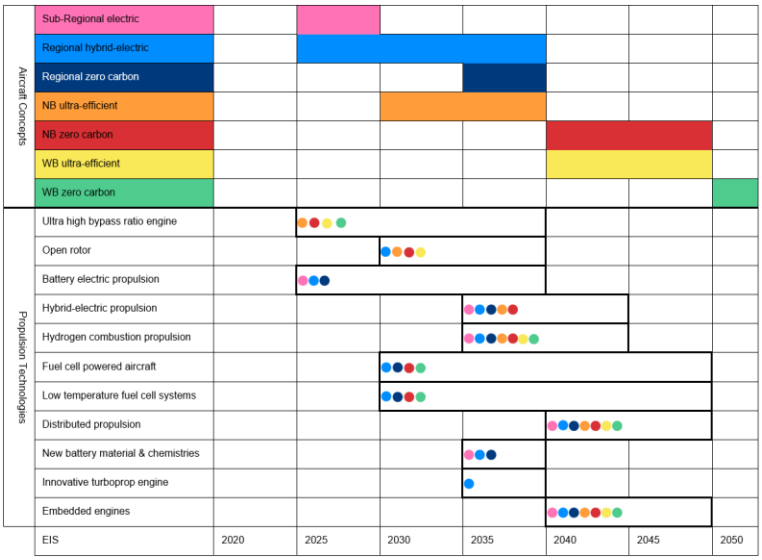

Figure 1: Roadmap for propulsion technologies

In the second step, 161 disruptive or advanced aircraft concepts[3] were found and analysed with respect to climate impact parameters fuel burn, CO_2 emissions, NO_X emissions and other climate metrics. The reported kerosine fuel burn reductions were up to 40-50% compared to traditional reference aircraft (EIS before 2015). Smaller gains were observed compared to state-of-the-art reference aircraft (EIS between 2015 and 2025), and even smaller gains compared to future reference aircraft (EIS after 2025). This is due to the fact that the more recent or future reference aircraft already include technology advancements with the connected benefits in fuel burn reductions. For some aircraft concepts, the fuel burn even slightly increases which stems from a trade-off with other climate effects.

The overview of CO_2 emission reductions in Figure 2 looks similar as the kerosene fuel burn reductions, because for aircraft concepts that only use kerosene or SAF[4] (and potentially batteries) as fuel, the reduction of kerosene fuel burn equals the reduction of CO_2. However, hydrogen aircraft stand out, as they lead to a 100% CO_2 reduction potential.

[2] More roadmaps for aerodynamic, system, structural and ATM technologies can be found in the CLAIM D3.1 report [5].
[3] The list of investigated aircraft concepts can be found in Appendix B of the CLAIM D3.2 report [6].
[4] Tank-to-wake emissions of SAF are taken into account, not considering well-to-tank CO_2 reductions and a possibly higher energy content of SAF.

Materials Research Proceedings 69 (2026) 442-447 https://doi.org/10.21741/9781644904251-80

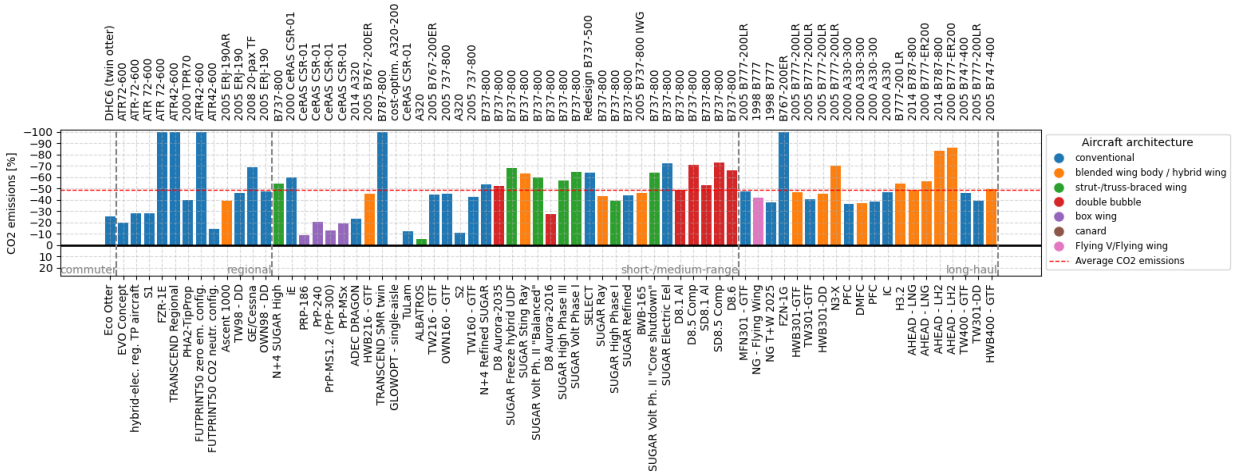

Figure 2: CO_2 emissions compared to traditional reference aircraft (EIS before 2015)

For NO_X emissions, reductions up to 70-80% were found compared to traditional reference aircraft (EIS before 2015). A plausible explanation for the high reduction values is that the NO_X reductions were a specific target for a subset of the investigated aircraft concepts. A few concepts lead to higher NO_X emissions due to trade-offs with CO_2 emissions.

It is hard to attribute general emission reductions to specific aircraft technology features and architectures. Some concepts apply only one or a few new technologies while other concepts have the intention to include a large number of technologies that are realistic for a future EIS. The aircraft concepts with several technologies are conceptualised to explore the possibilities of environmental impact reduction or to assess the integration and interaction of the different technologies. The relationship between the aircraft architecture and kerosene fuel burn reduction potential is complex, as multiple factors have an influence, such as energy carrier, aerodynamics, propulsion and structural advanced technology. From the overview, e.g. in Figure 2, it is not possible to identify one specific aircraft architecture that clearly leads to higher environmental performance improvements. One can observe that the blended wing body aircraft architecture and tube and wing architecture are mostly used for long-range aircraft and that commuter and regional aircraft mostly use a tube and wing architecture. For short/medium range aircraft more different aircraft architectures are explored such as tube-and-wing, box-wing, double-bubble or strut-braced wing aircraft architectures.

To identify promising technologies heat maps are used, an example is given in Figure 3. The heat map shows which technologies are utilised on which aircraft concepts and in which combinations the technologies are deployed. The metric, either kerosene fuel burn, CO_2 emissions or NO_X emissions, is visualised in a colour scheme, which is identical for each concept(/row), as it is not possible to attribute a single reduction potential to a single technology feature.

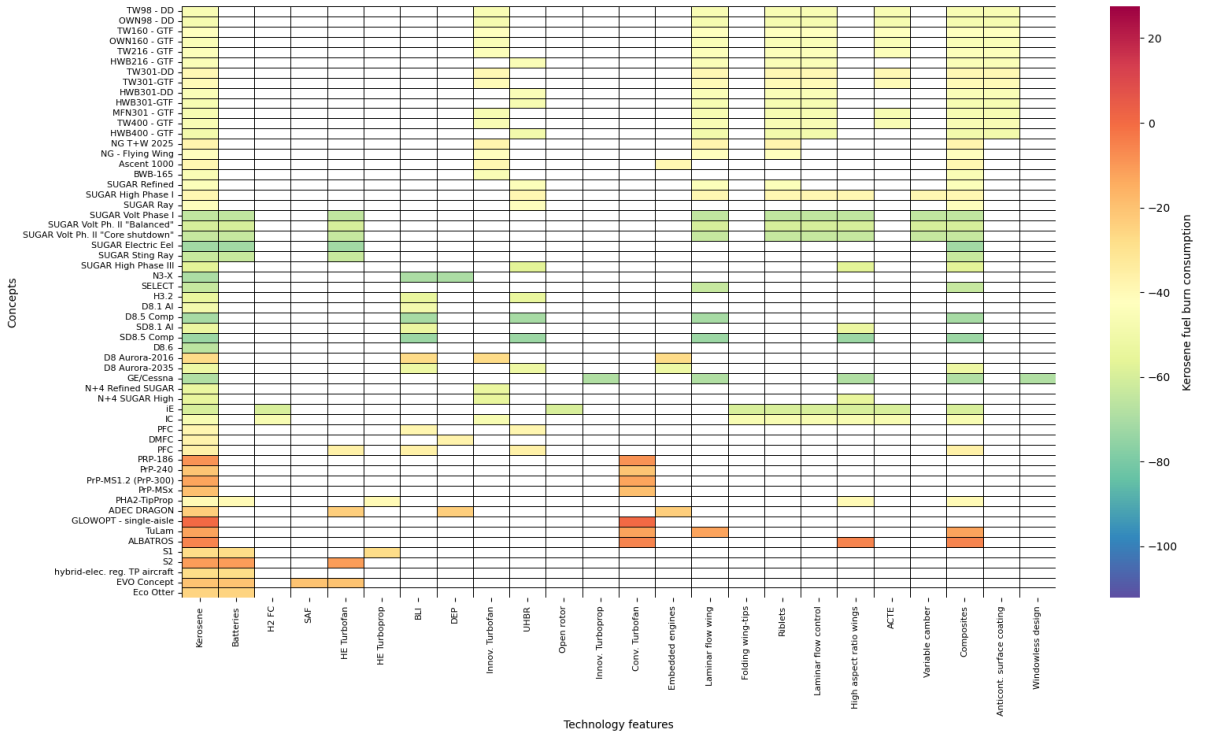

Figure 3: Heat map of the effect of technology features on fuel burn consumption compared to traditional reference aircraft (EIS before 2015)

The most promising fuels include sustainable aviation fuel (SAF) and hydrogen, while even kerosene-powered aircraft (either conventionally, or in combination with batteries or fuel cells) showed significant performance improvements. From the propulsion concepts, innovative turbofans (such as ultra-high bypass ratio turbofans), innovative engines (e.g. hybrid-electric fans) and to a certain extend the aero-propulsive concept of boundary-layer ingestion (BLI) had large improvements. For regional concepts, the hybrid electric powertrain enables distributed electric propulsion. In the field of aerodynamics, most applied technologies are high aspect ratio wings, drag reduction (e.g. riblets for skin friction drag reduction) and laminar flow control which can be well combined with high aspect ratio wings. In terms of structural technologies, the most concepts applied composite materials. Some concepts even include improvements in operations and from air traffic management (ATM) in their environmental reduction potential.

Discussion

Some of the roadmaps are more conservative whereas others are more progressive in the estimations. The entry-into-service window of a technology can be large or vary according to the source. Older sources, and the most progressive ones even foresee the EIS of some technologies in the timeframe 2025-2030 which seems questionable with today's knowledge.

The energy carrier strongly influences the CO_2 and NO_X reduction potential with hydrogen and batteries reducing CO_2 emissions by 100%. Purely battery-electric concepts were beyond the scope of this study, as they are currently hindered by the substantial weight penalty and energy density constraint of batteries.

The data of aircraft concepts was derived from conceptual studies in which usually low-fidelity methods are used. This leads to uncertainties, which can only be reduced during later design stages.

For some aircraft concepts the climate impact was measured with a climate metric such as ATR100 or GWP100. In some cases, trade-offs between total climate impact and fuel burn (with resulting CO_2 emissions) or between NO_X emissions and fuel burn reduction (either kerosene or

hydrogen) occurred, which can lead to the deterioration of one assessment value while another one is optimised.

The here presented technology scouting of the most promising aircraft technologies served as an input for a performance assessment of Clean Aviation-like aircraft concepts, using the climate metrics ATR100 and EGWP100, showing how climate metrics can be used to benchmark and monitor new aircraft concepts and technologies [7]. Furthermore, this systematic review can provide guidance for future research and deployment.

Funding

This research has been performed in the frame of the CLAIM project (Clean Aviation Support for Impact Monitoring), which is funded by the European Union Clean Aviation Joint Undertaking program, under Grant Agreement No. 101140632.

Keywords: Match-Range Operation, Flight Profile Optimization, Aircraft Sizing

Abstract. The close coupling between aircraft system and operations is often overlooked in design frameworks, where most of them are focused on optimizing one aspect while keeping the other fixed, potentially yielding sub-optimum fuel efficiency during real world operations. This paper introduces an aircraft design optimization approach that simultaneously considers both the aircraft configuration and flight profile during the on-design process. The effectiveness of this approach is demonstrated through a comparative fuel consumption analysis using historical flight data from 2019 to 2020. This analysis provides insights into achieving greater fuel efficiency in actual operations by employing the most optimal combination of aircraft configuration and flight mission profile.

Introduction

All manuscripts must be in English, also the table and figure text. The interconnectedness between aircraft configuration designs and operations calls for the simultaneous consideration of the two systems in achieving global optimum convergence [1] within an operation-aware aircraft design optimization process. However, most of the ex- isting design platforms focus solely on optimizing one aspect while keeping the other fixed, at the expense of suboptimal fuel efficiency in real-world operational scenarios. Ideally, air- craft should be operated following the match-range concept [2], where an aircraft is operated closer to its mission range by optimizing operational practices—which likely results in lower fuel consumption and reduced trip time, leading to decreased direct operating costs (DOC). However, this concept may not be practical with the limited fleet composition that airlines operate with, where a few aircraft types are operated for a wide range of flight missions.

To assist the match range operation, we propose a co-design optimization approach to simultaneously consider both the aircraft configuration and flight profile during the on- design process—by taking into account the aircraft's expected operations learned from data. Specifically, a data-driven analysis model will be utilized to generate the top-level aircraft requirements (TLARs) for design specifications and a segmented reference mission profile as the operational constraints in flight simulation. Subsequently, geometry and mass coupling will be performed to estimate the size and structural weight of the aircraft in each of the optimization iterations. An operation-based flight profile optimization method will then be applied to the mission analysis model to estimate the optimum fuel performance for the current designed configuration.

source design optimization framework that includes models from various disciplines, and is highly adaptable for modifications [3]. The schematic of the design optimization structure in MARILib is shown in **Fig. 1a**. In the base framework, wing area $S_{\text{wing}} \in \mathbb{R}$ and reference thrust $T_{\text{ref}} \in \mathbb{R}$ are optimized for one of the objective functions $J \in \mathbb{R}$, which can be maximum takeoff weight (MTOW), mission fuel, CO_2 emission, cash operating cost, or DOC. This base framework can design an aircraft specifically optimized for a fixed design mission. **Fig. 1b** shows the proposed framework structure developed and used in this study, which is built upon MARILib and incorporates three key enhancements: 1) our in-house flight data analysis module [4] to generate mission specification and operational constraints for high-fidelity flight simulation, 2) bi-level structure allowing for simultaneously optimizing aircraft configuration and flight profile, and 3) the functionality to allow for multi-mission based optimization if the aircraft's intended operations cover more than one mission range.

(a) Base framework

(b) Proposed framework

Figure 1: Schematic flowcharts of design optimization processes.

In our framework, two design variables—i.e., reference wing area and thrust—are considered in the fuel consumption minimization problem at the design mission range. A generalized optimization formulation for the proposed framework is shown below,

$$\begin{aligned} \min_{\mathbf{X}_{\text{design}} \in \{(S_{\text{Wing}}, T_{\text{ref}})\}} \quad & J(\mathbf{X}_{\text{design}}, \mathbf{X}_{\text{TLARs}}) \\ \text{s.t.} \quad & \mathbf{g}(\mathbf{X}_{\text{design}}, \mathbf{X}_{\text{TLARs}}) - \mathbf{g}^{\text{Constraint}} \leq 0, \quad \mathbf{g} = \{g_j \mid j = 1, \ldots, 6\} \\ & \mathbf{X}_{\text{design}_{\min}} \leq \mathbf{X}_{\text{design}} \leq \mathbf{X}_{\text{design}_{\max}} \end{aligned} \tag{1}$$

where $\mathbf{X}_{\text{design}}$ represents design variables and $\mathbf{X}_{\text{TLARs}}$ are the fixed inputs other than design variables, including TLARs and default configuration parameters that users can change.

$J(\mathbf{X}_{\text{design}}, \mathbf{X}_{\text{TLARs}})$ represents the objective function for optimization, which refers to fuel consumption value(s) in this study.

Materials Research Proceedings 69 (2026) 448-452 https://doi.org/10.21741/9781644904251-81

The flight profile optimization (FPO) module within each multidisciplinary design analysis (MDA) iteration is set up based on our previous work [5]. The schematic representation of the method used to obtain the optimal trajectory under constrained conditions is illustrated in **Fig. 2**. Preprocessed flight data are utilized to establish operational constraints for each flight phase, including flight speeds and altitudes. These constraints are analyzed using a mission analysis (MA) model to determine the climb fuel consumption (m_{fuel_1} in **Fig. 2**) and the flight states at the top of constant CAS climb segment [6]. Afterwards, the optimal cruise profile and fuel consumption (m_{fuel_2} in **Fig. 2**) during the cruise segment are determined by a continuous cruise climb operation (CCO) model, which is followed by the MA to solve the fuel consumption and flight dynamics for the rest of the flight phases (m_{fuel_3} in **Fig. 2**).

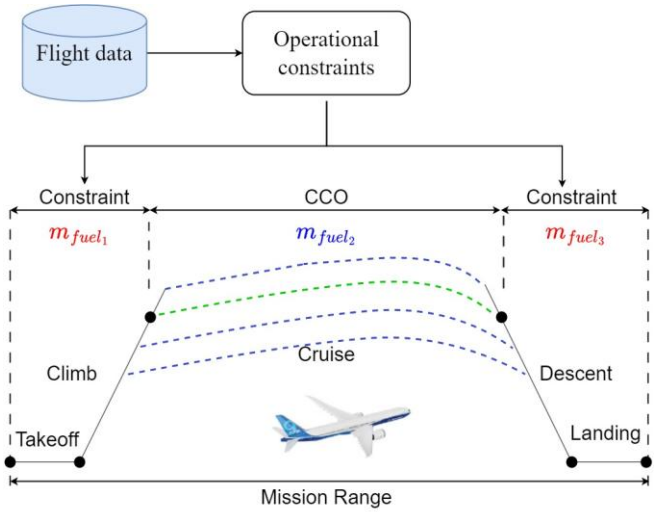

Figure 2: Schematic of the FPO method.

In the current framework, FPO is defined as an optional function for users. In the following section, we will compare the FPO-based (co-design) and FPO-free (fixed-operation profile) design optimization results to show the effectiveness of the co-design structure.

Results and Discussion

To demonstrate the benefits of the proposed method in this study, we conduct FPO-based and FPO-free design optimizations for three different-range missions. The mission scenarios are derived from flight data analysis using the eXtreme Gradient Boosting (XGboost) flight classification model as presented in [6]. The reference routes are from Hong Kong International Airport (HKG) to Taiwan Taoyuan International Airport (TPE) for the short-haul mission, Singapore Changi Airport (SIN) for the medium-haul mission, and to Heathrow Airport, London (LHR) for the long-haul mission.

The FPO-free design optimization results for the three missions are presented in **Table 1**. As the fuselage size depends only on the number of passengers, all three aircraft have the same fuselage size. There is no significant difference in wing area as the fuselage size is the same. However, longer mission range results in larger wing area. Longer mission range implies more fuel to carry, which leads to heavier weight, higher thrust, and higher lift from larger wing area and to the base aircraft (Boeing 777-300ER) operating the same mission. The greater improvement for shorter ranges can be attributed to the fact that the Boeing 777-300ER is designed for long-range operations---the operational optimality diminishes as the range deviates from its match range.

Materials Research Proceedings 69 (2026) 448-452 https://doi.org/10.21741/9781644904251-81

Table 1: Design optimization result (FPO-free).

Category	Item	HKG-TPE	HKG-SIN	HKG-LHR
Engine	Reference thrust (N)	298,793	420,753	481,866
	Bypass ratio	9	9	9
Wing	Wing area (m^2)	414.34	436.81	457.90
	Wing span (m)	61.07	62.70	64.20
Weight	MTOW (kg)	175,218	208,904	283,180
	MLW (kg)	175,210	205,498	237,743
	OEW (kg)	124,328	144,526	167,980
	MEW (kg)	120,481	137,100	145,627
Performance	Fuel consumption reduction (%)	20.45	9.15	2.53

The FPO-based design optimization results are presented in Table 2. Compared to the FPO-free design, all three aircraft configurations exhibit reductions in both reference thrust and wing area. This sizing reduction can be attributed to the decreased fuel consumption achieved through flight profile optimization within the same mission, which consequently reduces the required aircraft size while maintaining operational feasibility. It can be seen that the integration of FPO with the aircraft design optimization process demonstrates strong synergistic effects—the FPO leads to reduced fuel consumption, which enables smaller aircraft dimensions; conversely, the smaller aircraft size further expands the boundary of achievable fuel consumption improvements. This positive feedback loop enhances overall optimization effectiveness. Regarding fuel consumption reduction, the benefit of incorporating FPO is most pronounced for the HKG-LHR mission. The additional fuel savings achieved through FPO-based design optimization are 0.51%, 2.17%, and 3.73% for HKG-TPE, HKG-SIN, and HKG-LHR missions, respectively. This increasing trend correlates with mission range, as FPO is inherently more effective for longer-range operations where cruise range are larger.

Table 2: Design optimization result (FPO-based).

Category	Item	HKG-TPE	HKG-SIN	HKG-LHR
Engine	Reference thrust (N)	298,032	419,065	480,000
	Bypass ratio	9	9	9
Wing	Wing area (m^2)	414.34	435.90	455.36
	Wing span (m)	61.07	62.63	64.02
Performance	Fuel consumption reduction (%)	20.96	11.32	6.26

Conclusion

In this study, we propose an integrated framework for co-optimizing aircraft configuration and flight mission profile to achieve the "truly" global optimal design for specified mission(s). The results demonstrate that, compared to FPO-free design, the co-design approach yields aircraft with smaller dimensions for the same mission requirements—this reduction in size can be interpreted as achieving a better match-range for the designed aircraft. In the future, we will try to simultaneously optimize multiple operational conditions to address the complex and diverse operational requirements encountered in real-world scenarios.

Abstract. Thin and ultra-thin materials, such as Kapton foils or thin spread-tow carbon fabrics, are increasingly employed in spacecraft systems due to their low weight and high flexibility, which are suitable features for deployable reflector structures. However, these devices require a uniformly tensioned surface to ensure optimal signal reflection, which represents a challenging achievement due to the wrinkle formation induced by the tensioning process. This study investigates numerically and experimentally the mechanical behaviour of triangular Kapton foils subjected to a 3-point tensioning configuration. Moreover, a one-shot manufacturing process is proposed to realize the cable-membrane interface, conceived for minimizing surface defects and keeping membrane integrity.

Introduction

In recent years, ultra-thin materials have been increasingly employed in spacecraft systems, both for the realization of structural components and operational instruments. The main advantage of these devices lies in their high structural flexibility and low weight, features that are appealing for the development of compact structures capable of expanding once in orbit [1-4]. Such systems are well-suited for the development of foldable antennas, which often require a large, well-tensioned surface for effective signal transmission and reception. However, the requirements for low mass, high mechanical performance and resistance to the space environment are particularly stringent, limiting the choice of appropriate materials. Kapton foils are commonly used in these applications due to their favourable mechanical properties, low density, and thermal resistance [5,6]. Typically, Kapton foils are manufactured with thicknesses on the order of tenths of micrometres, allowing for efficient folding and unfolding, as controlled by the deployment mechanisms. Generating a uniform stress field inside large-scale surfaces is a challenging goal to achieve, as it is strongly dependent on material elastic properties, thickness, geometry and tension method. Therefore, a high level of accuracy in the tensioning process is essential, especially to avoid formation of wrinkles, which represent out-of-plane wavy deformations of the membrane, compromising its proper performance as a reflector [7,8]. Studying the effects of the cable-membrane interface on surface tensioning is one of the goals of the present research. Experimental tests were performed on reduced scale triangular Kapton foils, studying how the interface affects out-of-plane deformations. Such a junction was realized with a one-shot manufacturing process, avoiding any drilling operation to attach the cables. In addition, a numerical model was designed to replicate the tests and study more in depth the surface behaviour under in-plane loads. The aim is to develop a reliable numerical model suitable for scaling up the analysis to full-size membranes of different configurations.

Materials Research Proceedings 69 (2026) 453-456 https://doi.org/10.21741/9781644904251-82

Experimental study

To analyse the effects of the tensioning method on triangular Kapton foils, a one-shot manufacturing process was designed to realize the samples. Particularly, the aim was to co-bond the Kapton layer and the Kevlar cables in a single thermal cycle for efficient tensile load transfer. To this end, a hydraulic press with heating plates was used to reach the temperature for the curing cycle. Samples were obtained by cutting the Kapton foil (Dupont^{TM}) as triangles with edges of 20 cm and placing triangular patches of AF163-2K structural adhesive (3M^{TM}), with selected shapes, over the foil corners. Kevlar cables were then placed between 2 layers of adhesive. Material properties are summarized in Table 1, where Kevlar ones are taken from literature [9,10]. Such a manufacturing process avoids the need to drill the Kapton in the reinforced area to attach the tensioning cables, as is commonly done in similar applications, thereby establishing a non-invasive technique. For experimental tests, we have selected Kapton foils with a thickness of 2 MIL, ensuring low weight and flexibility at the same time. Experimental tests focused on the shape and size of the adhesive patches to minimize wrinkles formation. A simple triangular shape and a sector-like shape were adopted: the former to reproduce traditional supports used up to date, the latter to get a different load direction on the vertex, as shown in Fig.1, determining variations on the deformation field.

Later, cables are fixed on 3D printed supports, in such a way that the tension was equally distributed on the 3 vertices and adapted to Shimadzu AGS-X 10KN tensile machine. Tests were conducted at 2 mm/min, supported by a DIC optical system to monitor micro-displacements in the membrane. Results showed high load capacity of the interface, reaching over 300 N total load keeping the integrity of the membrane. An adhesive patch of 15 mm edge was observed to be the minimum size required to achieve adequate adhesion at high tensile loads. For smaller dimensions, there is a progressive detachment of the patches from the membrane and a clear formation of wrinkles near the vertices. In Fig.2 the out-of-plane displacement was analysed at low and high level of tensioning, respectively at 30 N and 300 N of total load, for both the adhesive shapes. Results highlight a flatter surface at low tension levels, generating depression regions near the corners. Such a behaviour is slightly reduced by the curved adhesive shape at 30 N of load, whereas an opposite outcome is observed at higher loads. Indeed, the curved triangle induces a much more pronounced bending of the membrane edges compared to the traditional shape.

Materials Research Proceedings 69 (2026) 453-456 https://doi.org/10.21741/9781644904251-82

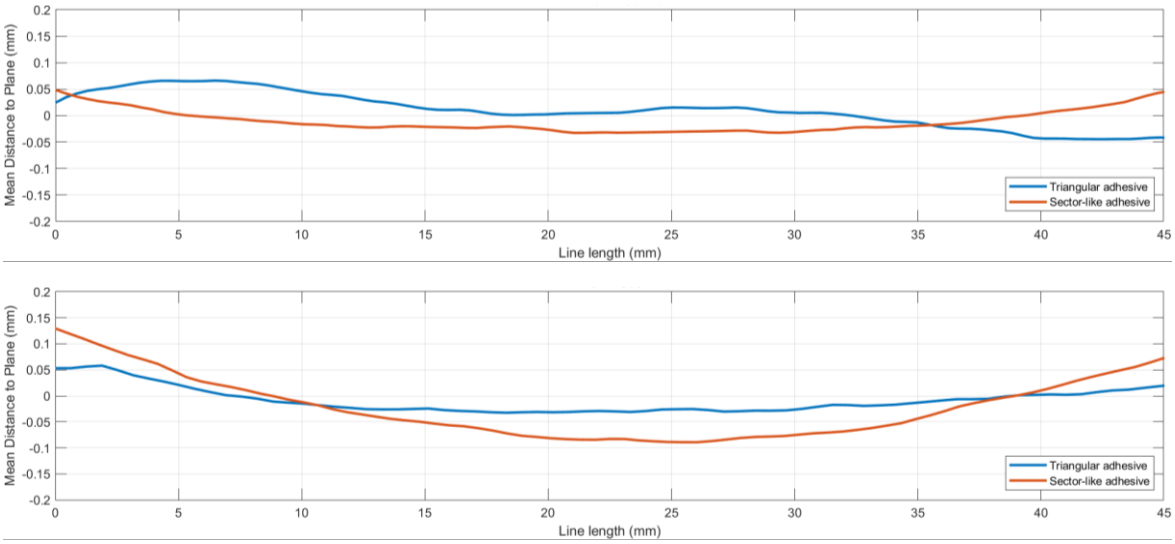

Fig. 2 Out-of-plane deformation of the membrane along side-to-side path at 30 N (top) and 300 N (bottom) total load.

Computational study

The numerical model was implemented on the finite element program ABAQUS and consists of a triangular Kapton membrane, reproducing lab scale experimental tests. The membrane was modelled as a 3D deformable shell, composed of 7500 S8R5 elements, with a structured meshing technique. For the cables truss elements (T3D2) were adopted, with a discretization of one element per cable. The external nodes of the cables were fixed, while the other end is joined to membrane vertices. Following the work of Galhofo et al., the compression state is firstly evaluated to observe the regions where buckling may occur [11]. With a pre-stress of 12.7 MPa on each cable, the membrane is subjected to an internal stress of 42 KPa, while compression regions are observed near the corners, as shown in Fig.3, and it is precisely in these areas that wrinkles appear during in-plane tensioning.

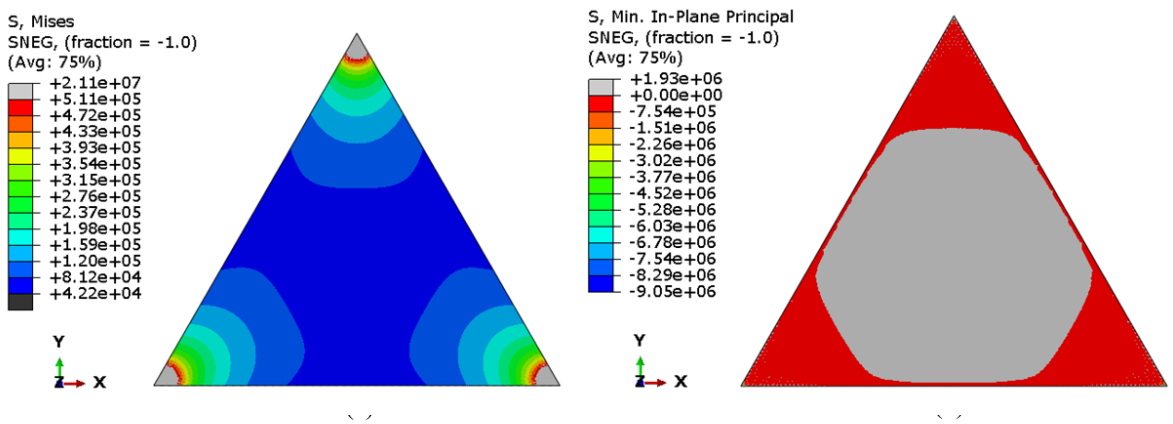

Fig. 3 Membrane's internal stress (a) and compression regions - in red - and tension region -in grey - at pre-tensioning configuration (b).

Conclusions

In this work, the structural response of a Kapton membrane to in-plane tensioning is investigated, both numerically and experimentally, aiming to reduce wrinkles formation. Lab-scale Kapton triangles of 20 cm per side have been bonded with Kevlar cables in a one-shot manufacturing process, using an epoxy structural adhesive, providing a non-invasive solution for membrane-cable interface. The adhesive was cut in two different shapes to analyse variations in the material behaviour. Experimental results highlighted an excellent resistance of the adhesive, reaching more than 100 N on each cable, establishing an effective manufacturing process. Additionally, from DIC correlation, limited out-of-plane deformations were observed for both the interface shapes, keeping wrinkles under a value of 10^{-5} m. Numerical simulations were performed for a comparison with experimental results. Here, the compression regions were emphasized, corresponding to the corners of the membrane. Such a stress configuration will be replicated in a buckling analysis to understand the wrinkles formation and evolution. Further analysis of the numerical model is planned, focused on better simulate the boundary conditions of the adhesive and on proportionally scale the model to greater membrane dimensions.

Abstract. This contribution illustrates a novel approach to aero-propulsive modeling and system identification for Distributed Electric Propulsion (DEP) aircraft. The placement of multiple propellers along the wing leading edge significantly alters the flow field, affecting both performance and flying qualities. A direct modeling approach based on simplified theoretical formulations is insufficient to accurately predict the complex behavior of the aircraft. Therefore, model identification is necessary to achieve some insight on the phenomenon. Based on the identified model, the aim is twofold: to generalize the modeling for aircraft design and analysis, and to develop a high-fidelity simulation tool for control law synthesis and advanced applications. The flight test campaign supporting the identification activities was carried out through fully automated flight tests using the scaled DEP demonstrator SwitchMaster, as discussed in [1].

Introduction

Distributed Electric Propulsion (DEP) represents a promising solution among unconventional aircraft design concepts, because the interaction between the propellers and the wing is exploited in the attempt of increasing the overall aerodynamic performance [2]. DEP offers several benefits in efficiency, control authority and system redundancy.

However, the aerodynamic coupling between propeller slipstreams and the airframe introduces strong nonlinearities that challenge conventional modeling techniques. To address this challenge, a dedicated research effort has been conducted at the Politecnico di Milano using the SwitchMaster demonstrator, an electrically powered, radio controlled aircraft featuring six propellers distributed along the leading edge of the wing.

Earlier studies [1, 3, 4] focused on the design, preliminary flight testing, and the development of an autonomous flight control framework based on a Total Energy Control System (TECS). Building on that foundation, the present work focuses on identifying a complete aero-propulsive model from flight data. The identification campaign was conducted using an autonomous flight test procedure designed to systematically excite the aircraft's dynamic modes under different blowing conditions. The identified model captures the impact of distributed propellers on stability and control derivatives, providing a formulation for subsequent simulation and control studies.

This paper details the applied methodology and estimation techniques, discusses DEP-specific identification challenges and shows results illustrating propeller-induced aerodynamic effects.

Aero-Propulsive Modeling

DEP introduces a strong coupling between aerodynamic and propulsive effects due to the blowing phenomenon, where the propeller slipstream accelerates the local airflow over the wing. This increases lift but also alters drag and aerodynamic moments, leading to a complex interaction in which aerodynamic and thrust contributions cannot be easily separated. While this coupling poses modeling and control challenges, it also offers opportunities for improved performance and innovative control strategies.

The identification campaign was performed exclusively under the Collective Thrust Control (CTC) conditions, with all propellers operating at the same rotational speed and producing equal thrust. The reference model adopted for parametric identification is a non-linear formulation of conventional fixed-wing aircraft dynamics. The propeller advance ratio, $J = \frac{U}{nd}$, where U is airspeed, n the propeller rotational speed and d the diameter, quantifies the influence of propeller-induced blowing relative to aircraft airspeed.

Aerodynamic coefficients in the equations of motion follow standard constitutive relationships:

$$C_{(.)_{(.)}} = C_{(.)_0} + C_{(.)_\alpha}\,\alpha + C_{(.)_{\hat{q}}}\,\hat{q} + C_{(.)_{\delta_e}}\,\delta_e + C_{(.)_{\alpha^2}}\,\alpha^2 \qquad \text{longitudinal}$$

$$C_{(.)_{(.)}} = C_{(.)_0} + C_{(.)_\beta}\,\beta + C_{(.)_{\hat{p}}}\,\hat{p} + C_{(.)_{\hat{r}}}\,\hat{r} + C_{(.)_{\delta_a}}\,\delta_a + C_{(.)_{\delta_r}}\,\delta_r \qquad \text{lateral-directional}$$

In the previous identification campaign [4], performed manually without the support of an automatic flight testing system, stability and control derivatives were found to vary with the propeller advance ratio J. Accordingly, each derivative is expressed as:

$$C_{(.)_{(.)}}(J) = C^{unb}_{(.)_{(.)}} + \Delta C_{(.)_{(.)}}(J)$$

where $C^{unb}_{(.)_{(.)}}$ denotes the unblown value, i.e., evaluated with $J \to \infty$ and $\Delta C_{(.)_{(.)}}(J)$ the blowing-induced contribution.

System Identification

The flight test methodology, including automated excitation maneuvers and trim management through the Total Energy Control System (TECS), followed the approach outlined in [5, 6]. The identification aimed at estimating the stability and control derivatives $C_{(.)_{(.)}}(J)$, including the propeller blowing effects $\Delta C_{(.)_{(.)}}(J)$.

The identification process involved two main steps: first, solving the Equation-Error Method (EEM) for each selected maneuver, and second, applying the Output-Error Method (OEM) [7]. The EEM provided initial parameter estimates by minimizing the squared differences between modeled and measured aerodynamic coefficients, using a least-squares solution. These estimates served as initial guesses for the OEM, which refined the parameters by minimizing, through an optimization problem, a cost function quantifying the difference between measured and model-predicted outputs, such as airspeed, angular rates and attitude angles. The cost function, expressed as a weighted sum of squared output errors over the maneuver duration, provides a quantitative measure of model fidelity. In the OEM, initial conditions were also treated as optimization variables to account for small state uncertainties, and parameters were normalized by their initial estimates to improve numerical conditioning. The optimization, performed via the *fmincon* algorithm, included physical bounds to avoid unrealistic solutions and local minima.

Compared to the EEM, the OEM provided higher fidelity and dynamic consistency, as illustrated in Fig. 1, which reports a representative elevator doublet maneuver. The simulated responses using OEM parameters showed a markedly improved match with measured data. Fig. 2 further shows that OEM-based simulations closely match the measured motion states and aerodynamic coefficients.

Materials Research Proceedings 69 (2026) 457-462 https://doi.org/10.21741/9781644904251-83

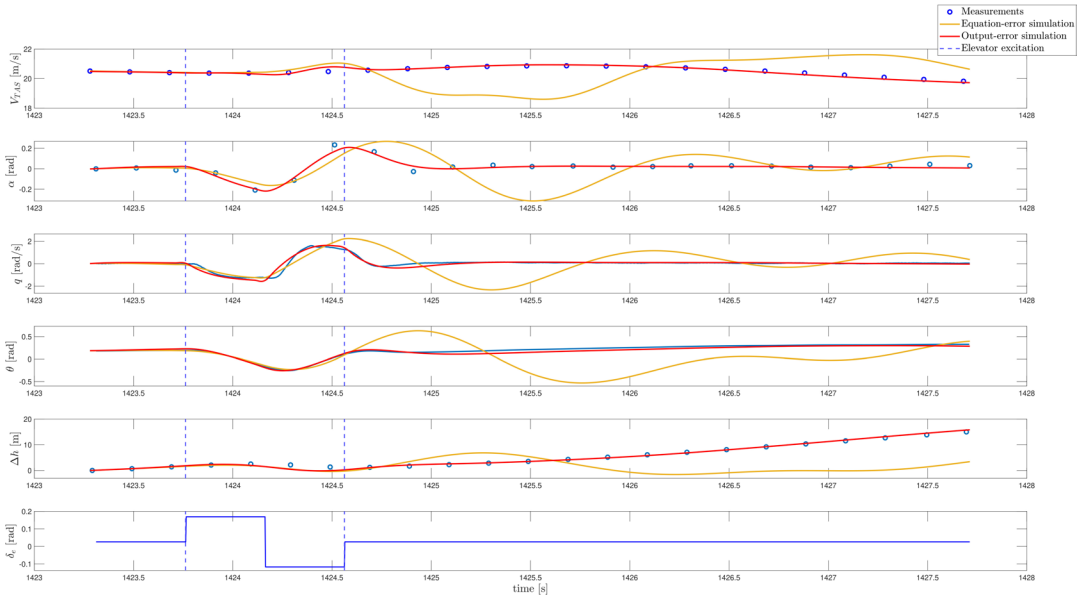

Figure 1: Longitudinal output time histories from measured data, simulated with Equation Error and Output-Error results.

Results

The identified aerodynamic derivatives were analyzed to evaluate the impact of propeller blowing on the aircraft's longitudinal and lateral-directional dynamics. Stability and control derivatives were identified for each stabilized maneuver, defined by its trim advance ratio J_{TRIM} and angle of attack α_{TRIM}. The resulting derivatives were plotted as functions of J and grouped into clusters based on α_{TRIM}, facilitating the interpretation of their trends across different flight conditions.

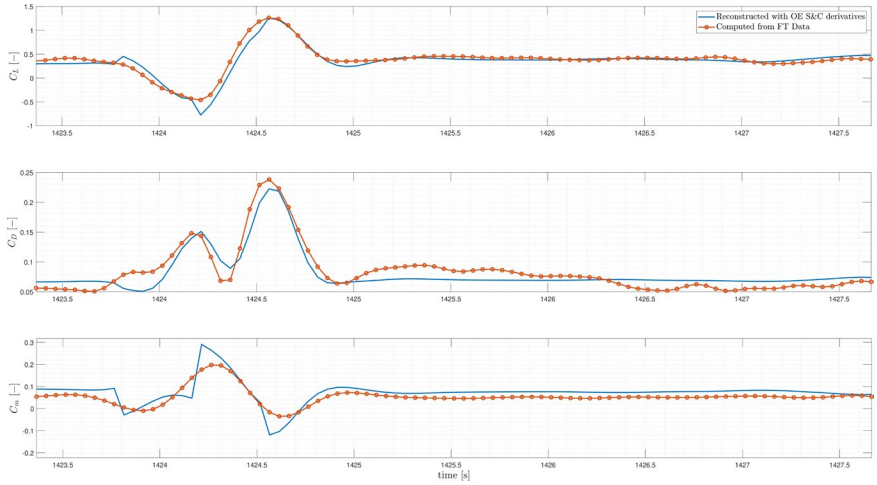

Figure 2: Comparison of longitudinal aerodynamic coefficient time histories, computed from the identified model (blue) and the flight data (red).

Several derivatives showed a clear exponential dependence on J: C_{L_0}, C_{m_0}, $C_{m_{\hat{q}}}$ and $C_{m_{\delta_e}}$ for the longitudinal dynamics, and C_{S_β}, C_{l_β}, C_{n_β} and $C_{l_{\delta_a}}$ for the lateral-directional dynamics.

The remaining terms exhibited only random fluctuations around a mean value, indicating negligible sensitivity to the blowing effect. Derivatives exhibiting a dependence on J were fitted using exponential functions $C(J) = C_\infty + p_1 e^{-p_2 J}$, or, in some cases, the sum of two exponential terms, where C_∞ denotes the asymptotic unblown value ($J \to \infty$).

Materials Research Proceedings 69 (2026) 457-462 https://doi.org/10.21741/9781644904251-83

As shown in Fig. 3, the lift coefficient increases with the blowing effect, thus at low J. In the unblown condition, data scattering led to adopting the mean value as representative. Improved accuracy is expected from refining the glide test procedure to ensure that the autopilot maintains properly trimmed flight conditions even without engine thrust. Variations in pitching moment derivatives mainly result from increased dynamic pressure at low J and from slipstream-tail interactions causing additional downwash.

In the lateral-directional dynamics, the derivatives linked to sideslip (C_{S_β}, C_{l_β}, C_{n_β}) show an exponential dependence on J due to propeller slipstream effects on the fuselage and vertical tail. Among the control derivatives, $C_{l_{\delta_a}}$ is the most affected, as the slipstream enhances ailerons effectiveness and roll control at low J.

Overall, the identified exponential trends confirm the strong aero-propulsive coupling introduced by DEP and offer a quantitative foundation for modeling and control analysis.

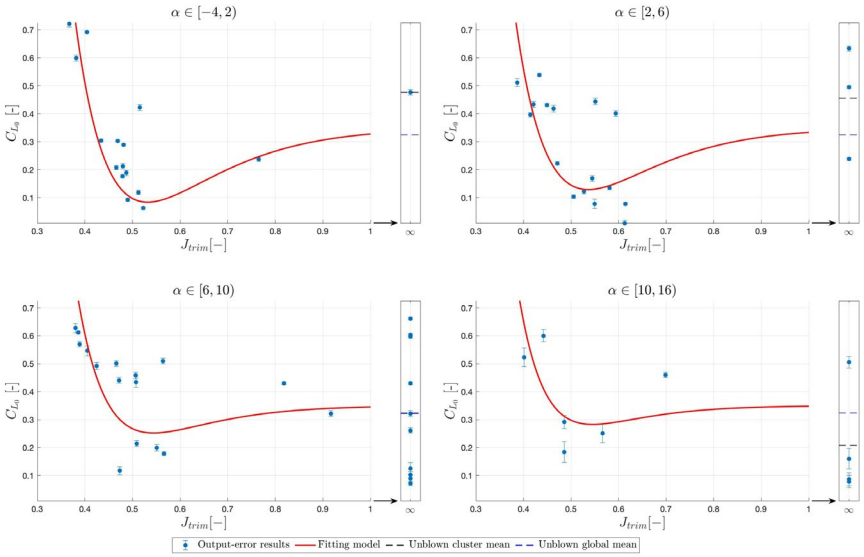

Figure 3: Trends of C_{L_0} with respect to J_{trim} divided into α_{trim} clusters.

Semi-Local Model Identification

The aerodynamic model obtained by fitting the clustered stability and control derivatives from the Output-Error identification was defined as the parametric global model, representing a generalized formulation compared to the local models, which are specifically optimized for each maneuver.

A refinement step followed, reapplying the Output-Error identification while constraining selected high-confidence parameters to the corresponding values from the global model within the equations of motion. In particular, C_{L_0} and C_{m_0} were fixed for the longitudinal dynamics, and C_{S_β} and $C_{l_{\delta_a}}$ for the lateral-directional dynamics, based on a trial-and-error tuning. The rest of the identification process remained unchanged, with derivatives estimated for each maneuver and fitted using exponential or mean-value models, depending on their sensitivity to J. The resulting formulation has been defined as semi-local model, since combines global constraints on selected derivatives with local estimation of the remaining ones. As shown in Fig. 4, it provides a more interpretable trend of the derivatives with respect to propeller advance ratio, compared to both the local and global models, confirming the enhanced predictive capability of this hybrid identification approach.

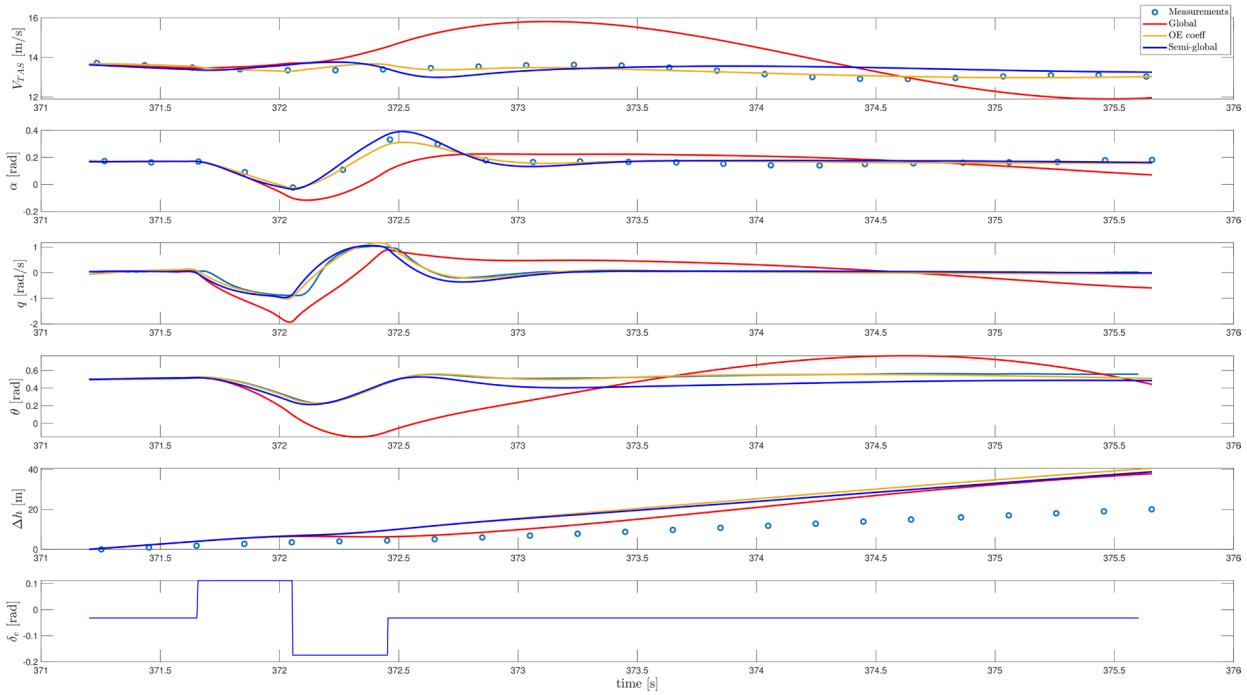

Figure 4: Longitudinal output time histories from measured data, simulated with Output-Error results and with global and semi-global fitted models.

Conclusions and Future Developments

This study presented an aero-propulsive identification methodology for a Distributed Electric Propulsion aircraft, integrating Equation-Error and Output-Error techniques within an autonomous flight testing framework. Applied to the SwitchMaster demonstrator, the approach successfully captured the non-linear aero-propulsive coupling introduced by the propeller slipstream and its impact on stability and control derivatives, leading to the development of both global and semi-global models. The semi-global formulation, incorporating selected global constraints, showed improved consistency and predictive accuracy, confirming its suitability for control-oriented applications.

Future work will extend the identification process by combining all maneuvers within similar α_{TRIM} ranges into a single optimization, where J-dependent derivatives are constrained to follow exponential laws. Successful convergence would validate the exponential dependence on the advance ratio and reinforce the robustness of the proposed aero-propulsive model.

Abstract: This research introduces an integrated, physics-based framework for the conceptual design and multidisciplinary optimization of next-generation aerial firefighting aircraft adopting a box-wing configuration. The study is motivated by the increasing frequency and intensity of wildfires, which call for novel aviation solutions with improved performance, payload capacity, and mission efficiency. Box-wing architectures, featuring two main lifting surfaces connected by vertical tip wings, offer promising aerodynamic benefits, including drag reduction and increased payload capability, and may serve as a viable alternative to conventional monoplane layouts in demanding aerial firefighting operations. The aeromechanic design of this innovative concept has been carried out through a vortex lattice method-based numerical optimization procedure; the structural design and weight estimation of the lifting-system has been performed by means of a physics-based ad hoc developed stick model. A conceptual design framework, integrating also propulsive design, mission simulation, and performance assessment, has been finally integrated, providing a platform for box-wing scooper conceptual design. The results highlight the potential of the box-wing in the context of aerial firefighting, mainly related to its increased lifting capability if the same wingspan of a conventional tube-and-wing aircraft is considered.

Introduction

Wildfires, although natural phenomena, have become increasingly intense due to climate change and urbanization, posing a growing threat to ecosystems and human settlements [1]. Rising temperatures and urban expansion amplify both the risk and the complexity of fire control, highlighting the need for innovative technological solutions, including the development of next-generation firefighting aircraft designed for more effective interventions. A scooper aircraft is a firefighting airplane designed to collect large amounts of water directly from lakes, rivers, or seas while flying at low altitude [2]. Equipped with retractable scoops and amphibious hulls, it can quickly refill and drop water to suppress wildfires efficiently. The objective of the study is to develop a parametric and flexible conceptual design tool capable of generating and evaluating candidate box-wing aircraft architectures starting from high-level mission and operational requirements. The box-wing configuration consists of two main horizontal lifting surfaces connected at the tips by properly designed vertical wings [3,4]. The main advantages of this configuration compared to a conventional aircraft lie in its ability to minimise induced drag [5] and in the possibility of increasing its lifting capacity while maintaining the same wingspan [6].

While closed-wing systems have been studied in academic aerodynamics, their application to specialized mission aircraft, such as aerial firefighting platforms, remains an open research field. By combining mission-specific requirements, parametric modelling, and cross-disciplinary coupling in a single toolchain, this study provides a foundation for evaluating the true potential of box-wing designs in this applied aviation context.

Methodology

The design framework adopts a Multidisciplinary Design Optimization (MDO) approach [7], enabling the concurrent management of heterogeneous subsystems and the iterative refinement of key design variables. The core of the framework is a set of modular disciplinary blocks, each based on simplified analytical, semi-empirical, numerical formulations derived from first principles. These blocks are structured to allow incremental fidelity upgrades, enabling coupling with high-resolution simulation tools as needed. The current implementation includes:

- **Aerodynamics and Flight Stability**: aeromechanic design is based on vortex lattice models and semi-empirical corrections for parasite and interference drag for box-wing lifting system. A numerical optimization procedure supports variables as aspect ratio, twist, taper, dihedral, sweep, and wings positioning, allowing exploration of multiple lifting system geometries under consistent design conditions and constraints. Details on the box-wing aeromechanic optimization procedure are available in refs. [8-10]. The optimization process provides as output a large number of possible box-wing planforms (an example in Fig. 1), among which the designer can select a specific configuration fulfilling pre-defined performance target. Detailed study on longitudinal stability and controllability is integrated in the lifting system design, see ref. [11]. In the present case the aircraft wingspan is set equal to that of the Viking CL-415, as the primary goal is to obtain a box-wing aircraft having the same overall size of a consolidated competitor, but with higher operating capabilities, i.e. larger water load.

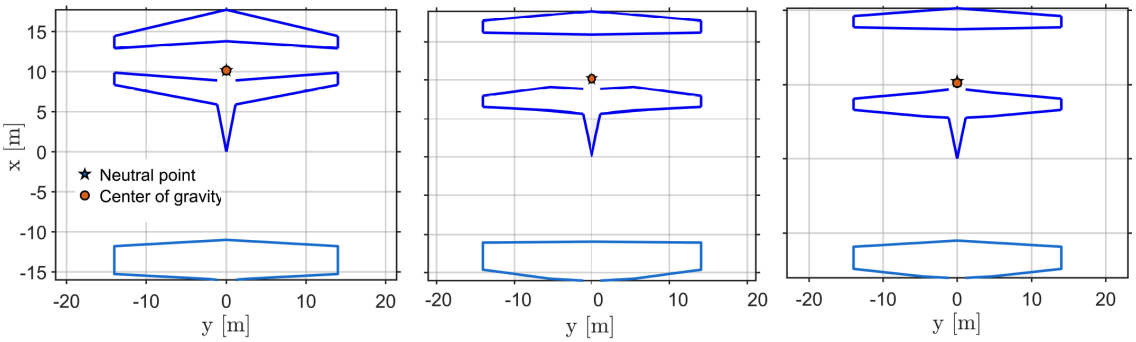

Figure 1. Subset of possible output of the aerodynamic optimization procedure.

- **Propulsion Sizing**: the matching chart tool has been adopted for the installed power sizing. The canonical power relations, for each flight conditions, have been adopted, see ref. [12]. In addition, the scooping phase has been modelled, as it could represent a limit sizing condition for the propulsion system, see the illustrative example proposed in Fig. 2. For the scooping phase, the power requirement mainly depends on the geometric parameters describing the aircraft hull, summarized in Fig. 3.

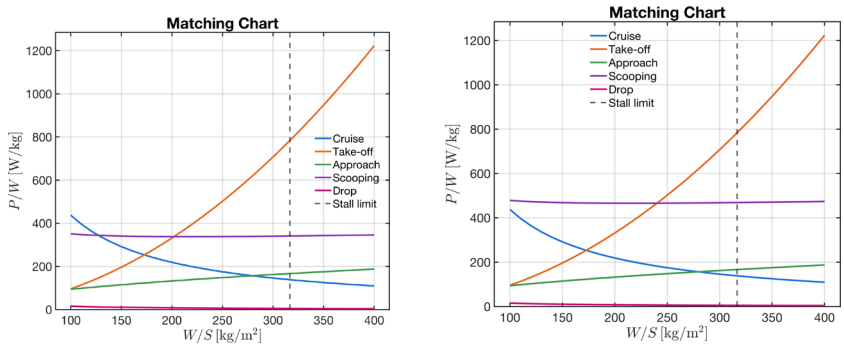

Figure 2. Matching chart for a scooper aircraft with different scooping conditions.

Materials Research Proceedings 69 (2026) 463-468 https://doi.org/10.21741/9781644904251-84

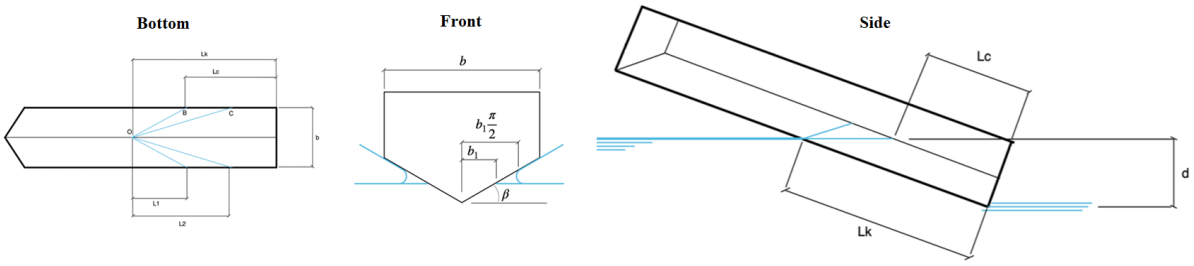

Figure 3. Illustrative scheme of the main hull dimensions.

- **Structural Sizing**: this module aims at designing the lifting system primary structures, calculating bending and torsional loads on the main wings elements using beam theory and simplified loading models. Particular attention is given to the closed-loop load paths in the box-wing arrangement and their impact on stiffness and weight. Indeed, in a conventional wing, an initial assessment of structural sizing can be obtained by modelling the wing as a cantilever beam subjected to design loads. In the box-wing case, however, the lifting system is overconstrained to the fuselage, see ref. [13,14], making the system statically indeterminate and the development of an analytical model more complex. To address this, the wing structure was modelled as a beam discretized into a number of elements defined in three-dimensional space, see Fig. 4. After applying the sizing loads, a simplified wing-box model was used to compute stress, enabling the determination of the required equivalent skin thickness to ensure adequate structural strength under the sizing loads, with the prescribed safety factor.

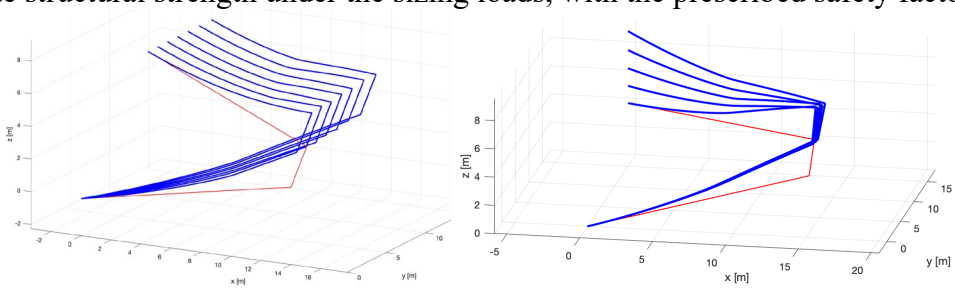

Figure 4. Stick model for the primary box-wing lifting structure.

- **Mission Modelling and Drop Envelope Analysis**: this module provides the time simulation of the flight profiles, including water drop fire zones. The simulation is made by means of Euler integration of aircraft equation of motion, considered as a point mass. The impact of repeated load cycles and water release on overall mission performance is captured, mainly in terms of fuel consumption and residual endurance. Fig. 5 reports illustrative profiles of power, aircraft trajectory, and weight evolution during a standard mission.

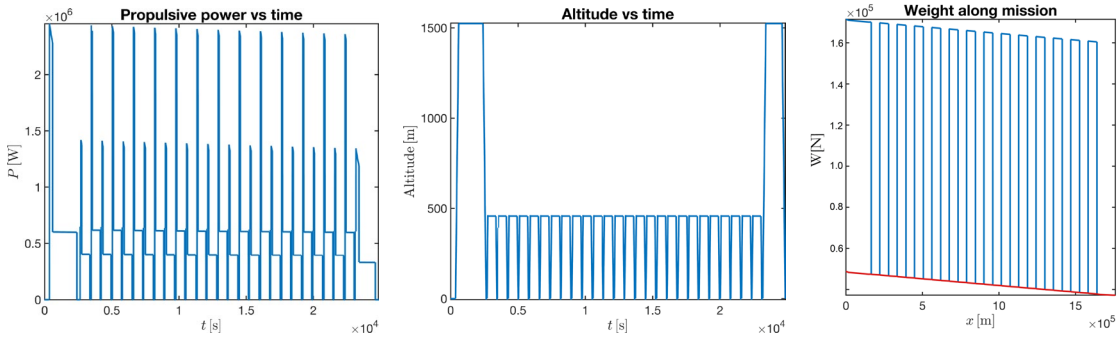

Figure 5. Power profile (left), trajectory (centre), weight profile (right).

Materials Research Proceedings 69 (2026) 463-468 https://doi.org/10.21741/9781644904251-84

- **Mass Budget Estimation:** this module estimates component-level mass breakdowns using both physics-based assessments and statistical correlations, and evaluates centre-of-gravity location and excursion during water load and release phases. The model accounts for tank placement and structural reinforcements due to sloshing and dynamic loads. As a final output of the MDO loop, the module aggregates the contributions of all subsystems and provides verification against take-off weight targets, regulatory limits, and payload-to-weight efficiency.

Each module communicates with the others via a centralized data structure, enabling full coupling and iterative convergence of design parameters. The system is designed to be reconfigurable, supporting both baseline studies of reference architectures and exploration of unconventional layouts for the box-wing family. The framework, sketched in Fig. 6 also includes capabilities for trade-off analysis and multi-objective optimization, allowing the user to evaluate performance trends across families of solutions.

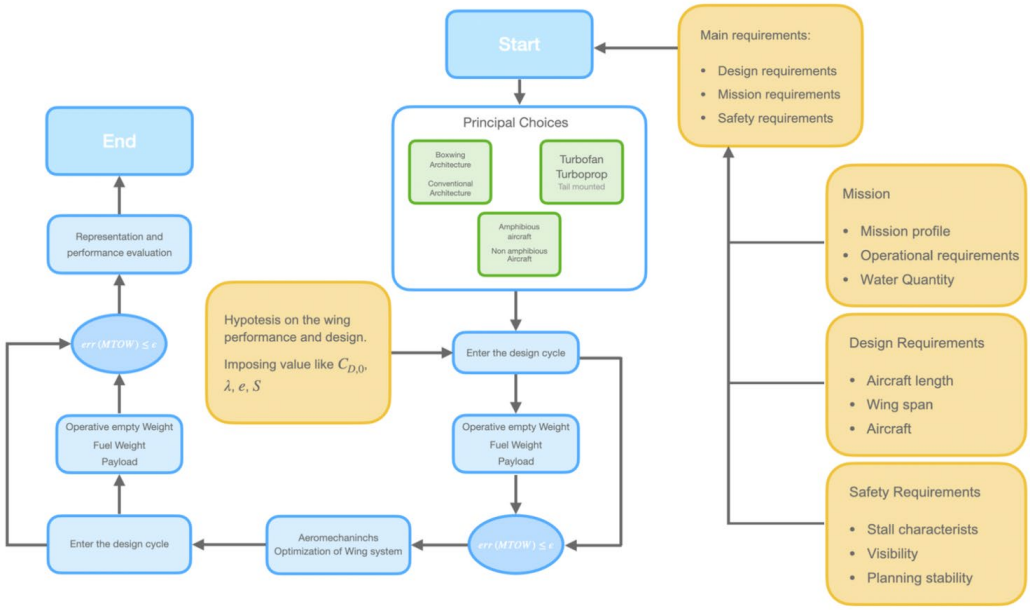

Figure 6. General scheme of the developed aircraft design framework.

Preliminary results

One of the selected criteria for comparative study between conventional and box-wing scooper aircraft is the total amount of water that can be dropped during a single mission, which is a key factor for this class of aircraft. A preliminary proposed box-wing concept has a water capacity of 12500 kg, maintaining the same wingspan of the conventional competitor, with a elongated and widened fuselage necessary to integrate the larger water tank; this philosophy is the same applied to the medium-range box-wing concept proposed in ref. [6]. A simplified sketch is provided in Fig. 7. The increase in drag caused by the larger fuselage is compensated by the reduction in induced drag provided by the box-wing configuration. The adoption of the box-wing configuration provides a clear advantage in reducing the overall dimensions for the same payload capacity, allowing the use of existing infrastructures designed for the CL-415 while doubling the aircraft water load capability; CL-415 maximum water loading capability is indeed equal to 6000 kg [15]. Attempting to reach the same payload increase with a conventional wing layout would require a much larger aircraft, especially with a larger wingspan. As a side effect, the configuration also improves aerodynamic efficiency, which, although not the main focus of the project, helps reduce fuel consumption and extend mission range, leading to improved firefighting performance.

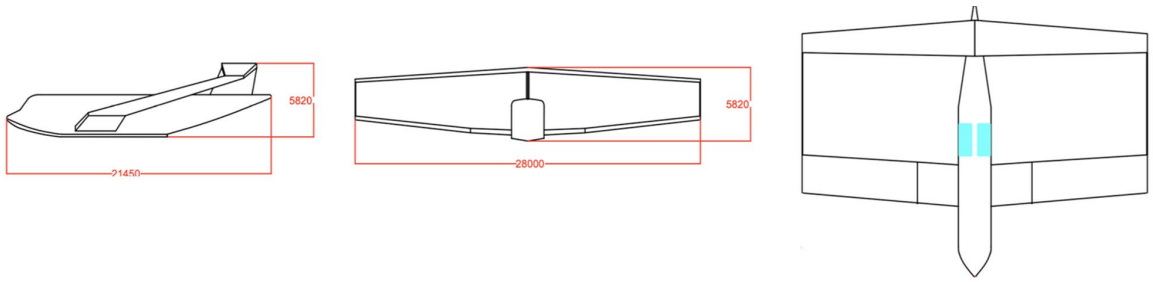

Figure 7. Simplified scheme of a possible solution of box-wing scooper aircraft. The units are mm.

Conclusions

This work presented a multidisciplinary, physics-based framework for the conceptual design and optimization of firefighting aircraft adopting a box-wing configuration. The developed tool demonstrated the ability to integrate aerodynamic, structural, and propulsive models within an integrated design environment, enabling the consistent assessment of unconventional aerodynamic layouts against mission-driven constraints. Preliminary results confirm that the box-wing architecture can substantially enhance lifting capability while maintaining the same overall wingspan of reference aircraft such as the CL-415, thus allowing higher water loads without requiring larger infrastructures or operational envelopes. The reduction in induced drag contributes to both aerodynamic and energetic efficiency, indirectly extending endurance during repetitive firefighting missions The developed framework establishes a solid foundation for future research on advanced firefighting box-wing architectures. Upcoming work will focus on a systematic exploration of the box-wing design space to identify the most promising trade-offs between aerodynamic efficiency, structural weight, and mission performance. This process will enable the selection of optimal configurations suitable for high-fidelity refinement and detailed development. Coupling with CFD and FEM tools will further enhance the predictive accuracy of the framework and support the transition from conceptual design to comprehensive multidisciplinary optimization of future firefighting aircraft.

Keywords: System Architecture, Automatic Architecture Generation, Safety, Aircraft Design, Hybrid-Electric Aircraft

Abstract. To mitigate the projected increase in emissions of the aeronautical sector, companies investigate novel propulsive systems. Three main aspects are considered: energy sources (e.g., electricity, hydrogen), powertrain technologies and equipment (e.g., fuel cells, smart motors), and propulsive architectures (e.g., series/parallel hybrid-electric, distributed propulsion). The need to study these alternatives results in a vast design space, as each potential solution has benefits and drawbacks. To facilitate the exploration of the design space, this paper presents a methodology to generate, evaluate and select aircraft propulsive architectures. The application of the method to design the propulsive system of a twin-engine commuter aircraft illustrates its capabilities. It enables easy comparison between propulsive architectures, hybridization strategies and technology assumptions.

Introduction

The aeronautical sector contributes to approximately 2.5% of the global greenhouse emissions [1]. Moreover, these contributions are expected to increase in the next decades [2]. To mitigate this impact, the members of the International Civil Aviation Organization (ICAO) have an objective to reach net zero emissions by 2050. Several levers will be necessary to reach this goal, such as improvements in technology and optimization of traffic management. This work focuses on technological enhancement, more specifically aircraft propulsion systems, considering three categories of decision-making levers coordinated through a systematic approach: the type of energy sources (e.g., electricity, drop-in fuel, hydrogen), the powertrain equipment and technologies considered (internal combustion engines, fuel cells, smart motors) and the propulsive architecture (e.g., hybrid-electric series/parallel, distributed propulsion).

The literature shows that numerous propulsive architectures are investigated for the purpose of decarbonizing air transport by increasing energy efficiency or the usage of less carbon intensive energy carriers [3]. Several studies explore the viability of hybrid-electric configurations [4–6]. Two types of hybridization are considered: series or parallel. The former consists of connecting a generator to the turbine in order to produce electricity, while the latter relies on separate electrical and thermal chains [3]. Hybridization may also be combined with other innovative technologies and configurations, such as distributed propulsion [7] or blended wing body aircraft [8]. Another potential solution for decarbonation is hydrogen-based propulsion. The hydrogen can either be

Materials Research Proceedings 69 (2026) 469-474 https://doi.org/10.21741/9781644904251-85

used for combustion directly [9–11], which eliminates the emission of CO_2 during flight, or to produce electricity via fuel cells [12,13], thus removing both NO_x and CO_2 emissions in flight. Studies suggest that fuel cell may be well-suited for small aircraft, whereas larger aircraft are more likely to require hydrogen combustion, as the higher efficiency of fuel cell powertrains does not compensate for their limited power density [3,14].

This diversity of energy sources, powertrain equipment and propulsive architectures expands the propulsive system design space significantly. Furthermore, according to the state of the art, hybrid-electric and fuel cell configurations appear to increase aircraft weight, but have a better carbon intensity. Thus, trade-offs are required to find the most appropriate solution in each technological scenario. In this context, automatic generation of propulsive architectures for their simulation and evaluation enables a broader range of potential solutions to be explored more rapidly than with the usual process. The aim of this work is to introduce a tool to systematically generate, evaluate and select propulsive system architectures. This tool is meant to help system architects in the exploration of the design space and in their decision-making process.

Proposition of a workflow to generate, evaluate and select propulsive architectures

The workflow is illustrated in Fig. 1 and consists of the following three major steps: propulsive architecture generation, systematic evaluation and selection of the most promising architectures.

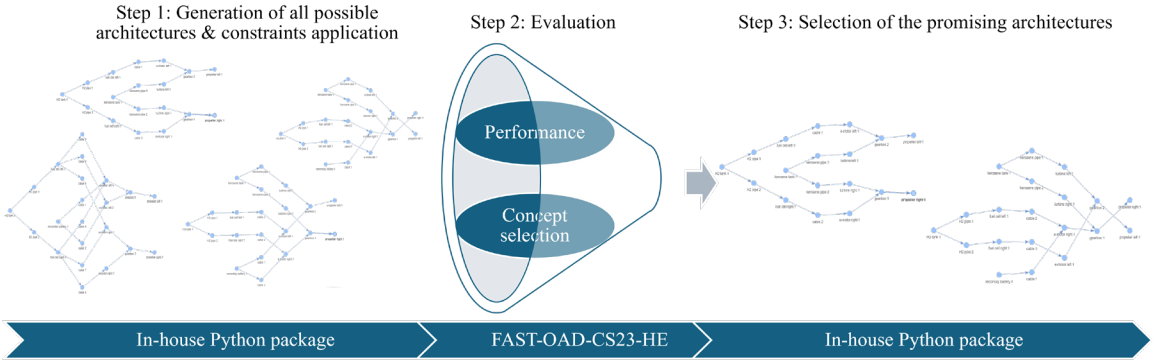

Fig. 1: Proposed workflow

The first step is the generation of the architectures. It explores all the decisions concerning the three decision-making levers mentioned in the introduction. The architecture generation algorithm, implemented as an in-house Python package, uses matrices [15] and combinatorial methods to explore the design space systematically, thus returning all possible propulsive system configurations with respect to the functional architecture and components compatibility. The exhaustive nature of the generation ensures the reproducibility of the process. The algorithm enumerates the propulsive system architectures and filters them using a sequence of constraints to ensure their validity according to relevant system safety requirements addressing the probability of occurrence of failure conditions related to loss of thrust failure scenarios. They verify the failure rate of the architectures using the minimal cut sets method [16] and the power loss associated with the failure of key components, such as power sources.

In the second step, the pre-selected architectures are evaluated one by one on a predetermined mission. This includes the sizing of the components of the propulsive system, and the estimation of the global energy performance of the aircraft. The overall aircraft evaluation is performed from scratch for each architecture to ensure a representative design. The open-source Python framework FAST-OAD-CS23-HE [17], which allows the preliminary design and analysis of hybrid-electric general aviation aircraft, was chosen to conduct this evaluation. It provides the flexibility necessary to evaluate the diverse architectures generated during the first step of the workflow. Extensive data

Materials Research Proceedings 69 (2026) 469-474 https://doi.org/10.21741/9781644904251-85

is available after the simulation, among which the mass breakdown of the aircraft and some performance figures (e.g., energy consumption, emissions).

Finally, these data are processed by an in-house Python algorithm that achieves the final selection according to predefined criteria characterized by metrics. They include, but are not limited to, the maximum take-off mass (MTOM), the operating empty mass, the energy and fuel consumption, and the CO_2 emissions for a typical mission. Even though this paper focuses on the evaluation and the selection of the propulsive configurations, the metrics concern the aircraft. Indeed, the design of a propulsive system cannot be separated from the design of the entire aircraft, as the mass and energy consumption of the aircraft are intertwined in a sizing loop.

Case study: twin-engine commuter aircraft

The tool presented in the previous section was used to design a twin-engine commuter aircraft, with either a conventional thermal propulsive system or a hybrid-electric configuration. Hybrid-electric systems present an additional variability with the number of batteries used and the way they are connected to the electric motors. Indeed, multiple batteries may be used, for instance to satisfy quantitative safety objectives from small airplanes certification requirements, and each battery may be connected to one or several electric motors. In this study, we consider either one or two batteries, each connected to either one or both electric motors. The aircraft is based on the geometry of the Daher Kodiak 100. However, the propulsion system is switched from a single- to a twin-engine layout, as illustrated in Fig. 2.

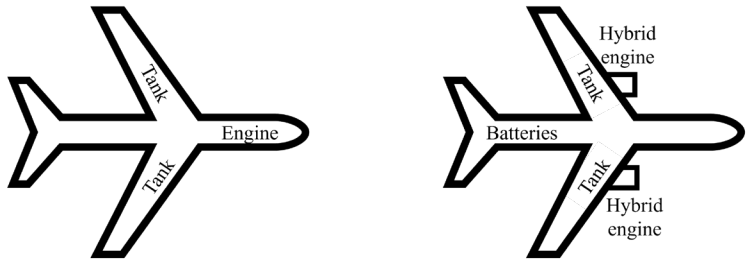

Fig. 2: Propulsive layout of the conventional Kodiak 100 (left) and of the twin-engine Kodiak 100 considered for this study (right)

Table 1 presents the top-level aircraft requirements considered for the sizing, with multiple options for the range. They were identical for all the propulsive architectures generated. In particular, the possible ranges were tested for each configuration. In addition, the tool supports multiple technology scenarios. This work specifically studies the influence of battery specific energy. The values considered are in Table 2. Scenario 1 represents state-of-the-art batteries, and scenarios 2 and 3 represent different levels of technology improvements, in line with values from battery technologies reviews [18,19].

Table 1: Aircraft requirements and mission definition

Range [NM]	**Cruise speed [kt]**	**Cruise altitude [ft]**	**Payload [kg]**
200, 300, 500, 700, 800, 1000	120	10000	400

Table 2: Battery specific energy scenarios

Scenario	1	2	3
Battery specific energy [Wh/kg]	250	500	1000

For each hybrid architecture, multiple hybridization strategies are considered. In this paper, hybridization ratio is defined as a fixed percentage of electric power over thermal power for each flight phase. In FAST-OAD-CS23-HE, the mission is divided into four phases (climb, cruise,

Materials Research Proceedings 69 (2026) 469-474 https://doi.org/10.21741/9781644904251-85

descent and reserves). The hybridization strategies chosen for this study follow the same split. Five hybridization ratios were considered (5%, 10%, 15%, 25% and 50%), combined with four combinations of phases: climb, climb-descent, climb-descent-reserves, and full mission.

The generation algorithm found, after the constraints, 9 architectures (1 thermal and 8 hybrid-electric) in 2 seconds. Combined with the 3 technology scenarios and 20 hybridization strategies, a total of 481 configurations (one thermal and 160 hybrid-electric for each scenario) were submitted for sizing and evaluation with FAST-OAD-CS23-HE. For reference, the computation time to size and evaluate all the configurations on a laptop using 11-core multiprocessing varies from 2 to 3 hours depending on the range, as the convergence is faster for shorter ranges.

Table 3 presents the overall results of the simulation. The first metric considered is the number of configurations that led to a successful sizing of the aircraft. For short ranges, up to 300 NM, sizing an aircraft is possible for 473 of the 481 configurations, at constant payload but with an increase in MTOM. The remaining 8 are hybrid configurations with a constant 50% hybridization in scenario 1. As the range increases, the number of feasible configurations decreases. As expected, the number of feasible configurations decreases faster for state-of-the-art batteries (scenario 1) than for the two future technology assumptions (scenarios 2 and 3). The second metric used in this work is the number of points on the Pareto front of each scenario, relative to two parameters: MTOM and emissions. In scenario 1, for all ranges, only one point is on the Pareto front: the kerosene configuration. Thus, state-of-the-art batteries do not allow for a hybrid configuration to improve the emissions on the considered missions. In scenarios 2 and 3, multiple hybrid configurations are on the Pareto fronts. As range increases, the number of points decreases, until no hybrid configurations are Pareto-optimal. Such a table shows up to which range hybrid-electric configurations are interesting compared to conventional propulsive systems for a given technology improvement scenario.

Table 3: Number of Pareto-optimal solutions / number of feasible solutions

Range [NM]	**200**	**300**	**500**	**700**	**800**	**1000**
Scenario 1	1/152	1/152	1/144	1/138	1/138	1/136
Scenario 2	7/160	5/160	1/152	1/152	1/152	1/145
Scenario 3	15/160	11/160	11/160	7/159	3/160	1/154

The selection process is based on Pareto fronts. Fig. 3 presents the Pareto front of emissions over the mission versus MTOM obtained for a range of 300 NM. They are normalized using the kerosene configuration as reference. The emissions are computed using the French electric mix for hybrid architectures. The graph highlights the impact of the battery specific energy on the performance of the configurations. The point of minimum MTOM (in green on the graph) corresponds to the conventional kerosene configuration. As the only variability in terms of technology assumptions is the specific energy of the batteries, this point is identical for all three scenarios. For scenario 1 (in green), none of the hybrid architectures are optimal. However, several architectures can bring improvements in terms of emissions in the more favorable scenarios 2 and 3 (in red and blue, respectively). The results also show that for both scenarios 2 and 3, a hybridization strategy increasing electrical energy consumption results in a reduction of emissions. The corresponding increase in MTOM depends on the technology assumptions.

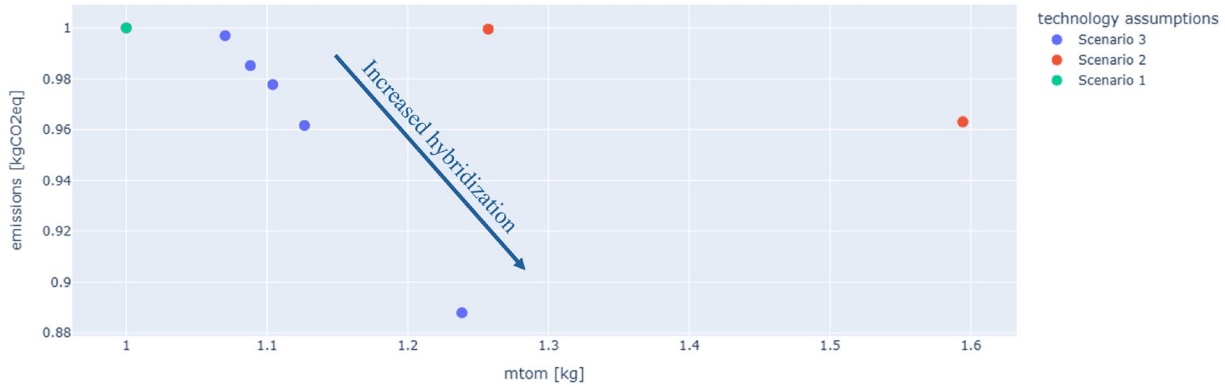

Fig. 3: Pareto front for a 300 NM range

This process provides interesting results. However, it presents some limitations. First, the sizing of the horizontal tail is not covered, which impacts the controllability of the aircraft. Furthermore, this work focuses only on hybridization with batteries. In future work, the scope will be extended to hybridization with hydrogen fuel cells.

Conclusion

This paper proposes a tool to assist system architects in the design of innovative aircraft propulsive systems. A matrix-based methodology is implemented to generate propulsive architectures systematically. A set of constraints is then verified to ensure compliance with reliability requirements. The second step is to size and evaluate the remaining architectures using the open-source aircraft sizing tool FAST-OAD-CS23-HE. The most promising architectures are then selected. An application on the propulsive system of a twin-engine commuter aircraft is presented. It investigated the feasibility of a battery-kerosene hybrid-electric configuration compared to the conventional kerosene propulsive system, with the inclusion of three technology assumptions regarding battery specific energy. The results show that batteries with the current level of technology cannot be used to reduce emissions for the considered missions. However, a reduction can be achieved with higher battery specific energy, and this reduction increases with higher degrees of hybridization. Perspectives for future work include a more complete aircraft design process, with the consideration of horizontal tail sizing, the addition of hydrogen-based propulsive systems, and an application to a regional aircraft.

Abstract. A tailless unmanned aerial vehicle (UAV) to measure the efficiency difference of stable and augmented unstable flight was developed, built and flown. An overview of the UAV and its systems is given along with the test flight procedure. The measurements are then compared between stable and augmented unstable configuration to draw conclusions.

Introduction

Rapid developments in hardware and software over the last decades have improved UAVs flight characteristics, autonomous capabilities and operational efficiency, making them a viable option for a wide range of applications. Tailless aircraft and flying wings are an attractive category of UAVs due to their structural simplicity and resulting robustness, as well as their potential for reduced parasitic drag. However, the compromises required to achieve longitudinal stability in these configurations, such as wing twist or reflex airfoils, reduce aerodynamic efficiency. By instead discarding inherent stability in favour of an unstable design with active stabilisation, these drawbacks can be avoided and conventional high-performance airfoils can be used. This approach potentially enables a tailless UAV to be more efficient than conventional configurations. An unstable tailless UAV was first designed and flown by S. Morris, R. Miley and D. Larkin in 1987 [1]. In a theoretical study S. Morris also found that a tailless aircraft with an augmentation system could result in a 13% reduction in drag compared to a non-stabilised tailless aircraft with the same handling qualities [2]. Similarly, a study by I. L. Ashkenas and D. H. Klyde found a potential improvement in range by 14% at best cruise altitude of an unstable flying wing compared to a stable configuration [3].

In order to test the above hypothesis a UAV test platform and control system have been developed to measure the efficiency difference between stable and augmented unstable flight. To measure the efficiency, the UAV was outfitted with instruments to measure the power consumption of its propulsion system, flight control system and actuators, as well as attitude, barometric altitude, airspeed and GNSS data.

Method

Test Aircraft. The test aircraft is a conventional tailless aircraft of moderate aspect ratio and without sweep, shown in Fig. 1. It has a mass of 1.92 kg, wingspan of 1.904 m and wing area of 0.5712 m^2. The centre of mass can be shifted from 77 mm to 106 mm, which corresponds to a shift in static margin from 5.18% to -4.40%.

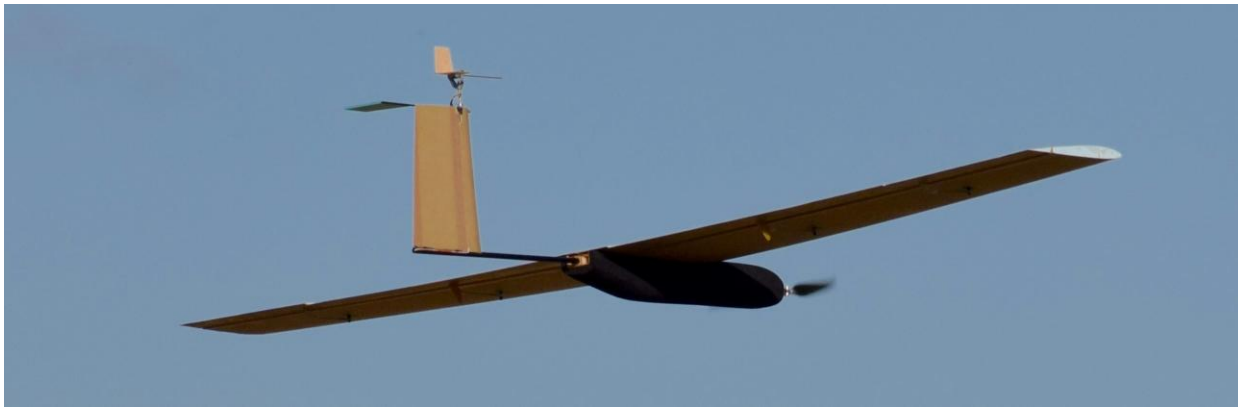

Figure 1: test aircraft

In order to balance the aircraft in statically stable configuration, an airfoil with a positive pitching moment is required. The test aircrafts airfoil (TAA) is a custom low camber and low moment airfoil. By deflecting the flap, the pitching moment coefficient can be increased to that of a high-performance reflex airfoil (HS-117) without large performance penalties, as shown in Fig. 2 [4, 5].

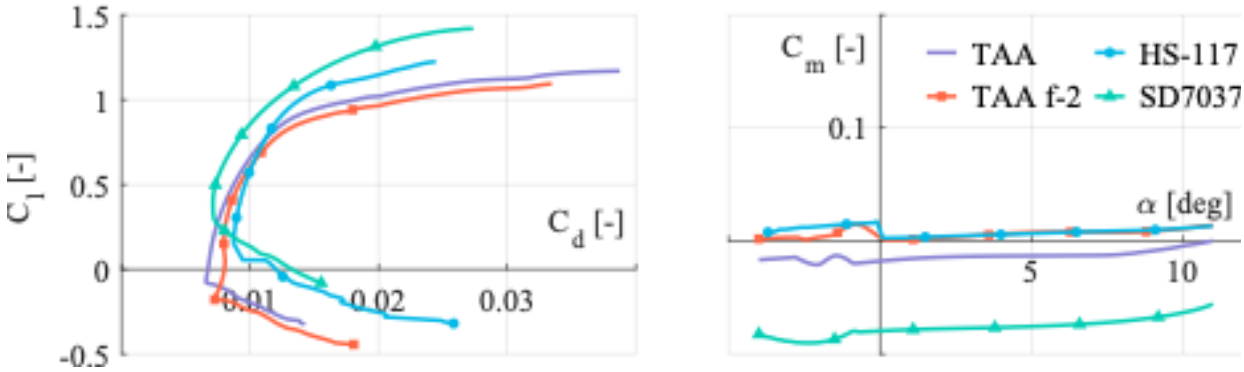

Figure 2: airfoil data (XFOIL simulation, Re = 3× 10^5)

The test aircrafts system diagram is shown in Fig. 3. Its propulsion side consist of a T-Motor MT2814 770 kV, aero-naut CAMcarbon 11 × 6" propeller with a 52 mm centre hub, 40 A Turnigy Plush electronic speed controller and a 4-cell 2.7 Ah lithium-polymer battery. The power consumption of the propulsion side was measured by the autopilots on-board current and voltage sensor, using the standard calibration parameters given by the manufacturer.

The autopilot is a Matek Systems H743-WLITE running Ardupilot v4.5.7 and used for automatic circling and data recording. Stabilisation of the aircraft in pitch is achieved through a custom flight controller, using a combination of pitch rate and angle of attack from its own set of sensors. Besides the on-board sensors, an external GNSS module (Matek Systems M10Q-5883), an airspeed sensor based on a Sensirion SDP31 with a pressure range of ±500 Pa, and an external current sensor to measure the power consumption of the actuator side are connected to the autopilot. The airspeed sensor was calibrated with the GNSS speed in automatic circle flight. Calibration of barometric altitude is done automatically by the autopilot at bootup. The actuator side consist of two Dualsky AS82MG servos used for the ailerons, two Align DS535 servos used for the pitch control flaps and a 2-cell 1 Ah lithium-polymer battery. The current sensor to measure the flight control battery power consumption is an Allegro Microsystems ACS71240KEXBLT-010B3 with a range of ±10 A on a carrier board made by Pololu. The flight control battery voltage was measured on the battery side of the sensor carrier PCB through one of the autopilots analogue

Materials Research Proceedings 69 (2026) 475-480 https://doi.org/10.21741/9781644904251-86

to digital converter inputs. The scaling parameters for the autopilots sensor inputs were calculated from sensor characteristics given by the manufacturer.

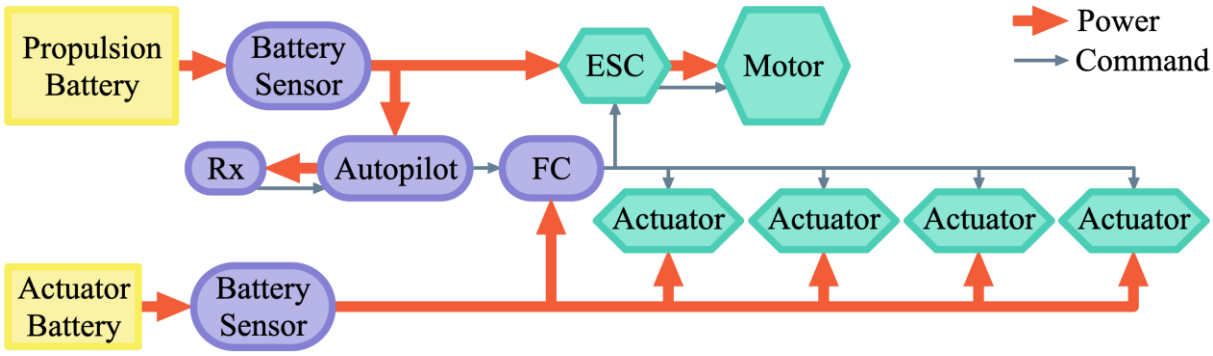

Figure 3: system diagram of the test aircraft

Test Flights. Each test flight consisted of three phases. The take-off and landing were controlled manually, while the measurement phase was controlled by the autopilot. After engagement of the automatic mode, the aircraft climbs to a set altitude and circles the point of engagement with a radius of 100 m while keeping the barometric altitude and airspeed constant at 80 m and 13 m/s. When the flight time reached 15 min, the last circle was completed and the automatic mode disengaged. After the landing the batteries were replaced and the centre of mass shifted to the alternate position for the next flight. The turnaround time between test flights was approximately 10 to 15 min.

Results

The test flights were conducted over three consecutive days. To process the data, the test flights were trimmed to the measurement phase and until airspeed and barometric altitude are stable. The points of largest longitude were then used to divide the test flights into circles and further trim the beginning and end of the flight. In total 34 test flights were conducted, amounting to 284 and 287 circles in unstable and stable configuration. The mean and median power draw per circle were calculated and are shown in histograms in Fig 4. Additionally, histograms of pitch and roll attitude, as well as barometric altitude and airspeed measurements are shown in Fig. 5. Mean, standard deviation, median and interquartile range values are listed in Table 1 and Table 2. The Fourier transform of pitch and roll attitude data is shown in Fig. 6.

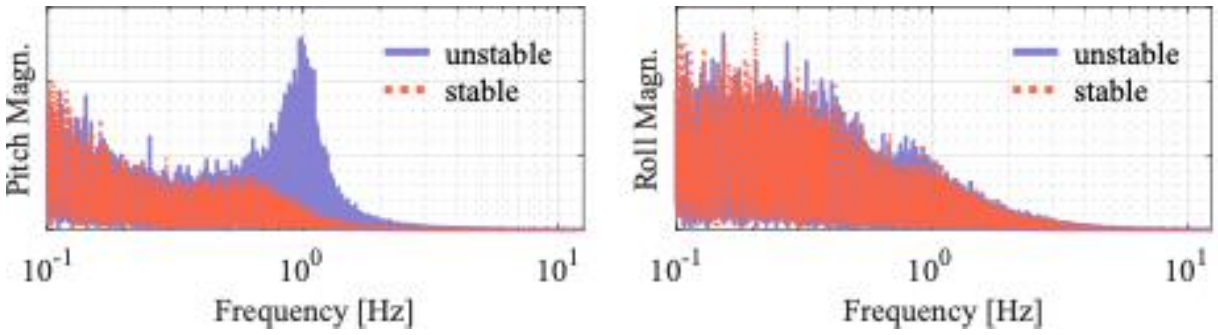

Figure 6: Fourier transform of pitch & roll attitude

Table 1: mean & standard deviation

	Mean		Standard Deviation	
	unstable	stable	unstable	stable
Mean Circle Power (Propulsion) [W]	48.34	52.87	10.99	10.12
Mean Circle Power (Actuator) [W]	3.80	3.64	0.33	0.50
Circle Duration [s]	49.25	49.19	1.07	1.20
Pitch Attitude [deg]	1.29	2.90	2.95	2.50
Roll Attitude [deg]	9.14	9.15	2.69	2.87
Airspeed [m/s]	13.01	13.00	0.42	0.40
Barometric Altitude [m]	80.60	80.34	1.15	1.12

Table 2: median & interquartile range

	Median		Interquartile Range	
	unstable	stable	unstable	stable
Median Circle Power (Propulsion) [W]	48.21	53.21	14.89	13.11
Median Circle Power (Actuator) [W]	3.52	3.30	0.44	0.38
Circle Duration [s]	49.22	48.98	1.40	1.44
Pitch Attitude [deg]	1.50	3.08	3.61	3.07
Roll Attitude [deg]	9.01	8.92	3.63	3.97
Airspeed [m/s]	13.00	13.00	0.47	0.41
Barometric Altitude [m]	80.60	80.27	1.20	1.24

Discussion

When comparing roll attitude, barometric altitude, airspeed and circle duration, it can be seen, that there are only minor differences between the two configurations. However, during the test flights in unstable configuration, an occasional oscillation in pitch was observed. This oscillation is visible through a distinct peak at 1 Hz in the Fourier transform of the pitch attitude data when compared to the stable configuration, see Fig. 6. The initial design of the aircraft and augmentation system did not include the autopilot and its sensors, which increased the mass of the aircraft by over 10%. The addition also decreased the static margin from -3.74% to -4.40%. Furthermore, the autopilot includes a stabilisation loop at lower rate, and test flights were performed in the lower half of the augmentation systems design speed range. Therefore, the controller gains are likely not optimal and a potential source for the oscillation. Comparing the distributions of pitch attitude data, no significant impact of the oscillation besides a small increase in standard deviation and interquartile

range is visible. In case the oscillation has an impact, it likely decreases the performance due to the dynamic loading of the wing and resulting increased average drag.

When comparing the actuator power draw, an increase is visible for the unstable configuration. This effect is to be expected as a consequence of the augmentation system correcting small disturbances, that would otherwise be damped by the aircrafts natural stability. The aforementioned oscillation possibly increase the actuator power draw further due to the resulting large control surface deflections and thus greater actuator loads. Comparing the propulsion power draw, a decrease by over 4 W is visible for the unstable configuration. Combining the propulsion and actuator power draw, the unstable configuration is at least 8% more efficient than the stable configuration. In addition, the efficiency of electronic speed controller and motor generally decreases at lower duty cycles [6]. This would result in a greater difference of the aerodynamic efficiency of the two configurations compared to the measured difference in power draw. Since the aircraft was to be flown both stable and unstable, a compromise in the airfoil selection had to be made. Generally, conventional airfoils tend to perform better than reflex airfoils, as visible in Fig. 2. Since unstable flight enables the use of conventional airfoils for tailless aircraft, it is likely that the use of such an airfoil would increase the performance difference further.

Conclusion

Efficiency measurements of a tailless aircraft in stable and unstable augmented configuration have been performed. The aircraft is at least 8% more efficient in unstable configuration at the tested airspeed of 13 m/s. Compromises in the aircrafts design point towards a possible further increase in efficiency of an augmented unstable tailless aircraft over a conventional stable design.

Keywords: Aircraft Design, Energetic Assessment, Climate Impact Assessment, Fractional Change

Abstract. Achieving net-zero emissions in aviation by 2050 requires systematic evaluation of emerging mitigation measures. Based on full pre-studies, this paper presents a methodological shift from complex approaches toward a sensitivity assessment. Building on the hypothesis that energy demand is the dominant cause of climate impact, a first-order approach is developed. It determines fractional change functions for mission energy and global warming potential depending on key aircraft and mission parameters. Based on a wide-body case study (70 missions and ten aircraft variants), the mission energy function results in a high goodness-of-fit and includes elasticity coefficients, which are statistically significant. Extended by a simplified climate impact model, the global warming potential function indicates a two-third contribution from fuel-related emissions (CO_2, H_2O, NO_x), with the remaining related to aircraft-induced cloudiness.

Introduction

Sustainability is one of the defining challenges shaping the future of aviation. For that, mitigation strategies, such as new aircraft concepts and technologies, have to be assessed in the early stages of conceptual aircraft design. While Life Cycle Assessment (LCA) provides a holistic framework for comparing strategies, its application in conceptual design is hindered by high complexity and data uncertainties. The reliance on numerous, often unavailable, inputs make the prediction of reliable absolute impact values - such as the climate impact in kg CO2-equivalent - a significant challenge, potentially obscuring the key drivers of change and leading to conclusions that are not robust. To address this, this paper introduces a methodological shift from absolute quantification to a sensitivity assessment. We propose a simplified, first-order framework *LEVER* (Low-fidelity Energy-based Valuation for Emission Reduction), built on the central hypothesis that ”energy demand is key”. By using a fractional change approach, the model is designed to provide clear, intuitive insights into fundamental design trade-offs. The research question is therefore:

Can a simplified, fractional change, energy-centric approach provide clear and intuitive insights for comparing the climate impact of future aircraft concepts?

To answer this question, this paper is structured in four objectives: (1) to research existing approaches and mitigation measures; (2) to develop a model of the aviation system’s energy and climate footprint; and (3) to present a case study for the wide-body aircraft cluster.

State-of-the-Art

Existing Approaches. The standard holistic approach is Life Cycle Assessment (LCA), as defined by ISO 14040. It is designed to evaluate multiple environmental stressors - such as climate change, resource depletion, and land use - across a product’s entire life cycle. However, this multi-indicator strength also poses challenges when applied to conceptual aircraft design [1, 2]. To address this complexity, three main categories of models have emerged. The first comprises streamlined LCA approaches, which preserve the multi-phase structure of a full assessment but rely on aggregated

Materials Research Proceedings 69 (2026) 481-486 https://doi.org/10.21741/9781644904251-87

or simplified data (e.g. [3, 4]). These tools are complemented by detailed, phase-specific process models (e.g., [5]). In contrast, parametric, first-order models adopt a different philosophy. Isikveren [7] presents a fractional change model for assessing the impact of parametric variations on aircraft performance and geometry, providing a fast estimation for conceptual design studies. The Aviation Integrated Model (AIM) [6] applies parametric methods to capture the interactions between aircraft technology, operations, and atmospheric effects, enabling system-level environmental assessments of the aviation sector.

Mitigation Measures. In line with global climate goals, the aviation sector has outlined a roadmap toward net-zero CO2 emissions by 2050. Mitigation strategies are generally defined in four sections [8]: technological advancements, operational improvements, sustainable aviation fuels (SAF), and market-based measures. *Technology* measures include next-generation aircraft designs, lightweight materials, advanced aerodynamics, and more efficient propulsion systems, including hybrid-electric and hydrogen concepts. *Operational strategies* focus on improved air traffic management, optimized flight trajectories, and enhanced ground operations. *SAF* aims to replace fossil fuels as low-carbon alternatives derived from biomass or renewable electricity, while *market-based measures* (Carbon Offsetting and Reduction Scheme for International Aviation (CORSIA) or emissions trading systems) address residual emissions that cannot be eliminated through technological means.

Methodology and Validation

The framework LEVER adopts the philosophy of parametric, first-order models.

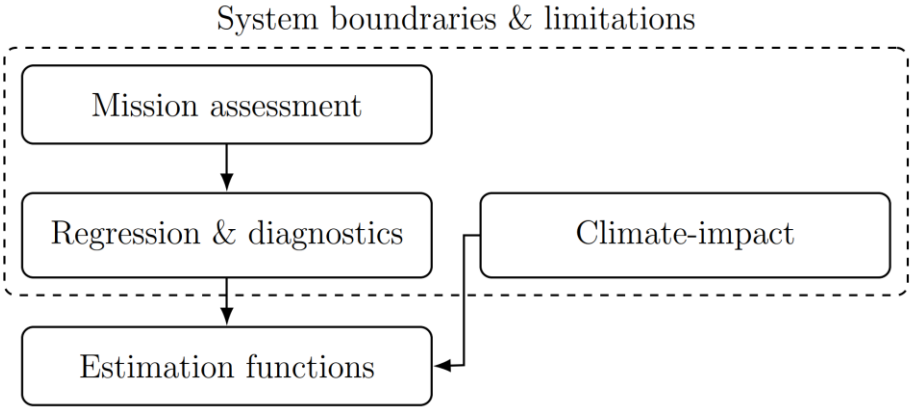

Fig. 1: LEVER workflow.

The methodology is shown in Fig. 1 and includes:

- *System boundaries*: We concentrate on aircraft operations (tank-to-wake, TtW).
- *Mission assessment*: The model processes aircraft, engine, and mission datasets based on publicly available data to estimate the selected key parameters. Empirical equations, additional mission performance assumptions, and energy balance calculations are added. The dataset is input for the regression.
- *Regression and diagnostics*: Log-log regression is applied with a 20% test split to determine elasticity. Diagnostics include R^2 and p-value.
- *Climate-impact*: The global warming potential with a time horizon of 100 years GWP_{100} is used. CO_2, NO_x, and H_2O are considered as well as aircraft-induced cloudiness (AIC).
- *Estimation functions*: We use two metrics ($\triangleleft$ adopted from [7]): 1) $\triangleleft E_{mission}$ as fractional change of mission energy, 2) $\triangleleft GWP_{100}$ as fractional change of global warming.
- *Limitations*: The regression model is applied for aircraft whose payload-range diagrams are sufficiently similar to justify a local linear approximation. Fractional change in mission energy

Materials Research Proceedings 69 (2026) 481-486 https://doi.org/10.21741/9781644904251-87

is assumed equivalent to elasticity, which is valid for small changes. As presented in the results, the use case is wide body aircraft flying > 4000 NM (from A330-300 to 747-400). Climate impact is focused on cruise-only operations and assumes an altitude of 39000 ft. HC, CO, and SO_x are neglected.

Mission assessment, regression & diagnosis. The goal is to derive the following:

$$\triangleleft E_{mission} = \alpha_1 \cdot \triangleleft m_{TO} + \alpha_2 \cdot \triangleleft R + \alpha_3 \cdot \triangleleft TSFC_{cr} + \alpha_4 \cdot \triangleleft L/D_{cr}, \quad (1)$$

with α as regression coefficients, Emission as mission energy, m_{TO} as take-off mass, $TSFC_{cr}$ as cruise thrust specific fuel consumption, L/D_{cr} as cruise lift-to-drag ratio, R as range. These parameters are aligned with the Coffin-Breguet equation (speed omitted as a constant in the data). Note that the parameters are dimensionless due to $\triangleleft x = \Delta x/x_0$ as fractional change [7]. Since $\ln(x/x_0) = \ln(1 + \triangleleft x) \approx \triangleleft x$ for small changes, $\ln(E_{mission}/E_0) = \sum \beta_i \ln(x_i/x_{i0})$ is locally identical to the linearized relation $\triangleleft Emission = \sum \beta_i \triangleleft x_i$. Consequently, the coefficients α represent the same elasticities as those obtained from the log–log regression β, which are interpretable as percentage sensitivities.

To derive the function and regression coefficients, data is required. The mission assessment model processes the following based on literature and publicly available data from Aircraft Commerce to estimate the parameters:

- *Mission data* containing equivalent still air distance (ESAD), block time & fuel, passenger number, cargo payload, taxi time, reserve rules (incl. alternate distance),
- *Aircraft data* providing mass breakdown (operating empty mass (OEM), maximum take-off mass (MTOM), maximum payload, fuel capacity, design range, engine variant),
- *Engine data* specifying type, bypass ratio, and empirical constants for $TSFC_{cr}$.

m_{TO} is assumed as the sum of OEM, payload, block fuel (without taxi-in), and reserve fuel. Reserve fuel is calculated with 5% trip fuel, a 30 min holding at FL150 at 20 kg/min and alternate airport flight at 5 kg/NM (data estimates based on UNICADO-LR-01 [10]). Range is equivalent to ESAD. $TSFC_{cr}$ is estimated based on Howe [9] at FL390 and M0.84 (altitude and speed not specifically provided in source). L/D_{cr} is calculated under the same operating conditions. Steady state flight is assumed:

$$\triangleleft L/D_{cr} = \frac{m_{midcruise} \cdot g}{\dot{m}_{cr}/TSFC_{cr}}, \quad (2)$$

with $m_{midcruise}$ as mid-cruise aircraft mass (OEM plus payload, reserve, descent, and 50% cruise fuel), g as gravitational constant, and $\dot{m}_{cr}$ as cruise fuel flow. m_{cr} and t_{cr} are assumed as block fuel and time, excluding taxi and descent (1800 ft/min descent rate, 8 min for approach/landing, fuel flow at 35 kg/min). The climb segment was initially heuristically estimated, but tests have shown that omitting it results in a minor error.

Climate Impact Model. For each flight mission, the model computes the Absolute Global Warming Potential $AGWP_{100}$ (100-year horizon) as the time-integrated radiative forcing associated with in-flight emissions. This is then expressed as equivalent CO_2 mass GWP_{100}. The formulation accounts for the main contributors - CO_2, H_2O, NO_x, and aircraft-induced cloudiness (AIC).

To calculate AGWP and GWP, the radiative forcing at time t is used as the sum of altitude-dependent responses for each contributor i:

$$RF_{tot}(t) = m_{CO2}\, RF_{CO2}(t) + m_{H2O}\, s_{H2O}\, RF_{H2O}(t) + m_{NOx}[s_{O3S}\, RF_{O3S}(t) + s_{O3L,CH4}(RF_{O3L}(t) + RF_{CH4}(t))] + r_{cruise}\, s_{AIC}\, RF_{AIC}(t), \quad (3)$$

where m_i are the emitted masses (or cruise distance for AIC), and $s_i(h)$ are altitude-dependent forcing factors [13]. The short-lived species (O_3 short, H_2O, and AIC) are treated as one-year box forcings, while the long-lived species (CO_2, CH_4, O_3 long) follow exponential impulse–response functions. Integrating the response over the time horizon H yields the AGWP for each species:

$$AGWP_{100,tot} = \int_0^H RF_{tot}(t)dt = \sum_i m_i \int_0^H RF_{tot}(t)dt.\ GWP_{100} = \frac{AGWP_{100,tot}}{AGWP_{100,CO2}}. \quad (4)$$

Emission masses are computed from mission fuel and engine data:

- CO_2 and H_2O from stoichiometric oxidation EI_{CO2} = 3.16 kg/kg fuel and EI_{H2O} = 1.23 kg/kg fuel.
- NO_x from the Boeing Fuel Flow Method 2 (BFFM2)[14], using sea-level emission indices $EI_{SL,NOx}$ from ICAO engine databank. The method converts in-flight fuel flow to sea-level equivalent conditions by applying altitude and humidity corrections:

$$m_{NOx} = EI_{SL,NOX} \left(\frac{\delta^{1.02}}{\theta^{3.3}}\right)^{0.5} e^{H} m_f, \quad (5)$$

with δ, θ, and H as pressure ratio, temperature ratio, and altitude.

For simplicity, $r_{cruise} \approx R$ and a constant cruise altitude of FL390 are assumed, which fixes the forcing factors $s_i(h)$ and NO_x altitude correction. $\int RF_i(t)\,dt$ are calculated as constant multipliers k_i, yielding:

$$GWP_{100,TtW} = (k_{CO2} + k_{H2O} + k_{NOx}) m_f + k_{AIC}\, R. \quad (6)$$

This linearized model allows to formulate $\gamma_i = GWP_i/GWP$, which represents the fractional share of each species in total GWP:

$$\triangleleft GWP_{100,TtW} = (\gamma_{CO2} + \gamma_{H2O} + \gamma_{NOx}) \triangleleft m_f + \gamma_{AIC} \triangleleft R. \quad (7)$$

Wide Body Case Study

The aircraft considered for this study are 777-200 (GE90, PW4000, Trent 800), 787-8/9/10 (Genx, Trent), A330-200/300, 747-400, A350-900/1000. In total, 69 missions are evaluated [11, 12]. The input data ranges are OEM [t]∈ [116.7, 188], ESAD [NM]∈ [3928, 7190], and payload [t] ∈ [25.6, 120] (A330 to 747). The calculated parameter are for TFSC [kg/s/N] = 1.68 · 10−5 ± 3.69 · 10−7 (mean) ∈ [1.64 · 10−5, 1.77 · 10−5] and L/D= 19.7 ± 2.1 (mean) ∈ [16.0, 22.9] (with ±1σ), resulting in

$$\triangleleft E_{mission} = 0.957 \triangleleft m_{TO} + 0.808 \triangleleft R + 0.916 \triangleleft TSFC_{cr} - 0.851 \triangleleft L/D_{cr}. \quad (8)$$

Each coefficient can be interpreted as elasticity - accordingly, a 1% improvement in cruise lift-to-drag ratio reduces mission fuel by roughly 0.85%, and a 1% higher specific fuel consumption raises it by 0.92%. All coefficients are statistically significant ($p < 0.001$), with high $R^2 = 0.964$.

It should be noted that since L/D_{cr} and $TSFC_{cr}$ are reconstructed via inverse mission analysis, the regression serves as a validation of the internal consistency rather than an independent discovery of airframe performance. For $GWP_{TtW,100}$, the average emissions contributions were derived from all missions as

$$\begin{aligned} \triangleleft \boldsymbol{GWP_{100,TtW}} &= (\boldsymbol{\gamma_{CO2} + \gamma_{H2O} + \gamma_{NOx}}) \\ &\cdot (\mathbf{0.957} \triangleleft \boldsymbol{m_{TO}} + \mathbf{0.808} \triangleleft \boldsymbol{R} + \mathbf{0.916} \triangleleft \boldsymbol{TSFC_{cr}} - \mathbf{0.851} \triangleleft \boldsymbol{L/D_{cr}}) \\ &\quad + \boldsymbol{\gamma_{AIC}} \triangleleft \boldsymbol{R}. \end{aligned} \tag{9}$$

with $\gamma_{CO2} = 0.366$, $\gamma_{H2O} = 0.003$, $\gamma_{NOx} = 0.352$, and $\gamma_{AIC} = 0.279$. This indicates that approximately two-thirds of the total GWP stems from fuel-related effects (CO_2, H_2O, and NO_x), while aircraft-induced cloudiness (AIC) contributes the remaining one-third. The very small share of H_2O reflects the low radiative forcing efficiency of water vapor compared to CO_2 and NO_x under typical cruise conditions.

Conclusion and Future Work

This study presents a simple, relative energy-centric approach that provides intuitive insight into comparing climate impacts for wide-body derivatives. The framework showed the impact of the key aircraft parameters take-off mass, range, TSFC, and lift-to-drag ratio on the global warming potential. Based on the derived sensitivities, a 1% increase of these parameters leads to +0.69%, +0.86%, +0.66%, and -0.61% change in GWP_{100}, respectively. This approach focuses on mitigation technology that enhances aircraft parameters. Future work can be an extension that includes the well-to-tank energy and climate impacts to address the benefits and drawbacks of the SAF mitigation measure.

Additionally, this approach can be applied to other aircraft categories such as turboprop, regional jets, narrow bodies, and other energy carriers such as hydrogen. This requires additional assumptions and modeling, including LTO emissions. Using aircraft design environments, such as UNICADO [10], enables detailed validation of the mission energy estimation. Furthermore, incorporating error propagation enables a more rigorous assessment of uncertainties, thereby enhancing the robustness and interpretability of the results.

Abstract. This work presents a modular framework for environmental impact assessment in conceptual aircraft design, developed within the UNICADO environment. The new architecture decouples individual life cycle phases and has been extended to various Sustainable Aviation Fuel (SAF) pathways. This enhanced flexibility enables a more robust and holistic trade-off analysis of an aircraft's environmental footprint early in the design process. The case study of UNICADO-LR-01 presents results on cumulative energy demand shares for each life cycle activity. Additional results reveal that the life cycle phases operations (62.0, 78.4, 84.6%) and energy carrier production (29.6, 14.3, 9.9%) are most dominant in terms of energy, CO_2, and NO_x, respectively. Results from SAF pathways suggest a shift towards the energy carrier production phase.

Introduction

The aviation industry is focusing increasingly on mitigating its environmental impact. Initiatives such as "Fly the Green Deal" [1] are being developed to promote sustainable aviation. The measures considered include novel aircraft configurations and sustainable aviation fuels, which could reduce climate impact compared to traditional fossil fuels. To appropriately assess these measures, a holistic approach in terms of a life cycle assessment (LCA) within the earliest stage of conceptual aircraft design has to be considered.

Most existing aircraft design and assessment tools are either not open code, lack flexibility for quick studies, or do not consider life cycle assessment evaluations at all. FAST (Future Aircraft Sizing Tool) [2] focuses on sizing and performance analysis for conventional and electrified aircraft without LCA evaluation. *AeroMAPS* [3] and *CASCADE* [4] serve as scenario-exploration frameworks for air transport decarbonization strategies, but provide little detail on aircraft life cycle phases. Tools such as *AD-LCA* Excel/Matlab methodology [5] and ecological assessment [6, 10] suffer from monolithic architectures that lack the flexibility required for advanced aircraft concepts and emerging technologies. And while offering LCA frameworks such as *qUWick* [7], *ecoLYFE* [8], or *AEco* [9], the implementations are not openly accessible to the broader research community.

To address this, an extensible *assessment framework* is being developed within the open-source conceptual aircraft design environment UNICADO [10]. As a use case, a long-range aircraft is assessed with multiple sustainable aviation fuel (SAF) pathways.

Methodology

Assessment Framework. The foundation for this work is the *ecological assessment* tool based on [6] (detailed documentation see [10]). While providing a solid basis for life cycle emissions and

Content from this work may be used under the terms of the Creative Commons Attribution 3.0 license. Any further distribution of this work must maintain attribution to the author(s) and the title of the work, journal citation and DOI. Published under license by Materials Research Forum LLC.

Materials Research Proceedings 69 (2026) 487-492 https://doi.org/10.21741/9781644904251-88

impact assessment, the original tool was built with a monolithic architecture. This posed challenges within the UniSELECT project [11], as its goal is a climate-efficient long-range aircraft considering disruptive technologies (e.g., open rotor), configurations (e.g., blended-wing body), or operations (e.g., stopover flights). The former logic is shown in Fig. 1 (left). The tool provides a single interface for inputs and focuses on internal calculations. It includes a database of materials, fuels, and primary energy factors, as well as methods for the cradle-to-grave (from development to end-of-life) inventory and impact assessment (air quality index calculation and application of an altitude-dependent climate model to evaluate average temperature response).

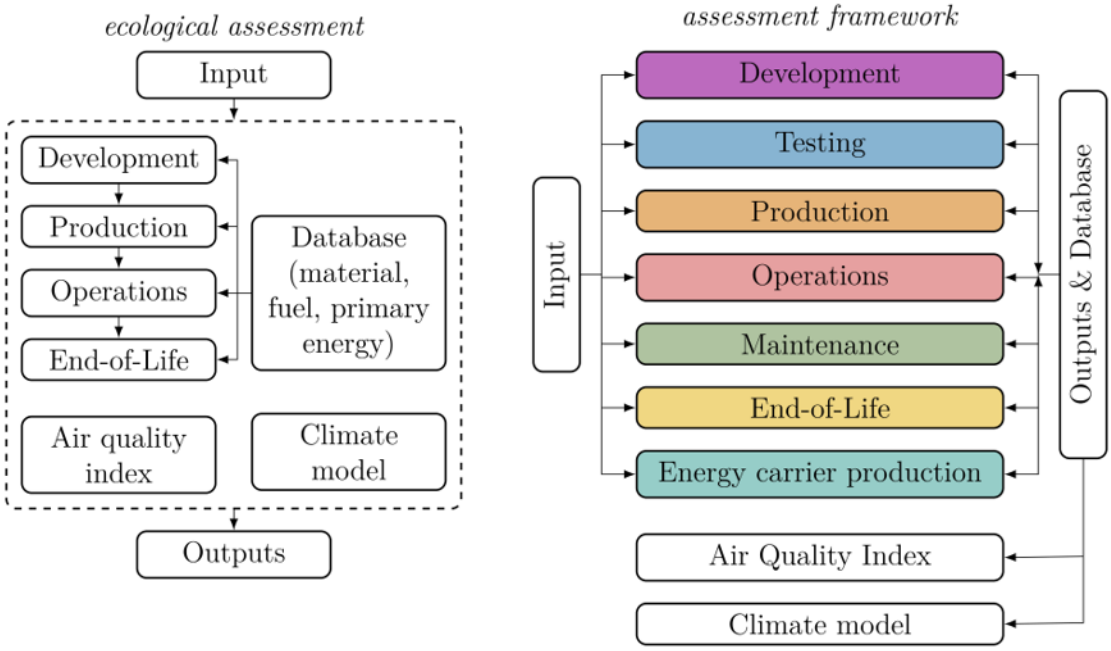

Fig. 1: Comparison of life cycle assessment tool by Schäfer (left, based on [6]) and assessment framework in UNICADO (right).

To address this issue, the tool was restructured into a modular *assessment framework* (right in Fig. 1). It treats each phase as individual stand-alone modules that have individual in- and output interfaces. This enables the exchange of phase-specific methods, e.g., by replacing the simplified electricity demand model in the development phase with more sophisticated data or higher fidelity methods. Additionally, several tools are split, e.g., the operations phase is divided into operations, maintenance procedures, and energy carrier production. The input settings are extended, e.g., Boeing Fuel Flow Method 2. For details, it refers to the open-source documentation [10].

Assessment Manager. To orchestrate the *assessment framework*, a manager tool was developed. This tool is integrated into the aircraft design platform (RCE) of UNICADO, enabling the connection of aircraft design results to the assessment. The data is exchanged with the common exchange file format (XML). Additionally, each tool has its own configuration file that varies depending on input settings (e.g., hours of system integration tests).

Sustainable Aviation Fuels. SAFs are one primary measure for decarbonization. Several production pathways are included in the *assessment framework*, such as Alcohol-to-Jet (AtJ), Hydroprocessed Esters and Fatty Acids (HEFA), Power-to-Liquid (PtL), and Biomass Gasification with Fischer-Tropsch (Gas+FT). For details, refer to [12].

Results and Discussion

A case study is presented of the long-range aircraft design UNICADO-LR-01 (Release 0.8.1). It is a kerosene-burning tube-and-wing turbofan configuration for 300 passengers and entry-into-

Materials Research Proceedings 69 (2026) 487-492 https://doi.org/10.21741/9781644904251-88

service 2020. The use case is the design mission with 6700 NM range with 77.8 t block fuel (details see aircraft references documentation [10]). Note that the results relate to the aircraft's lifetime with 369 flights/year for 30 years assuming:

- energy (heat, electricity) for personnel/offices developing the aircraft,
- energy (heat, electricity, fuel) for multiple tests & for additional test aircraft and engine (its production and end-of-life is allocated to testing),
- material and energy (heat, electricity, fuel) producing one aircraft (material production, component manufacturing, transport to assembly site, electric and heat energy needed for manufacturing & assembly personnel),
- fuel for operating an aircraft during its lifetime (total number of flights in its operating duration),
- material and energy (heat, electricity) maintaining an aircraft during its lifetime,
- energy for producing the required fuel (e.g., kerosene for flights, kerosene for transport during disposal, diesel during transportation to the final assembly site).

Fig. 2 shows the cumulative energy demand (CED) results for all phases. In the *development* phase, the impact is driven by electricity and heat demand for the offices with the primary energy demand for electricity being the highest share. In the *testing* phase, the energy for the test aircraft production (2 for fatigue, 6 for flight tests) requires 30% of the total testing CED. Both the material production (22%) and the component manufacturing (38%) dominate the *production* phase. To be noted is that the primary scrap is recycled (e.g., for aluminum, a scrap ratio of 0.85 and a recovery rate of 0.9 is assumed). In *operations*, the landing and take-off cycle is with 1% negligible in terms of energy. The dominant phase in maintenance is the spare part production (88%). The *end-of-life* phase includes both energy credit as well as demand. The credit due to material is five times higher than the energy required for recycling, incineration, and landfill. While the phases *testing*, *operations*, *production*, and *end-of-life* require energy carriers (kerosene, diesel), only the first two are relevant with 4% and 96%, respectively.

Materials Research Proceedings 69 (2026) 487-492 https://doi.org/10.21741/9781644904251-88

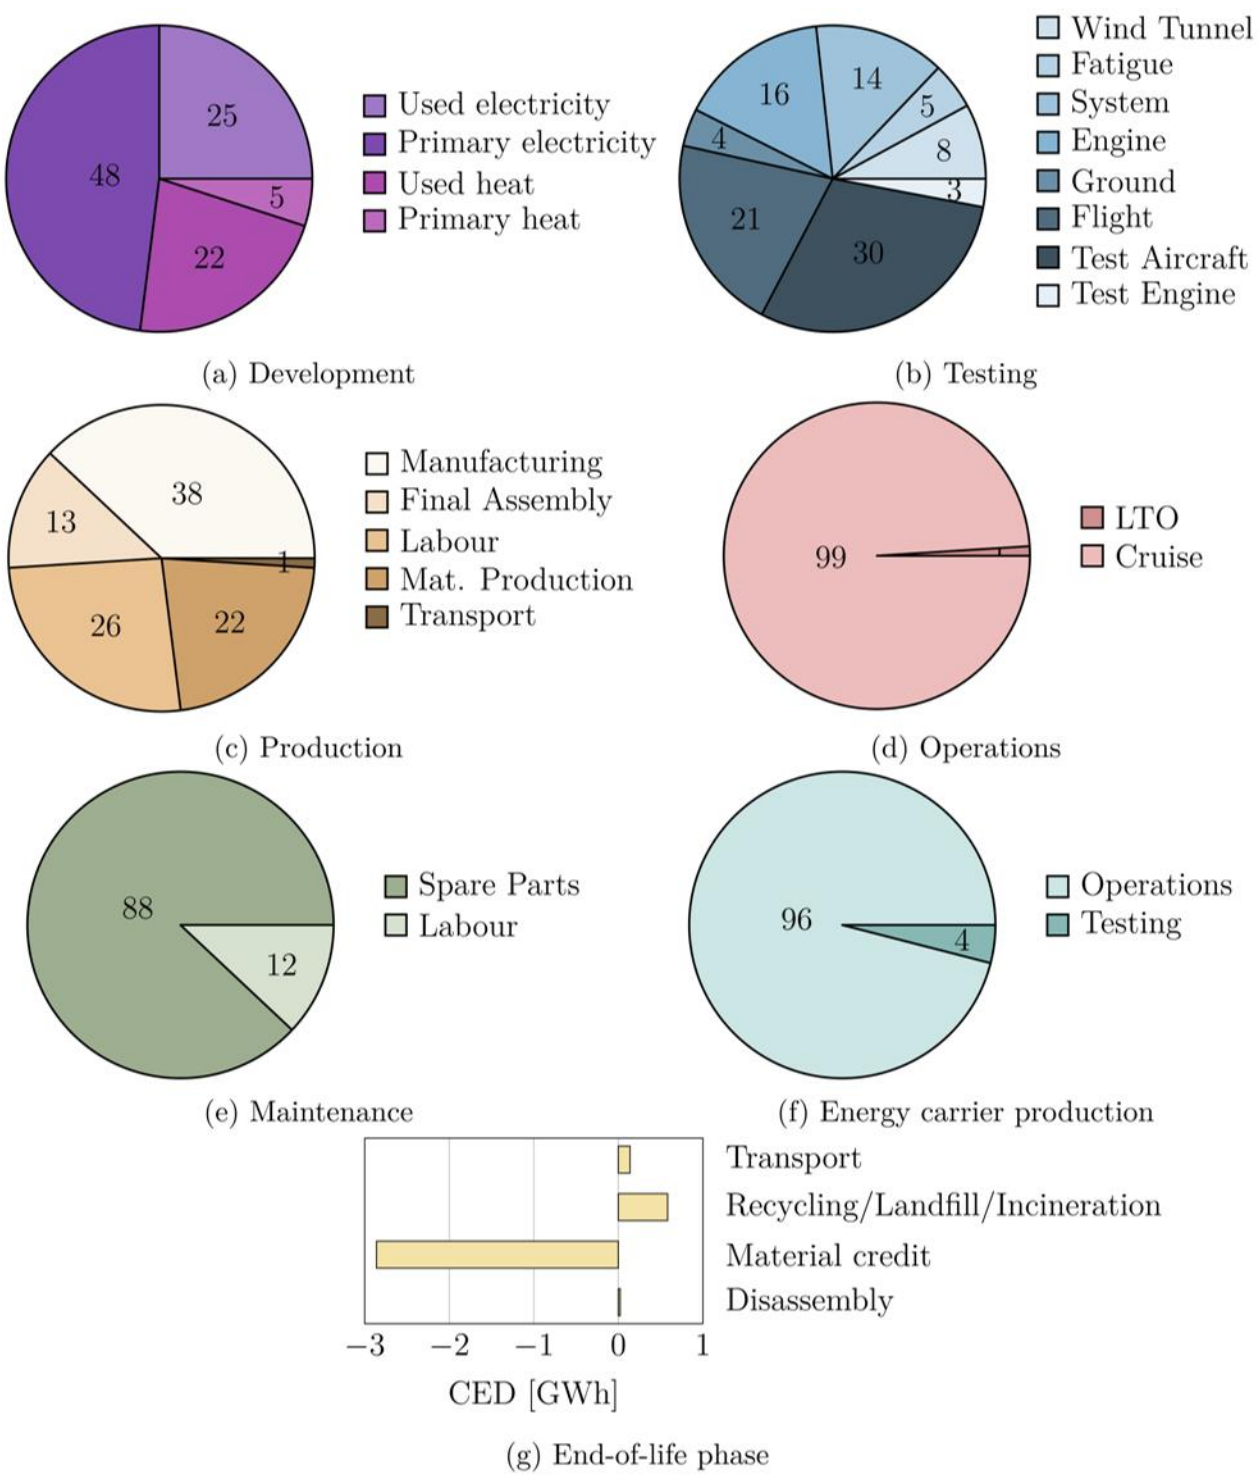

Fig. 2: Cumulative energy demand shares for life cycle phases of UNICADO-LR-01.

Table 1 shows how the individual phases contribute to the total impact with respect to CED, CO_2, and NO_x. The most influential phase is operations, followed by energy carrier production. This is due to the scaling to the entire service life (single mission operation requires 3.35 TJ which is < 1% of development CED). The total life cycle global warming potential (GWP) results in 93 gCO_2eq per MJ fuel burned during the operational flights (only CO_2 considered, cf. 89 gCO_2eq/MJ according to CORSIA [14]).

Materials Research Proceedings 69 (2026) 487-492 https://doi.org/10.21741/9781644904251-88

Table 1: Cumulative energy demand and emissions (CO_2, NO_x) inventory results for UNICADO-LR-01 lifetime.

	CED [%]	CO2 [%]	NOx [%]
Development	1.0	0.8	0.2
Testing	6.2	5.7	4.9
Production	0.3	0.2	0.1
Operations	62.0	78.4	84.6
Maintenance	0.9	0.6	0.2
End-of-Life	0.0	0.0	0.0
Energy carrier production	29.6	14.3	9.9
Total	**56.8 PJ**	**3.24 Tg**	**13.7 Gg**

Switching to SAF affects both dominant life cycle phases of aviation energy demand. Table 2 shows that the conversion efficiency of the different production pathways varies widely between 13.8% and 55.6%, reflecting substantial energy losses during synthesis and upgrading (note that a high efficiency does not automatically imply a low CED, since it depends on the primary energy factors; compared to fossil kerosene PEF = 1.24, efficiency = 80%). CORSIA eligibility (10% reduction to the fossil baseline) can thus only be achieved if biogenic CO_2 sources, renewable electricity, or carbon capture technologies (e.g., direct air capture) are applied to offset the combustion-related impact.

Table 2: Process energy efficiency and tank-to-wake global warming potential with and without offset.

	Energy efficiency [%]	GWP [g CO_2eq/MJ]	GWP (no offset)[2] [g CO_2eq/MJ]
AtJ (Alcohol-to-Jet)	35.5	45.7	153
HEFA	55.6	16.2	86.9
PtL[1](Power-to-Liquid)	13.8	22.6/513	91/522
Gasification +Fischer-Tropsch	27.2	4.52	266

[1] PtL electricity from wind or current German electricity mix.
[2] Biogenic offset for HEFA, AtJ, Gas+FT & DAC for PtL.

Conclusion and Future Work

This work has presented a fully modular and extensible Life Cycle Assessment framework in UNICADO. By decomposing the monolithic legacy tool into a suite of modules orchestrated by an assessment manager, the new architecture provides the flexibility required for holistic trade-off analyses of novel aircraft and fuel technologies such as SAF. Future work will focus on expanding the library of impact assessment methods like CED and ReCiPe midpoint categories to translate the calculated inventories into a broader range of environmental damage categories.

Abstract. This paper presents a validation of high-fidelity aeroelastic maneuver simulations using experimental data of the DLR Falcon 2000 ISTAR aircraft in a clean cruise configuration from the HighFly MaGE flight test campaign. The dynamic open-loop maneuver simulations of the flexible free-flying aircraft are achieved with the DLR multidisciplinary process chain UltraFLoads, which can combine a flight dynamics model with a CFD flow solver (URANS with the DLR TAU-Code) and an unsteady structural modal analysis computed from the FE NASTRAN model. Pull-up and push-down and bank-to-bank maneuver simulations of different flight points are investigated (subsonic and transonic). The static pressure distributions on three chordwise wing sections and global flight dynamic quantities are compared with experimental data. Three pressure distributions on the right wing of the ISTAR aircraft were dynamically measured during the MaGE flight campaign using pMEMS sensors (Micro Electro Mechanical System).

Introduction

The central goal in current aviation research and development is to increase the efficiency of aircraft and reduce their environmental impact. Achieving these goals is supported by the ability to accurately and quickly analyse aircraft characteristics, including flight performance, flight loads, aeroelastic phenomena, flight control, and stability. Continuous development in high-performance calculations enables the application of high-fidelity numerical methods such as computational fluid dynamics (CFD), computational structural mechanics (CSM), thermodynamic engine models, and flight dynamics models, and their integration into multidisciplinary analysis. These methods can be used at early design stages and for virtual flight tests during certification by analysis. Virtual flight tests as part of the aircraft development digitalization should enable faster, safer, and more cost-effective progress of new technologies towards climate-neutral air transport.

To validate virtual flight test methods and models, comparisons with experimental data are required. This was the goal of the DLR project HighFly (High-Speed Inflight Validation) 2018–2023 [1]. In this project, comprehensive flight test data in the high-speed range and at the edge of the flight envelope of the new DLR research aircraft Dassault Falcon 2000LX ISTAR (In-flight Systems & Technology Airborne Research) [2] were provided. The ISTAR measurement instruments of the flight campaign MaGE (Maneuvers at the Border of the Envelope) are depicted in Fig. 1. With the measured flight data, the validation of simulation models for virtual flight testing and the quantification of numerical uncertainties are carried out.

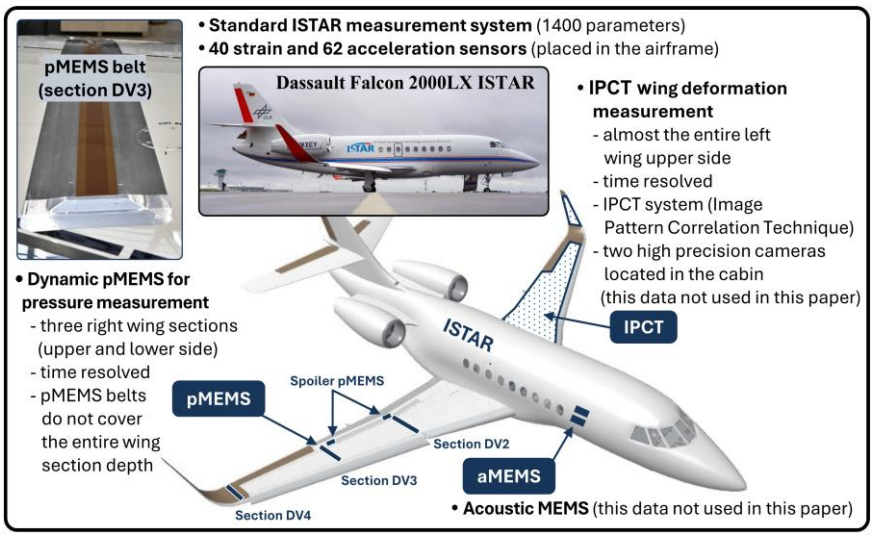

Fig. 1 DLR research aircraft Dassault Falcon 2000LX ISTAR with MaGE measurement instruments (project HighFly)

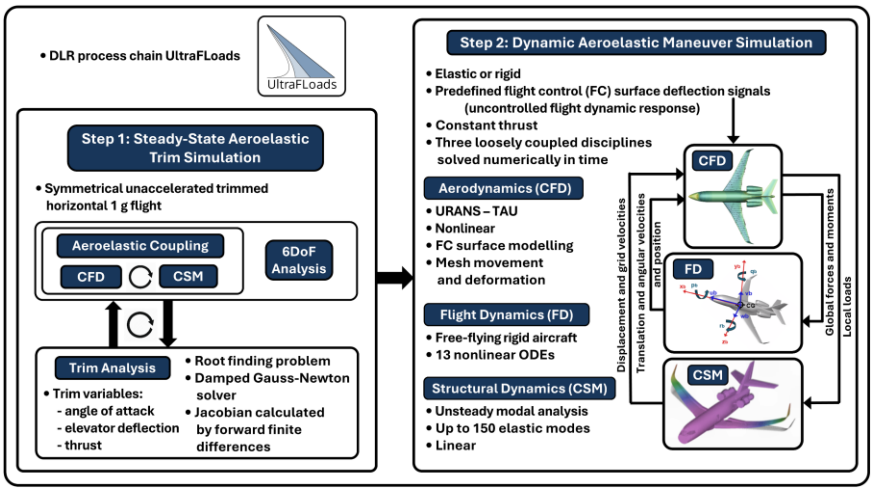

Fig. 2 UltraFLoads process of dynamic open-loop maneuver simulation

The first steady-state trimmed aeroelastic simulations and elastic dynamic maneuver simulations of the ISTAR aircraft with detailed descriptions of the individual numerical models and analysis were published in [3]. The first validation of the steady-state trimmed aeroelastic simulations with HighFly flight data was published in [4], where pressure distributions, trim variables, and elastic wing deformation were compared. These steady-state simulations serve as an initial solution for the dynamic maneuver simulations, which are introduced together with their validation in this paper.

Simulation Process Chain, Numerical Models, and Analysis

For maneuver simulations of the ISTAR aircraft, the UltraFLoads (UFL) process chain is used. It has been developed at the DLR Institute of Aeroelasticity in Göttingen. Fig. 2 schematically shows the overall UltraFLoads computation process. The first step is to trim the free-flying, elastic aircraft in a unaccelerated 1g horizontal flight. The second step, the open-loop dynamic maneuver simulation with predefined control surface deflections, starts from the trimmed state. The aircraft rigid body motion (flight dynamics) and the flexible degrees of freedom (structural modal analysis) are combined into one decoupled set of first-order ordinary differential equations, which is enabled

Materials Research Proceedings 69 (2026) 493-498 https://doi.org/10.21741/9781644904251-89

by the mean-axis condition. The equations are solved by the implicit linear multistep Adams-Moulton method, and their results are loosely coupled with the TAU-URANS simulation. The CFD mesh deformation based on RBF (Radial Basis Function) is performed at every time step (flight control surface deflections and aircraft elastic deformation) and the TAU-URANS simulation considers grid velocities due to mesh deformation and rigid body motion (ALE formulation).

Fig. 3 gives basic information about the CFD and CSM models and simulations of the ISTAR aircraft. More detailed information about these models can be found in [3]. A general description of UltraFLoads' architecture and capabilities can be found in [5], and three UltraFLoads applications are presented in [6, 7].

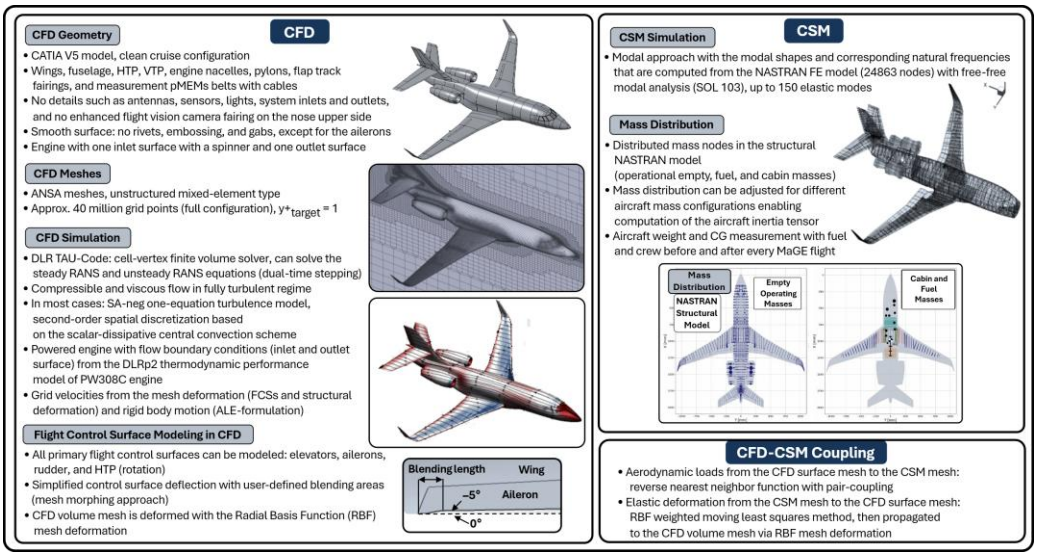

Fig. 3 CFD and CSM models and analysis of ISTAR

Results of Validation of Dynamic Maneuver Simulations with MaGE Flight Data

This section presents the first validation results of the dynamic maneuver simulations of the ISTAR aircraft against the MaGE flight data. It consists of three maneuvers (two pull-up and push-down maneuvers and one bank-to-bank maneuver), plotted in Figs. 4, 5, and 6. Local static pressure distributions on three wing sections (DV2, DV3, and DV4) at three time points, along with a few selected global flight dynamic variables, are depicted: red lines represent simulations, and blue solid lines and blue points represent flight measurement data. Dashed blue lines representing accuracy criteria from the Manual of Criteria for the Qualification of Flight Simulation Training Devices [8] are added to the diagrams. This ICAO document contains different criteria for different types of maneuvers. The following criteria are selected for the presented variables: ±1.0° angle of attack, ±0.1 g load factor, ±3 kt (±1.54 m/s) true air speed, ±2°/s pitch rate, ±1.5° pitch angle, ±2° roll angle, and ±2°/s roll rate. These flight simulator criteria can serve here as a preliminary accuracy assessment of the virtual flight tests. Figs. 4 and 5 also show the simulation wing upper side with surface pressure distribution for the initial trimmed flight state. A description of the simulation input parameter settings (such as Mach number, flight altitude, weight, and CG), a description of the CFD wing geometry details (pMEMS belts and cables), and a detailed comparison of the simulation results and the measurement data of the trimmed steady flight states (wing pressure distributions, trim variables, and wing elastic deformation) is presented in Section 3 in [4]. During the MaGE flight campaign, the dynamic maneuvers were flown manually in the calmest possible atmosphere without an autopilot and with a constant thrust setting.

Materials Research Proceedings 69 (2026) 493-498 https://doi.org/10.21741/9781644904251-89

The simulation results for the subsonic pull-up and push-down maneuver with only elevator deflection at a Mach number of 0.46 (Fig. 4) agree very well with the measured flight data. The most significant deviations in the static pressure distributions are observed at the wing section DV4 (the most outboard section), where the largest wing deformation occurs. The depicted simulation and measurement pressure distributions show local effects (local pressure peaks) at the beginnings and ends of all the pMEMS belts, which are caused by the leading and trailing ramps of the pMEMS belts with a thickness of 2 mm (also observed in Fig. 5).

Generally, a good correlation is observed in the transonic pull-up and push-down maneuver at a Mach number of 0.78 (Fig. 5), where only the elevator is deflected in the simulation. A minor tolerance violation of the simulation load factor can be observed in some areas. The pressure distributions show the largest deviations on the upper side of DV3, which is partially due to the absence of local spanwise surface waves on the wing in this region compared to the real aircraft (this deviation is described in Section 3.2 in [4]). Other larger deviations are visible in the front part of the DV4 lower side at time point 3, where the boundary layer separation appears in the simulation.

Fig. 6 presents only a comparison of the global flight dynamics parameters for the transonic bank-to-bank maneuver (+67º to −63º) at a Mach number of 0.78, with the ailerons and elevator deflected in the simulation. For roll rate and roll angle, the simulation values are within certain areas on the edge of the tolerance range (the highest deviation for roll angle is approximately 2º), but overall good agreement is observed.

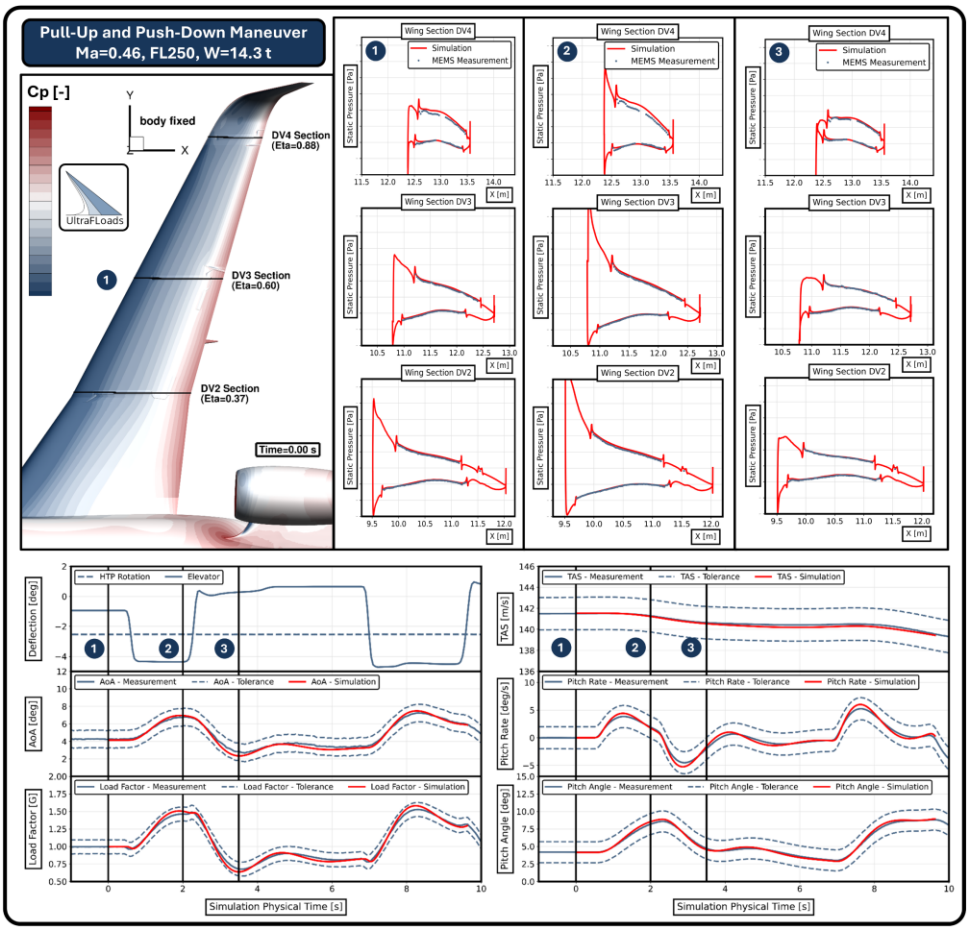

Fig. 4 Pull-up and push-down maneuver – Ma=0.46, FL250

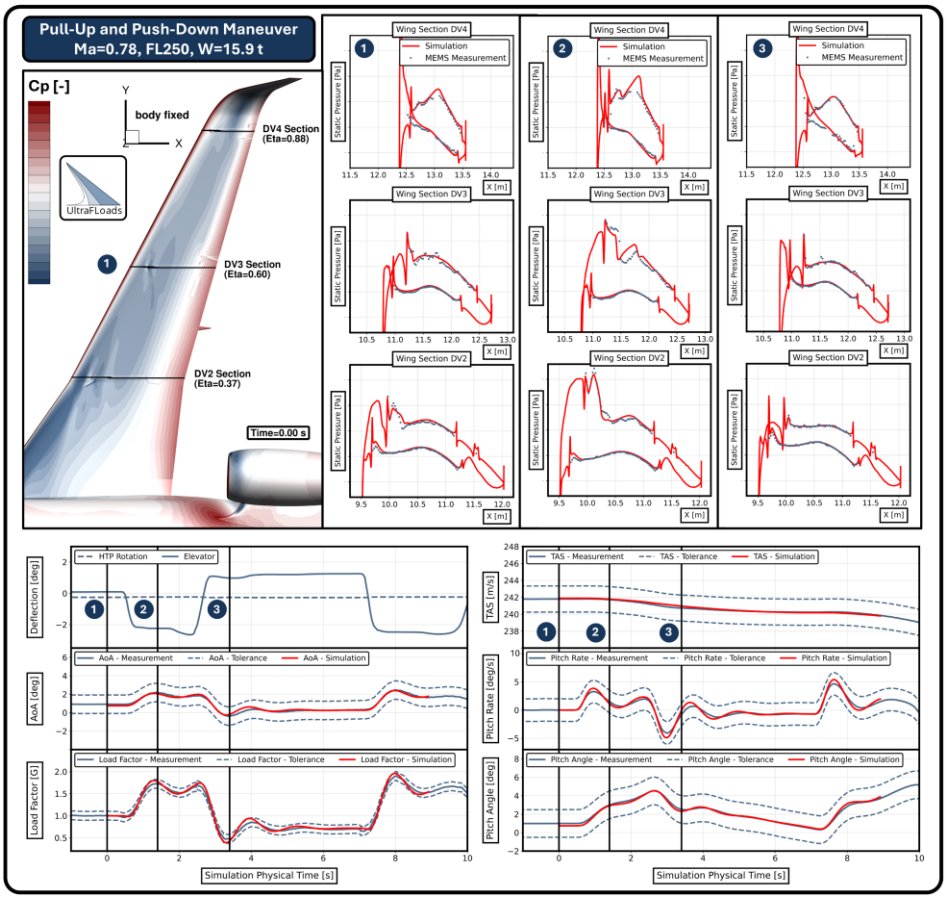

Fig. 5 Pull-up and push-down maneuver – Ma=0.78, FL250

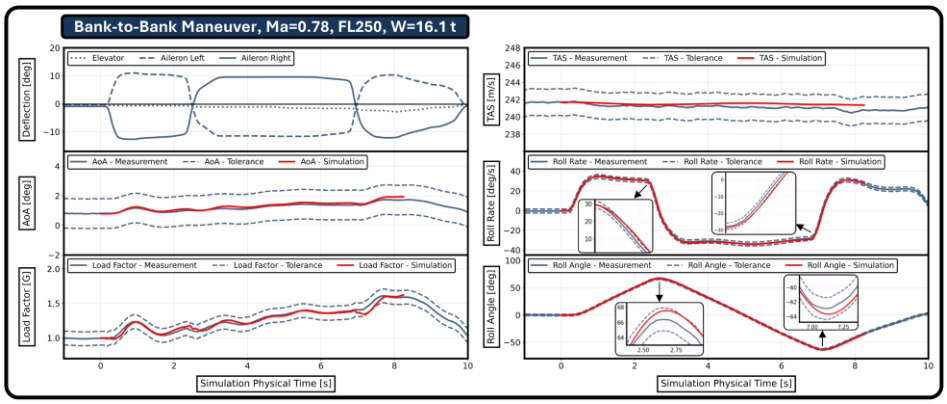

Fig. 6 Bank-to-bank maneuver – Ma=0.78, FL250

All presented UltraFLoads maneuver simulations are computed on the DLR HPC cluster CARO. The presented simulations with the CFD mesh with approximately 40 million points take about 330h on 480 CPUs on CARO (simulation physical time of approximately 9s, simulation time step of 0.0025s).

Summary and Outlook

In this paper, validation results for the first set of dynamic maneuver simulations, using experimental data from the DLR Falcon 2000LX ISTAR aircraft in clean cruise configuration during the HighFly flight campaign MaGE, are presented. This validation of pull-up and push-down and bank-to-bank maneuver simulations for Ma=0.46 and 0.78 shows a sufficient qualitative

correspondence between the simulations and measured data for the presented parameters (wing static pressure distributions and global flight dynamic quantities).

Further validation with MaGE flight data of different dynamic maneuvers will be performed in the next step. These will be more critical flight maneuvers: higher Mach numbers (closer to the maximum operating Mach number), higher flight altitudes, and maneuvers with a buffet onset (a light buffet onset occurred during some MaGE maneuvers). The influence of variations in different numerical parameters (CFD parameters, turbulence models, mesh resolution, inflow Mach number, weight, CG position, aircraft inertia properties, and elasticity variation) will be investigated.

Future DLR projects on validating virtual flight tests and certification by analysis are planned. The aircraft Falcon 2000LX ISTAR will be used again and will be equipped with a nose boom featuring more accurate measurement sensors, and additional pMEMS sensors could be installed on both sides of the aircraft, including the tail surfaces.

Abstract. The activities are based on the Sagittarius project, which introduces a simulation-coupled concurrent engineering framework for the preliminary design of a low-cost surface-to-air missile aimed at countering small hostile drones. The methodology integrates guidance, propulsion, aerodynamics, structures, and lethality within a unified workflow, enabling continuous exchange of boundary conditions and performance constraints across subsystems. Trajectory simulations are employed to validate the missile performance against representative mission scenarios, while warhead lethality and structural analyses are iteratively harmonized with aerodynamic and propulsion requirements to maintain design coherence. A reference case involving a target UAV flying at 60~m/s, positioned 8000~m from the defended zone and 5000~m in altitude, was used to assess nominal behavior and off-design robustness. Results demonstrate that the integrated workflow achieves consistent performance and high kill probability across different operational profiles, highlighting the benefits of multidisciplinary coupling in early-stage design. The proposed approach emphasizes the importance of scenario-driven, simulation-based interaction between subsystems as a key enabler for affordable and adaptable Counter-UAV missile solutions.

Introduction

The rapid proliferation of unmanned aerial vehicles (UAVs) and loitering munitions has reshaped modern warfare, introducing new paradigms in surveillance, reconnaissance, and tactical engagement. Their low cost, agility, and swarm capability have increased the complexity of airspace protection, as small UAVs can operate at low altitude with limited radar visibility, posing asymmetric threats to both military and civilian infrastructures [1, 2].

Conventional defense systems, conceived for high-value targets, are economically unsustainable against large numbers of inexpensive drones. Consequently, research has focused on affordable short-range missile systems capable of ensuring reliable interception performance [3]. These systems must guarantee adaptability to diverse UAV classes and flight profiles, requiring advanced detection, guidance, and control strategies.

Addressing these challenges demands an integrated approach combining aerodynamic, structural, guidance, and propulsion design under a unified optimization framework. Modern missile development therefore relies on simulation-driven, multidisciplinary environments that enable concurrent progress across domains, accelerating design and improving overall coherence [4].

Materials Research Proceedings 69 (2026) 499-503 https://doi.org/10.21741/9781644904251-90

Within this context, *Project SAGITTARIUS* was developed at the University of Naples Federico II, in collaboration with MBDA Roma, as a next-generation surface-to-air missile optimized for Counter-UAV missions (Fig. 1). The project applies a simulation-coupled concurrent engineering framework in which all primary subsystems—guidance, propulsion, aerodynamics, structures, and lethality—are developed in parallel through iterative data exchange and mission-driven constraints.

This paper outlines the design rationale and integrated workflow of the *SAGITTARIUS* project, demonstrating how scenario-based simulations and subsystem interaction lead to a coherent and adaptable missile configuration.

Figure 1: SAGITTARIUS Missile Design.

Methodology

The development of the *SAGITTARIUS* missile followed a concurrent engineering workflow aimed at ensuring tight integration among all subsystems from the earliest design phases. Each discipline was developed in parallel, with continuous data exchange and validation loops driven by mission-level simulations. The overall workflow is illustrated in Fig. 2.

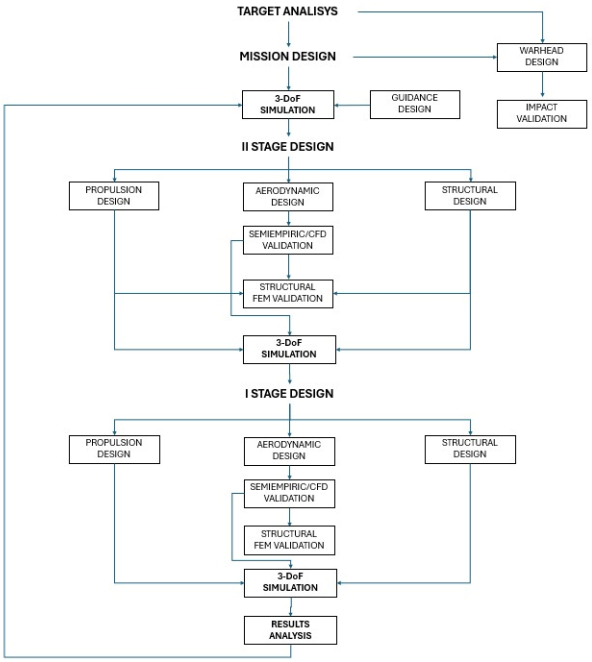

Figure 2: Concurrent engineering workflow adopted for the SAGITTARIUS missile design.

The process began with a comprehensive target analysis, defining the physical and operational characteristics of hostile UAVs, such as velocity range, altitude, and representative geometry.

Materials Research Proceedings 69 (2026) 499-503 https://doi.org/10.21741/9781644904251-90

These parameters guided the mission design, establishing engagement requirements including an interception range of 8 km, target altitude of 5 km, and velocity of 60 m/s.

A 3-Degree-of-Freedom (3-DoF) trajectory simulation was employed to assess mission feasibility and derive key metrics—acceleration limits, flight path, and kill probability (P_k). The simulation outputs served as boundary conditions for subsystem design, while the guidance and control logic were developed in parallel using a Proportional Navigation (PN) scheme integrated into the model.

The second-stage design followed a concurrent approach, combining propulsion, aerodynamic, and structural development. Propulsion parameters such as thrust and burn time were refined through iterative feedback with trajectory results. Aerodynamics were assessed using semi-empirical and CFD-based analyses, whereas FEM simulations validated the structural response of major components. Each iteration of the 3-DoF model ensured alignment between subsystem performance and mission objectives. After the second stage was finalized, its output conditions—velocity, attitude, and altitude—were transferred as inputs for the first-stage design, optimized to provide adequate thrust and stability during launch while maintaining overall mission coherence.

Missile Design & Reference Scenario

The interceptor was conceived as a compact, two-stage subsonic missile optimized for short-range air defense against small UAVs and loitering munitions. The architecture couples a booster stage for initial acceleration with a sustain stage for cruise and terminal engagement, balancing mass distribution, propulsion performance, and aerodynamic stability. The configuration was defined through a concurrent engineering process harmonizing subsystem constraints derived from trajectory simulations. The resulting main geometric and mass properties are summarized in Table 1.

Table 1: Principal characteristics (II stage / I stage / Total).

Characteristic	*II Stage (Sustain)*	*I Stage (Booster)*	*Total (Missile)*
Total mass	11.224 kg	5.470 kg	16.694 kg
Propellant mass	2.524 kg	1.288 kg	3.812 kg
Diameter	0. 0806 m	0.0806 m	0.0806 m
Length	0. 976 m	0.456 m	1.432 m
Reference Area S_{ref}	0.005 m^2	0.005 m^2	0.005 m^2
Nominal Thrust	150 N	3626.5 N	-
Average burn time	30.0 s	0.8201 s	-

The design workflow employs a hybrid MATLAB/Simulink environment coupling a 3-Degree-of-Freedom (3-DoF) trajectory solver with guidance, control, and propulsion modules. The booster provides initial conditions to the sustain stage, whose dynamics include aerodynamic forces, gravity, and actuator response. Launch geometry is computed through an *auto-aiming* routine solving the relative motion with gravity correction. Guidance follows a Proportional Navigation (PN) law generating commanded accelerations, converted into fin deflections by the autopilot. The simulation ends when the range-to-target R drops below 1 m or interception becomes unfeasible, providing data for subsystem sizing and P_k estimation.

The reference mission involves a small UAV flying at constant altitude and speed toward a protected area, representing a typical Counter-UAV engagement. The target travels at 60 m/s and 5000 m altitude, starting 8000 m from the defended zone on a 180° inbound heading. The protected area radius is 3 km, defining the interception boundary for neutralizing the threat. Fig. 3 shows the nominal engagement, highlighting missile and target trajectories together with the corresponding P_k evolution, confirming full interception and stable guidance under nominal conditions.

Materials Research Proceedings 69 (2026) 499-503 https://doi.org/10.21741/9781644904251-90

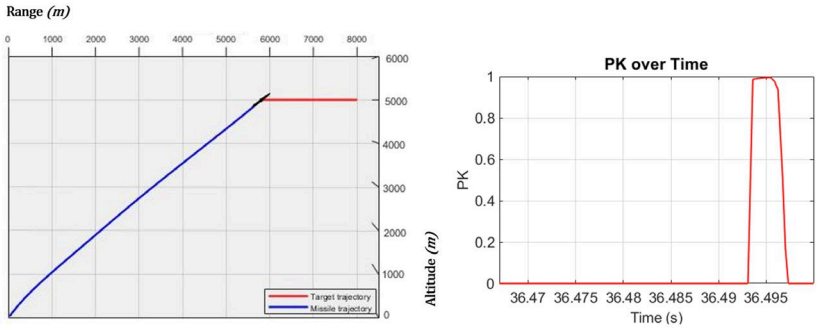

Figure 3: Nominal engagement scenario with time evolution of P_k.

Off-Design Conditions

To assess the robustness of the *SAGITTARIUS* missile, several off-design simulations were conducted by varying the target geometry and initial conditions, while keeping control laws and propulsion settings identical to the nominal case. This allowed the evaluation of guidance adaptability and overall system performance under realistic deviations from design conditions. Here two of these cases are represented.

The first configuration reproduces a *shallow dive attack*, with the target descending at 30° from 5000 m altitude and 8000 m ground distance at 60 m/s (Fig. 4). The interceptor adapts its trajectory through a progressive climb, completing the engagement after about 35 s with stable guidance and nearly unitary lethality ($P_k \approx 1$). The second case simulates a *close-range engagement*, with the UAV starting 3000 m from the launch point at 5500 m altitude (Fig. 5). Despite higher maneuver demand and shorter flight time (~33 s), the missile maintains control stability and achieves $P_k \approx 0.9$, confirming adequate energy and guidance margin.

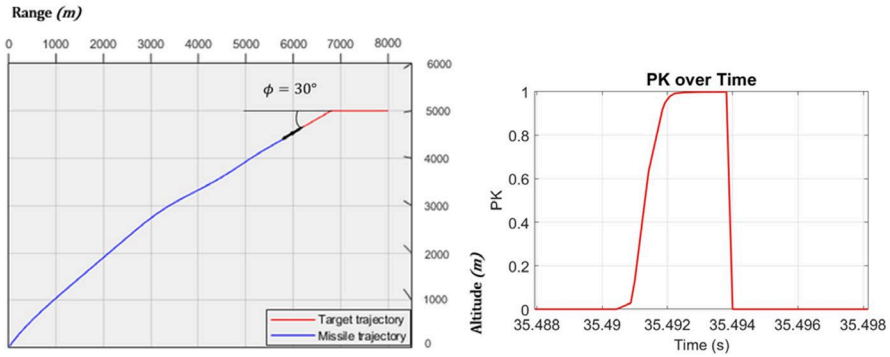

Figure 4: Off-design scenario 1 (Shallow dive approach) with time evolution of P_k.

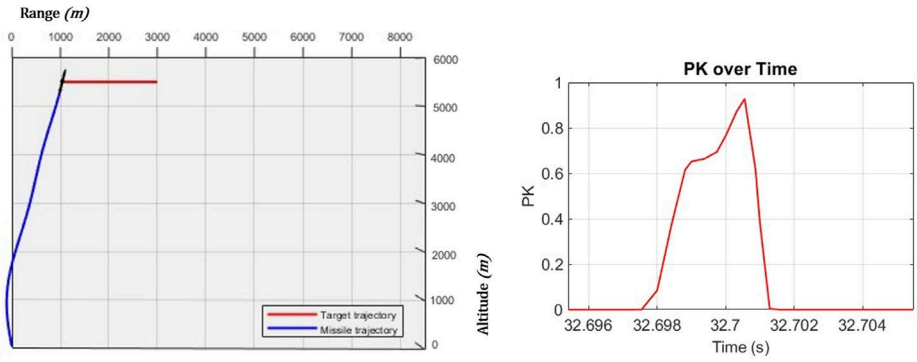

Figure 5: Off-design scenario 2 (Close-range engagement) with time evolution of P_k.

Conclusions

The *SAGITTARIUS* validated a simulation-driven, concurrent engineering framework for the preliminary design of Counter-UAV missile systems. The integrated workflow ensured coherence among propulsion, aerodynamics, structures, guidance, and lethality, maintaining performance consistency across nominal and off-design scenarios.

Results confirmed stable guidance, aerodynamic efficiency, and high lethality under varied mission geometries, demonstrating the robustness of the proposed approach. The methodology proved effective in enabling reliable and adaptable missile configurations through early multidisciplinary coupling.

Keywords: Aircraft Preliminary Design, Multi-Disciplinary Optimization, Reduced Order Model (ROM), Proper Orthogonal Decomposition (POD)

Abstract. Aircraft preliminary design requires the capability of rapidly exploring several different configurations without compromising the accuracy of the different physics involved, such as aerodynamics, structural analysis and low observability. In this work we propose a multi-fidelity methodology combining analysis with different levels of fidelity, where the high-fidelity is meant to be supported by Reduced Order Models (ROM). The purpose is to significantly accelerate the decision process, increasing the quality of the design already in the preliminary phases. Inspired by a previous ESTECO's experience [1], the methodology is applied by Leonardo Aeronautics in a study-case based on an example configuration of a fighter jet. The ultimate goal is to include this methodology among the tools available for preliminary aircraft design [2]. The design workflow begins with a conceptual phase that involves the rapid generation of several configurations through low-fidelity simulations. The purpose is not only to get a preliminary evaluation of the performances and requirements compliance, but also to find a region of interest in the input domain where to concentrate the analysis effort. In this region, we developed a Design of Experiments (DOE) Table containing different possible aircraft configurations to perform the high-fidelity simulations for the two selected physics: CFD for the aerodynamics and electromagnetic fields for the estimation of the radar cross-section (RCS). The resulting set is used as a training set for the development of the non-intrusive ROM models. This approach enables a detailed exploration of the solution space with limited computational costs, making it possible to converge on engineering-feasible configurations within the timeframes of the preliminary design phase.

Introduction

Engineering design processes commonly incorporate high-fidelity solvers to facilitate the acquisition of solutions characterised by high resolution. While the efficacy of these methodologies has been demonstrated, they are associated with a considerable computational cost. In the aerospace and defence sector, where rapid design iteration is paramount, this computational burden poses a substantial challenge, particularly in the initial stages of development that necessitate extensive parametric studies. Reduced order modelling represents a promising alternative to address these limitations. The purpose of this study is to demonstrate that, in a preliminary phase, ROM can act as an enabler for optimisation, reducing the quantity on high-

Materials Research Proceedings 69 (2026) 504-509 https://doi.org/10.21741/9781644904251-91

fidelity simulations while maintaining sufficient accuracy for decision-making. To do so, we apply the methodology to a design process carried out by the Leonardo S.p.A. aircraft preliminary design team. The original design process consists of several distinct phases, all integrated and automated through modeFRONTIER and VOLTA. The process starts with a parametric CAD model of the aircraft generated in CATIA V5, followed by a meshing step performed in ANSA BETA CAE. Subsequently, the CFD simulation is conducted in Ansys Fluent, and finally, a low-observability study is carried out in Ansys HFSS. The entire process for a single design lasts four hours on an HPC node with 48 CPUs showing an evident limitation to perform a multi-objective optimization within the industry timing. The output of interest for the CFD simulation includes the pressure and shear stress fields on the aircraft surface, whereas the electromagnetic result is the Mono-static RCS Total signal. This highlights the need to develop a surrogate model that preserves the space resolution of the Full-Order Model (FOM) to enable the analysis of physical phenomena, including flow separation and shock waves.

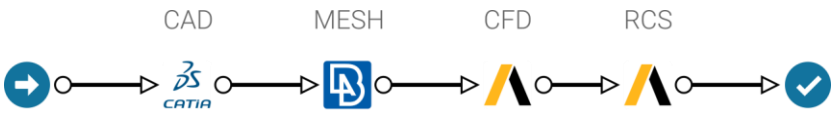

Figure 1: Original design process

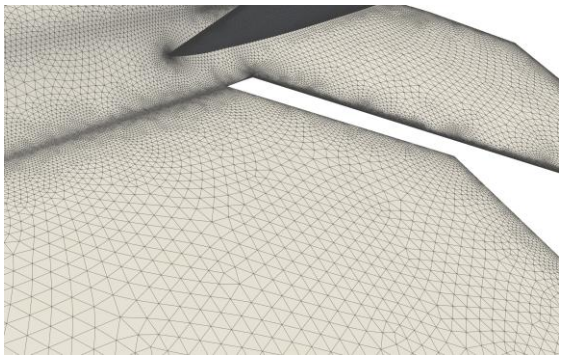
Reduced Order Models have emerged as a strategy to approximate the behaviour of complex systems with significantly reduced computational effort. The classification of ROMs is typically divided into two categories: intrusive and non-intrusive. While the intrusive operate directly on the governing equations, requiring modification of the underlying solver, non-intrusive ROMs treat the solver as a black-box and consider only input-output data for training. Among non-intrusive techniques, Proper Orthogonal Decomposition (POD) is one of the most widely used. The system extracts dominant modes from a set of high-fidelity solution snapshots and projects new queries onto this reduced space. When combined with interpolation schemes such as Radial Basis Functions (RBF), POD-based ROMs can reconstruct flow fields across a range of geometric parameter variations. This technique relies on matrix operations on the training samples, and consequently, it is required that training designs have equal dimension. For the CFD, this means that the fields must be defined on the same number of mesh nodes, that the meshes need to be topologically equivalent.

Low-fidelity Exploration

In the initial study phase, we explore a large number of configurations with a dual purpose: to perform a sensitivity analysis on the input variables and to identify a promising region for a high-fidelity optimization. Low-fidelity simulations, although simplified, are sufficiently accurate to capture general performance trends, providing valuable insight to set up the optimization problem. Aerodynamics is computed through a simulation based on the Vortex Lattice Method (VLM), while the electromagnetic analysis, relies on a high-frequency faceted scattering model. This exploration determines the input variables that most influence the performance metrics of interest and finds a design region that best balances: weight reduction, improved aerodynamic efficiency allowing for a smaller engine and reduced peak in the RCS. Additionally, we apply performance constraints to improve the Specific Turn Rate (STR) at two target altitudes and across multiple Mach numbers. The most relevant input variables and the variation limits are respectively: Reference Surface Area (Sref) in the range [65, 75], Aspect Ratio (AR) in the range [2.6, 3.1], Leading Edge Sweep Angle in the range [36, 46], and Thickness-to-Chord Ratio (tc) in the range [4, 5].

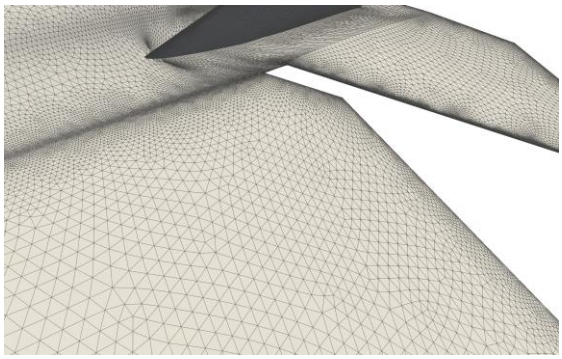
Materials Research Proceedings 69 (2026) 504-509 https://doi.org/10.21741/9781644904251-91

Table 1: Input Domain



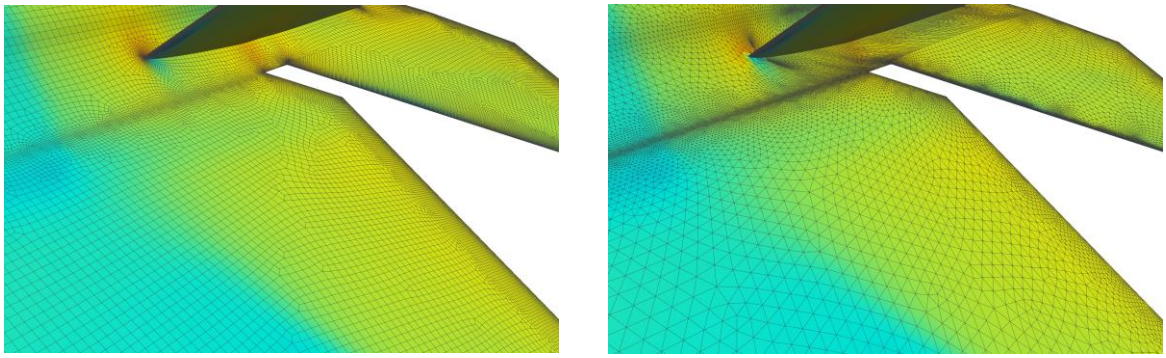
Input variables	Lower Bound	Upper Bound
Sref	65	75
AR	2.6	3.1
Sweep Angle LE Wing	36	46
Thickness wing root	4	5

High-fidelity



The High-Fidelity simulations are used to create a representative dataset for the region identified in the former phase; this dataset serves for the training of the ROM models. To distribute the data set uniformly, we used a Uniform Latin Hypercube (ULH) as the DOE algorithm. A DOE table of 40 configurations is set up directly in modeFRONTIER, which orchestrates the whole design process and enables to apply advanced sampling techniques to add new points at the training dataset during the ROM's quality assessment phase. Since the CFD and RCS simulations are performed on the same starting geometry, but they do not depend one to the other, they can be run in parallel.

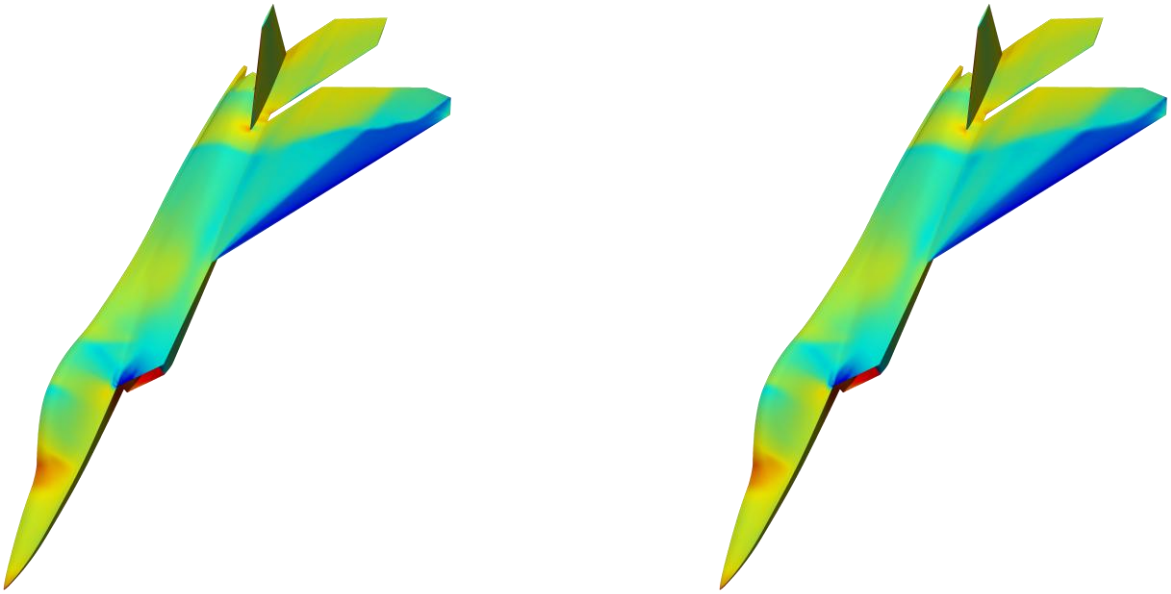
Registration and Mapping - CFD



As stated previously, the ROM used in this study requires field data of equal dimensions to create the snapshot matrix. Consequently, the resulting fields: pressure and skin friction, must be mapped on the same reference mesh morphed on different geometries. The original framework did not incorporate mesh morphing; instead, it involved a meshing phase for each geometry resulting from the parametric CAD model, thus yielding to typical CFD meshes with variable number of cells. To adapt to this framework, we integrated a mesh morphing procedure that adjusts a reference surface mesh to the geometries produced from the parametric model. This step, designated as "registration", necessitates a modification to the original modeFRONTIER workflow: the definition of Surface IDs and the export of the resulting surface mesh. This process enables Mimic, ESTECO's proprietary software, to identify the features and edges between the surface IDs for each input geometry, thus determining the computation of the deformation fields between them. Iterating this procedure among all the designs allows to collect all the so-called registered meshes, i.e. the baseline mesh overlapping with each different geometric configuration (Figure 2: a - b). The selection of the baseline mesh is crucial in this context. We chose the geometry with the largest reference surface to prevent certain elements from being enlarged during morphing, thus losing mesh resolution. After the registration phase, each field derived from CFD simulations is mapped from the original computational mesh to the corresponding registered mesh (Figure 2: c - d).

(a) Baseline Mesh

(b) Registered Mesh



(c) Original Pressure Field (d) Mapped Pressure Field

Figure 2: Registration and mapping

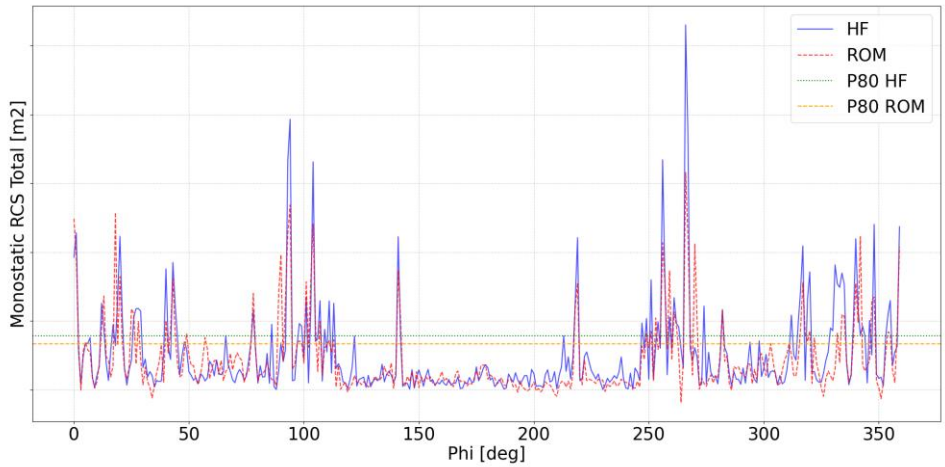
ROM Model - CFD

As previously stated, the ROM used in this study is based on POD techniques and nonlinear regression models, such as RBF [3].

(a) High fidelity pressure field (b) Predicted pressure field

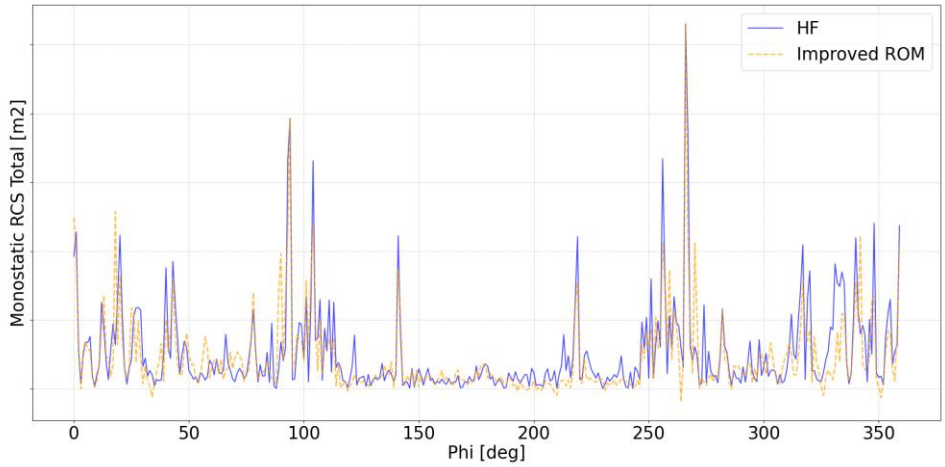
Figure 3: Comparison between the pressure field from the CFD and the ROM model

The generation of a solution for a new geometry is simplified by predicting, using regression models, the relevant expansion's coefficients of the POD. The training phase is performed through a dedicated ROM training node in modeFRONTIER. Through this node we can control the POD energy, the validation strategy and the regressor configuration.



The validation estimates the ROM's quality by calculating the projection and the validation error for each design in the validation set. The figure 3 shows a qualitative comparison between the pressure field obtained from the CFD simulation and the one predicted with the ROM model.

ROM Model - RCS



In the case of the RCS simulation, the ROM model predicts the Mono-static RCS Total, considering fixed values for the frequency and the elevation angle (θ) of the incident wave direction. Unlike the previous two cases, here the quantity is not predicted for a point on the mesh but for a given azimuth angle (ϕ). The ROM model therefore aims to predict the Mono-static RCS

Materials Research Proceedings 69 (2026) 504-509 https://doi.org/10.21741/9781644904251-91

Total signal as the azimuth angle varies from 0 to 360 degrees. The highly non-linear behaviour of RCS signals represents a particularly challenging case for prediction using a ROM model.

(a) Predicted RCS signal

(b) Improved prediction RCS signal

Figure 4: Predicted and Improved RCS

The ROM model trained only the initial DOE of 40 designs has a very high projection error, indicating that the starting dataset was insufficient to achieve an accurate representation. For this reason, an additional 60 configurations were added for the only RCS simulation, using modeFRONTIER's Incremental Space Filler algorithm based on Voronoi–Delaunay tessellation. These new points made it possible to significantly reduce both projection and prediction errors. As shown in Figure 4-a, the model still struggles to accurately predict peak values. With the aim of correcting the highest peaks value, a second ROM model was trained on the reordered peaks. The two ROM models were then combined for the final signal prediction, as shown in Figure 4-b.

Optimization

The trained ROM models can ultimately be used within modeFRONTIER as replacement to CFD and RCS simulations. A dedicated node allows for straightforward use of the ROM models and seamless integration with other disciplines in the design process. The optimization considers the same variables and input domain of the high-fidelity, and three objective functions: minimization of the drag coefficient (CD), maximization of the lift coefficient (CL), and minimization of the maximum peak of the RCS signal. The DOE of high-fidelity designs is used as first generation for

the NSGA-II genetic algorithm. The algorithm evolves over 20 generations, evaluating a total of 400 designs. The optimization yields a Pareto front of optimal designs, from which three configurations were selected, each representing a good balance between the objectives. Finally, the three selected designs were validated using high-fidelity simulations.

Summary

This case study highlighted how ROM models can enable optimization during the preliminary design phase of an aircraft, drastically reducing simulation times. The short training times and the relatively small number of designs required to create the training dataset allow the overall timeframe to fit within the constraints of the preliminary design phase. The modifications to the framework already used by the Leonardo team were acceptable, demonstrating the potential for adopting such a tool. There are numerous opportunities for future developments, both in improving the ROM model (through techniques such as error-based adaptive sampling) and in expanding the methodology to additional disciplines, ultimately enabling an effective optimization framework.

Abstract. This study explores the use of ESA's Aeolus satellite data to characterize wind gusts along a transatlantic flight corridor. A dedicated framework was developed to extract the power spectral density (PSD) of wind signals from temporally discontinuous satellite observations, enabling PSD-based gust characterization using spaceborne Doppler lidar data along operational flight routes. The proposed framework extracts and preprocesses wind data from ESA's Aeolus mission and applies Fourier-based spectral analysis to obtain the PSD of the signal, which is then fitted using two different approaches: a classical von Kármán turbulence model and a data-driven optimization method. Results reveal deviations from the von Kármán spectrum, highlighting regional variability and demonstrating the potential of spaceborne Doppler wind lidar for global gust characterization and improved aviation safety modeling.

Introduction

Space technologies play an increasingly vital role in sustainable development, driven by innovation and the widespread use of satellite services [1]. Earth Observation (EO) systems are key, supporting disaster management, environmental monitoring, and climate adaptation [2]. EO capabilities, especially satellite constellations and real-time data, enable high-frequency, wide-area observations suited to operational needs [3]. These are crucial in atmospheric science, where accurate wind measurements improve weather forecasts and climate models. ESA's Aeolus mission, the first to provide global wind profile data via space-based Doppler lidar, marked a milestone, offering new insights into atmospheric dynamics [4]. However, despite extensive use of satellite wind products in meteorology and climate studies, their exploitation for aeronautics, particularly for gust load assessment, is still largely unexplored. Wind gusts pose significant challenges for flight safety, passenger comfort, and aircraft integrity. Accurate gust characterization is vital for aircraft design and certification.

Traditionally, gust spectra are derived from dedicated flight-test campaigns, which are costly, geographically constrained, and limited to regions frequently flown by commercial traffic. The emergence of advanced EO platforms, such as the Copernicus Sentinel missions, may open new opportunities to complement in situ data with continuous, high-resolution atmospheric observations, offering a promising avenue for improving gust load prediction and hazard monitoring in aviation [5]. In parallel, the increasing vertical integration of New Space companies, spanning upstream, midstream, and downstream activities, amplifies the ability to harness EO data in operational aerospace applications [6]. Within this evolving framework, ESA's Aeolus mission stands out as a unique opportunity to extend wind and turbulence monitoring to remote and oceanic regions beyond the reach of aircraft-based sensing.

This study utilizes data from ESA's Aeolus satellite during a transatlantic flight to analyze wind gusts. A framework is developed to derive the PSD from the wind temporal signal, providing a

Materials Research Proceedings 69 (2026) 510-515 https://doi.org/10.21741/9781644904251-92

detailed characterization of wind gusts. The proposed framework extracts and preprocesses wind data from ESA's Aeolus mission and applies Fourier-based spectral analysis [7] to obtain the PSD of the signal, which is then fitted using two different approaches: (i) a parametric function based on the von Kármán turbulence model, and (ii) a data-driven approach from [8]. Notably, the latter approach, unlike the model-based fit, involves solving an optimization problem to maximize the R^2 between the PSD and the fitting curve without assuming an a-priori mathematical function. This comparison helps evaluate whether the von Kármán turbulence model adequately describes the wind gust signals.

This paper is structured as follows: Section 1 provides an overview of the Aeolus mission and the extracted data; Section 2 outlines the adopted methodology; Section 3 presents some preliminary results; and finally, Section 4 concludes the paper by summarizing the main findings.

Aeolus

The Aeolus mission, developed by the ESA, represented a technological milestone in atmospheric observation by delivering the inaugural global wind profile measurements from space through the Atmospheric Laser Doppler Instrument (ALADIN). Operating in a sun-synchronous low Earth orbit at an approximate altitude of 320 km, Aeolus achieved near-global coverage. It emitted ultraviolet laser pulses at 355 nm to detect the Doppler shift in the light backscattered by air molecules and aerosols. These measurements facilitated the estimation of both the line-of-sight (LOS) and horizontal line-of-sight (HLOS) wind components, which are vital for meteorological analyses.

Because Aeolus operates in a sun-synchronous Low Earth Orbit and measures winds along its ground track (see Figure 1), each location is observed only during short temporal windows. Consequently, each surface point is sampled only during the orbital pass, resulting in a dataset that is temporally sparse and spatially irregular.

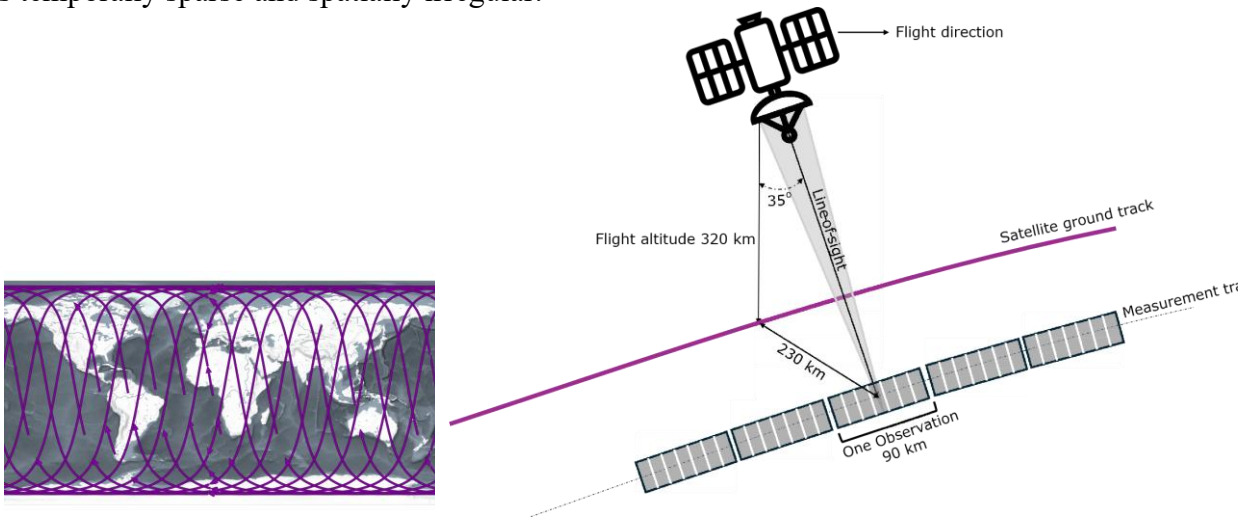

Figure 1. Aeolus' ground track in one day (left). Schematic view of Aeolus measurement geometry (right).

These characteristics prevent the direct application of standard spectral analysis procedures and require dedicated preprocessing before PSD estimation.

From an analytical perspective, these characteristics pose significant challenges for spectral analyses and time-domain studies of atmospheric dynamics. The gaps and irregular sampling intervals necessitate the adoption of specific pre-processing and reconstruction techniques before extracting spectral information such as the PSD of wind gusts. Despite these constraints, Aeolus data offer a unique opportunity to explore global wind variability, providing valuable input for

Materials Research Proceedings 69 (2026) 510-515 https://doi.org/10.21741/9781644904251-92

turbulence characterization and gust modelling in regions where conventional in-situ measurements are unavailable.

Methodology

This section outlines the methodology used to analyze the wind data collected from the Aeolus satellite. The approach follows the general framework shown in Figure 2. Once the signal has been extracted, time intervals with no data are removed, and the remaining intervals are concatenated into a uniformly sampled sequence. Welch's method is then applied to estimate the PSD. Subsequently, the fitting model is applied.

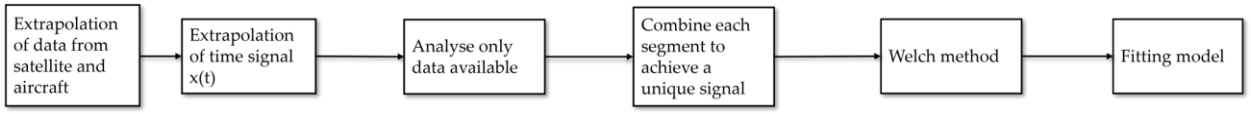

Figure 2. Workflow adopted in the proposed methodology.

Fitting Model

To accurately determine a representative curve of the PSD, the data have been fitted using a model based on the von Kármán equation, a renowned mathematical representation for the PSD of vertical and horizontal wind gust [9]. Eq. 1 is used for vertical wind gusts

$$\mathrm{PSD_{vk}}(f_k)=\frac{\sigma^2 L}{\pi V}\frac{1+\frac{8}{3}\left(1.339\frac{2\pi L}{V}f\right)^2}{\left[1+\left(1.339\frac{2\pi L}{V}f\right)^2\right]^{\frac{11}{6}}} \quad (1)$$

in which σ represents the root mean square of the vertical wind speed, L denotes the turbulence scale, and V is the air speed. The von Kármán model is calibrated using two key parameters: L and σ. The parameter L determines the frequency at which the slope of Eq. 1 increases, providing insight into how gust properties vary spatially, and it is influenced by factors such as altitude. Meanwhile, the parameter σ quantifies turbulence intensity, which depends on the average wind speed and altitude. These parameters are estimated using a non-linear least squares optimization approach to determine the PSD curve that best fits the data, based on the von Kármán equation. Eq. 2 is the parametric equation used in the optimization:

$$\mathrm{PSD_{vk}}(f_k)=a\frac{1+\frac{8}{3}(bf)^2}{\left[1+(bf)^2\right]^{\frac{11}{6}}} \quad (2)$$

with $a=\frac{\sigma^2 L}{\pi V}$ and $b=1.339\frac{2\pi L}{V}$.

While the von Kármán model is widely used in the aeronautical industry for sizing aircraft structural components, it is essential to note that recent climate changes have increased the frequency of hazardous phenomena [10]. Consequently, the von Kármán model may no longer effectively describe such complex and evolving phenomena. In this work, an alternative approach is introduced. This new model, called *agnostic* because it does not depend on a specific pre-existing equation, aims to determine the best-fit curve directly from data without relying on a predefined formula. The process begins by identifying a polygonal chain, followed by an optimization procedure to find the best-fit curve. The key steps to determine the polygonal chain are as follows: i) a set of n points, equally spaced on a logarithmic frequency scale, is defined; ii) for each point is calculated a specific frequency f_n and a corresponding value on the y-axis y_n is

Materials Research Proceedings 69 (2026) 510-515 https://doi.org/10.21741/9781644904251-92

assigned; iii) the polygonal chain is defined by the union of *n-1* segments that connect the n points, with each segment connecting two consecutive points.

The error e_k between the polygonal chain and the PSD is defined according to Eq. 3, where y_k represents the value of the polygonal chain at the *k-th* frequency f_k.

$$e_k = y_k - PSD(f_k) \tag{3}$$

Once the polygonal chain is defined, an optimization problem is carried out according to Eq. 4

$$\begin{cases} \min \dfrac{\sum_{k=0}^{N-1} e_k^2(y_n)}{\sum_{k=0}^{N-1}\left(PSD(f_k) - \frac{1}{N}\sum_{j=0}^{N-1} PSD(f_j)\right)} \\ y_{min} \leq y_n \leq y_{max} \end{cases} \tag{4}$$

The objective function chosen for the optimization problem is the complement of (R^2), as shown in Eq. 4. The design variables are the *y* coordinates y_n of the *n* points in the polygonal chain, with the upper bound y_{max} and lower bound y_{min} depending on the data used. The optimization utilizes gradient-based algorithms, along with a multi-start approach, to find a solution close to the global minimum. The output of the optimization algorithm is the polynomial chain that best fits the data. The shape of this curve varies with the number of points *n,* which is discussed in the next section.

Results

This section presents the main results, specifically considering one of the busiest routes, namely the transatlantic route, the data collected by Aeolus between 2019 and 2022 was used to compare the two fitting models presented in the previous sections.

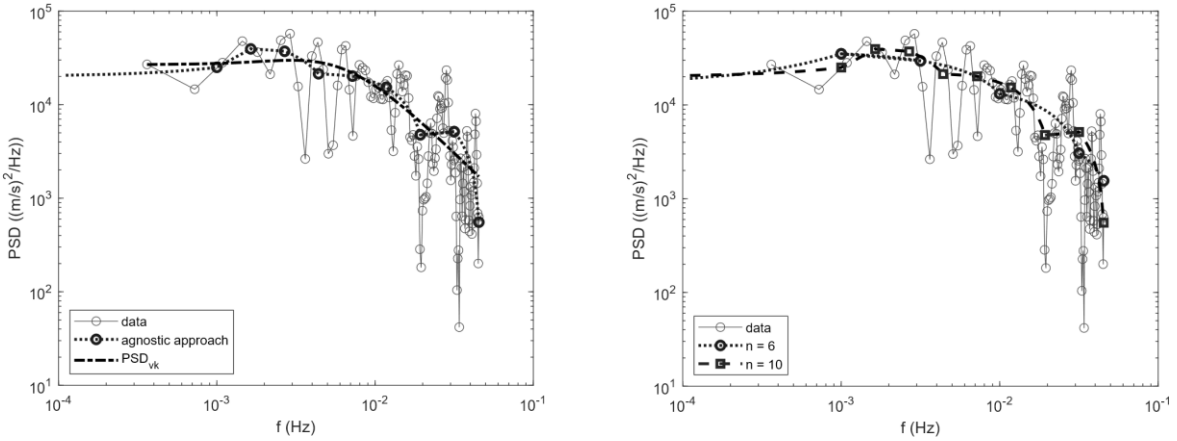

Figure 3. Comparison between the two fitting models, using 10 points for the agnostic approach. $R^2 = 0.54$ for von Kármán fitting and $R^2 = 0.59$ for the agnostic approach (left). Comparison using the agnostic fitting model but varying the points. $R^2 = 0.55.

Specifically, once the data were extracted and Welch's method was applied to derive the PSDs, the two fitting models were applied. Figure 3 shows the results on the data collected in the area from 50° to 55° North and from 33° to 43° West, during July and August 2021, at an altitude of 10 km.

Results indicate that both models capture the PSD trend with comparable accuracy. In this specific region (50°–55°N, 33°–43°W), the von Kármán model remains valid, likely because the model was historically derived from transatlantic flight-test campaigns.

Conclusion

This study demonstrates that ESA's Aeolus satellite observations can be used effectively for spectral analysis of wind gusts along transatlantic routes. A dedicated framework was developed to address challenges from Aeolus's irregular and non-uniform data, allowing for the estimation of the PSD of atmospheric wind signals using spaceborne Doppler lidar data

The comparison between the classical von Kármán turbulence model and a data-driven agnostic fitting approach offered important insights into wind gust spectra characterization. Results in the North Atlantic show both models can reproduce observed PSD trends with similar accuracy. This confirms the von Kármán model's relevance in regions where it was originally developed, while also highlighting the agnostic method's ability to adapt to various atmospheric conditions without relying on fixed assumptions.

This work demonstrates that satellite-based wind measurements can extend turbulence characterization globally. Integrating Aeolus data into gust models can improve aviation safety, aircraft design, and risk assessment, especially in data-scarce oceanic and remote regions. Future work aims to analyze different atmospheric layers, seasons, and areas. These efforts will help create a global turbulence database, aiding scientific research and aerospace safety by addressing atmospheric variability challenges.

Acknoledgment

This study was carried out within the Space It Up project funded by the Italian Space Agency, ASI, and the Ministry of University and Research, MUR, under contract n. 2024-5-E.0 - CUP n. I53D24000060005.

Abstract. Under the HERWINGT project, a comprehensive trade-off study was performed to assess advanced wing concepts for a next-generation regional aircraft, referred to as the Ultra Efficient Regional Aircraft (UERA). The investigation focused on aeroelastic implications of increasing wing aspect ratio up to 16, with the goal of reducing fuel burn, while limiting the structural weight growth driven by higher loads. Parametric analyses have been conducted along with the assessment of a load alleviation system. Study results provided wing structural and aero-servo-elastic requirements fundamental for the experimental demonstration phase, based on wing gust load alleviation system, to be tested inside POLIMI wind tunnel.

Introduction

Climate change has become a central rationale for disruptive technologies in the aviation field. In 2023, air transport was responsible for 2.5% of total CO_2 emissions [1]. The worsen scenario if contrails are kept into consideration, leading aircrafts to be responsible for 4% of global warming [2]. To mitigate the negative environmental impact of human-related activities, the European Union (EU) has settled an agreement - Green Deal - to reach net zero emissions by year 2050 [3]. The Clean Aviation Joint Undertaking was created to research new aviation technologies compliant with the climate crisis. In this context, the *Hybrid-Electric Regional Architecture* (HERA) project - coordinated by Leonardo (A/C Division), and the *Hybrid Electric Regional Wing Integration Novel Green Technologies* (HERWINGT) project - coordinated by Airbus Defence and Space, started in January 2023. The aim is to study a new regional aircraft configuration capable of reducing the emissions both flight-related and technology-based [4, 5]. Hybrid electric propulsion is introduced by batteries and Sustainable Aviation Fuels (SAFs). Aerodynamics efficiency is reached through high Aspect Ratio (AR) wing along with morphing control surfaces, to reduce drag. Since increasing wing AR leads to an increase in wing loads and, consequently, in wing structural mass, additional control surfaces with Load Alleviation (LA) purposes are considered.

The present work focuses on preliminary design of high AR wing for such aircraft, summarized in the following.

1. A reference aircraft - ATR72-600 - has been designed. The model is referenced throughout the work as ATR72-like.
2. The ATR72-like has been modified to account for the presence of batteries and lower fuel mass. The updated model is named UERA-like.

3. A parametric analysis has been computed on the UERA-like configuration, increasing wing AR and assessing its effect on sizing and loads. The set of obtained models are UERAAR, with AR substituted by its value (e.g. UERA16, for AR=16).

On such models, a LA system has been introduced through an additional wing control surface, here referenced as Load Control (LC) tab, along with the conventional aileron. Static aeroelastic analyses have been computed for different deflections - considered positive as the control surface goes downward - of LC tab, also coupled with ailerons, to quantify potential wing root load alleviations.

Models

The adopted tool to generate and analyze models in the current work is NeoCASS, an open-source code developed at POLIMI [6, 7, 8]. The procedure starts with the definition of geometry, maneuvers compliant with the certification regulations (EASA CS23, CS25) and mass configurations. Aerodynamics is modeled through Vortex Lattice Method (VLM), while structure is represented by beam elements. The sizing process leads to a stick model, whose inertia and stiffness distributions are evaluated through a physics-based approach. NeoCASS allows to compute trim, modal and flutter analyses, but also dynamic responses to gust or control deflections.

ATR72-like model. Starting from ATR72-600 public data, the ATR72-like model has been sized. The analyzed configuration considers a 72 passengers cabin arrangement, total fuel mass of 5000 [kg] - entirely stored in wing tanks - and aluminum alloy as material. Table 1 presents some data concerning the wing. The reference model has AR=12.

Table 1: Wing data for ATR72-like

Area	61 [m^2]
AR	12 [-]
Kink 1	0.176 [-]
Taper tip	0.59 [-]

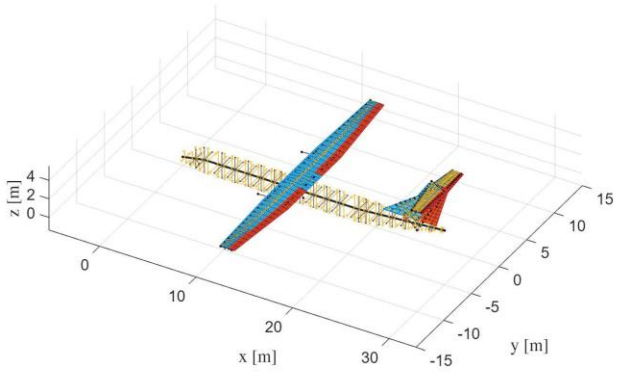

Figure 1: ATR72-like model

Sizing has been computed considering EASA CS25 maneuvers, for 4 mass configurations: Maximum Take-Off Weight (MTOW), Maximum Landing Weight (MLW), Maximum Zero Fuel Weight (MZFW) and Operative Empty Weight (OEW). The sizing results in terms of total masses are reported in Table 2, while Fig. 1 shows the aeroelastic model.

Materials Research Proceedings 69 (2026) 516-521 https://doi.org/10.21741/9781644904251-93

Table 2: Sized total masses for ATR72-like

MTOW	23000 [kg]
MLW	22350 [kg]
MZFW	21000 [kg]
OEW	13600 [kg]

UERA-like. As anticipated, ATR72-like model has been modified into UERA-like to account for the presence of the hybrid propulsive system of HERA aircraft, including two concentrated masses (the batteries) inside rear and forward portions of the fuselage, while fuel mass has been reduced of 70%. ATR72-like geometry has been kept unchanged.

Total masses obtained for UERA-like model are reported in Table 3. The last column represents the increase obtained with respect to the values of Table 2.

Table 3: Sized total masses of UERA-like, compared to ATR72-like

MTOW	27420 [kg]	+16%
MLW	27220 [kg]	+18%
MZFW	25920 [kg]	+19%
OEW	18520 [kg]	+26%

UERA with increased AR (UERAAR). To improve aerodynamic efficiency, a possible option is to increase wing AR. Indeed, the induced drag coefficient is inversely proportional to wing AR, as reported in Eq. 1.

$$c_{D_i} = \frac{c_L^2}{\pi e AR} \tag{1}$$

Nevertheless, this has an impact on wing loads and consequently on wing weight. To alleviate the excess of loading, LA systems can be implemented. They consist of dedicated control surfaces, generally placed close to the wing tip to increase their effectiveness in load redistribution. In principle, if the sizing is recomputed including the presence of such devices, wing weight can be kept limited. A quantification of these concepts is given in the current work, for different wing ARs.

Starting from UERA-like model, only wing planform has been adjusted to reach the desired values of ARs, as reported in Fig. 2 left. Also wing aileron and LC tab are displayed, with the former kept fixed for all the models. Sizing procedure is the same adopted for ATR72-like and UERA-like models. The results can be found in Fig. 2 right, where the induced drag coefficient has been estimated following Eq. 1 and, concerning the total masses, just MTOW has been reported for simplicity. As expected, as AR increases, MTOW increase, while c_{D_i} decrease. The data have been a-dimensionalized for the values correspondent to AR=12 model (i.e. UERA-like). Maxima deviations are reached for UERA16.

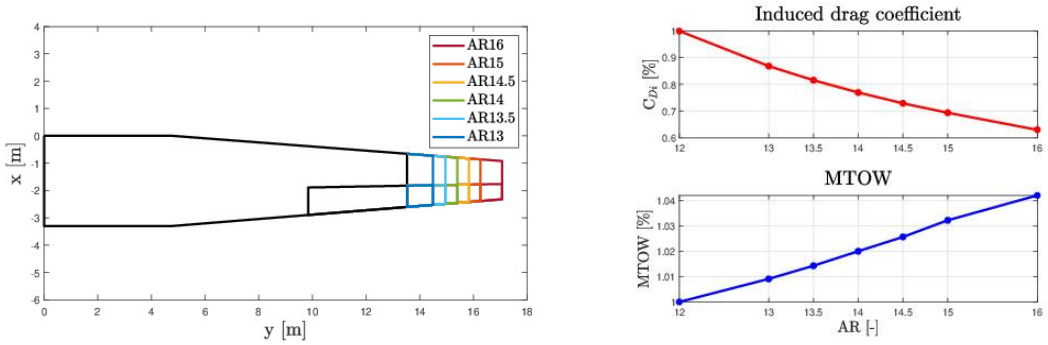

Figure 2: UERAAR, effects of wing AR on wing planform (left) and on induced drag coefficient and MTOW (right)

Analyses

To show the static effect of LA system, a pull-up maneuver at cruise design point has been computed for UERA-like model (black). Then, the same analysis has been applied to UERA16 in three different conditions: without any deflection of the LC tab (red); with $\delta_{LC_{tab}}$=10 [deg] (orange); with $\delta_{LC_{tab}}$=10 [deg] coupled with δ_{ail}=5 [deg] (yellow). These results, normalized for the wing root loads of UERA-like configuration, are shown in Fig. 3. As one can notice, for both bending and torsion, the increase in wing AR leads to a higher root load (red curve is higher than black one). A deflection of LC tab produces the expected load alleviations, bringing root torsional moment to even lower values than the reference one. The situation is even better if a deflection of the LC tab is combined to a deflection of ailerons.

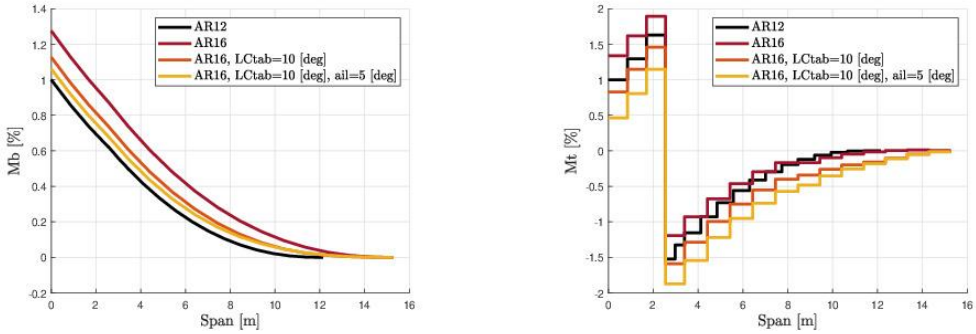

Figure 3: Effect of LC tab deflection on UERA16's bending moment (left) and torque (right)

Table 4 summarizes the root load alleviations obtained for different LC tab and aileron deflections, for UERA16, expressed as percentage of UERA-like root loads. Looking at the trend, it is possible to reach and reduce further the wing root loads with higher deflections.

LA systems are particularly suited when a gust is encountered during flight. This situation must be addressed carefully especially for future aircrafts, since, due to climate change, atmospheric turbulence is changing [9], and the probability to encounter a hard gust will increase. As anticipated, NeoCASS allows to compute also gust responses. In general, this kind of analyses are conducted simultaneously with the design of a control law - as it was done e.g. in [10] - whose output is the evolution of the LC tab deflection that matches the desired load alleviation level. These analyses are currently under investigation.

A preliminary estimation of the effectiveness of control surfaces deflection on Wing Root Bending Moment (WRBM) and Wing Root Torsion Moment (WRTM) is provided in Fig. 4, where

Materials Research Proceedings 69 (2026) 516-521 https://doi.org/10.21741/9781644904251-93

the Transfer Functions (TF) between the wing root load and a unitary gust, a unitary aileron deflection and a unitary LC tab deflection, for UERA16, are presented. Figure 4 left shows that aileron deflection is more effective on bending than LC tab. The opposite is valid for torsion: the blue peak at torsional frequency in Fig. 4 right is much larger than the black one.

Table 4: Root load alleviation, UERA16

$\delta_{LC_{tab}}$ [deg]	δ_{ail} [deg]	M_b [%]	M_t [%]
0	0	+27.3	+17.3
5	0	+19.9	+8.3
10	0	+12.6	-0.6
10	5	+6.1	-46

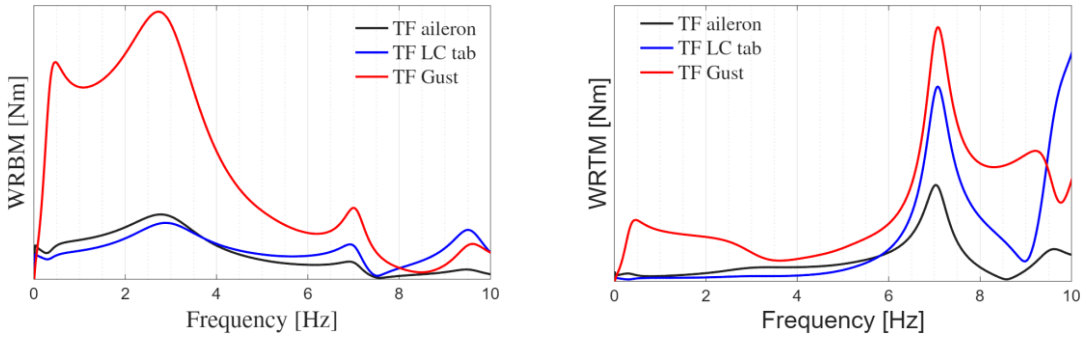

Figure 4: Transfer functions for UERA16, WRBM (left) and WRTM (right)

Conclusions and Future Work

Different models have been created and analyzed, with varying wing AR. The highest aerodynamic efficiency has been reached for UERA16, along with the highest wing root internal actions. An additional control surface has been introduced to alleviate such loads. Static analyses showed promising load reductions, within reasonable LC tab and aileron deflections. A control law for Gust Load Alleviation (GLA) is under investigation, along with the creation of the wing aero-servo-elastic experimental model, to be gust tested inside POLIMI Wind Tunnel.

Keywords: Reusable Launcher, Booster Recovery, Air Traffic

Abstract. To ensure economic access to space, re-using rocket boosters can be one key-element. In comparison to expendable boosters, reusable boosters need to perform additional flight maneuvers, resulting in different airspace demand. As a safety measure for air traffic, airspaces in which spacecraft operate are temporarily closed. Such airspace closures pose an additional challenge for planning flights and airspace capacities. The influence of different booster recovery methods on the airspace closure dimensions are investigated in a collaborative study between TU Braunschweig and DLR SART. Further, the effects of such closures on air traffic are analyzed. As a first proof of concept, this paper applies the developed methodology to quantify airspace closures and associated costs per affected aircraft for two scenarios. While demonstrating the capabilities of the methodology, its limitations and intended improvements are stated and discussed.

Introduction

The reusability of rockets has become crucial considering the cost advantages such systems show in comparison to expendable rockets. Although Europe's current launchers, Ariane 6 and Vega C, are still designed as expendable vehicles, concept studies for a European reusable launcher are already underway. As an example, the ENTRAIN study [1, 2] performed by the DLR SART investigates different rocket designs for a successor of Ariane 6 with a reference mission of delivering 7500 kg to a geostationary-transfer orbit (GTO). Besides various propellant combinations, different booster recovery designs are investigated like the downrange landing (DRL) of the booster on a barge, and the so-called in-air-capturing (IAC) recovery method. While the DRL method is already successfully operated by companies like SpaceX, the IAC method is still under development. This method foresees the capture of the booster after its ballistic flight and its subsequent towing of the rocket stage to a designated runway by an aircraft.

Because space vehicles are certified under a higher acceptable-risk standard than conventional aircraft, spaceflight operations are segregated from air traffic through temporary airspace closures. Such airspace closures are also denoted as Aircraft Hazard Area (AHA) and Temporary Flight Restriction (TFR). The ENTRAIN study enables direct comparison of reusable rocket designs and their booster recovery methods resulting in a different demand for airspace closures. The investigation of the needed airspace closure size for different booster recovery methods and potentially varying resulting impacts on air traffic is part of a collaboration between TU Braunschweig and DLR SART. In this paper, the preliminary procedure to perform this research is introduced and encountered limitations are discussed.

Methodology

To assess the results of the rocket design dependent AHAs, a seven-step process must be conducted for each investigated rocket design. This process is introduced in Fig. 1.

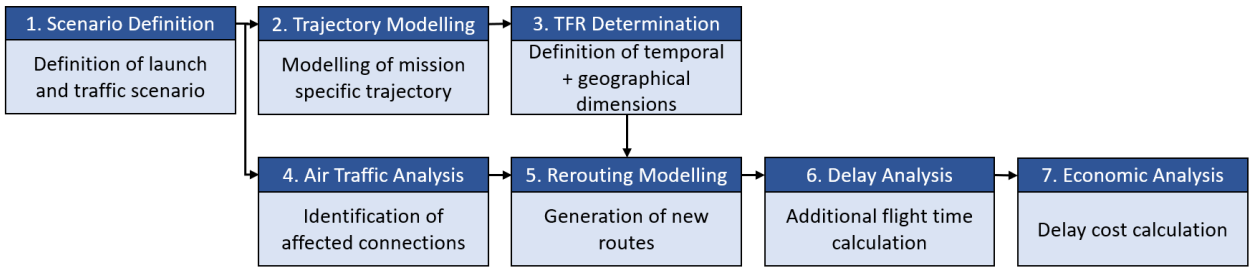

Figure 1 Process of determining additional costs for airlines from AHAs.

In the first step, the launch scenario comprising rocket-specific aspects like booster recovery method and propellants as well as mission-specific parameters including the target orbit and launch site is generated. In this paper, launches from Guyana Space Center (GSC) into GTO with an IAC and DRL rocket configuration propelled by methane and liquid oxygen are taken as scenarios. Based on existing trajectory data for the scenarios, the TFRs are determined in step two and three. In this first iteration, the temporal aspect of the TFR is not analyzed, but is intended to be further investigated in later research iterations. In addition to the TFRs, in the fourth step, an air traffic analysis for the launch scenario is conducted to obtain an overview about potentially affected flights. Such flights are then selected for the re-routing modelling in the fifth step. In the remaining two steps, the additional flight time of the rerouted flights along with the resulting delay costs are computed. Important aspects of the general approach are described in the following paragraphs.

Airspace closure definition

The airspace closures are determined in a conservative approach, accounting for the worst-case scenario. This scenario reflects in-flight fragmentations of the rocket stages and the resulting fallout of debris. In this study, the two graphs representing the ENTRAIN IAC and DRL ascent as well as booster trajectories shown in Fig. 2 are the baseline for the analysis.

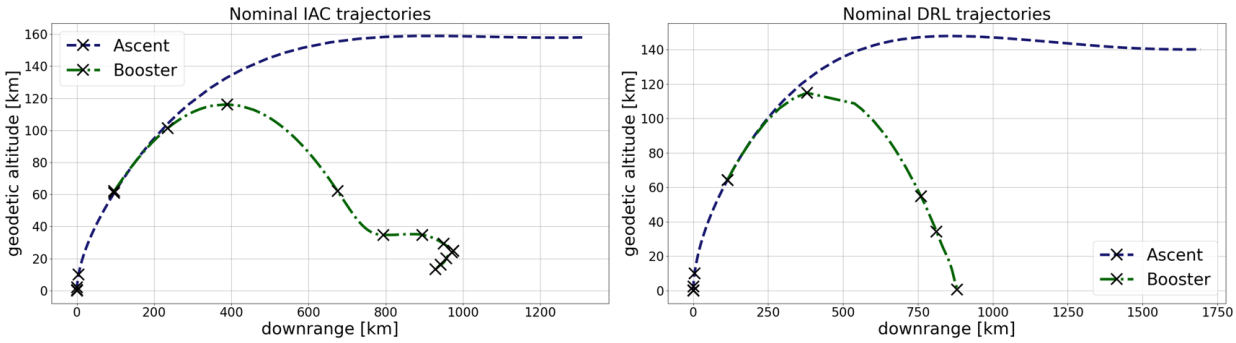

Figure 2 Trajectories of DRL and IAC rocket and booster configurations with the simulated breakup points marked with crosses.

Along the predefined points on the trajectories that are marked with crosses in the diagrams, fragmentation events are modelled. A fragmentation is a stochastic event that generates debris that is ejected during the event. The stochastic behavior means that the exact number of debris, their physical properties as well as the ejection direction and velocity of each fragment cannot be predicted in advance. Models to simulate such events are working on a stochastic foundation. In this work, the ballistic coefficients (the main physical property) are based on the Columbia

Materials Research Proceedings 69 (2026) 522-527 https://doi.org/10.21741/9781644904251-94

fragmentation catalogue and the ejection directions and velocities are determined with the NASA standard breakup model [3, 4]. Simulating the fragmentation event only once is not sufficient to determine TFRs due to the unpredictable behavior of the resulting fallout. To account for this, the potential fallout must be assessed with Monte Carlo-like approaches by simulating the stochastic fragmentation and propagation of the fragments several times. In this study, three independent fragmentation events per breakup point are modelled, resulting in 9133 fragments per breakup point for the whole DRL scenario. In the IAC scenario, only one breakup event per booster breakup point was modelled due to time constraints.

The resulting fragments are numerically propagated under the influence of gravity and aerodynamic drag (wind is neglected) until they either impact the ground or reach a maximum flight time of 24 hours. The resulting fallout distributions are then superposed, and the width and length of the AHA are estimated with the fragment density over longitude and latitude. The AHA boundaries are defined so that the longitude and latitude spans comprise 99.999 % of the debris. Figure 3 shows on the left side the impact areas and resulting AHAs of the IAC and on the right side of the DRL superposed fragmentation scenarios. For comparison purposes, the TFRs obtained from [5, 6] during the last Ariane V flight (*VA 261*) and the first Ariane VI flight (*VA 262*) are included in the graphic.

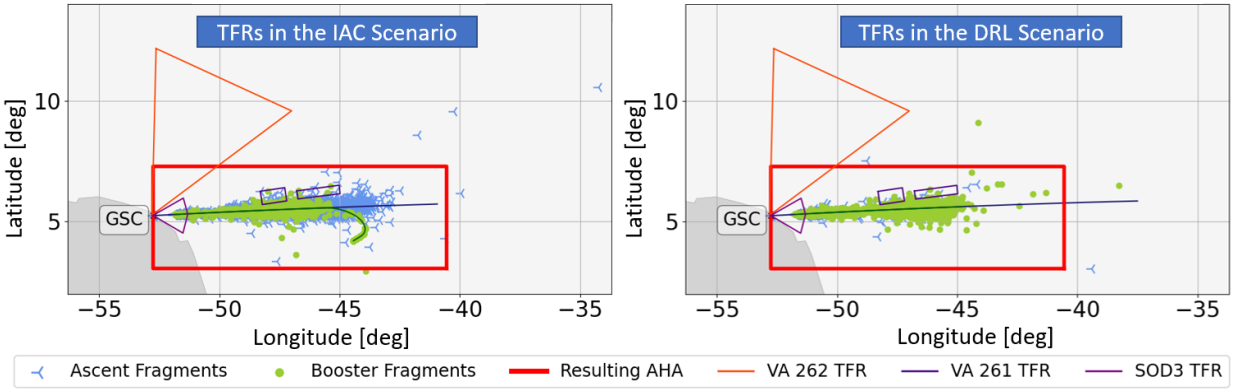

Figure 3 IAC and DRL determined AHAs with fragment distribution and reference AHA

In the first iteration presented in this paper, the AHA is implemented as a simple rectangular defined by the longitude and latitude threshold determined to contain 99.999 % of the debris. This conservative approach does not consider the increasing downfall area with the altitude of the rocket that leads to funnel-formed downfall area during a rocket launch. In real rocket launches, this behavior is converted into funnel-formed AHAs like in the *VA 262* TFR shown in Fig. 3. In the *VA 261* launch, the funnel-formed TFR *SOD3* is implemented in the near-field of the launch site. Such funnel-formed AHA designs for the near-field could also be used in later iterations to reduce the impact on traffic flying around the AHA close to launch site.

Traffic and cost analysis

The AHAs prohibit aircraft from flying through the airspace. To identify flights that normally would fly through the affected airspace, the publicly accessible ADS-B database from flightradar24 [7] was used. The data showed that besides traffic from and to Cayenne, routes between North America and Brazil, North America and South Africa as well Europe and South-America can be affected. The available flight data showed that some flights presented a significant deviation from the great circle distance between the airports. Several reasons like weather, airline specific operational regulations, other airspace closures or in-air re-routings from air traffic controllers can lead to such longer routes. Whether these longer paths were part of the original flight plans cannot be inferred from the available traffic data. To allow for a more representative

Materials Research Proceedings 69 (2026) 522-527 https://doi.org/10.21741/9781644904251-94

comparison, the great circle distance between the city pairs are used as baseline for the further investigations. Flights are only considered if the great circle line between the airports crosses the determined AHAs. For further analysis, two selected city pairs from the traffic scenario are taken for the delay and cost determination.

The re-routing is implemented with a single re-routing point that is first approached by the aircraft on its way from the departure to the destination airport. In the first iteration presented in this paper, the corner points of the AHA are used as re-routing point. The corner point allowing the plane to fly around the AHA in the shortest possible additional distance is selected as re-routing point. This re-routing algorithm represents the best-case delay scenario with the least possible flown extra distance. In future research iteration, existing airways and waypoints could be used for improved re-routing algorithms targeting for more realistic results. The flown rerouted distance is determined based on great circle distance sections between the departure and destination airports and the re-routing point. The original and rerouted trajectories of the two flights as well as their great circle lines for the IAC TFR are shown in Fig. 4.

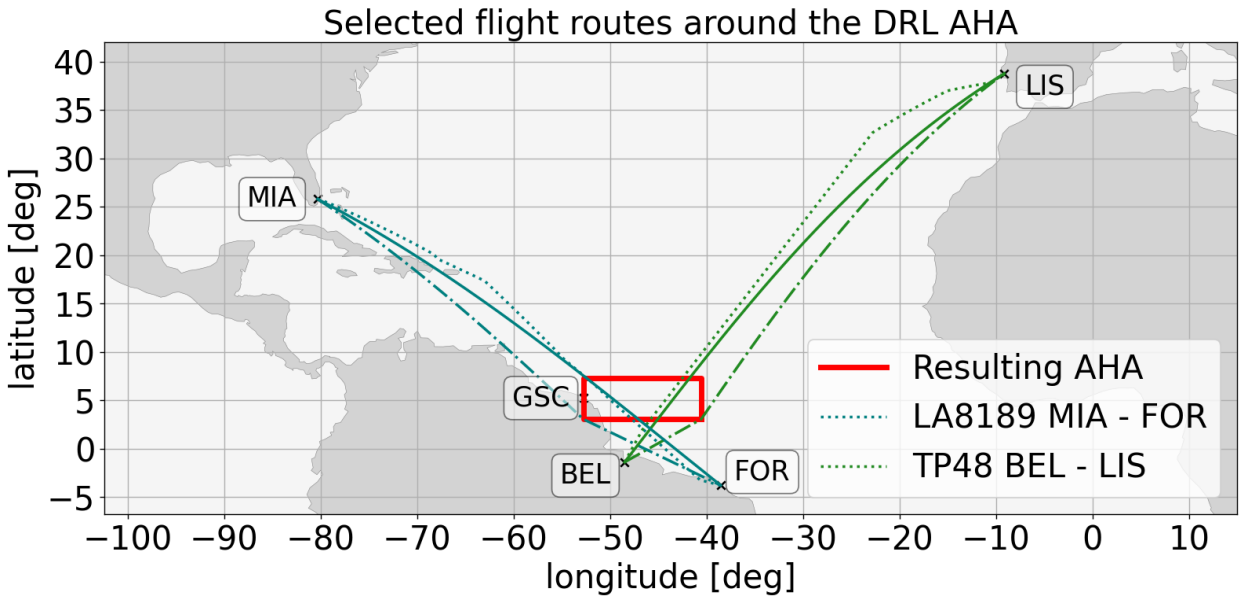

Figure 4 Impact of the IAC AHA on the two reference flights showing the reference flight routes as dotted lines, the great circle connection as line, and the rerouted flight routes as dash-dotted lines.

The flight delay due to the AHA is determined based on the obtained additional flight distance. It is assumed that the aircraft fly with cruise speed on the additional flight sections. The resulting delay costs are interpolated based on the average en-route delay cost values from Westminster University [8, 9]. The delay cost values for the Boeing *B787-9* is not included in this reference. Therefore, the mean value of the two cost values from *B767-300* and *B747-400* was used to estimate the cost value of the *B787-9*. To improve the cost calculation, a more precise approach for aircraft types that are not included in [8, 9] should be developed that also accounts for inflation.

Discussion of the results

The obtained flown distances, delays and resulting additional costs for the IAC TFR scenario are introduced in Table 1 and for the DRL TFR scenario in Table 2. In the IAC scenario, the flight between Belem and Lisbon shows an increased route length of about 1.5 % resulting into a delay of seven minutes. For the Miami - Fortaleza flight, the route length almost increases by one percent. The additional costs for the second flight are estimated to be higher than in the other flight.

Considering the different aircraft sizes, the resulting higher costs for the *B787-9* are deemed to be realistic.

Table 1 Obtained results from the IAC AHA rerouting scenario

Flight number	Connection	Aircraft type	Great circle distance [km]	Rerouted distance [km]	Delay [minutes]	Additional costs [€]
TP 48	BEL-LIS	A321-LR	6007	6099	7	478
LA 8189	MIA-FOR	B787-9	5572	5633	4	576

In the DRL scenario, the resulting additional flown distances are each less than one percent of the original flown distance. The resulting delay of four minutes can be expected to be compensated for by increasing the cruise speed of the aircraft. Therefore, in reality it can be estimated that the delay is eliminated in the end. The here investigated GTO launch scenarios from GSC show in general a low impact on air traffic. In the scenarios, the sustainability gain through the booster recovery does not significantly affect air traffic. Further investigation of these two and other scenarios must be performed to generate more data to fully address the stated research topic.

Table 2 Obtained results from the DRL AHA rerouting scenario

Flight number	Connection	Aircraft type	Great circle distance [km]	Rerouted distance [km]	Delay [minutes]	Additional costs [€]
TP 48	BEL-LIS	A321-LR	6007	6052	4	240
LA 8189	MIA-FOR	B787-9	5572	5623	4	576

Summary

In this work, an approach to determine the influences of different reusable rocket designs on the air traffic is introduced. A first methodology iteration is performed for an IAC and DRL booster recovery scenario launching from GSC into a GTO. These launch scenarios showed to have a low impact on air traffic as the investigated flights are long-distance flights with sufficient flight time to compensate for the delays. In general, more simulations per scenario should be conducted to ensure the data quality. The here performed analysis and its results are a proof of concept of the developed methodology. Further, encountered challenges of the methodology are described and a outlook for later iterations is sketched. For example, the current fragmentation model shows limitations as its components are intended to simulate other events than rocket fragmentations during launch. By implementing a better suited fragmentation model and including a propitiated wind model, the simulation results are expected to be closer to reality. The introduced investigation approach lays the foundation for future research.

Abstract. This study investigates the synergistic potential of integrating truss-braced wings, liquid hydrogen propulsion, and open rotor technology in a potential next-generation short-medium-range aircraft. Through exploration of the possible design space, the combined impact on aerodynamic efficiency, structural weight, and emissions reduction is evaluated. The analysis demonstrates that the synergistic combination of technologies can significantly reduce fuel consumption and climate impact while maintaining competitive performance metrics. This work provides a foundation for future sustainable aircraft development by optimizing the interactions of these advanced technologies.

Introduction

Addressing the air transport sector's target of reducing its climate impact will require the next generation of commercial airliners to achieve significantly higher energy efficiency [1]. To reach this goal, several levers are available: reducing the mass of the airframe or improving the aerodynamic efficiency can lower the required thrust; improved engine efficiency can reduce the energy consumption per unit thrust; alternative energy carriers can reduce the climate impact per unit energy consumed. In this study, three technologies which act on those levers have been selected based on their relevance for a potential next generation-aircraft on the short-medium-range (SMR) market:

On the airframe side, the truss-braced wing (TBW) has emerged as a promising alternative to the conventional tube-and-wing configuration: The addition of a strut enables higher aspect ratio wings, which improve the aerodynamic efficiency of the aircraft. This benefit comes with its drawbacks and challenges, but recent advancements in digital design methods demonstrated their maturity for tackling the challenges specific to TBW aircraft operating in the transonic regime [2, 3, 4].

On the propulsion side, efficiency gains have traditionally been gained in particular by increasing the bypass-ratio of turbofan engines. While this trend could be pursued further, this comes at the cost of an increased nacelle size and weight; the conventional turbofan architecture is therefore being challenged by the open-rotor technology: by combining a large-diameter unducted fan with a stator stage for swirl-recovery, very high bypass-ratios and therefore efficiency are anticipated [5, 6], while circumventing the nacelle drag and mass penalties, as well as the integration challenges of UHBR engines.

On the energy carrier side, liquid hydrogen direct combustion has emerged as the most serious

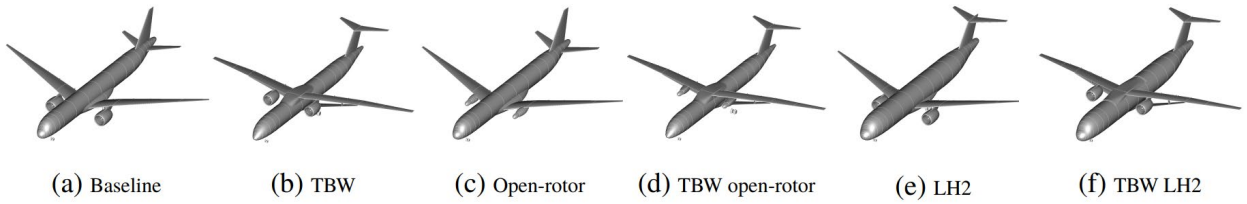

Figure 1: Axonometric view of the different configurations investigated.

contender to kerosene for all but the regional market segment. While it promises a significant reduction of the climate impact, the large tank volume necessary is detrimental to the overall efficiency of such aircraft.

Yet individually, none of these technologies are sufficient to meet the industry-wide climate targets on their own, and it remains to be seen which combination is the most promising. This study aims to address this question by investigating the interactions between the above-mentioned technologies.

Methods

The investigation is conducted with the German Aeropace Center's overall aircraft design process, as described in detail by Wöhler et al. [7]. This design framework is built around different tools exchanging information via the CPACS data format [8] combined into a workflow, which can be divided into three main parts: openAD is the central overall aircraft design and synthesis tool, which initializes the design according to the user-defined top-level aircraft requirements based on low-fidelity conceptual design methods. The resulting data is then processed by a series of higher fidelity tools in an iterative loop. The results of the analyses are fed back into openAD to adjust the initial design until convergence between the low- and higher-fidelity tools is reached. Finally, a post-processing phase ensues, in which the payload-range characteristics are computed, as well as the performance for the evaluation mission.

The capabilities of openAD have been extended to handle truss-braced wing configurations [9]. To this effect, the wing mass model of Chiozzotto [10] is implemented. This method is combined with the equation presented by Gur et al. [11] to account for the mass of folding wing-tips. Interference drag is considered through a surrogate model of CFD simulations [12], calibrated to wind tunnel test results [13]. The design lift coefficient of the strut in cruise condition can be varied, and is accounted for in the lift and drag predictions. Lastly, a simple method to consider the impact of a natural laminar flow (NLF) wing was incorporated.

The LH2-configurations are based on the assumptions and technology choices described by Kotzem et al. [14]: the cryogenic hydrogen tanks are rear-fuselage mounted, with an increased fuselage diameter housing an 8-abreast cabin to keep the fuselage slenderness ratio within reasonable bounds. The tank sizing tool chain is described by Burschyck et al. [15]. The cryogenic hydrogen tank is made of aluminium with a foam insulation architecture. Additionally, a mid-fidelity fuselage structure sizing tool chain is used to account for the effect of the LH2 tanks on the fuselage structure.

The Open-Rotor configurations are based on the findings of Ritter [5], and feature a 4 m diameter 12-blade propeller, and a 13-blade stator stage of the same diameter. The wing integration is of podded type, meaning that there is no separate pylon component. While it is planned to further extend the workflow in the future by tailoring the propeller to each design point, fixed propeller characteristics are currently assumed throughout the design space. A combined mass of 2800 kg for the propeller and stator is assumed, as well as a propeller efficiency of 81% with an activity factor of 180.

Materials Research Proceedings 69 (2026) 528-533 https://doi.org/10.21741/9781644904251-95

Table 1 Summary of aircraft top-level requirements

Requirement	Value		Requirement	Value	
Passengers	239		Max. operating altitude	12192	m
Design payload	25000	kg	Approach speed	136	knt
Design range	4630	km	Cruise Mach-number	0.78	
Evaluation range	1482	km	Wingspan (folded)	36	m
Take-off field length	2200	m	Wingspan (extended)	52	m

The study focuses on the short-to-medium range aircraft segment, with the Airbus A321 selected as the reference aircraft. Top-level aircraft requirements are detailed in Table 1.

While the comparison with the reference aircraft allows assessing the potential improvements against current in service aircraft types, the improvements of the individual technology bricks are can be assessed by comparison against the Baseline aircraft, which represents the anticipated state of the art for an entry-into-service in 2035, accounting for existing trends in technology maturation, but no significant architectural changes. The baseline used in this project is the DLR-F25 [16]. It notably features a 45 m span composite wing with an aspect ratio of 15.5 (these values will be varied in this study), as well as ultra-high bypass-ratio turbofan engines.

Results

The combinations of the 3 technologies to be investigated results in 7 possible configurations to be optimized in addition to the baseline.

This leads to a large design space where each configuration can potentially have different optima. Therefore, instead of manually optimizing each configuration, the approach selected is to perform parameter sweeps of key driving parameters to gain a generalized understanding of the behaviour of the different combinations of technologies. The main parameters selected for this study are the aspect ratio and wing loading, as these two parameters have a strong impact on all aspects of the aircraft design, including the aerodynamics, flight performance, engine sizing, and structural mass of the aircraft. The selected metrics are the block energy on an 800 nm evaluation mission, as an indicator for the fuel costs and in service emissions, and the operating empty mass (OEM), as it strongly correlates to the airframe acquisition and maintenance costs. The constraint on approach speed was not enforced on the individual designs, but rather used as a constraint on the feasible design space. This allows to assess the potential impact of an increase in approach speed, or alternatively of the installation of more advanced high-lift systems.

Figure 2 shows the results of the parameter sweeps for the different configurations. The following observations can be made based on these results: Generally, it is noticeable that despite the aggressive upper bound for the aspect ratio, there is no distinct optimum value after which an increase in aspect ratio is detrimental to the aircraft performance. This can be explained by the fact that the wing mass model has been evaluated outside the bounds of the data it was trained on, and fails to capture all the constraints and adverse effects linked to wings of very high slenderness. This limitation in the model must be taken into account in the interpretation of the data.

For all configurations, it is clearly visible that the fuel consumption is more sensitive to aspect ratio than to wing loading, indicating clearly that high-aspect ratio wings are one of the main lever to increase the efficiency of future aircraft configurations. The OEM on the other hand shows a higher sensitivity to the wing-loading: this metric is the main driver for favouring designs with smaller wings. Additionally, the optimum wing loading for fuel efficiency falls within the upper and lower bounds imposed by the constraint of the approach speed and maximum altitude for all configurations. Indeed, low wing-loadings lead to high thrust requirements at the top of climb,

oversized engines due to inadequate matching of the high- and low-speed performance. Generally, all SAF-powered configurations show a trend of increasing optimal wing loading

with increasing aspect ratio. This trend is however not visible for the LH2 aircraft, which show a relatively constant optimum wing loading, albeit at a lower wing loading than the SAF-powered equivalents. This lower wing loadings can be explained by the higher OEM which, given an identical optimum lift coefficient and engine thrust lapse, requires a larger wing to cruise at the optimum altitude.

Table 2 shows a summary of metrics for point designs selected according to the constraints defined in Table 1. In addition, the aspect ratio was limited to 16 for the cantilever wing and 20 for the TBW to keep the design in a realistic range despite the limitations of the mass model. The results for the energy consumed on the evaluation mission show the compounding effects of the technologies: combining the TBW with the open-rotor yields a performance effect larger than the sum of the individual contributions. In particular, the LH2 designs have particularly high snowball effects, as any reduction in fuel consumption leads to smaller tanks, and therefore to a reduction of fuselage length and drag. Consequently, adding a truss braced wing to the LH2 design yields a 7.3 % fuel burn reduction, instead of 5.4 % when the TBW is added to the SAF configuration. While the results for the OR-LH2-TBW configuration are not yet available, it is anticipated that the addition of the open-rotor will further narrow the gap between the LH2- and SAF-configuration.

Conclusions

In this study, the effect on fuel burn efficiency and OEM of the integration of truss-braced wings, liquid-hydrogen propulsion, and open-rotors on a potential next generation SMR aircraft were investigated across a range of aspect ratios and wing loadings. The results of this study show that for the considered technologies, all combinations are feasible under the given requirements. They further show that there is compounding effect between the technologies, opening the possibility of substantial performance gains relative to the baseline design, and further demonstrate that the LH2 configuration benefit more strongly of this compounding effect than the SAF configurations.

on the basis of a decision
by the German Bundestag

In future work, the limitations of the methods will be addressed by including higher-fidelity tools to increase the confidence in the results throughout the design space, in particular regarding the wing mass estimation and the propeller design. Additionally, detailed climate impact assessments including non-CO2 effects (contrails) will be performed for each configuration, such as to allow a holistic understanding of their respective total climate impact.

Abstract. Improvements in aviation are typically driven by innovative propulsion systems and unconventional configurations. However, since these novel technologies often require a significant leap to become industrially viable, less demanding alternatives can be profitably explored through intelligent adaptations of existing configurations. Three-surface airplanes can be considered as a realistic alternative to conventional back-tailed airplanes, particularly because this configuration allows for trim optimization to minimize drag, provided both the canard and tail are equipped with movable surfaces enabling redundant longitudinal control. The focus of this paper is twofold. First, it aims to provide the first field demonstration of the possible benefits of the three-surface configurations with redundant longitudinal control over equivalent back-tailed airplanes. Second, it presents a preliminary comparison between test data and numerical results obtained from a CFD simulation campaign.

Introduction

Improvements in aviation are typically driven by innovative propulsion systems and unconventional configurations. However, these novel technologies require significant changes in the way we design, build, and operate aircraft. Just consider the substantial modifications to the supply chain and storage systems at airports that may be required by a massive use of hydrogen as aircraft propellent. In this context, interesting and less demanding alternatives can be found by intelligent adaptations of conventional configurations [1, 2, 3].

Among all, three-surface airplanes can be considered as a realistic alternative to conventional back-tailed airplanes. Recently (see Ref.[4] and [5]), a three-surface configuration was employed to demonstrate the potential benefit of the redundant longitudinal control: when both the canard and tail have a movable part, the longitudinal trim, i.e. the equilibrium of vertical forces and moments about the pitch axis, becomes overdetermined: there is an infinite possible combination of canard and elevator deflections which can trim the airplane. This allows one to select the couple of elevator and canard deflections associated with an optimum of a particular merit function, such as for example the overall drag. As reported in preliminary works [4, 5], a comparison between a standard back-tailed four-seat propeller-driven aircraft and an equivalent three-surface aircraft with redundant longitudinal control predicted that the latter configuration exhibits a 4% improvement in the maximum lift-to-drag ratio, potentially leading to comparable fuel savings. It is noteworthy that such an improvement could be achieved through a relatively minor change to the airframe design, especially if compared to more impactful alternatives such as box-wing or blended-wing airplanes.

Building on this promising analysis, we are developing a flying prototype to demonstrate the effectiveness of three-surface configuration with redundant longitudinal control through a dedicated flight experimentation. To achieve this, we first designed a reference back-tailed

prototype optimized for a standard mission of a scaled remote-controlled airplane. Next, we turned the reference aircraft into an equivalent three-surface aircraft, featuring the same wing, fuselage, static margin, and empennage volume. For a given canard of a specific surface, the tail area must be reduced to maintain the same empennage volume and the wing shifted backward to keep the static margin unaltered. Both canard and tail are equipped with movable surfaces, yielding the desired redundancy in the longitudinal trim.

A parallel study was also performed based on Computational Fluid Dynamics (CFD) analyses. In particular, both airplane configurations (two- and three-surface) were modeled through a panel method-based tool, FlightStream [6], to compute the aerodynamic steady coefficients, C_L, C_D and $C_{\mathcal{M}_G}$, as functions of the angle of attack and the deflections of both control surfaces. The obtained aerodynamic database was then used to perform the comparison between the simulated data and the measured quantities obtained through the testing campaign of both airplanes.

Both the experimental and numerical studies on the scaled demonstrator provided evidence that the three-surface configuration with redundant longitudinal control is associated with a significant increase in the maximum lift-to-drag ratio over an equivalent back-tailed airplane, quantified in about 20%. The reasons for this improvement, still to be better understood, are manifold. First, by appropriately configuring the area and location of the lifting surfaces, it is possible to trim the aircraft such that all wings (main wing, tail and canard) generate positive lift. This leads to lower angles of attack and to a corresponding reduction in the overall airplane drag. Second, there could be a beneficial aerodynamic interaction between the canard and the wing, because the outer sections of the main wing experience upwash flow components entailed by the tip vortices of the forward surface. Third, redundant control allows one to optimize the aircraft trim across all flight conditions by directly setting the lift of all surfaces, as also reported in [4, 5, 7]. The study presented in this paper represents the extension of the work object of [8].

Experimental and numerical study on three-surface configurations with redundant control

In the present section, the procedure to design and build the equivalent two- and three-surface airplanes with redundant longitudinal control is first presented. Next, the process of modeling the aircraft in FlightStream is described.

First, it is necessary to define how the equivalence between a three-surface and reference back-tail airplane is established. Among all possible criteria, static margin and tail volume represent two parameters expected to strongly influence equilibrium, stability and maneuverability. Hence, in a preliminary design context, one may envision that airplanes with the same stability margin and tail volume should meet the same mission and design requirements. Accordingly, we first design a conventional aft-tailed aircraft and then convert it into an equivalent three-surface configuration, following the criteria, previously mentioned.

The design process for both prototypes utilized Digital Datcom [9] coupled with downwash/upwash models [10, 11] to render the aerodynamics of the reference and equivalent three-surface aircraft. The reference back-tail airplane was designed to perform a usual mission for remote-controlled demonstrators, as reported in [8]. In order to design the three-surface airplane, one has to find suitable values for the canard area S_C, the tail area S_T, the incidence of the canard i_C, and the location of the aerodynamic center of the wing x_{AC^w}. In doing so, one may consider that in the case of redundant longitudinal control lift C_L and pitch moment $C_{\mathcal{M}_G}$ coefficients are both functions of the angle of attack α, the elevator deflection δ_E and the canard deflection δ_C, as

$$\begin{cases} C_L = C_{L_\alpha}\alpha + C_{L_{\delta_E}}\delta_E + C_{L_{\delta_C}}\delta_C + C_{L_0}, \\ C_{\mathcal{M}_G} = C_{\mathcal{M}_{G_\alpha}}\alpha + C_{\mathcal{M}_{G_{\delta_E}}}\delta_E + C_{\mathcal{M}_{G_{\delta_C}}}\delta_C + C_{\mathcal{M}_{G_0}}. \end{cases} \quad (1)$$

Materials Research Proceedings 69 (2026) 534-539 https://doi.org/10.21741/9781644904251-96

When it comes to evaluating the vertical and pitch moment equilibrium, one immediately recognizes that there are infinite possible solutions for α, δ_E and δ_C. Each combination of these trim variables is associated with a drag coefficient $C_D = C_D(\alpha, \delta_E, \delta_C)$, that can be computed again using Datcom. The redundancy in the trim is leveraged to minimize drag across all speeds, resulting in quasi-linear relationships between the angle of attack, the canard and elevator deflections as function of the overall lift coefficients C_L^*, indicated as $\alpha = \alpha^*(C_L^*)$, $\delta_E = \delta_E{}^*(C_L^*)$ and $\delta_C = \delta_E{}^*(C_L^*)$ [4, 8]. The trimmed polar is than computed as,

$$C_D = C_D\left(\alpha^*(C_L^*), \delta_E^*(C_L^*), \delta_C^*(C_L^*)\right). \quad (2)$$

The design of the three-surface model, i.e. the selection of the values for canard area S_C, tail area S_T, canard incidence i_C and wing location x_{AC^W}, is carried out by maximizing the maximum lift-to-drag ratio of the trimmed polar, constrained by the reference static margin and tail volume.

Fig. 1 shows a picture of the two equivalent designs and reports the expected increase in the maximum lift-to-drag ratio of the trimmed polar as function of the canard surface, demonstrating that the three-surface prototype could feature an increment of almost 3%. The demonstrators were then built to allow for an experimental campaign aimed at providing evidence of the goodness of the proposed configuration. The flying platform was also given a name: Aether (Airplane in Three-Surface Configuration with Redundant Longitudinal Control). The Aether features a wingspan of 1.5 m and weighs 3.5 kg. Fig. 2 displays two pictures of the two airplanes during flight tests.

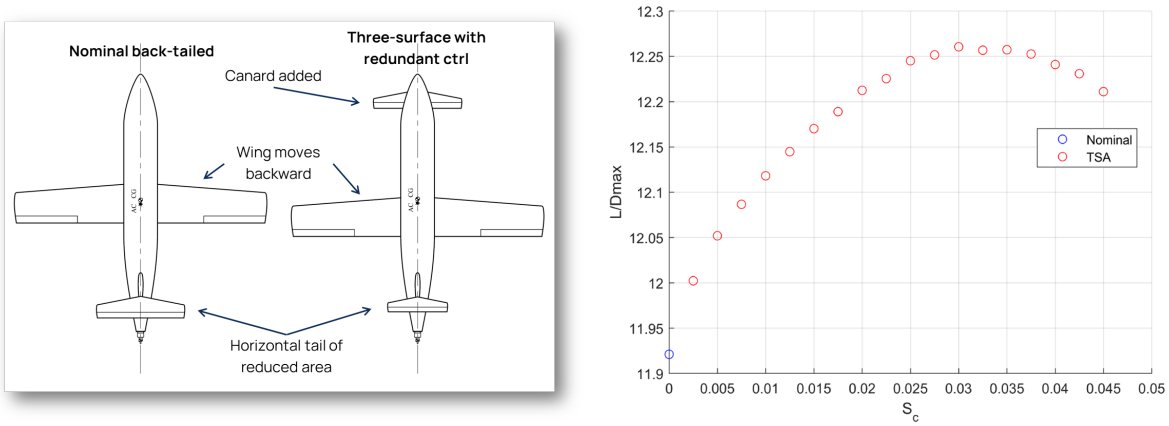

Figure 1: View of reference back-tailed (Nominal) and equivalent three-surface (TSA) airplanes (left). The three-surface airplane features a canard surface of 0.03 m2, associated with the optimal lift-to-drag ratio.

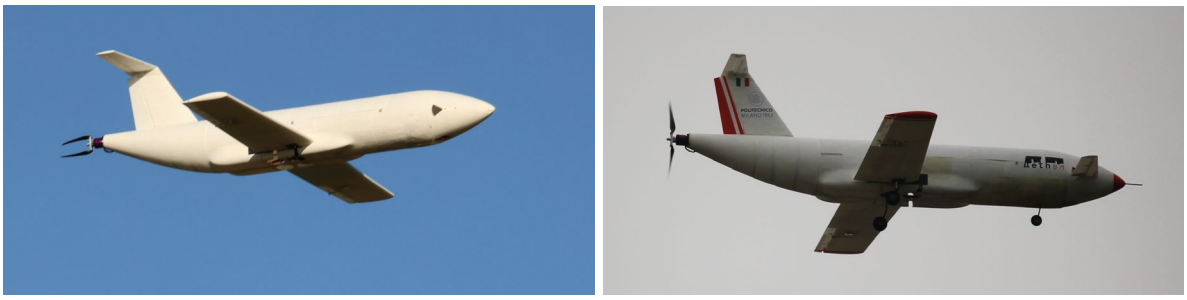

Figure 2: The Aether platform in two- (left) and three-surface (right) configuration, during flight tests.

The external shape of the aircraft is 3D-printed and connected to some carbon-fiber-made structural elements which provide stiffness to the system. The control of the platform is managed by the Pixhawk device and PX4 autopilot software. The system also integrates retractable landing

Materials Research Proceedings 69 (2026) 534-539 https://doi.org/10.21741/9781644904251-96

gears, off-the-shelf motors for the deflection of control surfaces and an electric motor linked to a propeller. A nose-mounted pitot tube, an inertial measurement unit (accelerometers and gyros) and GPS enable the measurement of the key flight mechanics variables. Telemetry, batteries and the remote-control unit complete the hardware setup.

The test campaign, aimed at determining and comparing the polars of both aircraft, was performed between March 2025 and June 2025. It initially focused on estimating the neutral point of the two-surface reference aircraft so as to impose a static margin of 12% through the introduction of an appropriate ballast. Finally, a series of gliding flights at varying speeds was conducted to allow the quantification of the polar. The same procedure was applied to the three-surface aircraft; however, in this case, gliding flights were also performed for several canard deflections chosen a priori. This resulted in multiple trimmed drag polars, each parameterized by the corresponding canard deflection. During each gliding flight, the aircraft speed and position were recorded using the pitot tube and GPS, respectively, enabling the estimation of glide angle. The glide angle and the speed measurements easily provided the lift-to-drag ratio and the lift coefficients (and consequently the drag coefficients), through the standard flight mechanics model of steady gliding flight to enable the estimation of the trimmed aerodynamic polar.

In parallel with the execution of flight tests, the software FlightStream was also used to model both demonstrators, with the goal of supporting the interpretation of the flight testing results. FlightStream is described as a modernized panel method that includes enhancements over other vortex lattice techniques associated with an increased accuracy in the results. For this reason and for its capability to model in a simple way the control surface motion, it was chosen in this study. With its reduced computational expense compared to traditional Navier-Stokes solvers, panel methods offer a good trade-off between fidelity and solver runtime.

FlightStream was then used to derive a complete aerodynamic dataset encompassing the lift, drag and pitch moment coefficients as functions of all trim variables, i.e. the couple α and δ_E for the reference airplane, and the triplet α, δ_E and δ_C in the case of redundant longitudinal control. Afterwards, the aerodynamic dataset was used to compute the equilibrium of the airplane for the same speed and static margin recorded in the experimentation. Although the adopted procedure could produce less accurate results than just running the simulations for the experimentally recorded trim variables, it was considered preferable due to, first, the inherent mismatches between the demonstrator and the numerical model and, second, to some uncertainties in the recorded angles of attack and control deflections during the experimental campaign.

Results

Experimental data were filtered and thoroughly analyzed to yield the polars of both airplanes. Similarly, numerical data were analyzed to ensure convergence of the solutions and used to derive the numerical trimmed polars for comparison with the experimental data.

Fig. 3 displays the experimental polar data of the two-surface reference airplane (thick dashed black line) and the three-surface one for three different canard deflections (thin solid lines). Each marker represents the flight data while the lines show the corresponding quadratic fittings. From this plot, it can be observed that the three-surface airplane with redundant longitudinal control exhibits lower drag within a lift coefficient range of 0.25 to 0.7, resulting in an increase in the maximum lift-to-drag ratio of approximately 19%, significantly higher than the one predicted by the flight mechanics models developed in the design phases.

To assess the accuracy of the two numerical methods against the flight data, Tab. 1 presents the induced drag coefficients k_2 of a parabolic polar approximation, fitted to both real and simulated dataset. The results indicate that Datcom tends to better capture the parasitic drag, while FlightStream performs more accurately in estimating the lift-induced component.

Materials Research Proceedings 69 (2026) 534-539 https://doi.org/10.21741/9781644904251-96

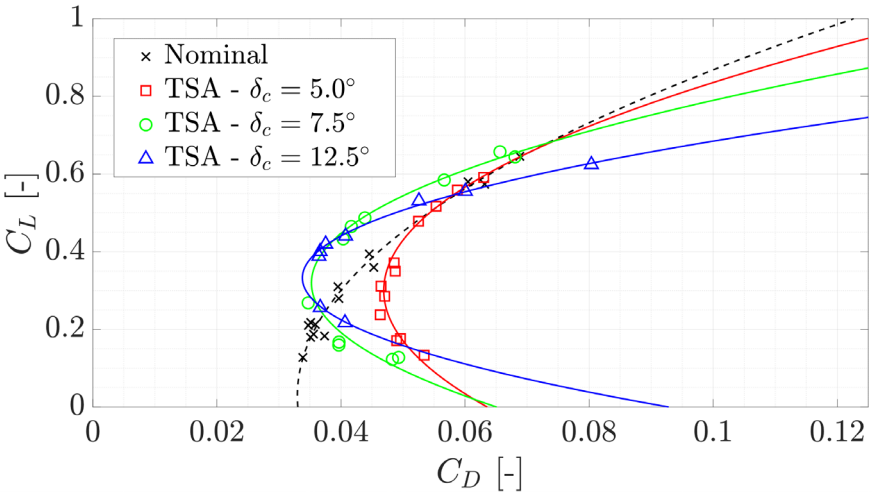

Figure 3: Polar data obtained from flight tests for the for two-surface (black dashed line) and three-surface airplane (solid lines and markers) for different canard deflections.

Table 1: Experimental and numerical polar comparison in terms of fitting coefficients.

	Two-surface k_2	**Three-surface** ($\delta_c = 7.5$ deg) k_2
Experimental data	0.095	0.293
Datcom	0.049	0.055
FlightStream	0.132	0.172

Conclusions and outlook

This study provides the first experimental evidence that a three-surface configuration with redundant longitudinal control can deliver improved aerodynamic performance over equivalent standard back-tailed airplanes. Complementary CFD simulations using FlightStream also estimated higher lift-to-drag ratios, supporting the experimental findings. There are still some non-negligible discrepancies in the matching between numerical and simulation data, particularly evident in the three-surface case. Such a mismatch can be due to multiple sources: incorrect treatment of the wake interaction among the wings in the numerical tools, geometric deviation between the modeled airplanes and the manufactured ones or deterministic biases in the outputs of the sensors used during the experiments. The continuation of this work will aim to address these modeling gaps, possibly through a new set of experimental data and a refinement of the numerical simulations.

Abstract. This paper proposes a methodology based on the Boing Fuell Flow Method 2 (BFFM2) in order to assess non-CO2 emissions resulting from the analysis of real-life aircraft Landing and Take-Off (LTO) cycles. The method is validated exploiting, as case study, the operational procedures in the vicinity of Torino Caselle airport, in the north-west part of Italy. Notably, this study focuses on the analysis of the individual operational procedures, including Standard Instrument Departures (SIDs), Standard Terminal Arrivals (STARs) and Approaches, published by the Italian Air Navigation Service Provider (ENAV), in order to assess the expected level of emissions for nominal trajectories, potentially identifying those flight legs which can be more relevant in terms of impact on air quality. This may open up for suggestions about updates to the procedures themselves, according to a trade-off with actual flown distance (i.e. fuel consumption), also looking at the most congested trajectories.

Introduction

The mitigation of aviation's environmental impact is a key requirement to ensure the sustainable growth of the sector, in line with regulatory demands and the continuous increase in air traffic. Following the goals of the 2015 COP 21 Paris Agreement [1], the International Civil Aviation Organization (ICAO) adopted the Carbon Offsetting and Reduction Scheme for International Aviation (CORSIA) [2], as part of the Long-Term Aspirational Goal (LTAG) [3] defined by the Committee on Aviation Environmental Protection (CAEP).

While CO2 reduction is critical in order to reduce global climate impact, the influence of non-CO2 emissions and, notably, Unburned Hydrocarbons (HC), Carbon Monoxide (CO) and Nitrogen Oxides (NOx) [4], directly affects air quality around airports. To quantify these pollutants, ICAO established an engines certification procedure based on standard operating points of the Landing and Take-Off (LTO) cycle [5], with results collected in a continuously updated database [6].

To extend such certification data beyond LTO conditions, Boeing introduced the Fuel Flow Method 2 (BFFM2) [7], which uses semi-empirical correlations to estimate continuous in-flight emissions. Compared to more detailed methods (such as P3T3 [8]), BFFM2 offers a simpler yet effective framework, which has been applied also to non-conventional configurations [9]. These approaches have since enabled preliminary assessments of local environmental impacts by combining traffic data with airport-specific characteristics and operational patterns [10, 11, 12].

This paper proposes a methodology based on the BFFM2 in order to assess non-CO2 emissions resulting from the analysis of real-life aircraft LTO cycles. The method is validated exploiting, as case study, the operational procedures in the vicinity of Torino Caselle airport, in the north-west part of Italy. Notably, this study focuses on the analysis of the operational scenario, including Standard Instrument Departures (SIDs), Standard Terminal Arrivals (STARs) and Approach procedures, published by the Italian Air Navigation Service Provider (ENAV) [13], in order to assess the expected level of emissions for nominal trajectories. The main goal is to provide a

Materials Research Proceedings 69 (2026) 540-545 https://doi.org/10.21741/9781644904251-97

preliminary evidence of the impact of current operational procedures on air quality, which can be used as basis for a potential update of the trajectories, also considering a trade-off with actual flown distance (i.e. fuel consumption), especially looking at the most congested paths (according to open flight tracking data).

The paper is organized as follows: after this short introduction, a methodological section is presented, with the aim of describing the approach used for the collection of flight data and the implementation of the BFFM2. A section including the main results is then described, with focus on emissions computed for all SIDs and STARs/Approaches. Ultimately, a short summary collects the main outcomes of the work and paves the way for future research.

Methodology

The modeling approach adopted in this work relies on dedicated datasets assembled to characterize inbound and outbound traffic, engine performance, and mission profiles. These inputs were used to estimate non-CO2 emissions in the proximity of Torino Caselle International Airport (LIMF) through the implementation of BFFM2 method.

The structure of such database was divided in three main, branches (Fig. 1): a collection of all information related to standard departure and arrival procedures (SIDs/STARs) involving the airport and derived by official documentation released by ENAV [13]; a catalog of aircraft engines performance across specific regimes obtained from the ICAO Engine Data Bank [6]; a flight database obtained from the sampling of a time frame that could be considered unaffected by bias due to traffic seasonal peaks, thanks to open tracking services.

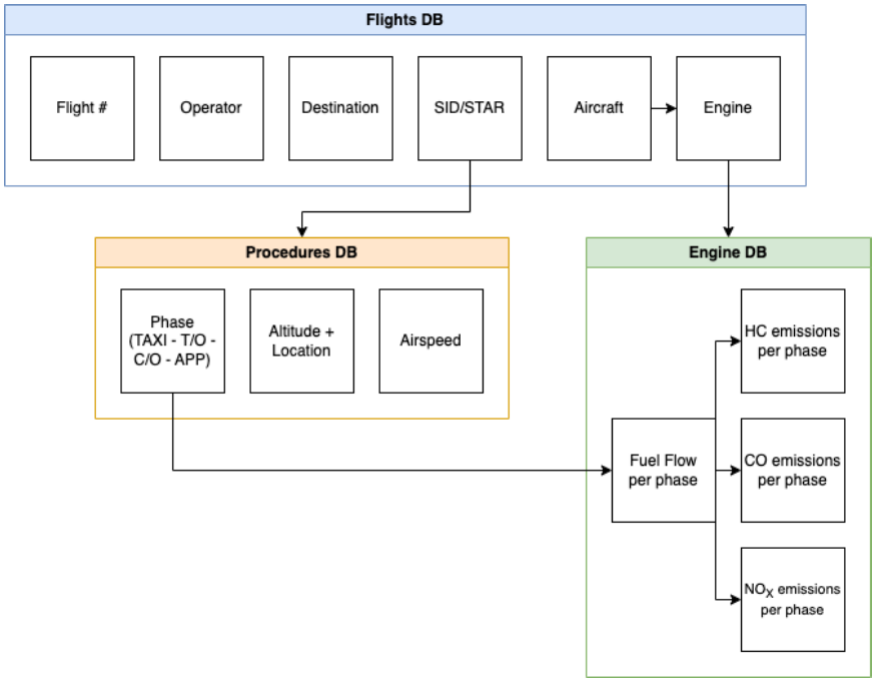

Figure 1: Datasets exploited and related links

Basic data specific to flights was collected exploiting the web based Flightradar24© service. The determination of aircraft model for each LTO cycle created an unambiguous link between the propulsive database, through the determination of the model, and number of installed engines. Furthermore, visual inspections of flight paths enabled the recognition of the actual procedures and consequent mission profiles followed. Samples presenting mismatches between actual tracks and official procedures were excluded from the study. In fact, differently from other works available in literature, such as [12], this paper does not exploit flight tracking service as unique

Materials Research Proceedings 69 (2026) 540-545 https://doi.org/10.21741/9781644904251-97

source of data to build the reference trajectory, but only as verification mean to quantify the usage of the operational procedures. Undoubtedly, in order to start an informed decision making process for procedures update, aimed at improving air quality around the regions affected by air operations, it is important to refer, in the first place, to the official procedures representing the intended paths published by the Authority, rather than looking only at flown trajectories, which may be affected by episodic bias, as well as tracking errors.

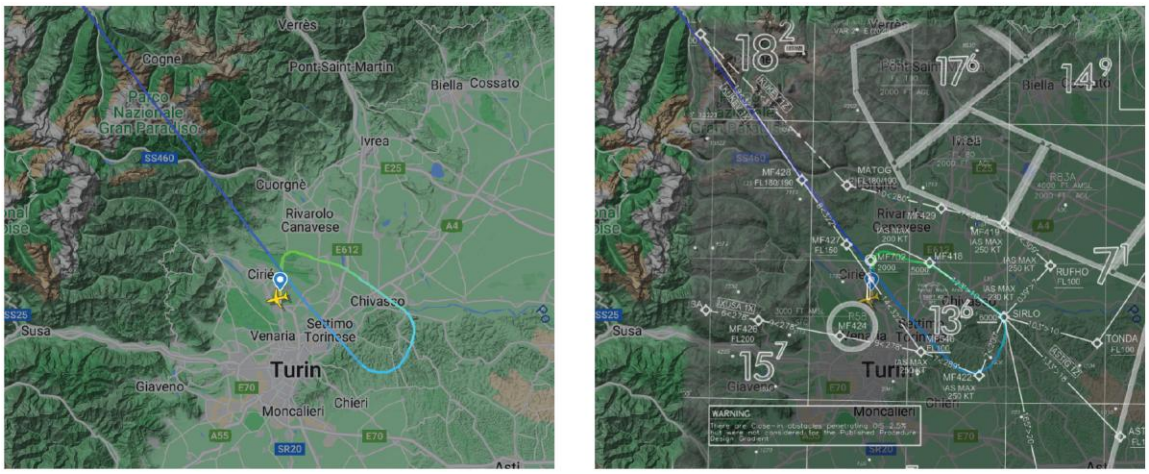

Figure 2: Example of valid trajectory (sources: FlightRadar24) and its adherence to official procedures [13]

The estimation of non-CO2 emissions was then carried out, as already mentioned, using the BFFM2 [7], a semi-empirical approach developed to extrapolate certification data to the entire operational envelope of the engine. The method establishes correlations between fuel flow rate and Emission Indices (EI), allowing the calculation of pollutant mass flows under arbitrary operating conditions. For each i-th pollutant, the emission index EI_i [g/kg_fuel], at a given operating point, is expressed as a function of the reference emission index at equivalent sea-level static conditions ($EI_{i,ref}$) (Eq. 1 to 3), associated, exploiting the data in the ICAO Databank [6], to the reference fuel flow rate $\dot{m}_{f,ref}$ (Eq. 4) computed by translating the actual rate $\dot{m}_f$ (in flight) to sea-level conditions as well.

$$EIHC = EIHC_{ref} \cdot \frac{\theta_{amb}^{3.3}}{\delta_{amb}^{1.02}} \tag{1}$$

$$EICO = EICO_{ref} \cdot \frac{\theta_{amb}^{3.3}}{\delta_{amb}^{1.02}} \tag{2}$$

$$EINO_x = EINO_{x_{ref}} \cdot \sqrt{\frac{\delta_{amb}^{1.02}}{\theta^{3.3}}} \cdot e^{H} \tag{3}$$

$$\dot{m}_{f,ref} = \frac{\dot{m}_f}{\delta_{amb}} \cdot \theta_{amb}^{3.8} \cdot e^{0.2 \cdot M} \cdot r \tag{4}$$

where δ_{amb} and θ_{amb} are ambient pressure and temperature ratios, M is the Mach number and H is a humidity correction factor. The reference flow rate is also multiplied by a coefficient r, which accounts for installation and bleed air extraction losses. Representative values of r for the different operating regimes are reported in Table 1.

Materials Research Proceedings 69 (2026) 540-545 https://doi.org/10.21741/9781644904251-97

Table 1: Correction coefficients $\boldsymbol{r}$ *for fuel flow*

	Idle	Approach	Climb-Out	Take-Off
Throttle [%]	7	30	85	100
r [-]	1.100	1.020	1.013	1.010

The methodology was applied to Torino Caselle International Airport (LIMF), selected as a representative regional hub characterized by mixed short and medium-haul operations. A traffic sample was collected for a reference period between 8-14 March 2024, chosen to minimize seasonal biases and ensure a statistically representative dataset. The resulting dataset included 232 departures and arrivals, covering 14 different aircraft/engine combinations. For each mission profile, the BFFM2 model was applied to compute continuous emission indices and pollutant mass flows up to 10,000 ft, thus extending the conventional LTO cycle and enabling the assessment of local air quality impacts in the airport surroundings. The equations were implemented in a Python model, allowing the automated processing of flight data and the discrete estimation of emissions at specific waypoints along each trajectory.

Results

The model application yielded quantitative estimates of HC, CO and NOx emissions for the reference time frame. Results are presented in terms of average emission rates per flight and their spatial distribution with respect to airport surroundings, according to the SIDs (Fig. 3) and STARs (Fig. 4) respectively followed.

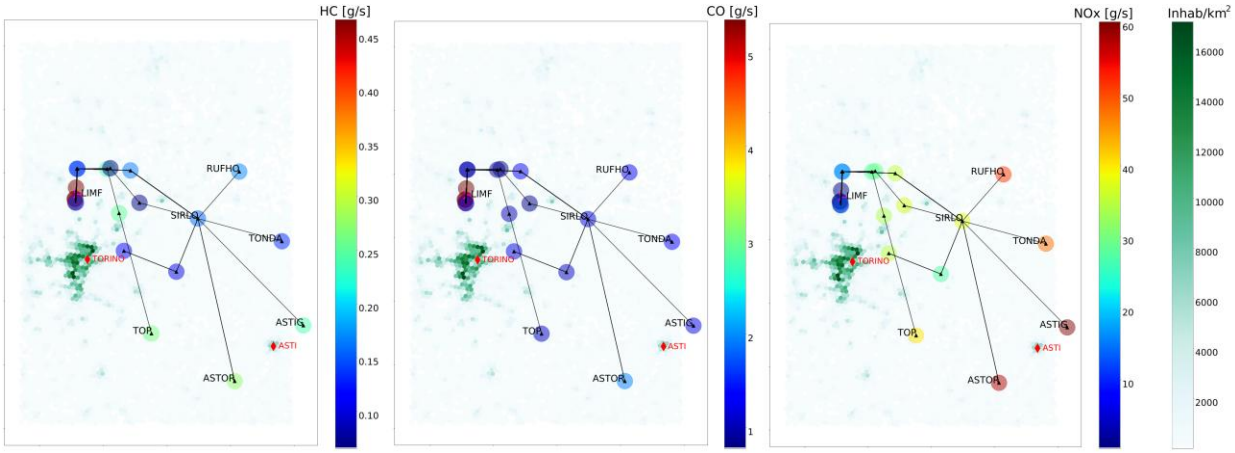

Figure 3: Visualization of emission rates according to SIDs (overlaid with population density)

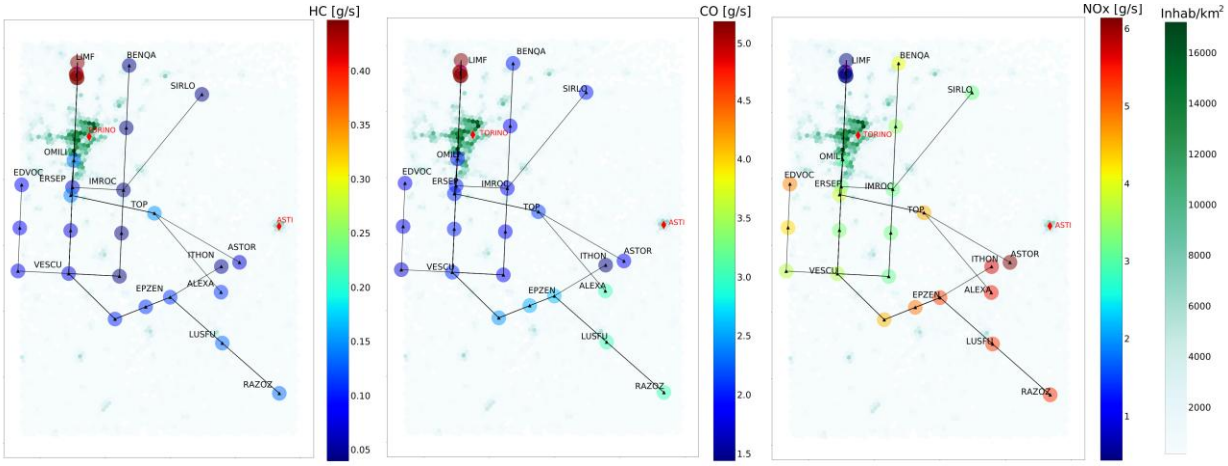

Figure 4: Visualization of emission rates according to STARs/Approaches (overlaid with population density)

Analysis of the emission profiles indicates that more than 50% of HC and CO emissions occur during ground operations (idle and taxi), with a marked reduction at take-off, where maximum thrust is applied. This confirms their nature as incomplete combustion products. In contrast, NOx production showed a strong dependence on altitude and engine thrust. Emission rates for NOx at take-off represented in fact approximately 15% of the peak values observed during climb-out segments around 10,000 ft, where temperatures and pressures combination in the combustor favour NOx formation. The spatial mapping of emission sources across procedures highlights that instantaneous peaks of NOx are concentrated along departure and initial arrival corridors, whereas HC and CO remain localized in the immediate airport vicinity. When overlaid with population density data, the results reveal that the areas most affected by pollutant emission sources are generally displaced from the most densely populated districts of Turin. This may be favourable from an exposure perspective, as the strongest sources are far from densely populated areas, even though a dispersion analysis is required to evaluate the true impact on ground, also according to meteorological data.

Summary

This work exploits the Boeing Fuel Flow Method 2 (BFFM2) in order to evaluate non-CO2 effects on local air quality referring to real world navigation and traffic data. The method is validated with reference to the Landing and Take-Off (LTO) cycles associated to operations in the vicinity of Torino Caselle International Airport (LIMF). In this case, results show that the positioning of emission sources along the trajectories is located far from densely populated areas, with the majority of HC and CO emitted on ground (on airport premises), while NOx have peaks at higher altitudes. The work confirms that this approach can be effectively adopted to potentially consider updates to operational procedures, in order to account for local air quality impact, even though dispersion analyses are needed, as future works, to better assess the distribution of pollutants with time, making benefit of meteorological data.

Keywords: Sustainable Aviation Fuels, CO2 Emissions, Cost Analysis, Life-Cycle Assessment, Environmental Impact

Abstract. This paper aims at evaluating the potential impact on CO2 emissions and cost as result of the exploitation of different kinds of SAFs, around different regions of the world. The study focuses, on one side, on the life-cycle emissions of the fuel, from production to aircraft operations, considering medium range flights from main hubs in Europe, United States, Brazil and Australia. This analysis makes benefit from a literature review on SAF producers around the world. The study of production processes allows in fact to identify the predicted life-cycle emissions of the specific fuel blend, up to the operational phase, also thanks to the adoption of the ICAO Carbon Emissions Calculator (ICEC). In parallel, an assessment of the cost associated to the use of SAF is also carried out, in comparison with conventional kerosene, along the years, up to 2050. Previsions on cost-per-kg of the different fuels are provided, taking into account the impact of the improvement of production process and increase of production quantity, together with inflation. The study demonstrates that, even if an increase of cost-per-kg for the fuel is always present, according to the predicted scenarios, the cost associated to the abatement of CO2 through the exploitation of SAFs has the potential of matching the equivalent cost of CO2 quotas in case an equivalent EU Emissions Trading System (ETS) is present, also considering the reduction of direct emissions over SAF lifecycle.

Introduction

Aviation de-carbonization has been an increasing worldwide effort for many years. In fact, even though commercial aircraft operations account for only 2% of global CO2 emissions, and 10% of overall transport means [1], their contribution is expected to grow due to the increase in traffic demand. During the last decade, also as result of the goals identified within the 2015 COP 21 Paris Agreement [2], the progressive reduction of CO2 emissions has been formalized within a roadmap named Carbon Offsetting and Reduction Scheme for International Aviation (CORSIA) [3] by the International Civil Aviation Organization (ICAO), being in line with net-zero 2050 objective of the Long Term Aspirational Goal (LTAG) [4] proposed by the Committee on Aviation Environmental Protection (CAEP). As demonstrated in [5], emissions reduction can be achieved by introducing new aircraft and powerplant technologies, new fuels, as well as improved operations and Air Traffic Management (ATM). Notably, the most relevant contribution to de-carbonization is associated to the introduction of new fuels capable of either reducing their carbon footprint acting on a more sustainable life-cycle, while maintaining similar operations. This challenge can be actually addressed exploiting the so-called Sustainable Aviation Fuels (SAFs), most of which are produced thanks to organic feedstocks (biofuels) or advanced technologies associated to renewable energy sources and carbon-capture strategies (synthetic fuels), which can replace conventional kerosene (Jet A) as drop-in blends.

Materials Research Proceedings 69 (2026) 546-551 https://doi.org/10.21741/9781644904251-98

Worldwide fleets are dominated by single-aisle short and medium range aircraft (70%), mostly flying along 2000 km routes [6]. This accounts for 65% of CO2 emissions of global aviation, while wide-body airliners flying long-range represent 30%, followed by regional and commuter services [6]. Acting on medium range aircraft is thus the priority to start make the difference. Notably, in the European market, the ReFuel EU plan [7], as part of "Fit for 55", aims at progressively substituting traditional kerosene with SAF in the amount of 2% by 2025, 6% by 2030 and 70% by 2050, which are considered mandatory targets for the airlines.

In this context, this paper aims at evaluating the potential saving in CO2 emissions as result of the exploitation of different kinds of SAFs, according to feedstocks and production processes, around different regions of the world. The study focuses on the life-cycle emissions of the fuel, from production to aircraft operations, considering medium range flights from main hubs in Europe, United States, Brazil and Australia. The work makes benefit from a literature review on SAF producers around the world, and it includes a brief analysis of the most promising production processes. On the other hand, the ICAO Carbon Emissions Calculator (ICEC) [8] is adopted to quantify the emissions for the flights considered within the study.

In parallel, an assessment of the cost associated to the use of SAF is also carried out, in comparison with conventional kerosene, along the years, up to 2050. Previsions on cost-per-kg of the different fuels are provided, leveraging information coming from the literature. A trade-off between emissions and cost is provided, with reference to the competitiveness of the exploitation of SAFs for CO2 abatement process in terms of cost per equivalent CO2 emission, if compared to traditional CO2 mitigation measures based on EU Emissions Trading System (ETS).

After this introduction, a methodological section is presented in order to describe the approach used for the determination of traffic demand for medium-range flight over different regions, as well as to present the results of the review about most adopted SAFs production processes around the globe, and related emissions/costs, hypothesizing a worldwide increase in SAF share according to the ReFuel EU-like plan. Then, a results section is provided to show the outcome of this analysis, also combining the data about emissions and cost in order to assess the competitiveness of SAFs adoption to comply with CO2 mitigation constraints if compared to the use of EU ETS. A summary section concludes the paper, paving the way for future works.

Methodology

As starting point of the workflow, an estimation of traffic demand is performed looking at the world regions previously specified (i.e. Europe, United States, Brazil and Australia), respectively in 2025, 2030 and 2050. The time span is selected in order to be in line with the goals of a ReFuel EU-like plan. References and literature models [9-10] are used in order to derive average traffic in million flights per year, as indicated in Table 1, looking at medium-range category.

Table 1: Hypotheses on traffic data (million flights per year)

Region	2025	2030	2050
Europe	2.02	2.24	2.67
USA	4.77	5.37	7.78
Brazil	0.32	0.44	0.93
Australia	0.66	0.72	1.01

Then, a set of relevant city pairs connected through medium-range flights is selected according to the information provided in [11], in order to consider the most representative missions for each world region. As result, an average value of distance vs fuel consumption is derived, taking into account a constant energy per unit mass of the fuel, equal to 43 MJ/kg, independently from the

Materials Research Proceedings 69 (2026) 546-551 https://doi.org/10.21741/9781644904251-98

blend actually used (SAFs and conventional kerosene have very similar lower heating values). Results of this approach are shown in Table 2.

Table 2: Average fuel quantity for medium range flight in different regions

	Europe	**USA**	**Brazil**	**Australia**
Fuel quantity per flight [kg]	10,685	11,800	10,310	11,000

Moreover, a literature review about the main SAFs producers and production processes around the world is performed, with the aim of determining the most relevant SAFs categories in the different regions and the related feedstocks used for the production. This step is crucial since emissions associated to fuel lifecycle are very specific depending on the type of fuel, production process and feedstock, as well as on the actual region in which they are produced. As result, the data collected in Table 3 have been derived, looking at studies [12] and information provided in literature by the most relevant companies listed in [11].

Table 3: Emissions per unit energy for main SAF type produced in different regions

Region	**Emissions per unit energy [gCO2eq/MJ]**	**(Fuel type) Feedstock**
Europe	19.51	(HEFA) – Agricultural residues, used cooking oil, fatty acid distillate
USA	24.54	(ATJ) – Switchgrass, muscanthus, corn grain, sugarcane
Brazil	44.48	(ETJ) – Forestry residues, corn grain, sugarcane
Australia	23.64	(ATJ) – Switchgrass, muscanthus, poplar, forestry residues, agricultural residues

Resulting emissions per unit energy (gCO2eq/MJ) of the different fuels take already into account production phase as well as operations (i.e. combustion), so they can directly be used for the estimation of the overall lifecycle emissions when applied to the operational context specified in Table 2 (since they are proportional to the quantity of fuel used). Emissions per unit energy can be compared with the standard value of 89 gCO2eq/MJ traditionally adopted for Jet A. As it can be seen, SAF are around 20 – 25 gCO2eq/MJ in most regions, benefitting from the adoption of feedstocks for the production of HEFA or ATJ, with the exception of Brazil, where the use of forestry residues for ETJ production may strongly increase the carbon footprint.

The overall quantity of CO2eq produced during the lifecycle can be computed according to (1). The computation shall take into account the amount of SAF blend specified by ReFuel EU (ϕ) for 2025, 2030 and 2050, respectively equal to 2%, 6% and 70% of the total mixture.

In parallel to emissions evaluation, it is also important to assess the economic impact of SAF adoption, especially looking at the operational costs of blends.

$$kg_{CO2_{eq_{yr}}} = \left(\left(\frac{kg_{CO2_{eq}}}{MJ}\right)_{SAF} \cdot \phi_{yr} + \left(\frac{kg_{CO2_{eq}}}{MJ}\right)_{Jet\ A} \cdot (1 - \phi_{yr})\right) \cdot \left(\frac{MJ}{kg}\right)_{fuel} \cdot m_{fuel_{flight}} \cdot n_{flights_{yr}} \quad (1)$$

According to the information present in [11-14], for the different world regions, considering the type of SAF described in Table 3, the costs reported in Table 4 apply for the different years used as reference in the study. The total Direct Operating Cost (DOC) for fuel can then be computed according to (2).

Materials Research Proceedings 69 (2026) 546-551 https://doi.org/10.21741/9781644904251-98

Table 4: Fuel cost [€/kg] in different regions

Years	Europe		USA		Brazil		Australia	
	Jet A	**SAF**	**Jet A**	**SAF**	**Jet A**	**SAF**	**Jet A**	**SAF**
2025	0.74	1.59	0.75	1.95	0.76	2.04	0.71	2.10
2030	0.77	1.41	0.78	1.73	0.80	1.73	0.75	1.89
2050	0.85	1.29	0.86	1.55	0.88	1.54	0.82	1.53

$$DOC_{fuel_{yr}} = \left(\left(\frac{€}{kg} \right)_{SAF_{yr}} \cdot \phi_{yr} + \left(\frac{€}{kg} \right)_{Jet\ A_{yr}} \cdot (1 - \phi_{yr}) \right) \cdot m_{fuel_{flight}} \cdot n_{flights_{yr}} \quad (2)$$

Ultimately, it is possible to relate costs and equivalent CO2 emissions for the different scenarios in order to estimate the cost associated to emissions reduction through the exploitation of SAFs. This relative cost (in €/kgCO2eq), specific for each year and world region, can be obtained by dividing the cost of fuel and the quantity of emissions, and it shall be computed incrementally, as differential cost, comparing the situation of the target year (i.e. the one under investigation) and a reference year (i.e. current situation or, in general, previous situation in which SAF exploitation is lower) in order to assess the viability of the solution. The mathematical relationship is shown in (3), where, for example, if the aim is to compute the cost per equivalent CO2 emission in 2030, if compared to the same value in 2025, taking into account aforementioned blend shares, i-th is 2030 and (i-1)th is 2025.

$$Cost_{CO_2eq} = \frac{DOC_{fuel_{yr_i}} - DOC_{fuel_{yr_{i-1}}}}{kg_{CO_2eq_{yr_{i-1}}} - kg_{CO_2eq_{yr_i}}} \quad (3)$$

In order to understand the cost-effectiveness of this measure, notwithstanding the obvious benefit in terms of absolute emissions, as specified in the next section, it is possible to compare the result with the relative cost of emissions abatement measures based on equivalent EU ETS. The cost of CO2 emissions on ETS-like quota allocation is also function of the related year, so an extrapolation of reference values used for this study are reported in Table 5 [5]. The application of ReFuel-EU-like plan as well as of an equivalent EU-ETS scheme is a strong hypothesis since different world regions would require specific policy making actions in order to obtain effective outcome, depending on the specific scenario.

Table 5: Reference value of cost for 1 tonn of CO2 in the EU ETS scheme

	2025	**2030**	**2050**
EU ETS – Cost per tonn of CO2 [€/tonn CO2]	78	101	188

The results in the next section shall then not be treated as universally applicable, but just as a starting point for the refinement of the theoretical approach.

Results

According to the methodology described in the previous section, total emissions trends per year, for the different world regions, can be shown in Fig. 1 (left). As it can be seen, after a couple of years, the adoption of SAF is generally beneficial for what concerns overall emissions quantity, expect for the Brazilian scenario, where the adoption of ETJ obtained from forestry residues do not ensure a positive abatement along the years. A similar trend summarizing the cost escalation due to the introduction of SAF blends, is shown in Fig. 1 (right), neglecting taxes. As it can be

Materials Research Proceedings 69 (2026) 546-551 https://doi.org/10.21741/9781644904251-98

seen, the exploitation of SAF has a negative impact on cost, since a general increase is present, with differences depending on SAF types and world regions.

The cost-effectiveness related to CO2 compensation exploited through SAFs introduction, in comparison with conventional EU ETS scheme adoption for CO2 quota compensation, is shown in Fig. 2. As it can be seen, a progressive adoption of SAF may allow to match the expenses associated to CO2 compensation through equivalent EU ETS scheme with time. The breakeven point (i.e. where the different lines matches the cyan one) depends on the scenario considered for the different regions and the type of SAFs.

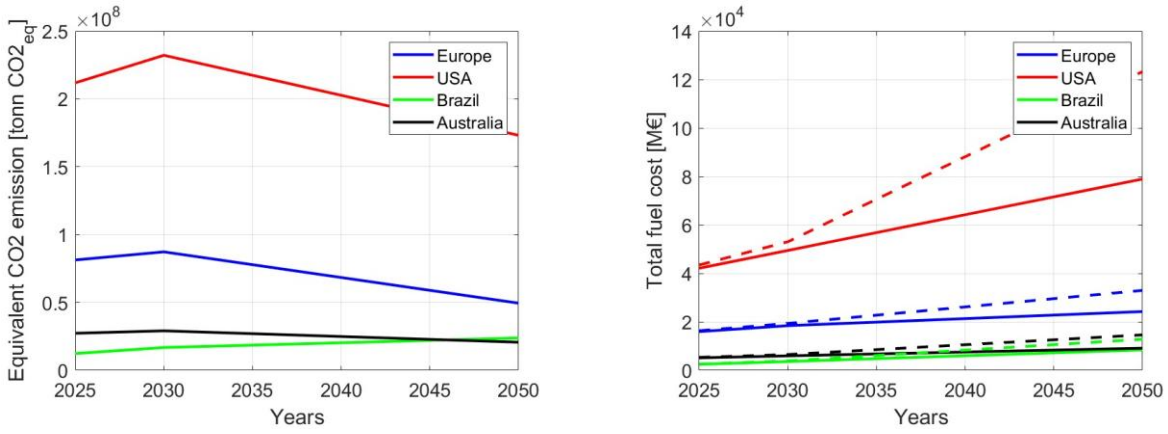

Figure 1: Total equivalent CO2 emissions (left) and total fuel cost (blends) (right) over the years

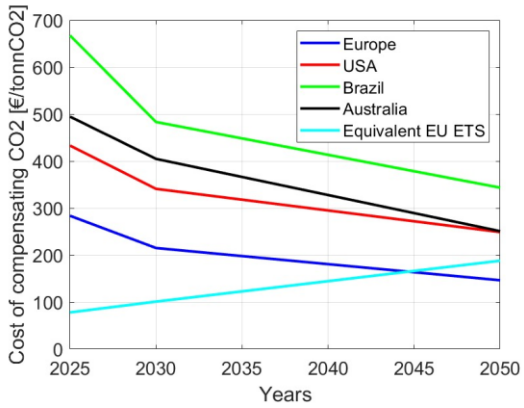

Figure 2: Cost per CO2 emissions and comparison between SAF adoption and EU ETS-like compensation

Summary

The methodology described in this paper demonstrates how to rapidly assess the impact of the progressive SAFs introduction in aviation on emissions and costs, according to international roadmaps, such as ReFuel-EU. The methodology is based on four main steps, consisting respectively in evaluation of traffic, analysis of SAFs production processes and feedstocks, assessment of cost associated to SAFs introduction and cost-effectiveness evaluation through the analysis of the trade-off between cost escalation and emissions reduction resulting from the increase in SAF blends over the years. Results demonstrate that different world regions shall be analyzed adopting different assumptions and policies, considering their specific needs and socio-economic situation. However, the results show that incremental introduction of SAFs in Europe can contribute, over the years, to a sensible reduction of CO2 emissions and that the cost associated to the introduction of new fuel can be competitive with reference to the traditional CO2 quota

allocation based on EU ETS scheme in the long term. Future works shall deal with detailed analyses on different world regions, as well as with assessment of the principles behind the ETS-like schemes in order to improve the cost-effectiveness evaluation.

Keywords: Aircraft System Design, System Context Input, Human-Machine Collaboration, Large Language Models

Abstract. Human-machine collaboration on systems design as well as on systems operation aims to face the intricacy and complexity of novel systems with artificial intelligence. This work aims to display a human-machine collaboration approach by front-end aircraft system design aiming to maintain human ownership and leverage artificial intelligence capabilities. Here, large language models (LLMs) gather information on system design to documental quality, to be reviewed and augmented with supervision by engineers. The study involves the following steps: firstly, a review on examples of using LLMs; then, prompt modelling on a search-and-rescue mission example; then, generating document-managed conversations.

Introduction

The complexity of automation in aircraft draws interest on human-machine interfaces as a matter of concern for aircraft systems engineering. The arrival of *artificial intelligence* (AI) as a component in aircraft automation requires an evolved perspective about *human-machine collaboration* to ensure the newly implemented systems can offer predictable and robust performance [1].

However, the implementation of AI to augment the control chains of novel aircraft systems also has implications that extend back to the design process. The realization of efficiencies from AI-enabled and connected smart devices entails added complexity and intricacy in the development of system designs as multi-domain system stacks [2].

This contribution aims to demonstrate an approach to human-machine collaboration making use of *large language models* (LLMs) to gather information on system design and yield work products with document quality, to be reviewed and augmented with supervision by engineers. It builds upon using *standard chatbox* tools [3] towards experimenting with a *custom chatbox* about how it affords interacting with LLMs onto traceable output.

About large language models (LLMs)

The prospects of using *large language models* (LLMs) attract attention to their use within systems engineering and design. Through the use of the transformer mechanism to neural networks [4], newer LLMs came with *problem-solving* abilities. This enables the prospect of generative AI (GenAI), regarding their ability to yield knowledge in its answers [5]. However, they have drawn criticism upon their lack of *matter-of-factness* [6], thereby with limited use for assurance cases of complex systems [7].

Materials Research Proceedings 69 (2026) 552-557 https://doi.org/10.21741/9781644904251-99

At the same time, their ability to compute language could support aircraft and aerospace design where traditional design automation methods have so far fallen short when the scope of inquiry is carefully managed [8]. Attempts at using LLMs to compute system design use embedded training patterns to yield deliverables, with examples reviewed on the following use cases [3]:

a) Processing of mission and design requirements,
b) Generation of structured system models,
c) Engineering assessment of hazards and assurance cases.

Common conclusions from these examples regard the remarkably short timeframe to building *reasonable* outputs. However, the quality of LLM-supported work products suffers from incompleteness to scope, or inaccuracy to intent, or non-compliance to rules. This means the usage of LLMs as GenAI tools requires attention by engineers about generating content upstream and downstream; The indiscriminate use of GenAI content without proper scrutiny results in the *workslop* phenomenon [9] with negative effects to productivity due to the rework needed.

Scope of work

We perform exploratory research on the use of LLMs in systems engineering, to understand *human-machine collaboration* with generative AI. The study illustrated in Figure 1 departs from the literature review onto experimenting with a prompt chain into developer-*standard chatbox*. Then, a *custom chatbox* is set to enable *human-in-the-loop* involvement in the inquiry process, to provide specification-quality outcomes from LLMs.

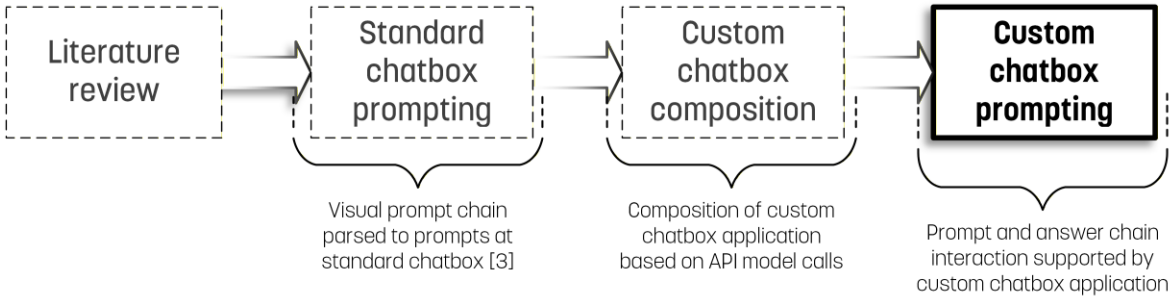

Figure 1 – Stepwise development of the study

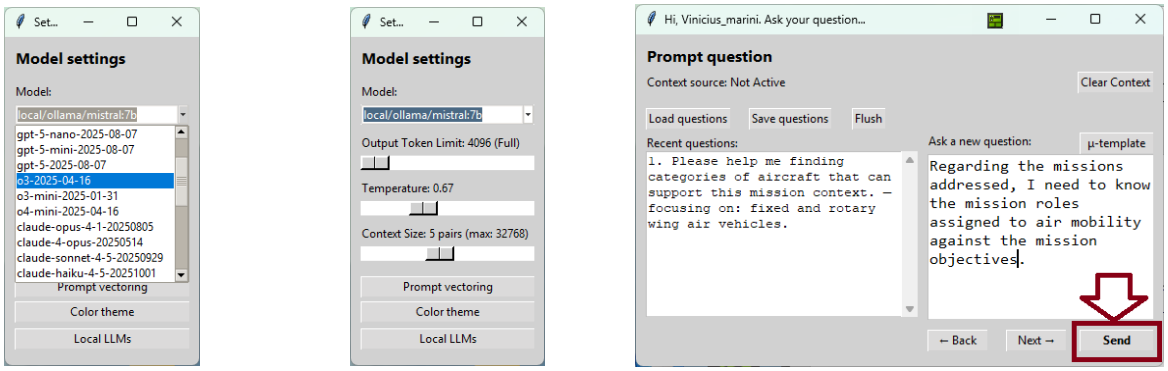

Visual concept mapping enables shaping the prompt question pathway, parsed onto topic questions and split in manageable chunks. This enables the buildup of conversation context in pre-specification level [3]. The conversation policy requires awareness to language processing and takes significant context space. While compliant to policy, standard chatbox responses require effort to monitor policy compliance and perform content review.

The custom chatbox

A *custom chatbox* application allows forwarding a planned question chain to a sequence of prompts at a LLM of choice through API calls. LLM model setup functionality is intended to augment the usability of the chatbox format towards better management of prompting and content review. The application is also intended to handle the streaming of context-supported and traceable answer content for editing and local saving.

The experimentation with standard chatbox resources [3] led to the understanding the need for improved human-machine interaction upon performing chained prompt inquiries. Here, Figure 2 displays the user interface approaches for selecting the intended model and performing/managing questions. It provides means to select the specific model for asking the questions (a), configuring context usage and temperature (b), and entering questions at the selected LLM (c).

Materials Research Proceedings 69 (2026) 552-557 https://doi.org/10.21741/9781644904251-99

a) Selecting model *b) Model selected* *c) Question history and next*

Figure 2 – Entering context information to prompt the selected LLM.

The model setting window (a, b) enables the choice of LLM and parameters on which to call it into *API calls*. The question window has a *question history* section (c) intended to manage the prompt chain, and a *single prompt* section to set one-time and recurring prompt questions. Figure 3 displays the setting of these different components for each model call requested through the *Send* button: the global prompt (a) to provide recurring instructions; the actual question in (b); and the boundary context prompt (c) as exemplar in each few calls.

Figure 3 shows the application windows including the question box (left), the prompt vectoring box (center) and the answer box (right). After setting up the intended model and adding the global and context in the question box (left), then it is possible to add *prompt vectors*[1], and choose between a single combined question or a batch prompt of several answers, each covering a different aspect. Here, question and prompt vectoring boxes allow including *µ-Templates*[2] as exemplars making part of the prompt [8].

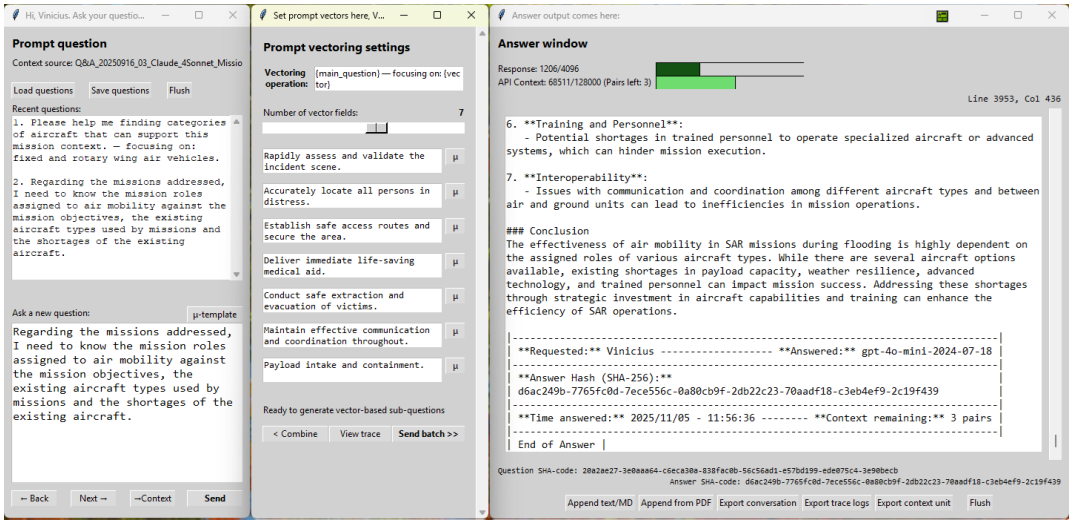

Figure 3 – Entering context information to prompt the selected LLM.

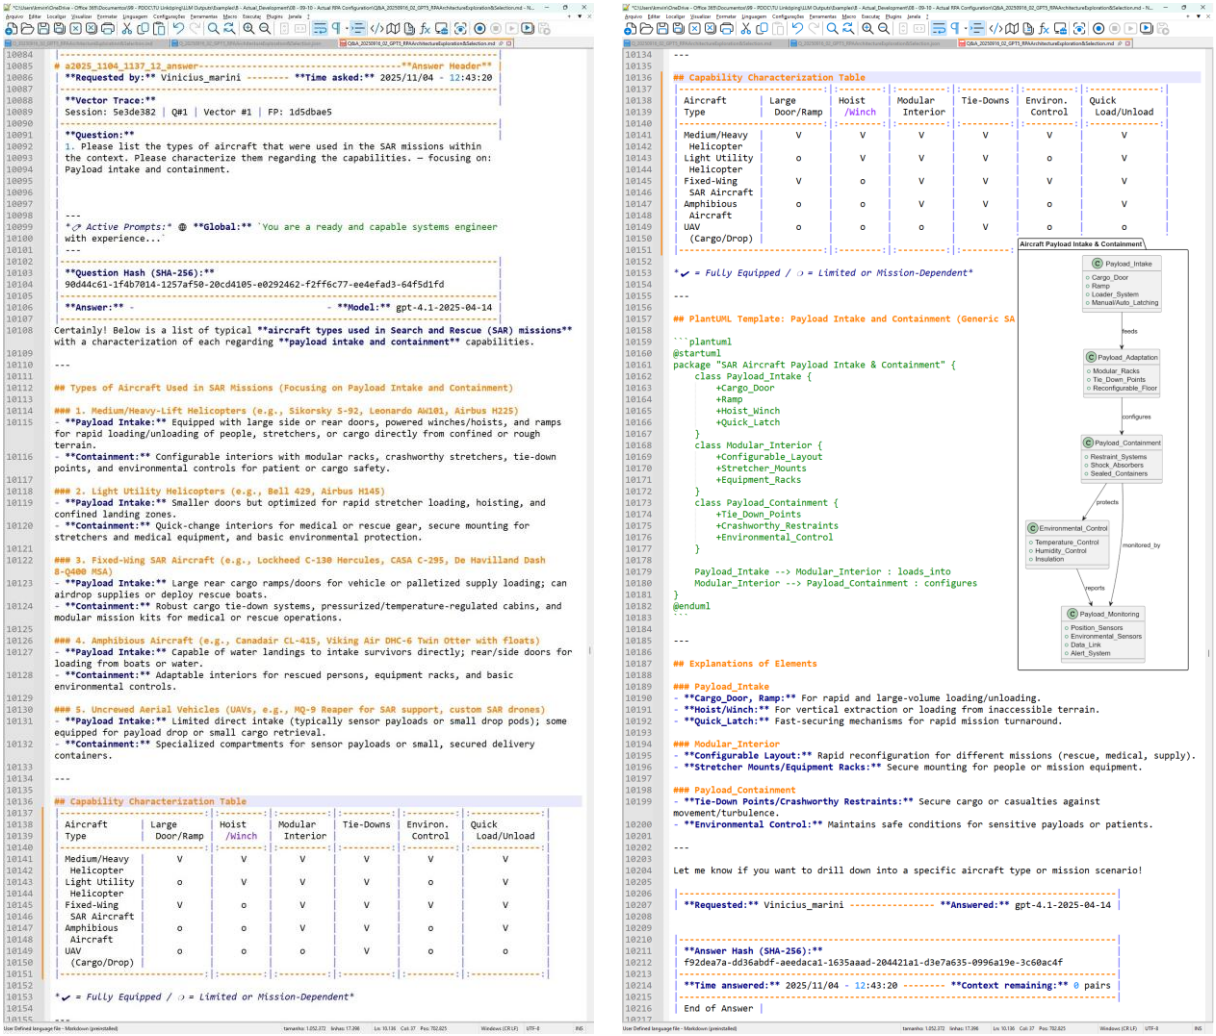
[1] *Prompt vectors* compose the prompt with aspect fields along a main question statement, intended to *steer* the answer to one or more specifics of the main question. Maintaining them along a question string enables *swimlaning* of related issues across specifics within the context window.

[2] *µ-Templates* (*micro-templates*) [8] are specific text or code snippets bringing in exemplars to the prompt, effectively enabling *one-shot* and *few-shot* prompting [10] with instances that the selected model is intended to follow and apply in generating its answer.

Materials Research Proceedings 69 (2026) 552-557 https://doi.org/10.21741/9781644904251-99



The answer window allows the addition of context references along with *μ-Templates*; here, token counting enables the verification of the ongoing context performance against the capabilities of the selected model. The sizing of individual answers and the API context in use allows estimating the LLM capability resources available in providing an answer. Here, prompt vectoring enables the choice between a combined single question/answer and a batch of question/answer pairs where each will focus a specific aspect.

The case study

This contribution will display the application and its use, with particular focus on the interface channels and the authentication information, towards mission and system design. The mission case is a large-scale flood [11] that occurred between April and June of 2024 with 100 municipalities affected, 600.000 displaced victims and 183 casualties.

Such large-scale and the urgency open prospects for enhancing aerial mobility, with the aim to simplify and leverage aircraft systems for large-scale lifting and medevac operations. Here, the mission context and the stakeholder needs have been established through a chain of prior questions, considering issues previously engaged with the use of standard chatbox input [3].

The resulting documentation from answers is in display by Figure 4.

a) First page with answer header *b) Second page with system model*

Figure 4 – Entering context information to prompt the selected LLM.

Figure 4 shows a saved answer about payload intake and containment capabilities for SAR aircraft. The synthesis of the specification benefits from context intakeStarting with a survey of aircraft design categories and existing products, the answer then characterises the capabilities per aircraft design category. Then it presents a *PlantUML* model (with graphic as reference) of the intended aircraft capabilities and concludes the specification with explaining capability highlights.

The answer includes authentication information in who requested information and the model providing the answers, including SHA-256 traceability codes for question and answer. The recording of the prompt chain - including vectors - enables reproducing the questions a number of times. However, long prompt chains - especially those involving the selection of batch prompts from vectoring - will also generate long conversations, which require significant workload for review.

Discussion

With Figure 4 shown as a single answer in a chain, the scope and sequence of questions shall be planned [3] with regard to reviewing workload. Our prompt composition approach provides some complementary resources to support this. Global and context prompts with guidelines help pre-organizing answer structure and focus, whereas *μ-Templates* constrain the LLM output to specific modelling guidelines.

Nevertheless, the use of LLMs to generating architecture models still requires review on the text and especially about codeblock output. The results have shown enough quality to be useful with replacement/incremental additions, without extensive refactoring.

Conclusion

The article focuses the synthesis of system design specifications for aircraft in displaying a human-machine collaboration interface. The proposed solution departs from the usual chatbox format, with generating system design specifications through a context assembly framework that manages requests to the model and enables curating the answer content.

Keywords: Artificial Intelligence, Aircraft Conceptual Design, Fully Electric Aircraft, Hybrid-Electric Aircraft, Correlation Analysis, Singular Value Decomposition (SVD)

Abstract. As the numerous aircraft concepts using electric or hybrid-electric propulsion remain at low technology readiness levels, there are no operational statistical data, and information on these concepts is comparatively scarce. The objective of this study is to explore alternative methods for early-stage estimations by evaluating and comparing design parameter predictions derived from conventional statistical methods and artificial intelligence (AI) for a 90-passenger hybrid-electric aircraft. The findings highlight the potential of AI as a tool for the early phases of aircraft conceptual design.

Introduction

Electrified aircraft propulsion remains in its early development phase due to technological, operational, and economic limitations. As these aircraft may have significantly different design characteristics when compared with conventionally powered aircraft, novel approaches for their design are required. To deal with these differences and the aforementioned data limitations, the present study explores alternative methods for early-stage parameter estimations of a 90-passenger hybrid-electric aircraft. Taking the number of passengers as the single input, estimations of key design parameters were obtained and compared from both statistical data and predictions generated by artificial intelligence (AI), proposing the use of AI as a supporting tool for initial parameter estimations in conceptual design.

Methodology

Design parameters of 52 fully electric (FE) and hybrid-electric (HE) aircraft concepts, chosen by relevance under the authors' criteria, were collected in a database whose extract is shown in Table 1. These parameters included the propulsion type, certification sought, number of passengers, maximum take-off mass (MTOM), wing loading (W/S), power-to-weight ratio (P/W) and battery mass fraction (BMF). The certification appears in Table 1 as CS-25, CS-23 or Light Sport Aircraft (LSA), which includes both general aviation and experimental categories. For turboelectric configurations lacking batteries (denoted T), BMF values were logged as 0* and were not included in any further analysis. Some parameters were directly reported by designers, while others were inferred. Those that were neither directly nor indirectly available in the sources were left blank (shown in red in Table 1). The methodologies applied to the collected data to support early-stage estimation of key parameters are now described.

The use of correlation and regression analyses constitutes a proven approach in aircraft conceptual design, as seen in design manuals [1, 2] and in recent research works [3, 4, 5], where the sample Pearson Correlation Coefficient, r_{xy}, has been used to explore the strength of linear relationships between pairs of variables [4, 5]. The statistical basis of this coefficient can be found in [6]. Aside from measuring the strength of the linear relationship through its numeric value, this sample coefficient can be used to make inferences on the population correlation coefficient ρ_{xy}. Of particular interest is the hypothesis test to check whether the obtained value of r_{xy} is such that a statistically significant correlation can be inferred for the population. This test can be undertaken through the statistic [6]:

$$t = \frac{r(n-2)^{0.5}}{(1-r^2)^{0.5}} \sim t(n-2) \qquad (1)$$

Materials Research Proceedings 69 (2026) 558-563 https://doi.org/10.21741/9781644904251-100

Which follows a Student's t-distribution with $(n-2)$ degrees of freedom. As this is a two-tailed distribution, the obtained p-value should be compared with half of the level of significance, α, that has been determined for the case study. Here, a value of α = 0.05 has been chosen, representing a 5% chance of making a Type I error. This choice has been made considering that in aircraft conceptual design an error of around 10–15 % can be accepted [1, 2], which is later refined in further design stages. Thus, the cut-off p-value would be 0.025 for the hypothesis test, where larger probabilities would result in the conclusion that no linear correlation can be assumed for the population in view of the results, whereas smaller probabilities would lead towards rejecting the null hypothesis and accepting that a statistically significant linear correlation may be inferred.

The second statistical method used was the Singular Value Decomposition (SVD) analysis described in [7]. It takes the intrinsic correlations between aircraft design parameters and transforms these into a smaller set of synthetic orthogonal parameters ordered by importance. This allows complex relationships to be approximated by only a few parameters. For the matrix-shaped dataset X, there exists a decomposition of the form:

$$X = s \times w \times V^T \quad (2)$$

Where s is an orthogonal input vector, w is a diagonal matrix with the singular values ordered by importance which weights how dominant design variables are. V is an orthogonal matrix that rotates the coordinate system from the original axes into the new axes. The matrix X gets transformed and centred to a base-2 log-scale for manipulation and then converted back to its original scale. An important limitation of this specific analysis is that they cannot handle missing data, and so any element with an incomplete row (at least one cell marked in red in Table 1) must be discarded. Consequently, the sample size is reduced, thus affecting the hypothesis testing and the statistical significance of the results. The following studies have focused on the first two categories due to their higher number of aircraft. Although the certification sought is critical for estimations of design parameters, no further category subdivisions were made in this study due to the mentioned limited sample size. For example, there is a single CS-25 compliant FE aircraft with full rows, which would make an analysis using these subdivisions impossible with the available data.

Lastly, queries to six Large Language Models (LLMs) were performed, namely Wolfram GPT, Meta Llama 3.2, Microsoft Copilot, ChatGPT o1, ChatGPT 4o, and ChatGPT 4o with Canvas. To account for the stochastic variability of the outputs, 28 queries per LLM were performed under four conditions: (i) without providing Table 1 in a single session, (ii) without providing Table 1 with a new fresh session for each run, (iii) providing Table 1 in a single session, and (iv) providing Table 1 with a fresh session for each run. The query performed was always the same: "*Give me the estimation for MTOM (in kg), cruise speed (in knots), Wing loading (in kg/m2), power to weight ratio (in kW/kg) and battery mass fraction for a HYBRID-ELECTRIC 90 PASSENGER AIRCRAFT."* The results totalled 168 answers for each parameter. The cruise speed was omitted from the analysis given its low impact as a design driver.

Results

Fig. 1 shows a correlation matrix where each combination between row and column corresponds to a pair of variables, with the Pearson Correlation Coefficient printed, with the main diagonal (where each variable is compared with itself) showing the corresponding histograms. The cells where the value of the Pearson Coefficient falls below the lower limit to achieve a p-value of 0.025 are shaded in a diagonal pattern, representing correlations whose statistical significance cannot be ascertained through the aforementioned hypothesis test. The limit values are r = 0.514 for a sample of 15 aircraft in the FE case, and a value of r = 0.482 for a sample of 17 aircraft in the HE case. Fig. 2 shows a heatmap of the values of the Pearson Coefficient with the corresponding p-values.

Materials Research Proceedings 69 (2026) 558-563 https://doi.org/10.21741/9781644904251-100

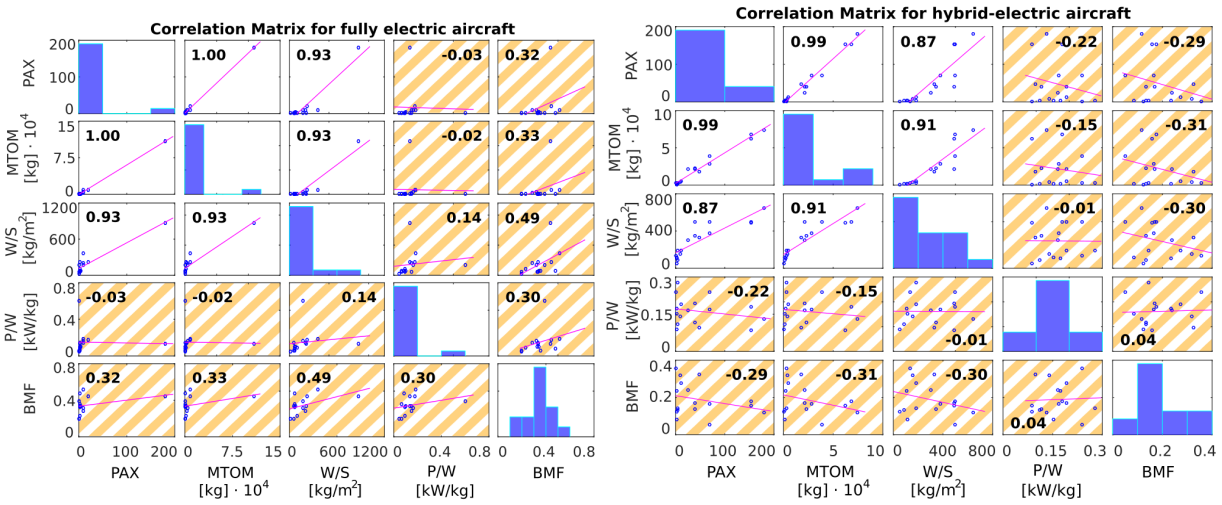

Figure 1: Correlation plots for fully electric aircraft (left) and hybrid-electric aircraft (right). Cells with shaded diagonals are correlations with low statistical significance.

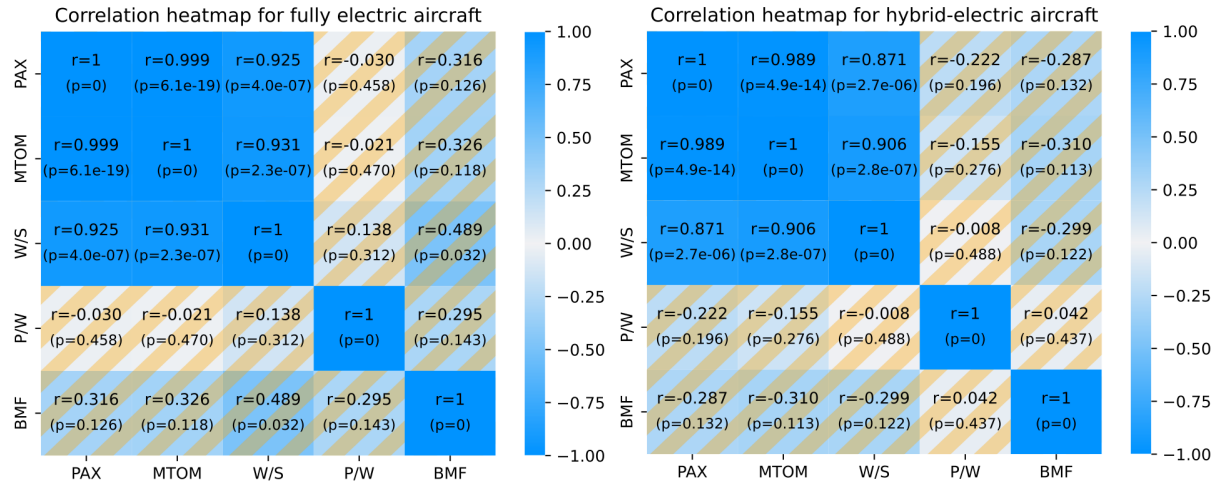

Figure 2: Heatmap of the Pearson Correlation Coefficient for fully electric aircraft (left) and hybrid-electric aircraft (right), with the corresponding p-values shown below in each case.

Regarding the SVD results, the predictions of the design parameters using 90 PAX as the only input are summarized in Table 3 for datasets including only full electric (FE), only hybrid-electric (HE), and both (FE+HE). Regarding the responses from the LLMs, Fig. 4 shows the distribution charts of the query responses for each model grouped by parameter. Wider areas represent higher data density, the central continuous line marks the median, the dashed lines indicate the first and third quartiles, and the dots individual points.

Table 2 SVD results using 90 PAX as input.

Type	MTOM [kg]	W/S [kg/m2]	P/W [kW/kg]	BMF
FE	61 275	820	0.22	0.47
HE	44 289	516	0.17	0.15
FE+HE	45 076	536	0.17	0.17

Discussion

With respect to the results of the correlation analysis, for both samples, very strong correlations can be seen among the number of passengers, MTOM, and W/S, fitting the conventionally-powered trends seen in previous research [3]. It should be noted that a single data point can be seen far from most of the other aircraft in the FE case (see Fig. 1), since this point corresponds to the only large transport category aircraft found within this powerplant type. By analysing the main group of points, the existence of a linear trend has been checked for them, but further study would be worthwhile to examine the influence of the furthest data point on the correlation of the whole group. As for the BMF correlation difference between FE and HE categories, it could be deduced that, when moving to higher passenger numbers, designers of HE aircraft might favour higher fuel mass fractions rather than battery mass to limit the increase in overall mass of the aircraft. However, FE aircraft possess low specific energy and therefore the battery mass increases faster than other mass elements of the aircraft, resulting in a higher BMF. These trends are in line with the current approach of favouring HE over FE aeroplanes for commuter and larger transport categories for the present battery state of the art. Nevertheless, it should be noted that from a statistical standpoint, the correlations of BMF in both cases would not be sufficiently strong to support their statistical significance through the hypothesis test. Larger samples reduce the value of the cut-off Pearson Coefficient following the statistical test commented beforehand, thus an increase in the database in future work, depending on the variation in the results, could serve to substantiate the significance of the correlations from a statistical standpoint.

In the case of the power-to-weight ratio, very weak correlations are observed in almost all cases. This is in part due to the fact of different battery energy densities being assumed by designers,

with values ranging from 250 up to 1500 Wh/kg, which has a direct impact in these powerplant-related variables. This is another reason why range was not included in the analysis, since the same aeroplane with different energy densities assumed would have significantly different ranges and performance. For the SVD analysis, the results from Table 3 agree with the trends from the correlation analysis. The fact that the number of passengers has the highest weight in all cases suggests that estimating other design parameters based solely on the number of passengers is reasonable. For electric aircraft, the large predictions for a 90 PAX design may result from not distinguishing certification categories, as the SVD uses data from all CS-25, CS-23, and LSA compliant aircraft to make the prediction. A larger dataset could enable this differentiation in future work. For HE aircraft, average values from the AI responses are comparable in most cases to the results from the statistical analysis. Considering that in aircraft conceptual design an error of around 10–15% can be accepted [1, 2], usage of AI to complement pre-design studies appears viable. Nonetheless, the spread of the predictions evidences the need to query the LLM multiple times to avoid obtaining an outlier if this method were to be used.

Conclusion

A dataset comprising 52 aircraft concepts was compiled for correlation and Singular Value Decomposition (SVD) analyses, whose results were compared with the responses of six large language models. Insights revealed that there are moderate to strong correlations among various parameters selected for the study. The SVD analysis indicates that the number of passengers was the dominant factor in determining other design parameters. AI predictions showed average values comparable to the results from the statistical analysis, although exhibiting a large scatter. For the aircraft types studied here, the use of the statistical test to check the significance of the Pearson Correlation Coefficient, the SVD analysis to discover underlying trends, and the exploration of LLM queries for parameter estimation constitute novel contributions of this research. The study therefore explores the possibility of using artificial intelligence not as inspiration or as an active decision-maker, but rather as an aid that complements pre-design statistical analysis.

Keywords: Distributed Propulsion, Urban Air Mobility, CABARET Method, Large Eddy Simulation, Rotating Meshes, Aeroacoustics, Trailing-Edge Serrations

Abstract. Urban Air Mobility (UAM) vehicles rely on distributed propulsion (DP) to achieve efficiency, control authority, and compact integration with lifting surfaces. The close spacing of multiple rotors, however, intensifies installation effects that elevate tonal and broadband noise. This work presents a high-fidelity Large Eddy Simulation (LES) study using the CABARET method on rotating meshes to quantify aeroacoustic and aerodynamic sensitivities of a three-propeller DP configuration. The campaign varies: (i) central-rotor axial position ($\Delta x = \{-0.2Db, 0, +0.2Db\}$), (ii) inter-rotor phase angle ($0°, 45°, 90°, 135°$), and(iii) blade trailing-edge geometry (baseline vs. sawtooth serrations). Band-limited overall sound pressure level (BL OASPL) is evaluated on a probe plane under the array between the 1st and 6th blade-passing frequencies. Key findings are: (a) serrations consistently reduce area-averaged and maximum BL OASPL by up to 2.4 dB, most notably around 90◦ phase; (b) moving the central rotor closer to the wing increases thrust coefficient by ≈ 7.8%, indicating a beneficial rotor–wing interaction akin to ground effect; (c) the aerodynamic penalty of serrations is modest and attributable to effective area loss near the tip. Flow visualizations show serrations disrupt spanwise coherence and trailing-edge vortex organization, explaining the observed acoustic benefits. The results highlight the importance of joint optimization of geometry and phasing to deliver quieter, efficient DP systems for UAM.

1. Introduction

UAM concepts increasingly adopt DP to distribute thrust and to leverage propeller–wing interaction for lift augmentation and control [1, 2, 3, 4]. Compact layouts, however, amplify noise through periodic wake–airframe interactions (tonal peaks at blade-passing harmonics) and broadband mechanisms associated with boundary-layer and wake turbulence [5, 6, 7, 8]. Prior work shows strong sensitivity of noise directivity and level to rotor placement and phasing relative to wings [9, 10, 11]. Passive serrated trailing edges, inspired by owl feathers, can reduce scattering efficiency and spanwise coherence [12, 13, 14, 15, 16, 17, 18]. Here we assess, within one

consistent LES framework, how axial position, phase, and serrations jointly govern the aeroacoustic signature of a representative three-rotor DP system based on TU Delft experiments [19].

2. Numerical Methodology

We employ a GPU-accelerated CABARET LES on rotating meshes [19, 20, 21, 22, 23]. Sliding interfaces conserve fluxes via a super-mesh projection and compact sub-cell reconstructions, preserving the dispersion and dissipation properties of the base scheme while avoiding re-meshing.

(a) Rotating and stationary zones with sliding interface. (b) *Analytical interface for conservative fluxing.*

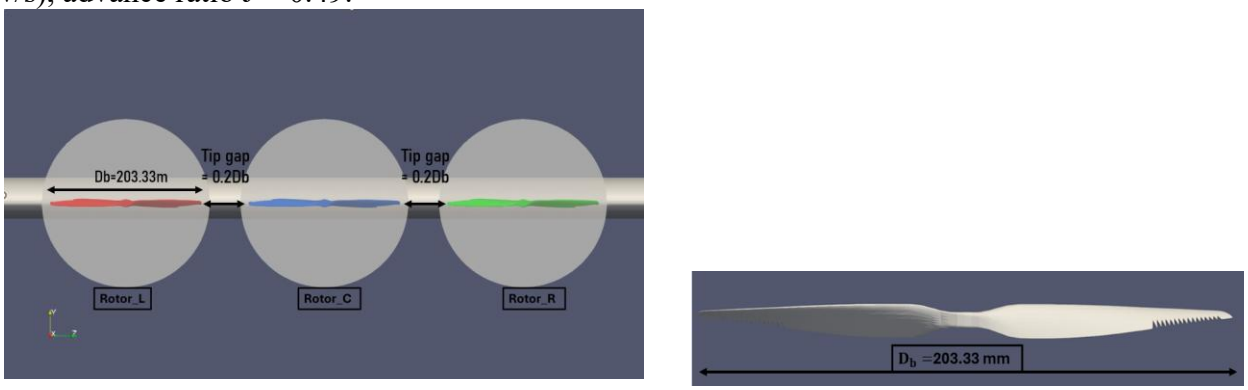

Figure 1: CABARET LES rotating-mesh formulation.

2.1 LES CABARET Solver

An improved-dispersion variant and asynchronous time-stepping enhance accuracy and efficiency. Wall modelling adopts Reichardt's law; the solver is MPI parallel and GPU-resident to minimize turnaround time. Prior validations include a single propeller in boundary-layer ingestion configurations [24].

2.2 Test Cases and Parametric Study

Three identical two-bladed Mejzlik propellers of diameter $D_b = 203.33\,mm$ are aligned span-wise and located 220 mm upstream of a wing leading edge; the central rotor (Rotor$_C$) translates axially by $\pm 0.2D_b$, while lateral rotors remain fixed. The phase of Rotor$_C$ relative to the others is set to 0◦, 45◦, 90◦, 135◦. Serrations (sawtooth, 16 wedges from r = 63.5–88.5 mm, depth 2.32 mm, spacing ≈ 1.55 mm) follow guidelines in [14]. Operating point: U∞ = 30 m/s, n = 5730 RPM (95.5 rev/s), advance ratio J = 0.49.

(a) Three-rotor configuration upstream of the wing. *(b) Serrated trailing-edge geometry.*

Figure 2: Configuration and serration concept used in the study.

Materials Research Proceedings 69 (2026) 564-570 https://doi.org/10.21741/9781644904251-101

2.3 Numerical grid
ANSYS ICEM generates hexahedral meshes with rotating zones around each rotor and a stationary outer domain. The domain extends $5D_b$ upstream and $10D_b$ downstream of the wing. Grids contain ~ 5.1M cells (serrated) and ~ 4.9M (baseline), refined near blades, wakes, and the wing.

2.4 Noise footprint of the DEP system
Pressure probes populate a plane at z = $-1D_b$ beneath the array to evaluate BL OASPL between the 1st and 6th BPFs. We report (i) area-averaged BL OASPL and (ii) maximum BL OASPL across all probes.

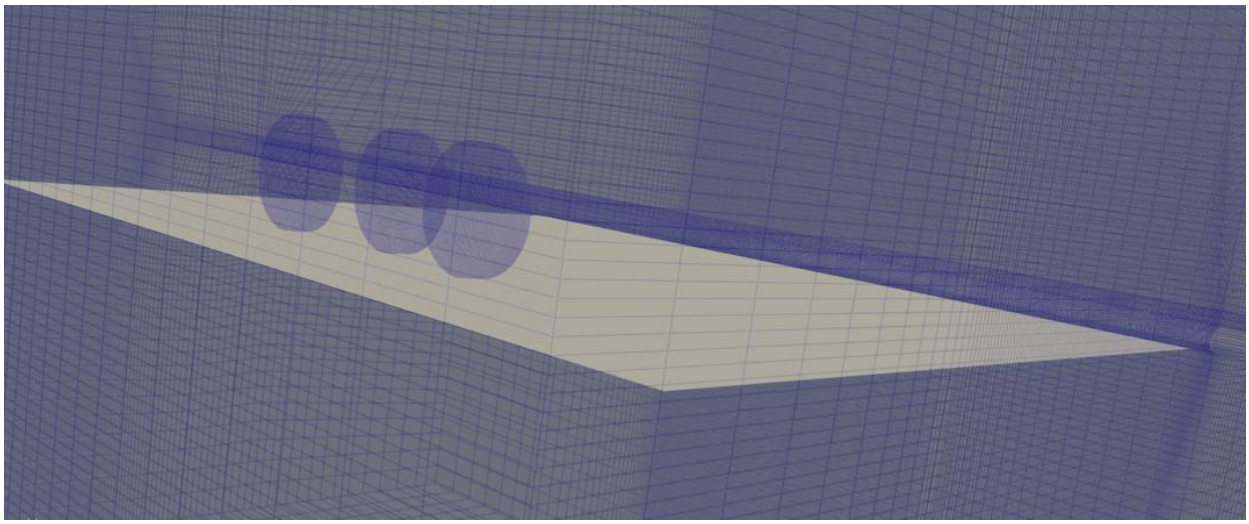

Figure 3: Probe plane used for BL OASPL evaluation beneath the rotors.

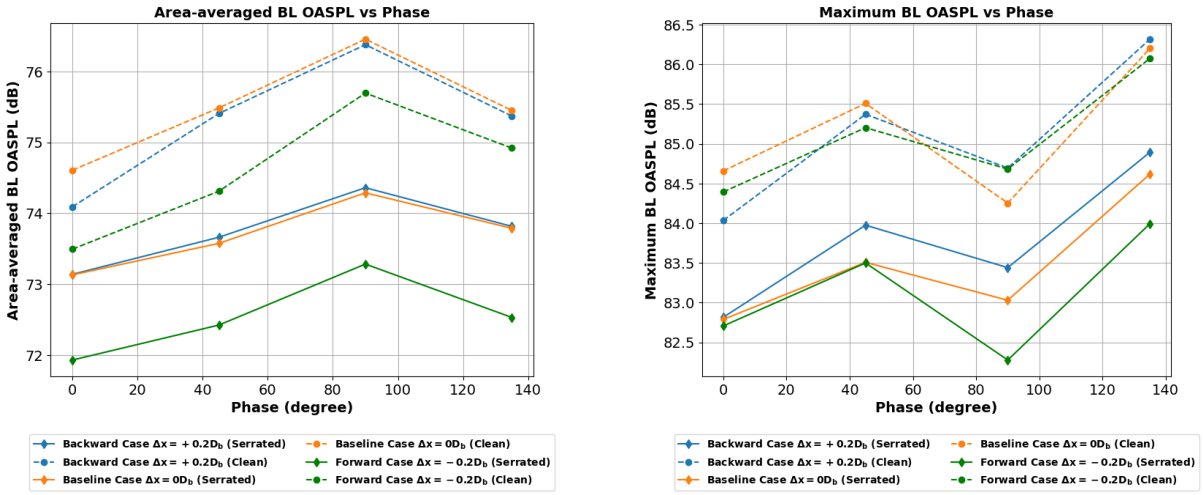
3. Results and Discussion

3.1 Aerodynamic Results
Rotor performance is characterized by thrust and torque coefficients:

$$C_T = \frac{T}{\rho n^2 D^4}, \qquad C_Q = \frac{T}{\rho n^2 D^5} \tag{1}$$



At fixed RPM and J, axial translation of Rotor$_C$ modulates rotor–wing interaction. Bringing Rotor$_C$ closer to the wing increases C_T by ≈ 7.8% relative to the baseline, consistent with an effective ground-effect mechanism that boosts induced velocities and pressure recovery below the disk. Phase primarily affects unsteady interference rather than mean thrust; thus, C_T is comparatively insensitive to phase. Serrations slightly reduce C_T (and C_Q) due to effective area loss near the tip, matching the expected aerodynamic trade-off.

3.2 Flow Field
Baseline blades shed coherent trailing-edge and tip structures whose interaction with the wing drives unsteady loading. Serrations fragment large coherent vortices into weaker, shorter-coherence structures, reducing spanwise correlation of surface pressure fluctuations. The resulting wake has diminished organized content at BPF harmonics, a precondition for lower tonal and mid-to-high-frequency broadband emissions.

3.3 Acoustic Pressure Fluctuations
Figure 4 summarizes BL OASPL trends versus phase for axial positions. Serrations reduce both area-averaged and maximum BL OASPL across all cases, with the largest benefit near 90°. Forward axial offset ($\Delta x = -0.2D_b$) generally yields the lowest BL OASPL; the backward case shows smaller gains, indicating geometry-dependent engagement of the serration mechanism with

Materials Research Proceedings 69 (2026) 564-570 https://doi.org/10.21741/9781644904251-101

installation effects. The peak reduction of ≈ 2.4 dB aligns with small-scale experimental ranges in the literature for sawtooth treatments [25, 26, 27] and with analytical predictions of coherence suppression [28, 29, 30, 31].

(a) Area-averaged BL OASPL vs. phase. *(b) Maximum BL OASPL vs. phase.*

Figure 4: Noise metrics for baseline and serrated blades across axial positions.

4. Conclusion

A GPU-accelerated CABARET LES framework was applied to a three-rotor DP system typical of UAM installations. We varied axial position, inter-rotor phase, and trailing-edge geometry to isolate drivers of aeroacoustic performance. Serrated trailing edges achieved up to 2.4 dB reductions in both maximum and area-averaged BL OASPL, with strongest gains near 90◦ phase. Moving the central rotor closer to the wing increased C_T by ≈ 7.8%, evidencing beneficial rotor–wing coupling; serrations incurred a modest aerodynamic penalty.

Flow analyses support a mechanism of reduced spanwise coherence and disrupted vortex organization. The combined results indicate that optimizing rotor placement, phasing, and serration geometry is essential to simultaneously mitigate noise and retain efficiency in DP architectures. Future work will extend to alternative serration metrics, flap-equipped wings, and advance-ratio sweeps to map robustness across flight phases.

5. Additional work to be reported on full paper

Noise directivity results of the above considered three propeller-wing configurations will be compared with the available experimental results of the 3D wing-flap and three electric motor-driven propellers in a similar ‘puller’ propeller setup. The latter setup corresponds to the recent H2020 CS2 European project VENUS, which investigated methodologies and tools to enable a concurrent design approach for both the aerodynamics and aeroacoustics of aircraft focusing on DEP. The details about the work are presented in DePaola et al. [32] The experimental tests comprise both measurements of acoustics and aerodynamics. A particular finding of the VENUS campaign was that the largest effect on DP noise was due to the propeller wake interaction with the deployed wing flap. Therefore, the best noise reduction was found for the propellers positioned closest to the wing.

In comparison with the VENUS configuration, the ENODISE setup does not include a deployed flap, and the best reduction there appears to correspond to the largest distance between the propellers in the forward staggered configuration. Nevertheless, regardless of the specific propeller/wing geometry details it is interesting to compare the acoustic directivity of the overall noise reduction achieved by changing the propeller installation with respect to the wing in the

ENODISE and VENUS DP configurations. This comparison will be performed for similar offset phase angles of the central propeller, with and without applying the noise reduction technique (trailing edge serrations) in case of the ENODISE propellers. Details will be reported in the full paper along with the LES grid sensitivity study.

In addition, aerodynamic performance of different DEP configurations corresponding to the ENODISE setup will be analyzed as well as the far-field noise will be computed based on the Ffwocs Williams-Hawkings's method. This will allow us to assess the trade-off between the aerodynamic and the aeroacoustic performance for the considered ENODISE DEP configuration, like the experimental investigation in the VENUS project.

Abstract. The performance of electric UAVs largely depends on the efficiency of their onboard energy storage systems. In battery-powered propulsion, maximizing battery life and flight time is a key function of the Battery Management System (BMS). This study presents an ageing test campaign to characterize the State of Health (SOH) of a Li-Po battery pack. The tests use a current load profile derived from a flight simulator that models UAV longitudinal dynamics, propulsion, and onboard systems for realistic current demand. When predefined ageing indicators, such as reduced end-of-mission voltage variation, exceed set thresholds, Hybrid Pulse Power Characterization (HPPC) tests are conducted to characterize the battery at different ageing states. The resulting parameters support dynamic battery modelling at various ageing stages.

Introduction

Within the broader goals of global transport decarbonization, the electrification of propulsion systems for airborne vehicles remains a critical challenge, significantly affecting flight performance (e.g., endurance) and reliability. Electrification efforts are primarily focused on Unmanned Aerial Vehicles (UAVs) since they not only serve as effective platforms for prototyping advancements for future manned systems, but have also gained increasing attention due to their wide range of applications [1] and economic advantages [2].

In particular the endurance is predominantly influenced by the onboard energy storage system. Li-Po batteries, lead the market for small UAVs due to their favourable balance of energy density (approximately 100–200 Wh/kg) and power density (around 200–1000 W/kg), which better suits the demands of UAVs applications [3], [4], [5], [6]. Moreover, since battery performance can significantly vary based on their condition and operating environment [5], energy storage module, which is usually composed of multiple batteries connected in series and parallel, is usually equipped with a Battery Management System (BMS) which primary objective is to optimize battery utilization aiming to extend battery cycle life and flight time, while ensuring the safety and reliability of battery operation [7]. In particular, among all the batterie states, the State Of Charge (SOC), the State of Temperature (SOT) and the State of Health play a crucial role in the performance of lithium batteries [8], [9], [10]. Consequently, to ensure operation within a safe and optimal range, the monitoring section of BMSs must be capable of estimating the battery states.

In a previous work [11], the authors developed a State of Charge (SOC) and State of Temperature (SOT) estimator based on model-based observer algorithms. To now enable the development of a State of Health (SOH) estimator, it is necessary to characterize the battery pack under ageing conditions [12], [13]. Therefore, this study focuses on the design and testing of procedure for the ageing characterization of a 6-cell, 22.2 V, 2000 mAh Li-Po battery pack used in a 25 kg dual electric Vertical Take-Off and Landing (eVTOL) UAV.

The manuscript is organized as follows: Section 2 provides a description of the system; information on the experimental test plan and test setup are proposed in section 3. Finally, the result section shows an excerpt of the experimental test and the ageing results.

System description

The reference eVTOL UAV, shown schematically in Figure 1, is a 25 kg hybrid copter-plane designed for VTOL and forward flight. It features two groups of non-tilting rotors: eight motors for vertical take-off, landing, and low-speed control, and two motors for forward flight. The propulsion system includes ten fixed-pitch, two-blade APC 18x5.5MR propellers, each driven by its own ESC. Power is supplied by a Battery Pack System (BPS) consisting of 18 parallel-connected batteries. Additional components include onboard systems and payload (absorbing 250 W), a BMS and a Flight Control Computer.

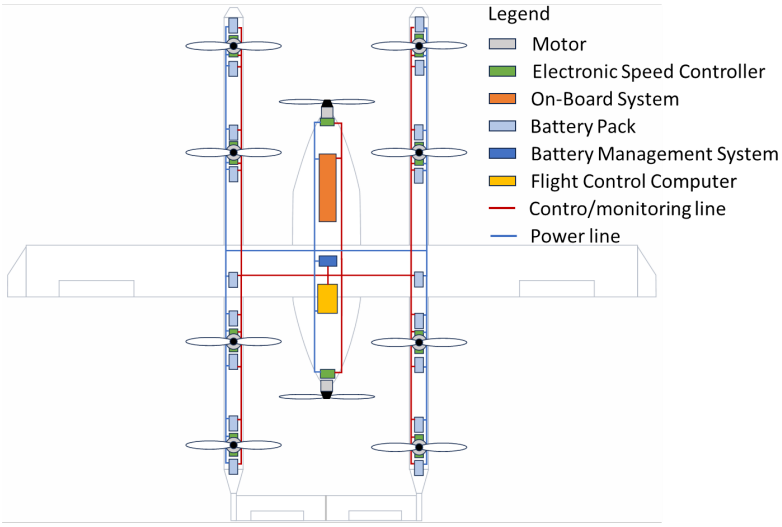

Figure 1. Conceptual schematic of the reference eVTOL UAV (top view).

Test plan and experimental set-up

To create a suitable database for the development of a SOH observer, HPPC tests and flight mission simulations have been combined, by evaluating internal resistance, capacity, and voltage response at various SOCs to identify key battery model parameters [14], [15]. Throughout the tests, the battery operates in a thermal chamber to control the environmental conditions. The ageing is monitored by tracking voltage drops at the end of missions and temperature rises between cycles. When these indicators exceed predefined thresholds, HPPC tests are performed to assess the impact of ageing on capacity and internal resistance, supporting the development of an accurate SOH estimator. The test setup, illustrated in Figure 2, also includes an electronic load simulator (Electronic Power Unit, EA-EL 9000 DT 500W), which applies the current load for the battery and provides voltage and current feedbacks. The data acquisition and the monitoring of the battery is managed by the Electronic Control & Monitoring Unit, featuring an NXP S32K144EVB microcontroller, an MCP4725 DAC for analog signal control, and eight Type-T thermocouples with MAX6675 modules for temperature sensing. Test logic, monitoring algorithms, and protection routines are developed and deployed in the MATLAB/Simulink environment.

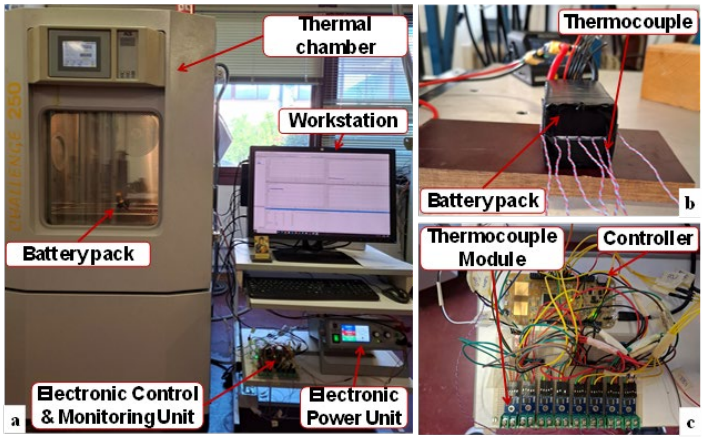

Figure 2. Experimental set-up (a) with focus on battery pack(b) and on Electronic Control & Monitoring Unit (c).

Results

An excerpt of the test campaign outputs is reported in Figure 3 in terms of current, voltage and the battery temperatures along the cells for a flight mission simulation. while reports. From the thermal-related measurements, it appears that the thermal stress experienced by the third cell is higher than the one of the other cells. This condition could lead to accelerated ageing over time and, in the short term, this causes a faster discharge rate due to the reduced internal resistance at higher temperatures. The battery capacity and the internal resistance with the ageing cycles are reported in Figure 4. The internal resistance trend with the temperature confirms literature results [14], [15]. Similarly the total capacity trend with the ageing cycles is coherent with the maximum number of cycles of the reference battery technology.

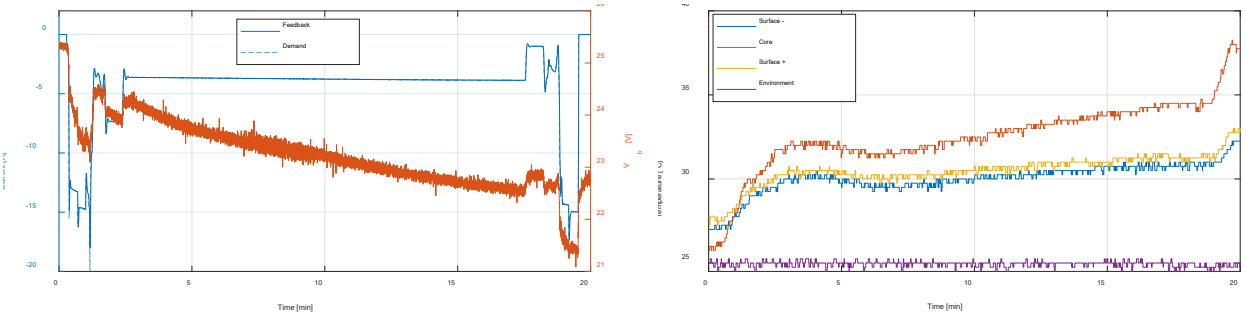

Figure 3. Flight mission time histories: (left) current input and terminal voltage; (right) temperatures.

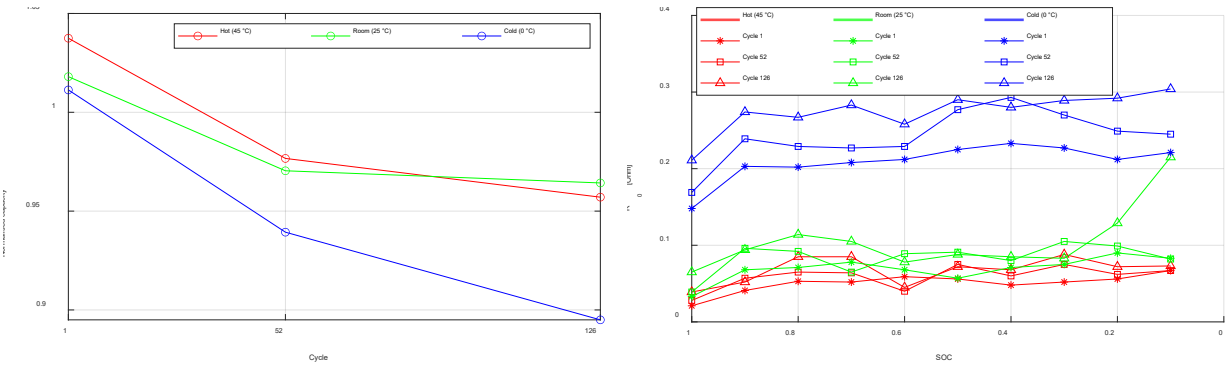

Figure 4. Battery pack parameters with ageing cycles: (left) total capacity, (right) internal resistance.

Summary

An experimental test setup for the performance characterisation of a Li-Po battery pack in terms of temperature and ageing is presented. The battery pack, designed for a 25 kg eVTOL UAV, is subjected to repeated discharge cycles based on the flight mission load profile of the reference UAV. The results show that, after approximately 130 flight missions, the internal resistance increases by about 15 %, particularly at low temperatures. Similarly, under cold conditions, the capacity decreases by roughly 10 %. The identified parameters will be employed in the development of a model-based monitoring system for the online estimation of the battery states.

Abstract. In order to evaluate the potential of different electrified aircraft propulsion system topologies, accurate and efficient sizing models as well as performance evaluation techniques are necessary. To accommodate for this, the presented study introduces a comprehensive methodology for electric machine sizing and performance estimation. Therein, static and dynamic modelling approaches are combined to investigate both steady-state operation as well as the transient behaviour. The dynamic model is verified against the already validated static one and both models are used for the simulation of a realistic test case from the literature, showing very good agreement for the steady-state operation phases while highlighting key differences during transient operation. Based on these results, the presented study enables a detailed static and dynamic performance analysis of electric machines while coupling it to the sizing process.

Introduction

To effectively address climate change, the transportation sector must achieve a substantial reduction in greenhouse-gas emissions. In aviation, a considerable portion of these emissions originates from the carbon-based fuels that power today's propulsion systems. One promising pathway to limit this impact is the development of novel propulsion technologies, such as using electrically driven propellers. Particularly for aircraft operating up to the regional market, electrically supported or electric-driven concepts are drawing research attention as they hold the potential to lower the carbon footprint while maintaining operational efficiency and performance [1], [2]. Besides full-electric powertrain concepts which are solely powered by electric energy, hybrid-electric or more-electric propulsion systems arise as intermediate step for electrification – especially for aircraft classes beyond the regional sector [2]. One approach for electrifying conventional aircraft engines was presented by the NASA in their Turbine Electrified Energy Management (TEEM) [3]. In this concept, electric machines are placed on either the low-pressure shaft, the high-pressure shaft or on both shafts to support and optimize the gas turbine operation. The electric machines are meant to draw power from or supply power to the shaft dependent on the flight phase to power secondary aircraft systems and optimize the turbine operation. In addition, the electric machines should also be used for shifting safety margins in critical flight phases, such as the stall margin while rapidly powering the turbine up or down. As this represents a highly transient operation of the electric machines, e.g. increasing its torque supply from 0 to over 250 Nm within seconds [4], the dynamic performance behaviour of the machine needs to be assessed based on its initial design. Therefore, this study introduces a comprehensive methodology which includes both the initial sizing of an electric machine sizing as well as the performance estimation for steady-state and transient operation, which can be applied to such use cases.

Methodology

To facilitate the preliminary sizing of an electric machine, a static model of a permanent magnet synchronous machine (PMSM) is used. The model published by Bahrs *et al.* [5] allows for preliminary machine sizing with a high degree of detail. Therein, the most important parts of the machine are sized individually while taking their interdependencies as well as an initial performance estimation into account. Furthermore, the analytical character of the model allows for computationally inexpensive calculations and is therefore optimal for fast investigations of numerous propulsion system architectures in early design phases. To enhance the coupling of this steady-state model with a transient counterpart, its formulation was updated to represent a non-linear mathematical model. Therein, the objective is defined as

$$min\ F\left(\eta, h_{sl}, N_t, \lambda, \hat{B}_{gap}\right) = \left[\left(\frac{\eta-\tilde{\eta}\left(\eta,N_t,\lambda,\hat{B}_{gap}\right)}{\tilde{\eta}\left(\eta,N_t,\lambda,\hat{B}_{gap}\right)}\right)^2 + \left(\frac{h_{sl}-\widetilde{h_{sl}}\left(\eta,h_{sl},N_t,\lambda,\hat{B}_{gap}\right)}{\widetilde{h_{sl}}\left(\eta,h_{sl},N_t,\lambda,\hat{B}_{gap}\right)}\right)^2 + \left(\frac{N_t-\widetilde{N_t}\left(\eta,N_t,\lambda,\hat{B}_{gap}\right)}{\widetilde{N_t}\left(\eta,N_t,\lambda,\hat{B}_{gap}\right)}\right)^2 + \left(\frac{\hat{B}_{gap}-\widetilde{\hat{B}_{gap}}(h_{sl})}{\widetilde{\hat{B}_{gap}}(h_{sl})}\right)^2\right] \quad . \tag{1}$$

which represents the iterative character of the sizing detailed in [5]. Initial values for the efficiency η, the sleeve thickness h_{sl}, the number of stator turns N_t, the relative length λ and the peak air gap flux density $\hat{B}_{gap}$ must be set to initiate the sizing, but they are refined based on the results of the sizing process. Therefore, the main goal of the objective function is to find a valid design of an electric machine given a set of boundary conditions and requirements. Using $\eta, h_{sl}, N_t, \lambda$ and $\hat{B}_{gap}$ as model variables, the constraints from Eq. (2) - (5) and the sizing equations from Bahrs *et al.* [5], a valid preliminary design is achieved by solving the objective function in Eq. (1)

$$\text{s.t.} \quad \tilde{\eta}\left(\eta, N_t, \lambda, \hat{B}_{gap}\right) = \frac{P_{\text{mech}}}{P_{\text{mech}} + P_{\text{loss}}\left(\eta, N_t, \lambda, \hat{B}_{gap}\right)} \tag{2}$$

$$\widetilde{h_{sl}}\left(\eta, h_{sl}, N_t, \lambda, \hat{B}_{gap}\right) = -\frac{m_{\text{mag}}\left(\eta, h_{sl}, N_t, \lambda, \hat{B}_{gap}\right) r_{sl}\left(\eta, N_t, \lambda, \hat{B}_{gap}\right) \omega^2}{\pi\, l_{\text{rot}} \left(\rho_{sl}\, r_{sl}^2\left(\eta, N_t, \lambda, \hat{B}_{gap}\right) \omega^2 - \frac{\sigma_{y,sl}}{K_{sl}}\right)} \tag{3}$$

$$\widetilde{N_t}\left(\eta, N_t, \lambda, \hat{B}_{gap}\right) = \frac{S_{ph,Co}\left(\eta, N_t, \lambda, \hat{B}_{gap}\right)}{S_w\left(\eta, N_t, \lambda, \hat{B}_{gap}\right)} \tag{4}$$

$$\widetilde{\hat{B}_{gap}}(h_{sl}) = \frac{B_r}{1 + \frac{h_{\text{gap}}(h_{sl})}{h_{\text{mag}}}} \quad . \tag{5}$$

As detailed in [5], m_{mag} represents the combined mass of the magnets, r_{sl} the inner radius of the sleeve, ω the angular speed of the machine and l_{rot} the length of the rotor. The density, yield stress and safety factor of the sleeve are denoted by $\rho_{sl}, \sigma_{y,sl}$ and K_{sl} respectively. Furthermore, $S_{ph,Co}$ and S_w are the usable cross section area in the slots of one phase and area of one wire, respectively, while B_r represents the remanent magnet flux density, h_{gap} the air gap thickness and h_{mag} the thickness of the magnets.

Besides the sizing, the analytical model can be used for steady-state performance estimation of the machine for different operating points as well. Therefore, Eq. (2) contains the static efficiency relations that are relevant for the performance analysis. In addition to the geometric dependencies, the efficiency also depends on the current i and the angular rotational speed ω [5]. Consequently,

the efficiency expression in Eq. (2) can be rewritten for static models with arbitrary but fixed geometric parameters $\eta, N_t, \lambda, \hat{B}_{gap}$ and a given mechanical power $P_{\text{mech}}(\omega)$ as

$$\eta(i,\omega) = \frac{P_{\text{mech}}(\omega)}{P_{\text{mech}}(\omega) + P_{\text{loss}}(i,\omega)} \quad , \tag{6}$$

where $P_{\text{mech}}(\omega) = M_L \cdot \omega$ with the load torque M_L.

The power losses $P_{\text{loss}}(i,\omega)$ are in particular composed of current dependent copper losses $P_j(i)$, speed dependent mechanical losses $P_{\rho w}(\omega)$ and iron losses P_{vu} which are constant with respect to both i and ω. Following Bahrs *et al.* [5], these contributions can be expressed as

$$P_{\text{loss}}(i,\omega) = P_j(i) + P_{vu} + P_{\rho w}(\omega)\,, \quad \text{with} \tag{7}$$

$$P_j(i) = R_S\, i^{\top} i \quad \text{and} \tag{8}$$

$$P_{\rho w}(\omega) = \frac{\pi}{32}\, k_{\text{rou}}\, C_{M1}(\omega)\, \rho_{\text{air}}\, \omega^3\, d_{\text{rot}}^4\, l_{\text{rot}} + \frac{1}{64}\, C_{M2}(\omega)\, \rho_{\text{air}}\, \omega^3 \left(d_{\text{rot}}^5 - d_{\text{sha}}^5\right) \,. \tag{9}$$

In addition to this static model, a dynamic model is created to analyse the transient efficiency and operation of the machine as a function of time t using machine parameters obtained by the initial sizing. Therefore, the time-dependent form of the efficiency relation in Eq. (6) is examined. The temporal influence is mainly determined by the variables current $i(t)$, angular speed $\omega(t)$ and rotor angle $\theta(t)$, which arise as solution of the differential equation system of the PMSM. In the present study, the electric frequency is assumed to be constant, wherefore the iron losses P_{vu} are treated as constant values as well. For models that also allow variations in the excitation frequency, extensions of the iron-loss model and of the stator-resistance term R_S must be taken into account. By employing the three-phase back electro-magnetic force (EMF) voltages $e(t)$ equations as

$$e(t) = -\psi_f\, N_{pp}\, \omega(t) \begin{pmatrix} \sin\left(N_{pp}\, \theta(t)\right) \\ \sin\left(N_{pp}\, \theta(t)\right) - \frac{2}{3}\pi \\ \sin\left(N_{pp}\, \theta(t)\right) - \frac{4}{3}\pi \end{pmatrix} \tag{10}$$

a dynamic expression for the mechanical power in terms of the flux-linkage constant ψ_f and the number of pole pairs N_{pp} is obtained:

$$P_{\text{mech}}\big(i(t), \omega(t), \theta(t)\big) = e^{\top}(t)\, i(t) \quad . \tag{11}$$

The dynamic efficiency equation for given initial values $[i_0, \omega_0, \theta_0]$ can be written as

$$\eta\big(i(t), \omega(t), \theta(t)\big) = \frac{P_{\text{mech}}\big(i(t), \omega(t), \theta(t)\big)}{P_{\text{mech}}\big(i(t), \omega(t), \theta(t)\big) + P_{\text{loss}}\big(i(t), \omega(t)\big)} \quad , \quad \text{with} \tag{12}$$

$$\frac{di(t)}{dt} = \frac{1}{L_S}\big(v(t) - R_S\, i(t) - e(t)\big) \quad , \tag{13}$$

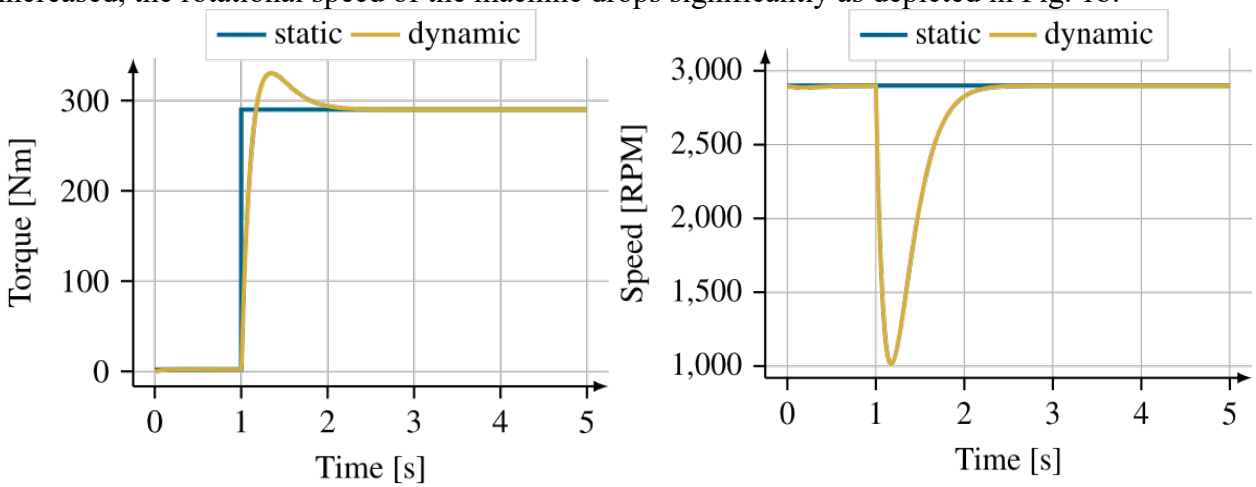
$$\frac{d\omega(t)}{dt} = \frac{1}{J}\left(\frac{e^{\top}(t)\, i(t)}{\omega(t)} - M_L(t)\right) \quad , \tag{14}$$

$$\frac{d\theta(t)}{dt} = \omega(t) \quad . \tag{15}$$

Materials Research Proceedings 69 (2026) 577-582 https://doi.org/10.21741/9781644904251-103

whereby $i(t), v(t), e(t) \in \mathbb{R}^3$ and $\omega(t), \theta(t), M_L(t) \in \mathbb{R}\ \forall t \in \mathbb{R}$. The set of equations (13) - (15) constitutes a phase-resolved dynamic model of the PMSM [7], [8].

A fundamental distinction of the dynamic model to its static counterpart is that the mechanical power of the machine is no longer prescribed as the desired input, but rather arises as the solution of the governing differential equation (cf. Eq. (11)). In addition, the differential equation model must be augmented with a speed- and current-control law, which is realised by basic proportional-integral (PI) controllers in the present study.



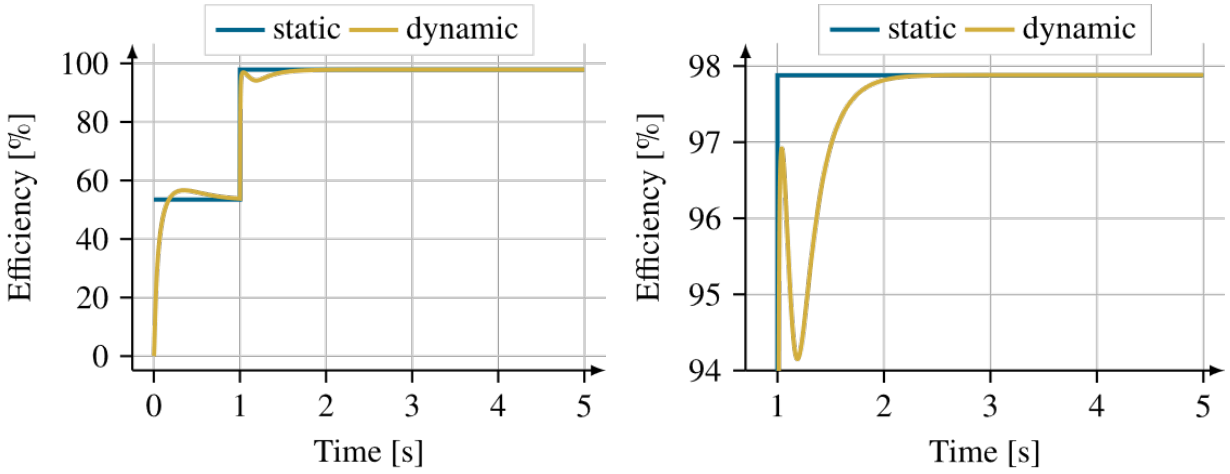
Results

To validate the dynamic model against the static one, different operating points as parts of a realistic load profile for an aviation application are simulated. To enable the analysis of the dynamic behaviour a discrete step increase of the load torque M_L is considered as test case. Based on the take-off phase from the mission profile compiled in [6], a torque increase from 2 to 290 Nm at 2900 RPM is simulated. Followed by the machine sizing for the given set of torque and speed requirement, both models are applied to calculate the efficiency of the machine throughout the simulation. Therein, the machine parameters listed in Table 1 are used to characterise the dynamic model, whereas R_S and J are directly calculated based on the sized machine while L_S and ψ_f are selected as academic values appropriate for the machine size and operation.

Table 1: Machine parameters used for dynamic model

Parameter	Symbol	Value	Unit
Phase resistance	R_S	0.03539	Ω
Phase inductance	L_S	0.001	H
Flux-linkage	ψ_f	0.4	Wb
Rotor inertia	J	0.094	kg m^2

Fig. 1 shows the resulting torque and speed profile of the selected test case for both static and dynamic model. While the step in the mechanical torque at $t = 1$ s is directly transferred into the static model, a clear difference to the dynamic behaviour can be seen. As the mechanical torque is increased, the rotational speed of the machine drops significantly as depicted in Fig. 1b.



(a) Electromagnetic torque profile (b) Rotational speed profile

Fig. 1: Comparison of results for torque (a) and speed (b) for static and dynamic machine model

Materials Research Proceedings 69 (2026) 577-582 https://doi.org/10.21741/9781644904251-103

Using the PI controllers within the dynamic model, both speed and torque are effectively regulated to achieve their respective target values by increasing the phase currents in the machine. Accordingly, the results of both the electromagnetic torque and the rotational speed match between both models after approximately 2.5 s.

A similar behaviour can be observed for the efficiency calculated with both models, as depicted in Fig. 2.

(a) Complete efficiency profile (b) Efficiency after torque step

Fig. 2: Comparison of efficiency results for static and dynamic machine model

The divergence between the calculated efficiency of both models has to be examined in two different areas, namely before and after the torque step increase at $t = 1$ s (cf. Fig. 2a). Up until the torque increase the initial start of the electric machine is visible in the efficiency of the dynamic model. While the initial speed is set to the target speed of 2900 RPM, the torque and, subsequently, the power start at zero. During the first second of the simulation the initial torque of 2 Nm has to be build up which leads to the deviations in the calculated efficiency. As the machine reaches its steady-state operation shortly before the torque increase, the efficiencies predicted by the two models are matching at $t = 1$ s.

As shown in detail in Fig. 2b, the performance estimation of both models deviate again following the torque increase at $t = 1$ s. Referring to Fig. 1, the speed and torque of the machine must be controlled in the dynamic model to reach the desired targets. Accordingly, the transient power and performance of the machine differ from the nominal steady-state operation, resulting in a reduced efficiency in the transient phase. Initially, the mechanical power P_{mech} is increasing faster than the power losses P_{loss}, which results in a temporary efficiency peak directly after $t = 1$ s before the efficiency drops intermittently. After the local minimum has been reached around $t = 1.2$ s, the dynamic efficiency starts to increase again. Eventually, the predictions of the efficiency start to converge after $t = 2$ s and match for the remainder of the simulation beyond $t = 2.5$ s.

Summary and Outlook

This paper presents an integrated methodology for sizing electric machines and predicting their performance. By coupling the dynamic model with the previously developed static model, it captures both steady-state and transient behavior. Using a benchmark case from the literature, the models are cross-validated against each other showing excellent agreement in steady-state operation and clearly revealing differences during transients as expected. Future studies will improve the interdependence between dynamic model and the preliminary design of the machine.

Namely, important machine parameters such as the phase inductance L_S and flux-linkage constant ψ_f can be linked to the sizing, while the rotor inertia J should also factor in the inertia moment of all connected parts – for instance, the propeller. Furthermore, additional use cases such as the TEEM concept [4] or the over-torque behaviour of a machine will be analysed.

Keywords: Aero Engines, Heat Exchangers, Transient Modelling, Hydrogen Conditioning, Response Time, Wall Thermal Inertia, Residence Time

Abstract. Compact heat exchangers must be integrated into advanced aero-engine concepts; therefore, thorough analysis is needed in the preliminary phase. This work advances an early aero-engine heat-exchanger design tool by extending methods beyond stationary analyses to fully transient operation. Flight conditions change within seconds during maneuvers, so pressures, temperatures, and mass flows on both sides of a heat exchanger vary simultaneously. Steady analyses cannot capture response times, while many transient models treat only single-inlet disturbances or simple layouts. High-fidelity simulations are also too slow for broad design sweeps of the preliminary phase. The proposed tool retains the three-dimensional, cell-based framework and solves an unsteady wall energy balance with finite differences to represent thermal inertia. Between cells, fluid enthalpy information is propagated using the concept of residence time, allowing for arbitrary, coupled inlet ramps. Validation against a Modelica benchmark model shows close agreement for fluid temperatures. Runtime remains in minutes on modest hardware, enabling rapid exploration of the parameter space. A multipass counter-crossflow hydrogen conditioner is further evaluated for a Go-Around maneuver, revealing a lag between boundary changes and temperature propagation, as well as a nonlinear dependence of transient duration on ramp time.

Introduction

Implementing concepts like hydrogen combustion and hybrid-electric requires novel aeroengine architectures and advanced heat exchangers. At DLR's Institute of Propulsion Technology, the PreHEAT tool is being developed for preliminary heat-exchanger design [1]. It employs a cell-based framework that enables rapid parameter changes and, by assembling simple flow cells, analysis of complex geometries. Prior to this work, capabilities were limited to steady-state P-NTU calculations at the cell level. While the industry typically optimizes for steady operation, unsteady behavior can be critical, necessitating estimates of how boundary condition changes affect performance and how much time remains to avert system-level impacts. In 1992, Spiga et al. analyzed the step response in a crossflow heat exchanger, considering the finite heat capacity of the wall [2]. In 2003, Yin et al. presented an analytical solution for a heat exchanger scenario where one fluid maintains a constant temperature, while the other fluid experiences temperature changes along the heat exchanger [3]. In 2021, Yang et al. introduced a transient analytical model for heat exchangers with counterflow geometries, using Laplace transformations to determine the temperature response for each fluid and wall [4]. When examining the analytical models presented in the literature, it is observed that most analytical works have focused on simple flow configurations. These works with simple geometries could be used as the building blocks in the PreHEAT code's cell-level hierarchy. However, in many cases of transient behavior analysis of aircraft heat exchangers, there are simultaneous and combined boundary condition changes on both fluid side inlets. These combined shifts are expected to occur during the transition between different flight phases. Hence, it is not feasible to implement each analytical solution found in the literature as a separate switch case in the cell-level hierarchy. Instead, the developed methodology

Materials Research Proceedings 69 (2026) 583-588 https://doi.org/10.21741/9781644904251-104

takes into account the wall thermal inertia at the cell level, with an energy balance along the wall. Additionally, the thermal disturbance introduced at the boundaries is then propagated according to the fluid's residence time and the simulation time steps. Due to the preliminary design focus, the PreHEAT code has been reutilized and expanded to integrate these physical principles effectively while prioritizing simulation speed.

Methodology

As a starting point, the steady-state PreHEAT solver was looped over varying inlet conditions to compare its behavior with the desired dynamic response. It was observed that boundary changes propagated instantaneously through the exchanger, indicating the need for a mechanism that de-celerates information propagation. It was also observed that wall thermal inertia was neglected in the P-NTU calculations, necessitating an unsteady wall energy balance to capture the physical lag. These two aspects could be addressed within two hierarchical levels of the code structure, namely the heat-exchanger and cell levels. The cell-level hierarchy calculates the heat transfer in simple geometries using the P-NTU method for each cell. The second level of the hierarchy is at the heat-exchanger level, considering the configuration of each cell in a flow geometry [1]. PreHEAT produces a result data object, which contains both the geometry and simulation results. In the transient modeling, each result data object represents a single time step of the dynamic simulation. The result data list enables transient boundary conditions to be defined at each time step, ensuring the delayed propagation of inlet changes through the heat exchanger. It is also essential for obtaining fluid state information from previous time steps at both hierarchy levels.

Heat Exchanger Level Hierarchy. In a discretised geometry, each cell has two residence times, one for each side, defined as the average time a fluid particle spends. Inlet disturbances should influence downstream cells only after a time proportional to their residence times. The methodology considers changes in inlet mass flow rate, temperature, and pressure. Two modeling assumptions are introduced. First, mass-flow-rate change affects all cells immediately along the flow direction, assuming incompressible flow. While this assumption is not strictly valid when the cold side is gaseous, it remains acceptable for preliminary design. Once the incompressible- flow assumption is adopted, a second assumption is that pressure drop and pressure information also propagate instantaneously within each cell. Once mass-flow-rate and pressure propagation is handled, thermal information propagation is considered. Direct temperature propagation is avoided because temperature remains constant during phase change. Instead, enthalpy flows, $\dot{H} = \dot{m}h$, are used. Since the specific enthalpy, h, continues to evolve through phase change, it serves as a robust carrier of thermal information. State transfer between connected cells is organized through a result list that stores, for every time step, the fluid states of cells and the intermediate connector states.

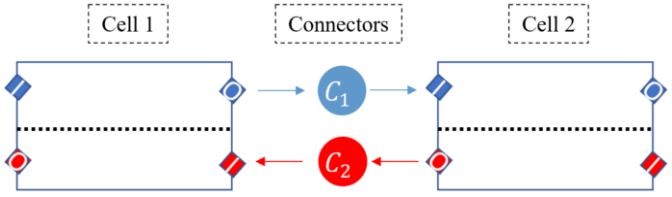

Figure 1: Example configuration for counter-flow with cells and connectors.

An example counter-flow configuration can be seen in Fig. 1. Focusing on the cold (blue) side, Cell 1 is upstream, and connector C_1 Cell 1's outlet to Cell 2's inlet. The key concept is that the connector (ghost) state may differ from the upstream outlet. At each time step, the upstream cell is solved first; then the connector state is updated; finally, the downstream inlet takes the connector state. With incompressible flow assumption, the upstream outlet pressure and mass-flow-rate is

Materials Research Proceedings 69 (2026) 583-588 https://doi.org/10.21741/9781644904251-104

assigned directly to connector and downstream inlet. Weighted update of specific enthalpy enforces delayed propagation of information:

$$h_{con}^{n} = {(h_{con}^{n-1}\dot{m}_{con}^{n-1}/\Delta t + h_{up}^{n}\dot{m}_{up}^{n}/t_{res,up}^{n})}\Big/{(\dot{m}_{con}^{n-1}/\Delta t + \dot{m}_{up}^{n}/t_{res,up}^{n})}. \quad (1)$$

Here, superscripts denote time steps; “con” and “up” refer to connector and upstream-outlet states; Δt is the simulation time step; $t_{res,up}$ is the upstream cell’s residence time. The ${}^{1}/_{\Delta t}$ weight scales information from the previous time level, while ${}^{1}/_{t_{res}}$ scales information arriving from the previous spatial location. Those scaling terms are constructed from internal energy balance equation of a fluid control volume, in which diffusive term is neglected:

$$\frac{\partial T}{\partial t} + u\frac{\partial T}{\partial x} = q'_{ex,i} \quad (2)$$

The balance equation indicates a relation between unsteady term, advection term, and external heat transfer rate. The influence of the unsteady term scales with ${}^{1}/_{\Delta t}$. On the other hand, the advection term’s effect scales with the residence time expressed as ${}^{u}/_{\Delta x} = {}^{1}/_{t_{res}}$. These scaling factors are used in Eq. 1. Consequently, higher upstream mass flow accelerates the connector-enthalpy change, whereas lower mass flow slows it. The smoothing inherent in Eq. 1 yields physically consistent transition curves and reduces time-step-related numerical instabilities, while enabling coupled inlet ramps to propagate across complex cell networks with controlled delay.

Cell Level Hierarchy. Transient cell-level modeling can involve conduction along the heat exchanger wall with Neumann boundary conditions, which are heat fluxes from both fluid sides. Let us assume a one-dimensional wall with thickness $2\Delta x$ discretised as three nodes at the hot side, mid-plane and cold side. One can write internal energy balance equation for each node with unsteady term and diffusion term; followingly, rewrite them in the finite difference form. Finite difference form of energy balance equation for mid-plane node is written as such:

$$\frac{T_{wall,mid}^{n+1} - T_{wall,mid}^{n}}{\Delta t} = \kappa\frac{T_{wall,out}^{n+1} - 2{\cdot}T_{wall,mid}^{n+1} + T_{wall,in}^{n+1}}{\Delta x^2}. \quad (3)$$

In this equation, $T_{wall,mid}^{n+1}$ and $T_{wall,mid}^{n}$ represent the temperatures at the midpoint of the wall at times $n + 1$ and n, respectively. κ is thermal diffusivity which includes thermal conductivity, k, specific heat capacity, c_p, and density of wall, ρ; hence, one considers wall thermal inertia. The left-hand side uses a first-order, forward finite difference scheme. The term Δt is the time step, and Δx is the spatial step size along the wall. Considering heat fluxes through the boundaries of wall control volume, linear equation system can be build in the form of $Ax = b$:

$$\begin{bmatrix} 1+\frac{2\kappa\Delta t}{\Delta x^2} & -\frac{2\kappa\Delta t}{\Delta x^2} & 0 \\ -\frac{\kappa\Delta t}{\Delta x^2} & 1+\frac{2\kappa\Delta t}{\Delta x^2} & -\frac{\kappa\Delta t}{\Delta x^2} \\ 0 & -\frac{2\kappa\Delta t}{\Delta x^2} & 1+\frac{2\kappa\Delta t}{\Delta x^2} \end{bmatrix} \begin{bmatrix} T_{wall,in}^{n+1} \\ T_{wall,mid}^{n+1} \\ T_{wall,out}^{n+1} \end{bmatrix} = \begin{bmatrix} T_{wall,in}^{n} + \frac{2\kappa\Delta t}{\Delta x\cdot k} q''_{hot} \\ T_{wall,mid}^{n} \\ T_{wall,out}^{n} + \frac{2\kappa\Delta t}{\Delta x\cdot k} q''_{cold} \end{bmatrix} \quad (4)$$

Time steps for the temperature values are intentionally selected as they appear in Eq. 4 to construct an implicit finite difference scheme. Right-hand side is known, and one solves this equation system by using Gaussian elimination for the wall temperature values of next time step.

Materials Research Proceedings 69 (2026) 583-588 https://doi.org/10.21741/9781644904251-104

Validation & Results

In the literature, various papers have utilized numerical models created in the Modelica environment to validate their analytical models [3, 4]. This work applies the same approach. A benchmark numerical model or concentric double pipe counterflow arrangements is created within the Modelica environment. An example configuration is shown in Fig. 2, and the geometrical and material details are provided in Table 1. In the methodology, two different hierarchy levels are explained. First, changes to the heat exchanger level hierarchy are implemented in the code, along with the residence time calculations for the cells. A good level of agreement is observed between the Modelica and PreHEAT results, with the implementations only on the heat exchanger level hierarchy. Cell- level calculations are conducted using the P-NTU method in those prior observations. Then, implementations on the cell-level hierarchy are applied to the code to include the wall thermal inertia. As expected, a much better agreement is observed in the results, but this comes with the cost of higher computation times. Both in Modelica and PreHEAT, ramps are applied linearly in 5 seconds starting at $t = 150s$.

Figure 2: Configuration for counter-flow with cells.

Table 1: Benchmark model geometry and material data.

	Tube Diameter [m]	Tube Length [m]	Heat Transfer Area [m^2]	Flow Area [m^2]
Inner Pipe	0.020	2.00	1.25E-01	3.14E-04
Outer Pipe	0.034	2.00	1.38E-01	5.20E-04
	Thermal Conductivity [W/(m · K)]	**Thickness** [m]	**Specific Heat Capacity** [J/(kg · K)]	**Density** [kg/m^3]
Wall Properties	9800.0	0.001	434.0	8440.0

In Figure 3, temperature results for multi ramp case are plotted at two spatial points along the two-meter-long pipe: $x = 0.5m$ and $x = 1.5m$. For each spatial point, three different results are provided: one from Modelica, another from the PreHEAT using the P-NTU method at the cell level, and a third that incorporates Wall Thermal Inertia (WTI) into the cell-level hierarchy. Inner side inlet temperature decreased from $50°C$ to $20°C$, while outer pipe inlet temperature is decreased from $90°C$ to $70°C$. Inner side mass-flow-rate is decreased from $60^L/_h$ to $30^L/_h$, while outer pipe mass-flow-rate is increased from $60^L/_h$ to $120^L/_h$. Pressure values of both side are constant at $1atm$. Also, heat transfer coefficients are held constant at 100 $^W/_{m^2 \cdot K}$. For the inner flow, temperatures start to increase slightly at the beginning since the volumetric flow rate of the inner pipe decreases, and its effect is immediate along the pipe. However, the decrease in the inner flow's inlet temperature starts to impact temperature values along the pipe according to the residence time of the inner flow. Again, both versions of PreHEAT start to react quicker than the benchmark model when the temperature values decrease. However, the WTI version captures almost exact dynamic response characteristics with the Modelica before the transient phase ends.

Materials Research Proceedings 69 (2026) 583-588 https://doi.org/10.21741/9781644904251-104

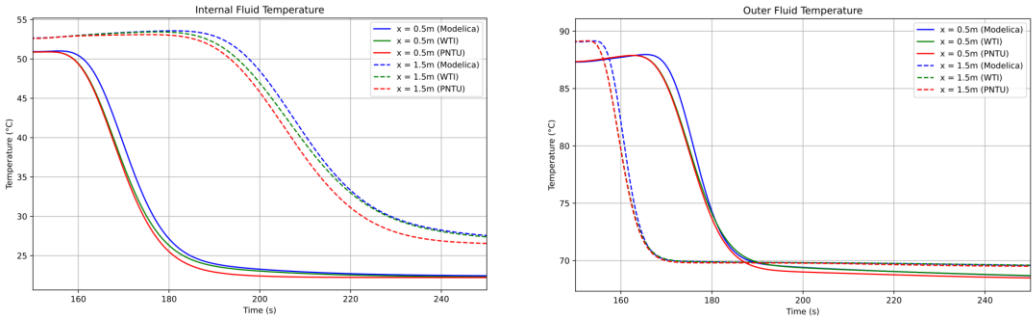

Figure 3: Temperature values of Modelica and PreHEAT models for multi-ramp.

At the outer flow temperature results, both PreHEAT models perform well. Again, the WTI version catches almost the same characteristics as the Modelica before the transient phase ends. Once the validation with benchmark assessed, as a demonstration case, the dynamic response of a hydrogen conditioning heat exchanger is presented. Görtz et al. proposed a turbofan engine layout for hydrogen combustion, and its integration with heat exchangers is illustrated in Fig. 4 [5]. Detailed geometry and material properties can be found in that article. A part of the compressed air is utilized to heat the liquid hydrogen before it is pumped into the combustion chamber. In the simulated Go-Around maneuver, the operating point (OP) Maximum-Take-Off

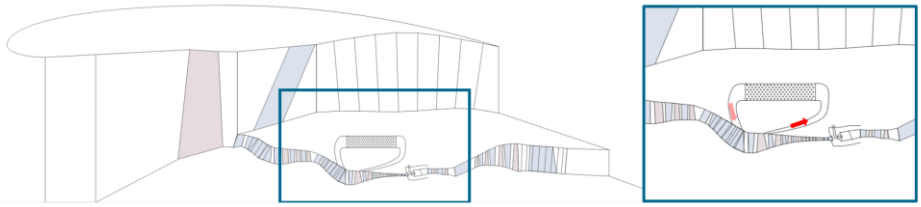

Figure 4: Heat Exchanger Integration Concept for Hydrogen Conditioning [5].

(MTO) is reached in 5 seconds, starting from the Approach OP. Accordingly, inlet boundary conditions for the air and hydrogen sides are provided in the Table 2. Ramp starts at 0.5 seconds, follows a linear characteristic, and ends at 5.5 seconds. In Fig. 5, two snapshots of the transient simulation are shown. The one on the left shows the temperatures along the tube at t = 1 second, and the other plot at t = 3 seconds. In both snapshots, initial and final temperature characteristics are plotted with the OP names. In many transient modeling studies, one should verify that the simulation terminates at the intended final OPs, meaning that the propagated temperature profile along the heat exchanger converges to the last steady-state profile. The developed PreHEAT transient model fulfills this requirement. In Fig. 5, one can also observe the temperature profile of the heat exchanger wall. In this demonstration case, wall thermal inertia is taken into account. Hence, the increases in hot-side temperature do not immediately affect the hydrogen temperature, and a non-linear dynamic response is observed. Together with the increase in temperature of the hot-side inlet, the mass-flow rates also increase, creating less time for heat transfer. As a result, a decrease in cold side temperatures are observed.

Table 2: Go-Around Manoeuvre: Inlet Conditions for Hydrogen and Air.

		Hydrogen		Air	
Inlet Property	**[unit]**	**Approach**	**MTO**	**Approach**	**MTO**
Mass Flow Rate	[kg/s]	6.3E-03	4.6E-02	1.7E-01	5.8E-01
Temperature	[K]	20.0	20.0	337.7	459.0
Pressure	[Pa]	5000000.0	5000000.0	175564.4	444828.6

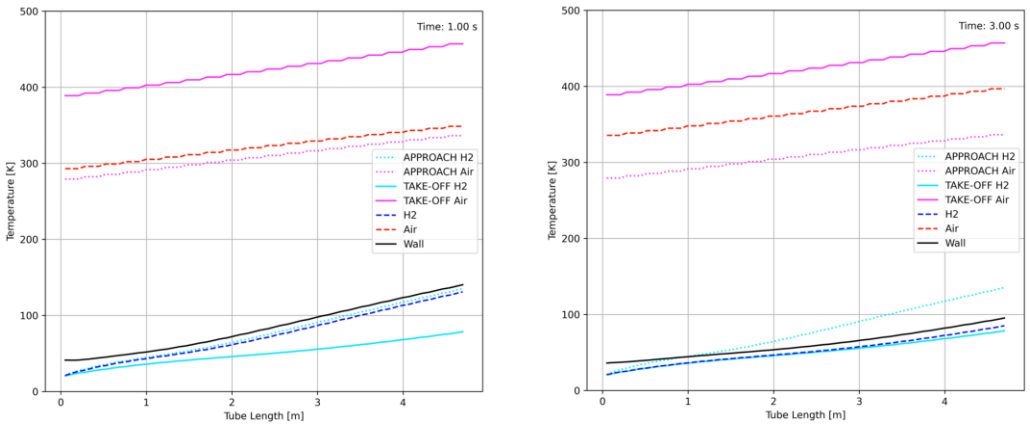

Figure 5: Temperatures along the heat exchanger at $t = 1s$ and $t = 3s$.

Conclusion

The proposed transient model attains the accuracy and computational efficiency required for preliminary design across complex geometries and operating conditions. A residence-time/step-size methodology, derived from simplified energy balances, is embedded within PreHEAT's heat-exchanger level hierarchy. Advective and unsteady internal-energy terms are treated via a weighted formulation. At the cell level, wall thermal inertia is incorporated using finite differences. This hybrid analytical–numerical framework extends PreHEAT for fast transient modelling. Validation against a concentric flow configuration benchmark with simultaneous inlet temperature and mass-flow perturbations indicates excellent agreement in temperature propagation along the pipe. Inlet-temperature changes propagate with a delay due to the residence times of the fluids and wall thermal inertia. Go-Around case study of hydrogen conditioning heat exchanger reveals that hydrogen temperatures approach almost steady profiles before the boundary ramps are completed, indicating the need for transient analysis in aero-engine context.

Keywords: More Electric Aircraft, Electrical Energy Storage System, Battery, Flywheel, Supercapacitor, Aircraft Subsystems, Suitability Analysis, Sustainable Aviation

Abstract. The emerging electrification of aircraft aims to extensively reduce emissions. One near term mitigation strategy can be the implementation of electrical energy storage systems (EESSs) such as batteries, flywheels and supercapacitors to power subsystems of more electric aircraft. However, these EESSs are subjected to various advantages and drawbacks. Therefore, this study provides a detailed assessment of the suitability of integrating these systems into aircraft applications. For this purpose, aircraft design criteria relevant for the analysis are derived and their relative importance is determined through pairwise comparison. To ensure comparability among the subsystems, they are categorized based on their operating time. The subsequent rating of the EESSs suggests, that supercapacitors may be best suited to short- and medium-duration operations, while batteries seem to be more beneficial for long-duration applications. However, flywheels appear to be unsuitable for either. For further assessing the feasibility of integrating EESSs in aircraft, the weight penalty associated to each system can be investigated.

Introduction

Over recent decades, global warming has become a major challenge. The aviation industry contributes around 2.5% of global CO_2 emissions, a number expected to rise [1]. To address this, new propulsion concepts such as all-electric (AEA), hybrid-electric, turbo-electric, and more-electric aircraft (MEA) have been introduced. In the AEA concept, all energy for thrust and subsystems is supplied by electrical energy storage systems (EESSs) [2]. These can be battery- (BSs), flywheel- (FSs), and supercapacitor-systems (SCSs).

An exploration of the future aircraft concepts reveals that, in advanced electrified configurations beyond the MEA, BSs are typically considered [3]. They usually outperform other storage technologies in terms of mass specific energy (SE), and their lower mass specific power (SP) is offset by the total capacity of the installed BSs. However, current state of the art (SoA) EESSs still require improvements in SE to meet even short-range aircraft mission demands [4].

Thus, in the near term, electrifying subsystems of MEA may offer promising potential for reducing emissions. These are typically powered by generators [5], but integrating EESSs could lower fuel burn and enable new use cases Especially, the high SP of supercapacitors and flywheel systems may be particularly beneficial for short, power-intensive operations such as actuation. Several studies have examined EESSs for propulsion support or powering aircraft electrical subsystems (AESs) [6–8]. Nonetheless, factors such as safety, SE, and SP must be considered, and a detailed assessment of EESSs suitability for MEA applications is still lacking in the literature.

Consequently, this study covers such an evaluation and rating of EESSs according to their suitability for aircraft applications. First, it presents the SoA performance characteristics of the EESSs. Then, it discusses aircraft secondary power consumers. Finally, the EESSs options are rated according to their suitability for operating these AESs. Therefore, relevant criteria for aircraft applications are derived, and their relative importance is determined through pairwise comparison.

State of the art

Batteries, flywheels, and supercapacitors each offer distinct advantages in terms of their performance parameters, while the most significant are the SP and SE. Due to their electrochemical nature, BSs can store comparatively larger amounts of energy per unit weight than other technologies [9–11]. Conversely, SCSs excel at delivering very high power outputs because of their ability to discharge stored electrons almost instantaneously, making them well suited for meeting peak power demands [12, 13]. On the contrary, BSs demonstrate comparatively moderate SP, while SCSs typically exhibit low SE [12, 14]. FSs, on the other hand, are usually recognized for offering a balanced compromise, with SP and SE values that lie between those of BSs and SCSs [9].

In addition to their high energy density, BSs are susceptible to external factors such as temperature changes, which can result in degradation and, in extreme cases, thermal runaway. To protect the system, energy and temperature management systems are required [15]. Furthermore, extracting the materials required for production can be hazardous and recycling remains difficult. Nevertheless, they remain widely available, cost-effective, and relatively easy to integrate into aircraft through modular designs [10]. FSs, on the other hand, must meet stringent safety standards due to their high-speed rotating components, and their installation can be complex, particularly because the system's moment of inertia requires careful compensation [8]. Additionally, high self-discharge losses and power control elements must be considered [14]. Nonetheless, FSs offer strong resilience against external environmental influences, require minimal maintenance, and contain no hazardous materials, offering favorable recyclability [9, 14]. SCSs, despite being disadvantaged by low energy density and moderate self-discharge, share many of the benefits of BSs, such as availability and ease of integration due to modular configuration. Although elevated temperatures may degrade the electrolyte, SCSs are not prone to thermal runaway. However, to prevent the system from overcharging and thus bursting, an energy management system is required [12]. Beyond that, many of the system's components are non-hazardous and recyclable [16]. Table 1 summarizes the SP and SE of the EESSs, also considering cycle life, daily losses, cycle efficiency, and response time. Reported values for the systems may differ across references as a result of technological evolution and variations in research focus. Nevertheless, the order of magnitude is similar, and the data is provided for guidance [9–14, 17, 18].

For comparison purposes, the available specific energy of jet fuel can be assumed to be approximately 6.5 kWh/kg [8]. Furthermore, the integration of an EESSs may lead to a fuel penalty if the fuel savings do not offset the additional system mass [19]. Therefore, incorporating an EESSs into aircraft requires a comprehensive assessment of the resulting increase in fuel consumption.

Table 1 *State of the art performance characteristics of energy storage systems*

EESS	SP [kW/kg]	SE [Wh/kg]	Cycle Life	Loss [%/d]	Eff. [%]	Rp. time [s]
BS	0.3–0.5 [10]	250–400 [10]	10^3 [14]	< 0.1 [13]	~ 95 [13]	< 1 [13]
FS	1–2 [11]	20–80 [11]	10^6 [14]	50–100 [13]	80–95 [9]	~ 0.01 [13]
SCS	1–10 [12]	1–10 [12]	10^6 [14]	0.4–5 [17]	95–98[18]	< 0.01 [13]

In conventional aircraft, secondary (non-propulsive) systems, or subsystems, are often operated using either pneumatic or hydraulic energy, both extracted from the aircraft engine. Current trends aim to replace these systems with electrical ones to enhance efficiency, reduce weight, and/or increase mission range [20]. The corresponding power requirements range from a few kilowatts up to several hundred kilowatts. As a result, the total electrical load of the aircraft increases. Multiple studies estimated the required power for the AESs, aiding in determining the electrical energy demand of MEA [21–24]. As some of the advantages and disadvantages of the EESSs strongly correlate with the operating time, it is essential to define groups of AESs operating under similar conditions. Therefore, three groups are established: short-duration operations lasting up to

Materials Research Proceedings 69 (2026) 589-594 https://doi.org/10.21741/9781644904251-105

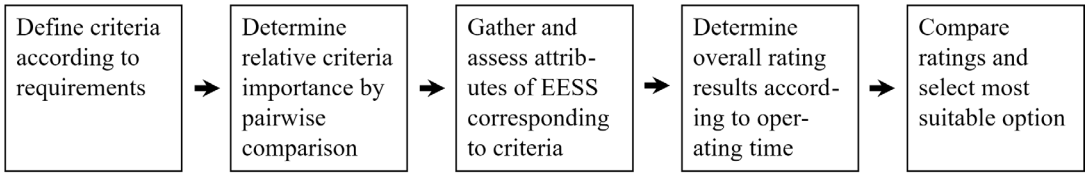

Fig. 1 *Evaluation process for rating the EESS suitability, adopted from[25]*

one minute, medium-duration operations ranging from one minute to 15 minutes, and long-duration operations covering all operations beyond that.

In the realm of short-duration operations, representative power consumers are the landing gear actuation, door actuation, thrust reverse actuation and the engine starter. To eliminate the hydraulic system and thereby improve efficiency and safety, electromechanical actuators are being developed as replacements for hydraulic components, with the first commercial implementations already in use [23, 24]. In comparison, the engine starter in MEA is powered by an electric motor instead of using pressurized air [24]. For medium-duration applications, the ice protection system and electric taxiing may be considered. Among the relevant long-duration electrical loads are the environmental control system, flight control system, and miscellaneous systems such as the galley.

Methodology

The first step of building a basis for the suitability analysis is the aforementioned categorization of the AESs with respect to their operating times. Subsequently, the relative suitability rating of each EESSs in terms of the derived evaluation criteria and with regard to the time categories is determined. A general evaluation process to identify suitable EESSs is shown in Fig. 1.

At this preliminary stage of the assessment conducted here, it is necessary to employ an evaluation method that will facilitate an initial estimation of suitability. Therefore, the EESSs are benchmarked using evaluation criteria. These criteria are derived according to aircraft design requirements and their relative importance is determined using weighted point rating [26]. The criteria are defined as follows and are adapted from Franke et al. [25]:

1. *Short Term Performance (ST):* Fast power handling ability
2. *Long Term Performance (LT):* High time independent energy supply
3. *Ease of Integration (I):* Necessary integration efforts
4. *Safety (S):* Safe and reliable operation of aircraft, vulnerability of the system to failure, failure probability and severity
5. *Cost (C):* Cost of development, manufacturing and maintenance
6. *Sustainability (U):* Reducing the emission impact of aircraft and resource conservation

Table 2 lists the results from the criteria weighting using a color coding to illustrate the different operating time categories. Here, performance and safety emerge as the most important criteria.

Table 2 *Criteria weighting according to the time categories using pairwise comparison*

Criteria	ST			LT			I			S			C			U			Weighting		
ST	-	-	-	2	1	0	2	2	0	1	1	0	2	2	0	2	2	1	0.30	0.27	0.03
LT	0	1	2	-	-	-	0	2	2	0	1	1	0	2	2	1	2	2	0.03	0.27	0.30
I	0	0	2	2	0	0	-			0			1			2			0.17	0.10	0.17
S	1	1	2	2	1	1	2			-			2			2			0.30	0.27	0.30
C	0	0	2	2	0	0	1			0			-			1			0.13	0.06	0.13
U	0	0	1	1	0	0	0			0			1			-			0.07	0.03	0.07

Color coding: green = short-duration ($t \leq 1$min); blue = medium-duration (1min $< t \leq 15$ min); red = long-duration (15 min $< t$); Values: row criterion is more important than column criterion = 2, equally important = 1, less important = 0

Results and discussion

Table 3 *Relative Rating of EESSs with respect to aircraft design criteria and time domain*

Criteria	Battery	Flywheel	Supercapacitor
Shor Term Performance (ST)	moderate SP, moderate reaction time	high SP, fast rection time	very high SP, very fast reaction time
	o	+	+ +
Long Term Performance (LT)	high SE, excellent long-term storage, low self-discharge	moderate SE, high self-discharge	very low SE, self-discharge
	+ +	–	–
Ease of Integration (I)	modular configuration, thermal and energy management required	compensation of rotor inertia required, bulky design, safety and control equipment required	modular configuration, implementation of energy management required
	o	–	o
Safety (S)	risk of fire due to thermal runaway, sensitive to external influences, emergency energy storage	severe safety hazard due to material rupture, high resilience against external influences, quick short term power supply	no thermal runaway, quick short term power supply
	o	o	+
Cost (C)	available, high TRL, mass production, exchange every few months, exchange of whole module	high manufacturing cost, low maintenance cost, easy part exchange, rare system replacement	vastly available, high TRL, mass production, exchange after years, exchange of whole module
	+	+	+
Sustainability (U)	relatively short lifetime, resource extraction harmful, recycling difficult	almost infinite lifetime with maintenance, no hazardous materials, good recyclability	long lifetime, almost no hazardous materials
	–	+	+
Rating	0.53	0.65	0.67	0.58	0.51	0.44	0.77	0.67	0.57

Symbols: – – = 0, – = 1, o = 2, + = 3, + + = 4; SE: specific energy, SP: specific power

The assessment of the EESSs according to each criterion and the corresponding relative ratings are outlined in Table 3. The relative rating is obtained following the process defined in [25, 26]. It can be observed, that the SCSs show a good overall rating for most of the criteria, while BSs and FSs exhibit rather moderate results. In the case of BSs, the major positive contributing factors are the excellent long-term energy storage capability and their availability. This is opposed by a moderate SP, a low cycle life, low recyclability and safety concerns due to the risk of thermal runaway and degradation. SCSs on the other hand exhibit an excellent SP, cycle life and a rather low risk of failure, while the technology is vastly available as well. However, they are subjected to a very low SE making them unsuitable for high energy applications.

Despite the fact that FSs are usually recognized for combining both a good SP and SP, in the context of the suitability analysis, this type of EESSs demonstrates limited performance. The results indicate that SCSs and BSs are the most suitable systems for empowering MEA. For comparison, Lukic et al. investigated the integration of both for covering the energy demand of aircraft taxiing [6]. The study demonstrated the promising opportunities arising from the combination of BSs and SCSs. This hybrid approach appears particularly well suited for medium-duration operation, as both systems exhibited comparable rating for this time domain. A similar benefit was also reported by Gladin et al. [7]. In contrast, Frederick et al. pointed out that the anticipated increase in the SE of FSs may surpass that of BSs at some point [8]. However, due to rotor material scaling limitations, these developments seem to be of theoretical nature for now. Hence, focusing on SCSs and BSs for aircraft applications seems to be the most reasonable choice.

Conclusion

This study analyses the suitability of batteries, flywheels and supercapacitors for supplying energy to AESs in electrified aircraft. The AESs are categorized by operating time to enable comparison. Based on aircraft design requirements, evaluation criteria are derived and weighted using pairwise comparison. The suitability of different electrical energy storage systems (EESSs) across operating time categories is then assessed against these criteria. The results show that supercapacitors are well suited for short- and medium-duration operations, while batteries appear most suitable for long-duration applications. In contrast, the use of flywheels in aircraft is limited by moderate specific energy, safety concerns, and installation constraints.

Overall, the specific energy of all examined EESSs remains significantly lower than that of jet fuel. Additionally, a potential fuel penalty due to the added weight of EESSs must be considered. This penalty occurs when the mass of the energy carrier exceeds the fuel saved through energy substitution. Therefore, future work should include preliminary sizing of EESSs based on current performance data and an estimation of the resulting fuel penalty.

Abstract. This paper presents a study on the functionality of a microjet engine prototype, developed by COMOTI - Romanian Research and Development Institute for Gas Turbines focusing on vibration, FFT analysis and speed extraction across all four operating regimes. Despite the compact size, the microjet engines are emerging as a solution for propulsion units for drones, small electrical generator unit or other particular application for civil and military domain. However, even at this scale, prototype designs can exhibit significant vibration levels that compromise structural integrity, mission reliability and the functionality in terms of performance. During these experiments, three single axis accelerometers from PCB were mounted on the metal structure supporting the engine and one triple axis accelerometer was mounted on the engine, near the compressor in a relatively cool region of the flow path. The experimental campaign aimed to evaluate the influence of intake geometry on the vibrational behavior of the engine. Two configurations were tested: one equipped with a Venturi-type air intake and one with a direct open inlet, lacking any aerodynamic shaping at the compressor entry. The test stand was realized using compactDAQ hardware from National Instruments with LabVIEW software for main and auxiliary parameters and PCB accelerometers with Dewesoft software for vibration levels and speed extraction.Results showed that the venturi intake can influence the vibrational levels for the engine during start-up, idle, working and shutdown regimes compared with the second configuration, without the venturi intake.

Introduction

Microjet engines have gained increased attention in recent years due to their compact size, relatively low maintenance cost, lower NO_x emissions, high specific power and the compatibility for both civil and military applications, represent a promising solution for propulsion systems in UAVs [1], small to medium portable power generation units combined with cogeneration systems for heat and electrical generation [2] or other application where the report from weight to size reduction is a critical requirement [3]. Compared to the large gas turbines using jet as a source of force, microjet engines face unique challenges arising from the small scale, which include high sensitivity to intake conditions (ambient pressure, temperature or humidity), lower thermal inertia and most importantly, increased susceptibility to vibration related issues [4].

One factor that can strongly influence microjet functionality is the extremely high range of shaft speed, which can exceed 100.000 [RPM]. At such rotational speeds, even small mechanical or aerodynamic asymmetries can generate significant vibrational dynamics [5]. The consequences of vibration phenomena are particularly critical, as they can compromise structural integrity, reduce overall performance, accelerate mechanical fatigue of internal components, and shorten bearing

Materials Research Proceedings 69 (2026) 595-600 https://doi.org/10.21741/9781644904251-106

life. Furthermore, excessive vibration can induce instabilities in the compressor or turbine stages, originating from rotor-stator misalignments, aerodynamic flow disturbances, or resonance phenomena [6].

The development of microjet engines therefore requires dedicated test benches that combine advanced instrumentation, robust data acquisition systems, and appropriate mechanical support structures for the engine under investigation [7]. In this context, vibration analysis represents a crucial step in the development and validation process. Beyond simple monitoring, advanced signal processing techniques such as FFT analysis enable the identification of characteristic frequency components linked to rotor dynamic and structural behavior. Moreover, vibration signals can also be exploited for indirect speed extraction, providing redundancy to traditional measurement system and enabling insights into transient engine regimes.

The present study focuses on the vibrational behavior of a microjet engine prototype, developed by INCDT COMOTI, with particular emphasis on the influence of intake geometry. By employing multiple PCB accelerometers both triaxial and single axis, in different location on the engine and its support structure, the analysis aims to provide a deeper understanding of how the intake can affect vibration levels across all operating regimes, using Dewesoft DAQ and software.

Experimental setup and test methodology

The experimental campaign was conducted on a microjet engine prototype developed by e National Research and Development Institute for Gas Turbines (COMOTI). The engine is a single-shaft configuration, consisting of a radial-flow compressor, annular combustion chamber, single-stage axial turbine and an exhaust nozzle. All components are directly mounted on the same shaft, resulting in a compact and mechanically simple architecture that is representative of current microjet engine designs [8].

Two intake models were investigated in order to assess their influence on the vibrational behavior of the microjet engine, besides the parameters measured from the main DAQ. The first configuration employed a Venturi intake, specifically engineered to provide aerodynamic shaping of the incoming airflow. The venturi geometry was expected to improve the acceleration and conditioning the air, before it reaches the compressor to improve the stability and efficiency for both compressor and burning chamber. This component also introduces additional structural mass close to the engine, which could affect local vibration levels during testing. The second configuration consisted of a direct open inlet, in which the compressor entry was left exposed without any flow-shaping component. This arrangement represented the simplest possible intake solution, eliminating the aerodynamic and structural influence of the venturi intake. The absence of flow conditioning can increase the sensitivity to ambient conditions and introduce higher levels of turbulence at the compressor intake, that can affect the vibration levels during testing.

The data acquisition was designed to provide high-resolution and synchronized measurements of all relevant parameters during the microjet testing phase. For the main parameters, the inputs and outputs for the auxiliary systems (pressurized air, fuel and gas) and microjet engine, a cDAQ system was developed from National Instruments, equipped with 8 modules. The software that handles the inputs, outputs and automated algorithm was developed in LabVIEW and can operate on all regimes, including start-up, idle, working and shutdown regime, including protection for the engine. For vibration, a Sirius Dewesoft data acquisition system was installed, equipped with PCB mono axial and triaxial acceleration sensors.

Materials Research Proceedings 69 (2026) 595-600 https://doi.org/10.21741/9781644904251-106

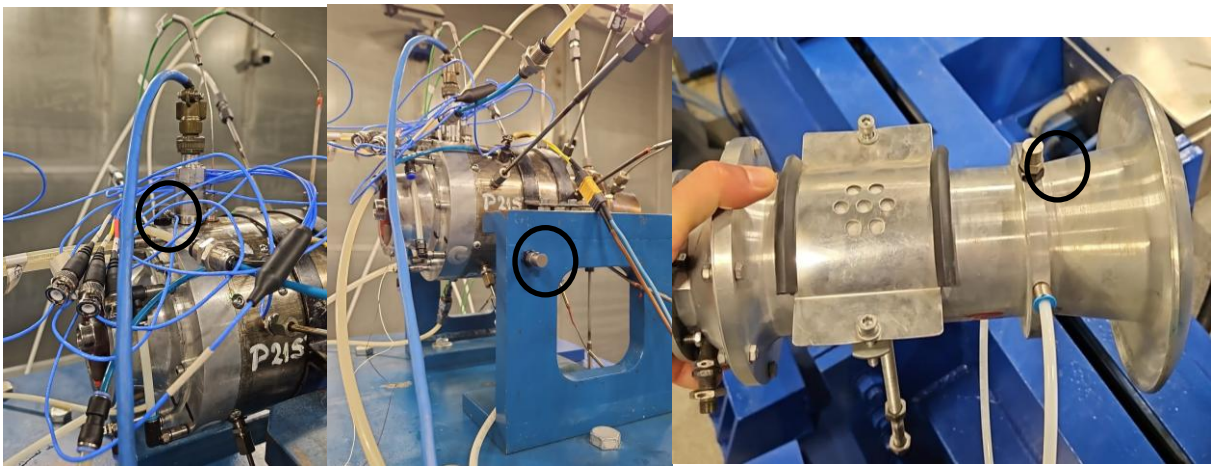

Figure 1. Engine triaxial vibration sensor (The left picture), Engine support monoaxial vibration sensor (Middle picture) and Venturi intake monoaxial vibration sensor (Right picture).

The test bench was equipped with a dedicated control setup, capable of adjusting fuel flow with a P control and monitoring the engine's operating regime. Instrumentation included sensors, for thrust, shaft speed, temperatures, pressures, fuel flows, vibration, placed at strategic points along the engine.

Results

To evaluate the influence of intake geometry on engine dynamics, vibration velocity measurement was recorded for both cases, with and without the intake installed. The speed regimes are based on the speed extracted from vibration using exact-frequency function from Dewesoft. Based on the common regimes, the data was extracted and presented in Table 1 for both configurations and Y axis, on engine and intake.

Table 1. Engine data for both configurations based on Y axis.

Speed [RPM]	Equipped with venturi intake		Without venturi intake	
	Engine Y [mm/s]	Venturi intake [mm/s]	Engine Y [mm/s]	Venturi Intake Y [mm/s]
27300	3.10	1.10	2.91	-
34500	3.13	2.91	2.82	-
39700	4.76	2.82	3.71	-
45130	7.24	5.61	3.11	-
50000	21.77	7.28	25.57	-
52000	26.76	8.30	-	-

Fig. 2 and Fig. 3 presents the vibration and speed evolution of the microjet engine prototype under two intake configurations. In the first case in Fig. 2, with the venturi intake installed, the plots show a more structured vibration response across the different operating regimes, with distinct peaks emerging during acceleration phases and a correlation with shaft speed increases (upper plot). The additional measurement channel (middle plot) also highlights fluctuations captured at the intake, indicating that the venturi introduces measurable vibrational dynamics in the engine.

Materials Research Proceedings 69 (2026) 595-600 https://doi.org/10.21741/9781644904251-106

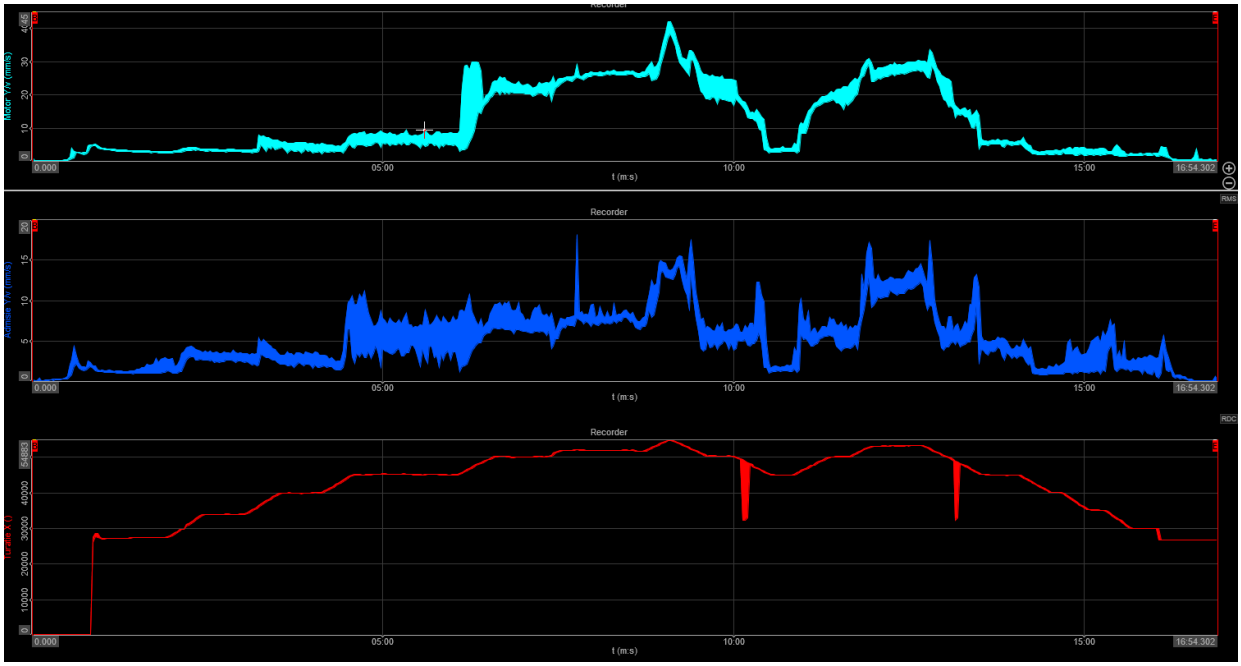

Figure 2. Velocity level for Engine Y, for Intake Y and Speed during test with venturi intake

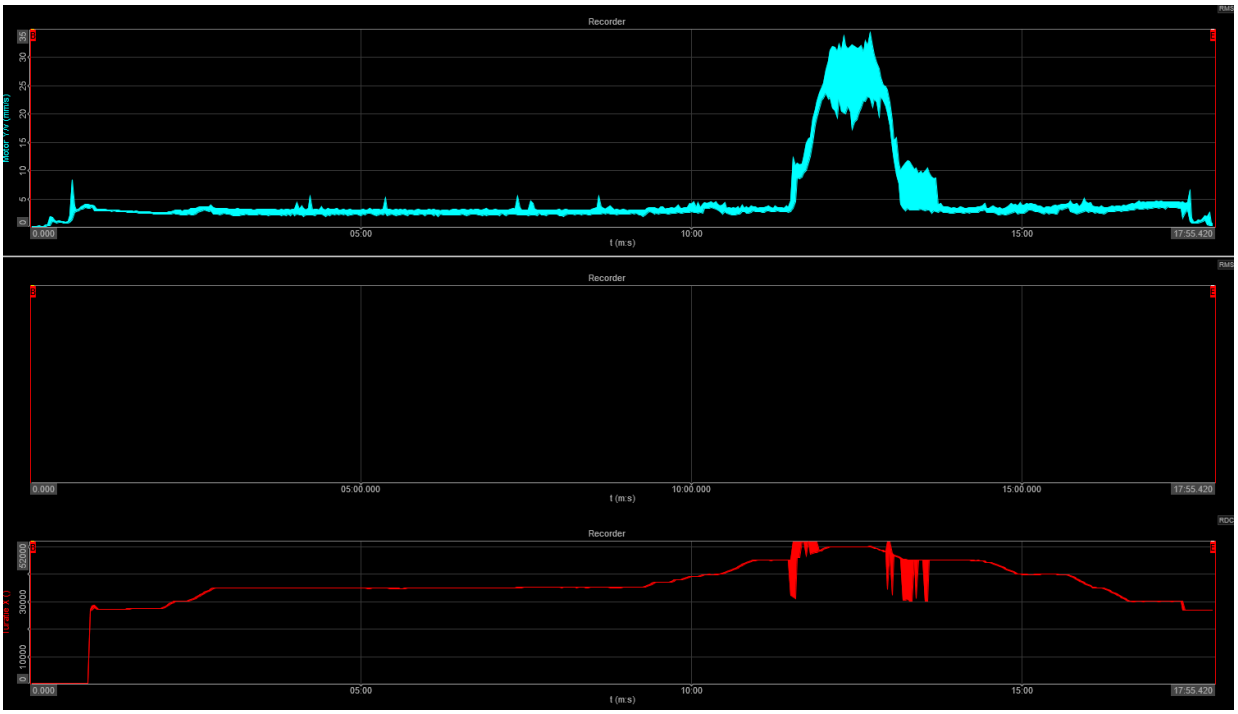

Figure 3. Velocity level for Engine Y and Speed during test without venturi intake

In second case, Fig. 3, without the venturi intake, the vibration response appears simpler, without an increase in the shaft speed and a critical section during high speeds of the engine.

In addition to the velocity measurements, an order tracking analysis was carried out for both the engine and intake. The order maps show that the fundamental order and two harmonics are present in the set frequency interval of 0 – 2000 [Hz]. Setting the shaft speed on minimum and maximum measured, corelated with the main data acquisition system, Fig. 4 and Fig 5. presents the order tracking analysis for both cases. It is shown that the first configuration implies more

structural lines that are pronounced in the intake section and that will influence the vibration levels on the engine.

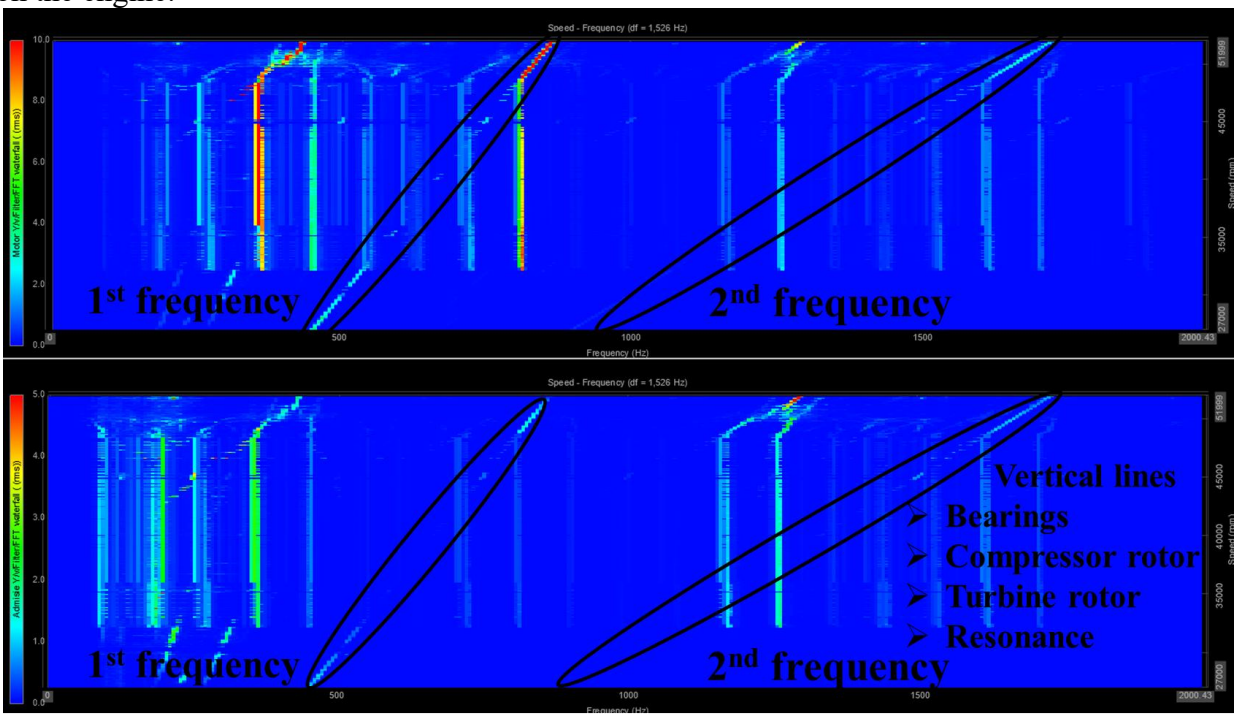

Figure 4. Order tracking for Engine Y and Venturi Y during test with venturi intake

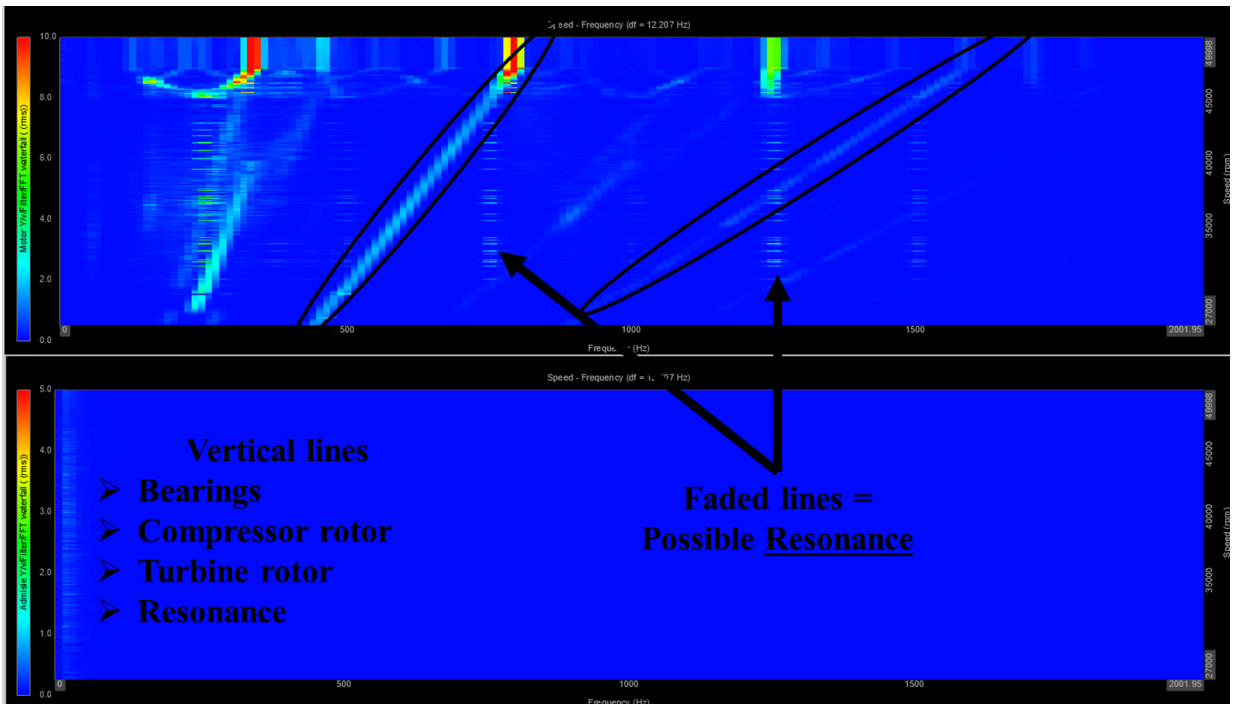

Figure 5. Order tracking for Engine Y and Venturi Y during test without venturi intake

On the other hand, without the intake, most of the structural lines disappear at lower regimes, following the fundamental order at higher regimes.

Conclusion and discussion

The comparative analysis of the two operating configurations highlights a notable influence of the intake geometry on the microjet engine's vibration response. When the venturi intake is used, the

vibration velocity on the engine casing increases progressively in shaft speed, showing a consistent upward trend that becomes irregular at high speeds. In contrast, the second intake configuration results in lower vibration amplitudes at lower operating regimes, with a distinct critical point observed at maximum speed, associated with an unstable dynamic. Order tracking indicates that the venturi intake can introduce specific structural vibrational frequencies, potentially affecting the engine's performance under these conditions comparing to the second configuration, where a part of the frequency lines are not visible.

Summary

This paper describes the experimental setup and procedures used to evaluate a vibrational behavior of a microjet engine prototype developed by COMOTI - Romanian Research and Development Institute for Gas Turbines. A few operating regimes were investigated, combining accelerometer measurements and order tracking to capture vibration velocity and harmonic content. The results indicate that intake geometry has a clear influence on the dynamic response of the engine, with differences becoming more pronounced at higher operating regimes.

Keywords: Hybrid Rocket Propulsion, Green Propellants, Paraffin/HTPB Fuel Blends, Mission Design

Abstract. The growing relevance of small satellites in space exploration, which in 2023 accounted for 97% of all spacecraft launched worldwide, requires addressing the challenges of propulsion miniaturization. To meet these needs, the GREEN FOXFIRE (Green Fuel and OXidizer For Innovative hybrid Rocket Engines) project investigates compact, efficient, and environmentally responsible hybrid systems, aiming to develop a sustainable hybrid rocket engine (HRE) capable of inserting a 24U CubeSat into Martian orbit from an Earth-orbit transfer. In this work, the performance of paraffin/HTPB fuel blends using gaseous oxygen as oxidizer was evaluated through a combination of numerical simulations and experimental ballistic tests. Paraffin offers high regression rates but limited mechanical strength, whereas HTPB improves structural integrity with lower combustion efficiency. Blended formulations (70/30, 50/50, 35/65, and 25/75 paraffin/HTPB ratios) were analyzed using NASA's Chemical Equilibrium with Applications (CEA) code and validated experimentally. Results confirmed that paraffin enhances regression rate and combustion efficiency, while HTPB contributes to mechanical robustness. Preliminary design activities also included a four-cluster thruster configuration with dual oxidizer tanks optimized for CubeSat mission requirements. Overall, the study demonstrates the feasibility of green hybrid propulsion as an enabling technology for interplanetary small-satellite missions, combining environmental sustainability with system scalability and performance.

Introduction

The rise of small satellites has reshaped space missions: from under 2% of total launch mass in 2013 to 97% of spacecraft by 2023 [1,2]. This miniaturization demands compact and efficient propulsion systems. Rocket engines are typically classified as solid, liquid, or hybrid. Solid motors are simple and reliable but lack controllability. Liquid engines offer precise thrust control but involve complex systems and hazardous propellants. Hybrid rocket engines (HRE) combine a solid fuel with a liquid or gaseous oxidizer, offering a compromise between safety, simplicity, and controllability.

Unlike traditional spacecrafts' mono- and bi-propellant systems that often rely on toxic substances like hydrazine [3], HRE can use greener propellants such as paraffin and nitrous oxide, reducing environmental and health risks [4].

Within this context, the GREEN FOXFIRE project proposes a hybrid propulsion system designed to insert a 24U CubeSat into Martian orbit. The mission profile was preliminarily

Materials Research Proceedings 69 (2026) 601-606 https://doi.org/10.21741/9781644904251-107

analyzed to define performance requirements, leading to the development of a four-thruster configuration optimized for the spacecraft's mass, geometry, and delta-V needs [5].

To meet these demands with a sustainable approach, GREEN FOXFIRE investigates paraffin (P) and hydroxyl-terminated polybutadiene (HTPB) as solid fuels, paired with nitrous oxide (N_2O) and gaseous oxygen (O_2) as oxidizers. Paraffin offers high regression rates but lacks mechanical strength, while HTPB provides structural integrity with lower combustion efficiency [6,7]. Blending these fuels in various ratios (e.g., 70/30, 50/50, 35/65, 25/75) enables tailored performance characteristics suited to mission constraints. This integrated strategy supports the broader goal of enabling efficient, green propulsion for small-scale interplanetary exploration.

This work focuses on O_2 as oxidizer and integrates numerical simulations using NASA's Chemical Equilibrium with Applications (CEA) software and experimental ballistic testing to evaluate combustion behavior, regression rates, and performance metrics.

Fuel Preparation and Test Methodology

This study employs paraffin ($C_{28}H_{58}$) and HTPB ($C_{10}H_{15.4}O_{0.007}$) as solid fuels. HTPB is synthesized using poly bd® R45 V resin, with dioctyl adipate (DOA), toluene diisocyanate (TDI), and glycerol as additives to enhance flexibility and curing properties. Fuel blends were prepared with varying paraffin content, from 100% paraffin (100P) to 0% paraffin (0P), to assess the influence of composition on both material and combustion properties. All fuel formulations were tested using gaseous oxygen as oxidizer to evaluate the effects of fuel blending on combustion performance. Nitrous oxide will be introduced in future phases of the study.

Thermochemical analyses were performed using NASA's CEA software to predict the combustion behavior of the paraffin–HTPB blends. The simulations provided key performance parameters, including adiabatic flame temperature (T_{flame}), characteristic velocity (C*), and specific impulse (Isp). Simulations were conducted across a range of chamber pressures (50, 40, 30, 20, 10, and 5 bar) and oxidizer-to-fuel (O/F) ratios (0.5 to 7).

To experimentally evaluate the combustion performance of the paraffin–HTPB fuel blends, ballistic tests were conducted in the ASP Laboratory-scale hybrid rocket motor (Fig. 1). The setup included a thrust stand-mounted motor, an oxidizer feed line with a stainless-steel axial flow injector, a pyrotechnic igniter and a NI lab view based data acquisition system. The combustion chamber measures 240 mm in length and 80 mm in diameter and is equipped with a convergent-divergent nozzle featuring a 12 mm throat and semi-angles of 45° (convergent) and 13° (divergent).

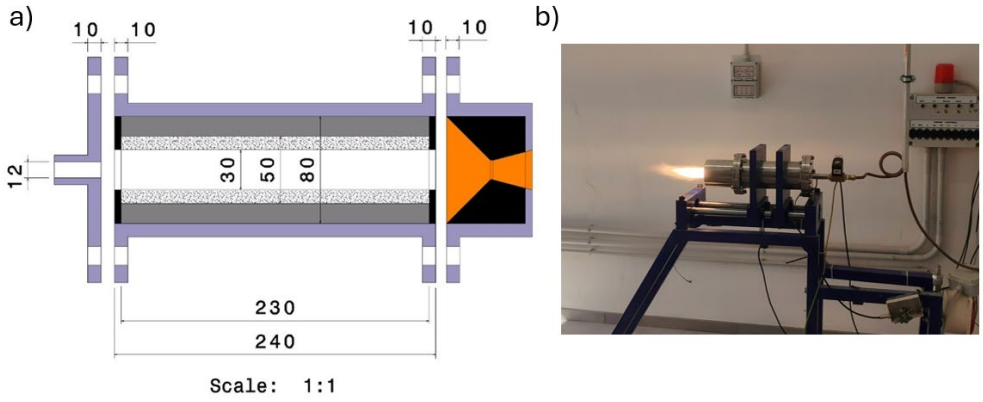

Fig. 1. HRE at the School of Aerospace Engineering: (a) motor schematic; (b) operational phase.

Each firing test lasted 5 or 10 seconds, with oxidizer flow regulated by a pressure controller and solenoid valve. After each test, the fuel grain was extracted and weighed to determine mass loss.

Materials Research Proceedings 69 (2026) 601-606 https://doi.org/10.21741/9781644904251-107

The regression rate ($\dot{\mathbf{r}}$) was calculated using the weight loss method, based on the difference between initial and final fuel mass ($\mathbf{m_b}$), burn duration ($\mathbf{t_b}$), and port geometry using port area diameter before ignition ($\mathbf{d_{ig}}$) and after burning ($\mathbf{d_b}$), using the following equations [8]:

$$\dot{r} = \frac{d_b - d_{ig}}{2t_b} \tag{1}$$

$$d_b = \sqrt{d_{ig}^2 + \frac{m_b}{\frac{\pi}{4}\rho_f l_f}} \tag{2}$$

$$G_{ox} = \frac{\dot{m}_{ox}}{\frac{\pi}{4}\left(\frac{d_b + d_{ig}}{2}\right)^2} \tag{3}$$

ρ_f and l_f refer to the fuel density and grain length, respectively, while $\dot{m}_{ox}$ and G_{ox} denote the oxidizer mass flow and oxidizer mass flux rate.

Theoretical Results

The CEA analyses were performed using five fuel combinations (100P, 70P, 35P, 25P, 100HTPB) and six pressures (from 5 to 50 bar), across O/F ratios ranging from 0.5 to 7. Fig. 2 presents the adiabatic flame temperature for the investigated pressures as a function of O/F ratio. All fuels show low adiabatic flame temperatures at low O/F (<2) due to insufficient oxidizer and incomplete combustion.

Maximum temperatures (of order of 2900 K) are observed between O/F 2–4. This range is coherent with stoichiometric ratios found in literature that are 3.4 for O_2/P combustion [9] and 2.95 for O_2/HTPB combustion [10], respectively, where combustion is nearly complete. Beyond this range, excess oxidizer lowers flame temperature. As shown by the temperature trend (T25P > T35P > T70P > T100P), fuels with higher hydrogen content exhibit lower flame temperatures at low and mid O/F ratios, indicating a greater oxidizer demand for complete combustion.

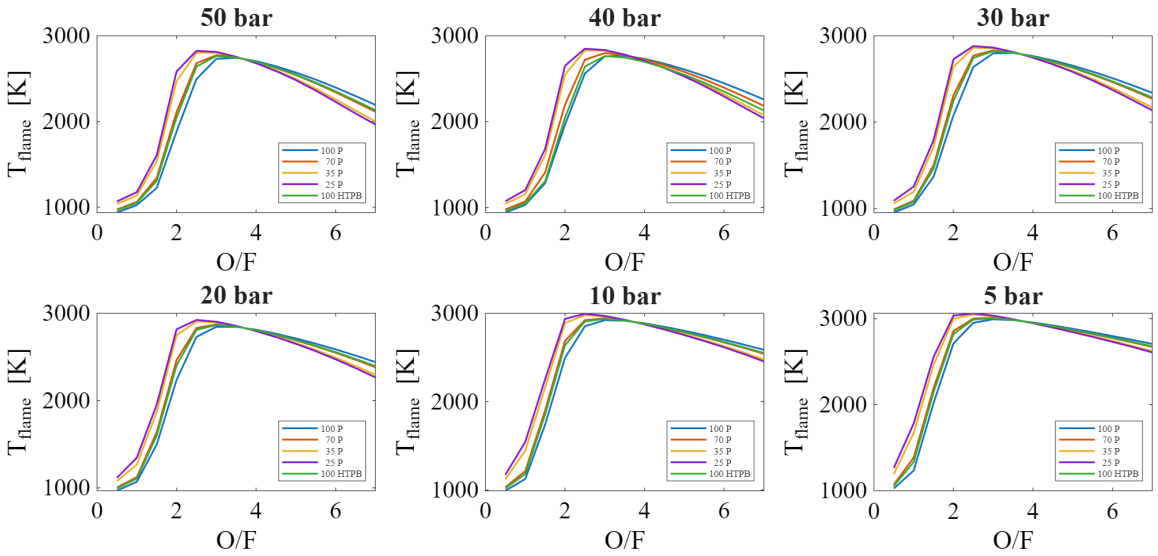

Fig. 2. CEA adiabatic flame temperature, for investigated fuels, as a function of O/F for various pressures.

Between 100P and 100HTPB, the latter exhibits higher flame temperatures at low to mid O/F due to its lower hydrogen content and better reactivity with limited oxidizer. At high O/F, the temperature trend reverses: T100P > T100HTPB > T70P > T35P > T25P.

Materials Research Proceedings 69 (2026) 601-606 https://doi.org/10.21741/9781644904251-107

Regarding characteristic velocity (C*, plots in Fig. 3), low O/F ratios yield lower values due to incomplete combustion. The optimal range for C* (1700 m/s for 25P to 1900 m/s for 100P) is O/F 2–2.5. Across all O/F values, 100P shows higher C* than 100HTPB (1800 m/s).

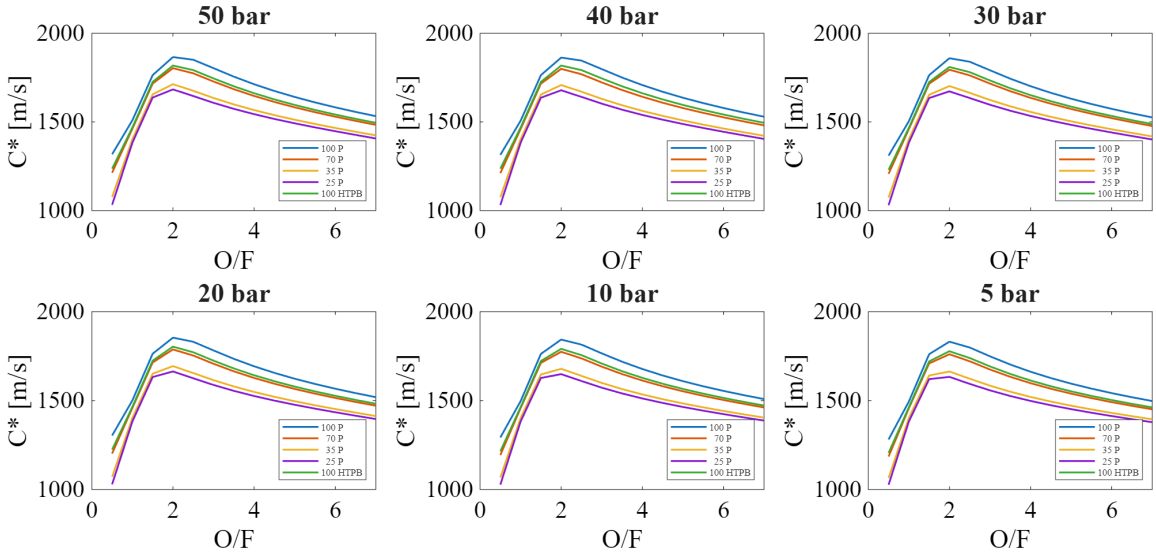

Fig. 3. CEA characteristic velocity, for investigated fuels, as a function of O/F for various pressures.

Specific impulse follows the C* trend, being lower at low O/F ratios due to incomplete combustion, peaking near stoichiometric conditions (O/F 2–3), and decreasing with excess oxidizer. Fig. 4 reports the peak specific impulse values for various propellants as a function of chamber pressure. The plot highlights how Isp decreases with lower pressure, as reduced pressure promotes product separation, thereby diminishing both thrust and specific thrust.

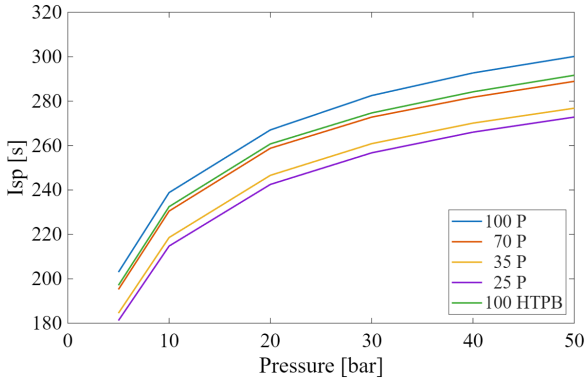

Fig. 4. CEA specific impulse, for investigated fuels, as a function pressure at stoichiometric O/F.

Experimental Results

The ballistic tests (Table 1) were conducted at the ASP Laboratory (Fig. 1). Pure paraffin fuel exhibited the highest regression rate (0.9 mm/s) at the lowest oxidizer mass flux (25.25 kg/m²·s), with a final port diameter of 47.8 mm. In contrast, blended fuels showed reduced regression rates, clustering around 0.3–0.4 mm/s despite varying HTPB content. The 25P and 0P formulations reached 0.4 mm/s, while 35P, 50P, and 70P blends maintained 0.3 mm/s across different mass fluxes. These results indicate a general decline in regression rate with increasing oxidizer mass flux and highlight the trade-off introduced by HTPB: although it lowers regression rates, it enhances structural integrity.

Materials Research Proceedings 69 (2026) 601-606 https://doi.org/10.21741/9781644904251-107

Table 1. Data from ballistic testing.

Fuel	Gox [kg/(m^2·s)]	O_2 mass [g]	Grain initial mass [g]	Grain final mass [g]	ṙ [mm/s]	Final port diameter [mm]	O/F
100 P	25.25	300	820	600	0.9	47.8	1.4
70 P	35.40	140	780	745	0.3	33.5	4.0
50 P	25.36	100	800	766	0.3	33.4	2.9
35 P	30.52	120	812	779	0.3	33.3	3.6
25 P	30.24	120	829	793	0.4	33.6	3.3
0 P	27.56	110	743	708	0.4	33.8	3.1

The motor firing sequence included ramp-up, steady-state, and cut-off phases, as illustrated in Fig. 5. After ignition, a rapid pressure spike was followed by combustion stabilization around 0.5 s. During steady-state operation, 100P fuel delivered the highest performance, reaching ~3.5 bar chamber pressure and 3500–4000 g thrust. Blends like 25P and 35P sustained ~3.0 bar and ~2500–3000 g thrust, while 50P and 70P showed intermediate and stable behavior, respectively.

The 0P formulation matched or exceeded the 50P blend, achieving ~3.5 bar and ~5000 g thrust. All fuels exhibited a sharp drop in pressure and thrust during the cut-off phase, marking complete flameout.

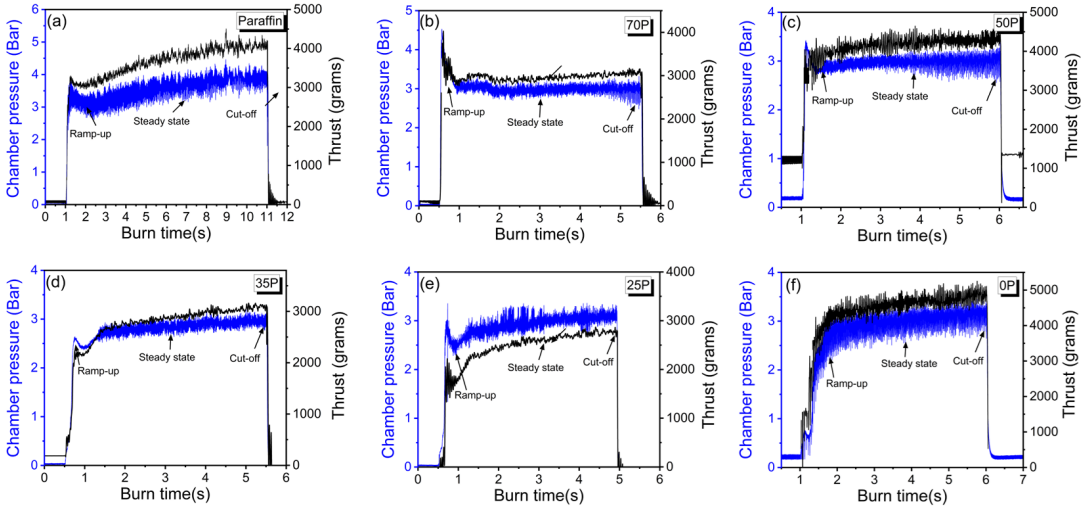

Fig. 5. Combustion chamber pressure and thrust profile for 100P (a), 70P (b), 50P (c), 35P (d), 25P (e), and 0P (f) combustion with gaseous oxygen.

Conclusion

The GREEN FOXFIRE project aims to demonstrate the feasibility of sustainable hybrid propulsion for small satellite missions, specifically targeting Mars orbit insertion for a 24U CubeSat. Through a combination of numerical simulations and ballistic testing, paraffin–HTPB fuel blends paired with gaseous oxygen were shown to offer a viable balance between combustion efficiency and structural integrity. Pure paraffin achieved the highest regression rates (0.9 mm/s), while HTPB contributed to mechanical robustness. During steady-state operation, thrust levels were ~3500–4000 g for 100P, ~3000 g for 70P and 50P, ~2500–3000 g for 35P and for 25P, and ~5000 g for 0P. Performance metrics such as adiabatic flame temperature, characteristic velocity, and specific impulse confirmed optimal combustion near stoichiometric O/F ratios, with pressure-dependent enhancements. The successful integration of a multi-thruster configuration and oxidizer injection system will support the potential of this green hybrid architecture for future interplanetary missions.

Off-Design Performance Consequences of Design Payload and Range Requirements for SPPH Hybrid-Electric Aircraft

Keywords: Aircraft Design, Hybrid-Electric Aircraft, Off-Design Performance

Abstract. This article illustrates the variations in off-design performance for a serial-parallel partial hybrid regional aircraft when varying design range or payload. It leverages recent work exploring off-design performance of hybrid electric aircraft and shows the impact of TLAR selection on the operational bandwidth of such aircraft. The latter is important to exploit installed battery capacity, especially when considering a tighter coupling between conceptual aircraft design and strategic airline planning. Comparisons are made to baseline kerosene aircraft, designed for identical TLAR flying identical missions. Results highlight the importance of TLAR selection to achieve both operational flexibility and fuel savings, especially concerning the selection of design range, payload and battery supplied power ratio.

Introduction and motivation

Aircraft electrification is considered as one of the pathways to address the environmental targets. Among targeted solutions distinctions can be made between so-called mild and heavy hybrids (typically including a battery and combustion engine), as well as fully electric designs.

Design solutions typically evaluate performance for a single design mission. However, especially for hybrid-electric aircraft, off-design performance becomes interesting from the perspective of leveraging installed battery capacity for shorter missions or missions with less payload. Such off-design performance is important if we consider the typical average usage of aircraft, see for example the study by [1] or [2]. Recent studies investigating off-design performance of hybrid-electric aircraft ([3], [4], [5], [6]) show potential benefits/penalties on aircraft performance across the payload-range diagram for hybrid-electric aircraft.

Studies coupling aircraft design with strategic airline planning indicate that a tighter coupling can achieve emission benefits at little consequence for profitability. ([7], [8]). These studies, however, also indicate that aircraft design points in terms of, for example, payload and range should be coupled with strategic airline planning where including off-design performance is essential to find more sustainable designs.

However, we may wonder how the off-design performance is impacted by the chosen design point, and whether it is possible to achieve a larger bandwidth leveraging installed battery capacity. This study addresses these points for the most promising hybrid-electric architecture found in a comparative study for off-design performance of various hybrid-electric powertrain architectures [6]; the serial/parallel partial hybrid (SPPH) (as defined by [9]).

Method

The studies presented in this article use the same method as outlined in *[6]*. It relies on a conceptual aircraft design framework *[10]*, adapted to analyze hybrid-electric aircraft according to the methods by *[11]* and *[12]*. As the control variables for the hybrid-electric powertrain allow for infinitely many possible combinations, a strategy is used that is maximizing the battery supplied power in cruise (whilst considering the operating limits of all powertrain components) to leverage

Content from this work may be used under the terms of the Creative Commons Attribution 3.0 license. Any further distribution of this work must maintain attribution to the author(s) and the title of the work, journal citation and DOI. Published under license by Materials Research Forum LLC.

Materials Research Proceedings 69 (2026) 607-613 https://doi.org/10.21741/9781644904251-108

the efficiency of the electric part of the powertrain. Ideally, the gas turbine is downsized to its cruise condition, with the battery complementing it to meet other design constraints, and the battery providing a constant positive amount of power during the cruise phase. Though not necessarily optimal, this strategy allows for a consistent comparison.
The SPPH powertrain operates two propulsor paths. In this particular article, a single propeller (on each wing) is attached on the primary path, and three distributed electrical propellers are on the secondary path. To minimize powertrain mass, conversion losses should be minimized by choosing a strategy that is "decoupling" the two branches of the SPPH powertrain. Decoupling results in minimizing EM1 in Figure 1, thereby minimizing the mass of this powertrain component and minimizing conversion losses. For more details, the reader is referred to *[6]*.

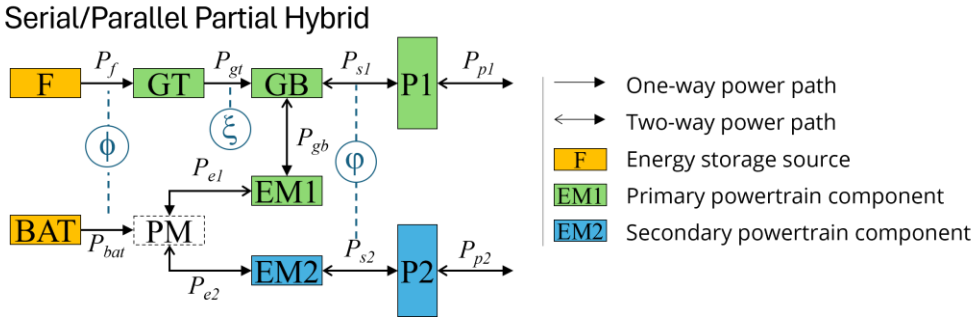

Figure 1 – Serial/Parallel Partial Hybrid (SPPH) powertrain architecture

Analysis and results

A sweep of design payload, at constant design range, and a sweep of design range at constant design payload has been performed for regional SPPH aircraft, along with kerosene baselines for identical top-level aircraft requirements (TLARs), based on the ATR 72-600. The baseline kerosene and SPPH versions are sized for 70 passengers (100kg each, plus 500kg additional cargo mass) and a design range of 926km. For SPPH aircraft a cruise battery supplied power ratio (φ*) of 10% or 20% is used, with a shaft power ratio (ψ) of 30% or 50%, respectively. TLARs and technology scenario (2035 entry into service, battery at 340 Wh/kg usable pack level and 20% maximum depth of discharge) are detailed in [6]. Note that all comparisons are made to baseline kerosene aircraft flying identical off-design missions. Analyses are presented graphically in terms of delta fuel consumption with respect to the kerosene aircraft and in terms of cruise supplied power ratio (maximizing usage of installed battery capacity).

Off-design performance sensitivity to design range

The baseline design point (70 pax, 926km) has been varied to 648, 1019 and 1111km, for the same design payload. Off-design performance is illustrated in Figures 2-5 in terms of delta fuel consumption with respect to kerosene baselines for an SPPH with design $\varphi^* = 10\%$, designed for identical TLAR flying the same off-design missions. Figures 6-9 show the cruise supplied power split for these aircraft.

The figures show a quickly narrowing band of fuel reduction when increasing design range for operational flexibility. Interestingly, it is possible to increase the cruise supplied power ratio for both shorter and longer off-design missions for longer design range. This highlights the impact of MTOM on the absolute fuel consumption as the larger electrification is not reflected in delta fuel consumption. It also marks the importance of the selection of the design TLARs when balancing operational flexibility and fuel efficiency.

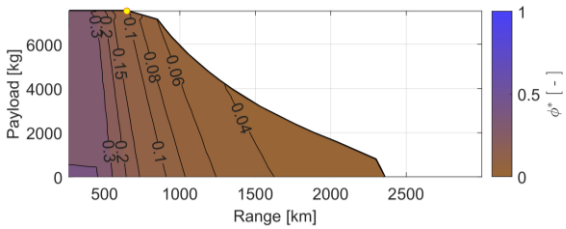

Figure 9 – Design point 70PAX @648km

Figures 10 – 13 and 14-17 illustrate the same comparison for of a SPPH aircraft with design *φ* = 20%*. These figures show two clear additional trends; (1) operational flexibility in terms of range is greatly reduced and (2) these heavier hybrids offer significant relative fuel savings over almost their entire payload range envelope. This illustrates an important design trade-off.

Off-design performance sensitivity to design payload

The baseline design point (70 pax, 926km, 500kg extra cargo) has been varied to 40, 50 and 80 passengers. Off-design performance is illustrated in Figures 18-21 in terms of delta fuel consumption for a design $\varphi^* = 10\%$ with respect to kerosene baselines, designed according to the same requirements, flying the same off-design missions. Figures 22-25 show the cruise supplied power split.

Increased payload offers both operational flexibility and increased electrification over a larger bandwidth of missions. In fact, the cruise supplied power split can be higher for more ranges and the increased payload does not seem to penalize the relative energy saving (compared to identically designed kerosene aircraft). This seems to confirm the possibility to design for larger design payloads, when a 36 meter span limit is no longer a concern [13] [14].

Materials Research Proceedings 69 (2026) 607-613 https://doi.org/10.21741/9781644904251-108

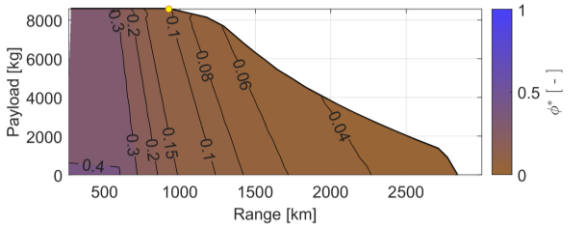

Figure 23 – Design point 40PAX @926km

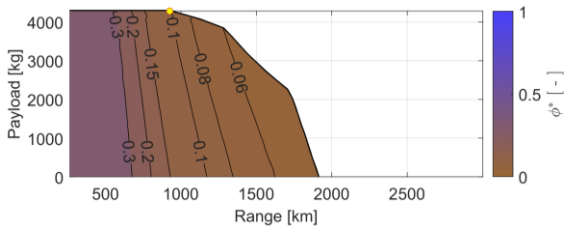

Figure 24 – Design point 80PAX @926km

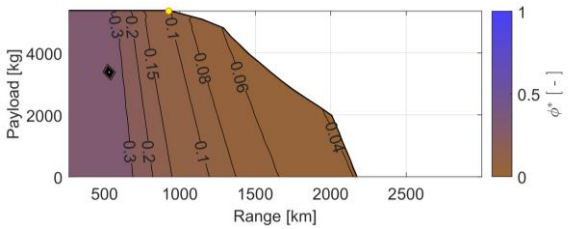

Figure 25 – Design point 50PAX @926km

Similar studies for *SPPH with design φ*=20%*, as illustrated in Figures 26 – 29 and Figures 30 – 33, respectively, confirm that the relative fuel saving is (almost) not penalized by design payload. Additionally, they offer significant relative fuel consumption benefits over almost their entire payload-range diagram. However, the range flexibility seems much less sensitive to design payload as the powertrain mass is more dominant on MTOM than payload. Consequently, the larger payload variant does not offer much more range flexibility anymore.

Conclusions

A sweep of design payload, at constant design range, and a sweep of design range at constant design payload was performed for regional SPPH aircraft (with design supplied power ratio of 10% and 20%), along with kerosene baselines for identical TLARs, flying identical missions. Results illustrate quickly narrowing bands of fuel reduction potential when increasing design range. Heavier hybrids demonstrate that operational flexibility in terms of range is greatly reduced when increasing design supplied power ratio although they offer significant relative fuel savings over almost their entire payload range envelope. This illustrates an important design trade-off. Increased payload offers both operational flexibility and increased electrification over a larger bandwidth of missions for light hybridization. Increased payload does not seem to penalize the relative energy saving compared to kerosene aircraft (with same TLARs and flying identical missions). However, heavier hybrids with increased payload do not offer more range flexibility anymore as the powertrain mass becomes dominant on MTOM.

Abstract. Polyimides are a well-established class of high-performance polymers known for their excellent thermal and chemical stability, mechanical robustness, low outgassing, and radiation resistance. These properties have made polyimides essential in aerospace applications, both for systems operating in low Earth orbit and for those used in long-term exploration missions. In recent years, polyimides have attracted growing interest for planetary exploration, particularly for lunar missions. The critical challenges of these missions include mechanical abrasion from regolith dust and the extreme temperature fluctuations. These conditions can damage exposed surfaces and compromise system performance. To overcome these challenges, self-healing materials represent a promising strategy, enabling polymers to autonomously repair mechanical damage and thereby enhance the reliability and operational lifetime of spacecraft components.

Introduction

Among the different classes of high-performance polymers, polyimides (PIs) are recognized as one of the most reliable options for aerospace applications. Their combination of thermal and chemical stability, mechanical strength, low outgassing, and resistance to radiation has made PIs widely used in many aerospace systems, from satellites in low Earth orbit (LEO) to components for future lunar missions [1, 2]. For LEO applications, PIs are commonly used as insulating layers in multi-layer insulation systems and as protective coatings against atomic oxygen erosion, which can severely degrade polymeric surfaces [3]. This class of polymers also finds application in flexible solar arrays, solar sails, and high-temperature adhesives [3]. In recent years, PIs have attracted growing interest for their applications in planetary missions, especially for lunar exploration missions. The critical challenges of these missions, such as mechanical abrasion from regolith dust, demand materials that can withstand harsh environments while maintaining structural integrity. Indeed, the surfaces of exposed materials may suffer progressive damage, for instance due to the accumulation and adhesion of abrasive lunar dust [4, 5]. This phenomenon can degrade the surface, and compromise the functionality of systems, posing a risk to mission success.

Over the last decade, self-healing materials have gained increasing interest in the aerospace field, thanks to technological advances that allow the development of systems able of repairing mechanical damage [6]. Integrating these materials into the design of spacecraft components can enhance structural integrity, safety, and mission reliability, extending the operational lifetime of space systems [7, 8]. Based on this ability, self-healing mechanisms are classified as intrinsic or extrinsic [9]. Extrinsic self-healing refers to systems in which the healing agents are embedded

Materials Research Proceedings 69 (2026) 614-619 https://doi.org/10.21741/9781644904251-109

within the material structure, typically stored in microcapsules networks that release the agent upon damage [10]. Intrinsic self-healing mechanisms do not require healing agents. They are typically based either on dynamic covalent chemistry, such as Diels–Alder reactions, dynamic urea and imine bonds, or on supramolecular interactions, including H-bonding, van der Waals forces, hydrophobic interactions, π–π stacking, and interdiffusion mechanisms [11]. According to the type of recovery process, self-healing materials are autonomous and non-autonomous [9]. Non-autonomic self-healing materials require an external trigger, like heat. Autonomic self-healing materials do not require any additional external trigger, but the damage itself is the stimulus for the healing [9].

In this context, the development of PI with self-repair capabilities and shape memory behaviour is a promising strategy to enhance the resilience and longevity of components during long-term exploration missions. This work focuses on the design, synthesis and characterization of flexible supramolecular PI materials with non-autonomous intrinsic self-healing and shape-memory properties. These results highlight the strong potential of polyimide systems engineered via supramolecular interactions to act as multifunctional materials for future space missions.

Experimental section

Polyimide synthesis. Three types of PIs were synthesized under an argon atmosphere via the polycondensation reaction between the same aromatic fluorinated dianhydride and two different diamines (one aliphatic and one aromatic). The corresponding diamine(s) were dissolved in a mixed DMAc/IPA solvent under mechanical stirring, and a stoichiometric amount of dianhydride was subsequently added to the solution. The reactions were carried out for 24 h at room temperature. After reaction, the solutions were heated in oven to evaporate the solvent. Finally, a thermal imidization process was optimized to obtain homogeneous PIs membranes (thickness ~ 300 μm).

Characterization methods. Density was measured by the hydrostatic weighing method in ultrapure water using the Sartorius YDK01 kit [2]. The wettability was assessed using the DataPhysics OCA15 PRO tensiometer, and the surface free energies (SFE) was calculated following the Owens–Wendt method [2]. In order to assess the self-healing behaviour of materials, optical images were acquired using a Leica polarized light microscope (DMLP series, Leica Microsystems, Germany). The sample surfaces were mechanically scratched with a scalpel, simulating external mechanical damage that may occur during exploration missions. Subsequently, the samples were heated at different temperatures (T = 50 °C and 150 °C). The two temperatures were chosen to provide a representation of the thermal conditions encountered on the lunar surface. Images were acquired immediately after the mechanical damage and subsequently after the repair induced by heat exposure.

Results and discussion

The fully aromatic PI is referred to as PI-1 (Fig.1a), the supramolecular semi-aromatic PI containing an aliphatic diamine and the same aromatic dianhydride as PI-2 (Fig.1b), and the supramolecular copolyimide prepared from both an aliphatic and an aromatic diamine with the same aromatic dianhydride as coPI-3 (Fig.1c).

Materials Research Proceedings 69 (2026) 614-619 https://doi.org/10.21741/9781644904251-109

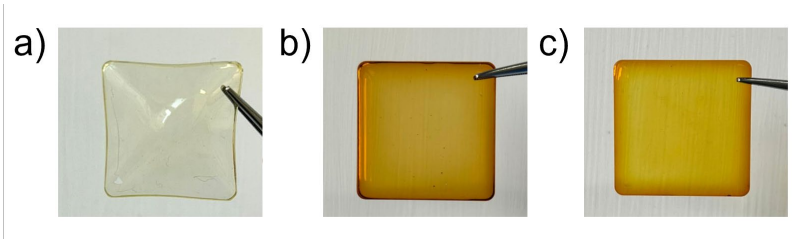

Fig.1 *a) Fully aromatic polyimide PI-1, b) semi-aromatic polyimide PI-2, and c) semi-aromatic copolyimide coPI-3 membranes obtained after thermal treatment.*

The density values of PI-1, PI-2, coPI-3 are reported in Table 1. The analysis indicates that the density decreases from 1.452 g·cm^{-3} (PI-1) to 1.107 g·cm^{-3} (PI-2) and 1.154 g·cm^{-3} (coPI-3) with the introduction of the aliphatic diamine. This reduction can be attributed to the lower packing efficiency and higher free volume associated with the flexible aliphatic segments. The reduction in density contributes to lowering payload mass, a key factor in spacecraft design and mission cost efficiency.

The WCA and the SFE with its dispersive (γ^d) and polar (γ^p) components are reported in Table 1. The wettability analysis unveiled the high level of hydrophobicity for all samples, with WCA ≥ 100°. The SFE showed a noticeable decrease, from 30.08 mJ m^{-2} for PI-1 to 24.69 mJ m^{-2} for PI-2, due to the introduction of the aliphatic diamine. The increase of hydrophobicity and the decrease of surface energy play a crucial role in dust mitigation. The reduction in SFE as it decreases the van der Waals and electrostatic forces responsible for lunar dust adhesion. Consequently, materials with higher hydrophobicity and lower SFE are less inclined to particle accumulation. In addition, hydrophobicity represents a critical requirement for space materials, as it effectively mitigates moisture uptake. Indeed, during ground handling and launch, materials may absorb water from the terrestrial environment, which in orbit can sublimate under specific conditions and generate structural defects.

Table 1. *Density, WCA, SFE with dispersive (γ^d) and polar (γ^p) components, for the aromatic PI-1 and the semi-aromatic PI-2 and cPI-3 samples.*

Sample	Density [g cm^{-3}]	WCA [°]	SFE [mJ m^{-2}]	γ^d [mJ m^{-2}]	γ^p [mJ m^{-2}]
PI-1	1.452 ± 0.024	100.0 ± 0.8	30.08	29.02	1.06
PI-2	1.107 ± 0.021	103.7 ± 2.3	24.69	23.75	0.94
coPI-3	1.154 ± 0.063	101.1 ± 1.6	25.07	24.03	1.04

Fig.2 shows the optical images of the materials surface immediately after the damage and subsequently after the repair induced by heat exposure. For brevity, only two representative samples (PI-1 and PI-2) at one self-healing temperature (T = 150 °C) are shown. The fully fluorinated aromatic PI-1 exhibited no self-healing (Fig.2a). Indeed, even after 40 min, the cut is still clearly visible. The same behavior was also observed at T = 50 °C. Fig. 2b shows the intrinsic self-healing behavior of PI-2 upon heating at T = 150 °C, where the damage disappears immediately.

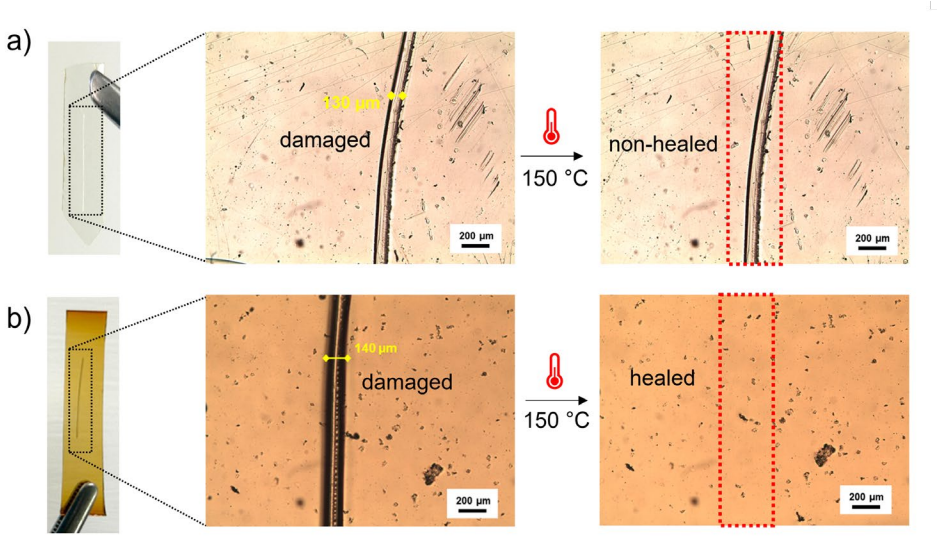

Fig.2 *Optical microscopy images of cut surfaces (left) and their response after heating at 150 °C (right). a) Aromatic PI-1, which does not self-heal even after 40 min, and b) semi-aromatic PI-2, showing rapid intrinsic self-healing within few seconds.*

Overall, all semi-aromatic PIs developed in this work exhibit intrinsic self-healing ability, and the repair process becomes progressively faster with increasing temperature, reaching healing times of only a few instants under elevated conditions (T = 150 °C). An increase in temperature enhances the segmental mobility of the polymer chains, allowing them to diffuse more across the damaged interface. Also, dynamic supramolecular bonds become more reactive, as higher thermal energy facilitates their reversible recombination. At T = 50 °C, PI-2 required approximately 20 min to restore the damaged area, whereas coPI-3 exhibited much faster recovery, completing the healing process in less than 20 s. When the temperature was increased to 150 °C, both materials healed significantly faster, with PI-2 achieving complete recovery in under 1 min and coPI-3 in less than 10 s. These results clearly indicate that higher temperatures enhance chain mobility and dynamic bond exchange, leading to accelerated self-repair. The self-healing rate is a critical factor for space applications, where rapid recovery from mechanical damage is essential to maintain structural integrity and functionality in harsh environments. Indeed, materials exhibiting fast self-healing can significantly enhance the reliability and lifetime of spacecraft components.

The supramolecular semi-aromatic PIs (PI-2 and coPI-3) developed in this work exhibit also shape memory behavior, being capable of recovering their original shape after deformation. Fig. 3 shows a schematic representation of the shape memory behaviour of PI-2. Specifically, the sample is deformed (Fig.3a) and subsequently recovers its original shape (Fig.3b-c), with the recovery time decreasing as the temperature increases.

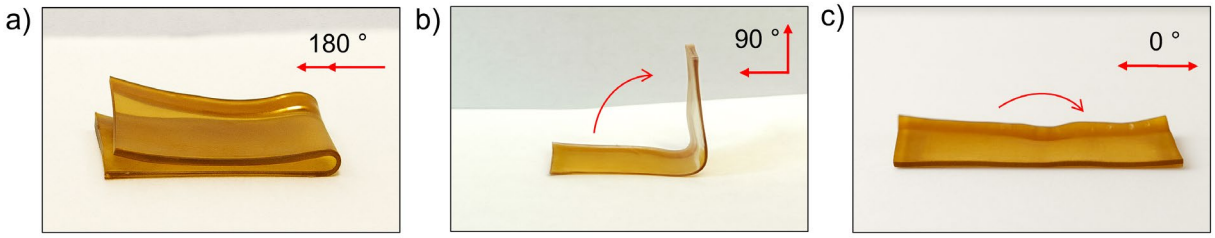

Fig.3 *Representative illustration of the shape memory behaviour of PI-2. a) The sample is deformed to 180°; b) bent to 90°, with a recovery time dependent on temperature; c) recovery of the original flat shape (0°). The images highlight the high elasticity and excellent shape recovery ability of the material after deformation.*

The test was carried out at 50 °C and 150 °C. The fully aromatic sample does not exhibit shape memory behaviour, as it is unable to recover its original shape after deformation. For both supramolecular materials, at T = 50 °C, the restoration process requires approximately 10 s, while at higher temperatures (T = 150 °C) it occurs instantly. This thermally induced response highlights the presence of dynamic reversible interactions within the polymer network, which enable rapid and efficient shape recovery. The shape memory process occurs even at room temperature, although the complete restoration may require up to 20 min for PI-2 and coPI-3. This behaviour is particularly advantageous for space applications, where shape memory capability can be exploited for deployable structures and adaptive components. Moreover, shape memory polymers could be integrated into deployable components, antennas, solar arrays, or dust-mitigation systems, where controlled deformation and recovery are crucial for operation and compact storage during launch.

Conclusions

Fully aromatic (PI-1) and supramolecular semi-aromatic (PI-2 and coPI-3) materials with a thickness of approximately 300 µm were successfully fabricated in DMAc/IPA. All materials exhibited low density, particularly in the case of polyimides containing aliphatic diamine. High hydrophobicity was observed for all materials, while the surface free energy decreased for the supramolecular polyimides. These characteristics are particularly relevant for space applications, as low density contributes to mass reduction, while hydrophobicity minimizes moisture uptake, preventing defect formation during mission operations. Moreover, a low surface free energy helps reduce lunar dust accumulation on the surface. Optical microscopy revealed the ability of the semi-aromatic materials to fully recover their morphology after mechanical damage, with healing efficiency strongly dependent on temperature. Higher temperatures enhanced chain mobility and dynamic bond exchange, leading to faster repair. The semi-aromatic PIs developed in this work also demonstrate shape memory behavior suitable for advanced space applications. Their thermally triggered recovery allows compact storage and autonomous deployment of structural elements, reducing both mass and mechanical complexity in spacecraft design. This functionality, combined with intrinsic self-healing capability, provides a dual advantage for long-duration missions where maintenance and repair are particularly challenging.

Abstract. Radiation exposure is one of the main obstacles to long-term human space exploration. Beyond Earth's atmosphere, astronauts are subjected to galactic cosmic rays and solar particle events, which can cause severe biological damage. The development of lightweight and efficient shielding materials is therefore crucial to ensure crew safety during missions in low Earth orbit and on the lunar surface. This study investigates hydrogen-rich polymer blends based on polyethylene and newly developed polyimides synthesized through environmentally sustainable, green-solvent routes. Polyimides exhibit excellent thermal resistance, mechanical robustness, and structural integrity at elevated temperatures, properties that complement the hydrogen-rich shielding capabilities of polyethylene. Radiation transport simulations were conducted using NASA's OLTARIS tool to evaluate exposure conditions in both low Earth orbit and lunar environments. The combination of polyethylene with advanced polyimides and boron-containing additives, such as boric acid, results in hybrid materials that are effective in radiation attenuation while remaining lightweight, flexible, and mechanically durable. These multifunctional composites represent promising candidates for integration into personal protective equipment and other shielding systems essential for future human space missions.

Introduction

Human space exploration is progressing toward missions of increasing duration and complexity, ranging from extended operations in low Earth orbit (LEO) to long-term habitation on the Moon and future expeditions to Mars. One of the major challenges to these endeavors is the hazardous radiation environment encountered beyond Earth's protective atmosphere and magnetic field. Astronauts operating in space are continuously exposed to a complex spectrum of ionizing particles, primarily galactic cosmic rays (GCRs) and solar particle events (SPEs), capable of penetrating spacecraft structures and biological tissues. These interactions can lead to ionization, molecular damage, and biological effects, such as acute radiation syndromes, degenerative pathologies, and an elevated lifetime cancer risk [1].

In LEO, astronauts are partially shielded by Earth's magnetic field, although radiation levels remain substantially higher than those at Earth's surface. In contrast, on the Moon, the absence of geomagnetic protection exposes crews directly to cosmic and solar radiation, resulting in a significantly harsher radiative environment for both human health and material integrity. The development of advanced shielding solutions is therefore a fundamental prerequisite for ensuring the safety, reliability, and long-term sustainability of human operations beyond Earth orbit.

Materials Research Proceedings 69 (2026) 620-625 https://doi.org/10.21741/9781644904251-110

Traditional metallic shields, though structurally robust, tend to generate secondary radiation when interacting with high-energy ions, thereby reducing their overall effectiveness. Hydrogen-rich polymers, composed of low atomic number elements, have emerged as promising alternatives due to their high efficiency in attenuating charged particles and minimizing secondary radiation [2,3]. Among them, polyethylene (PE) has long been considered a benchmark material for radiation protection because of its high hydrogen content, low density, and ease of processing. However, PE alone suffers from limited thermal stability and mechanical strength, restricting its use in demanding space environments.

To overcome these limitations, this study explores hybrid polymeric systems that combine PE with newly synthesized polyimides (PIs) obtained via environmentally sustainable, green-solvent routes [4]. Polyimides exhibit outstanding thermal resistance, mechanical robustness, and radiation tolerance, making them ideal candidates to complement the shielding performance of PE. The addition of boron-containing compounds, such as boric acid (BA), further enhances protection through neutron capture, providing a more comprehensive response to the mixed radiation fields typical of both LEO and lunar environments [5].

Radiation transport simulations were carried out using NASA's OLTARIS tool to model particle interactions and organ dose deposition under realistic mission scenarios. The synergistic integration of hydrogen-rich PE, high-performance polyimides, and boron-based additives results in hybrid materials that combine radiation attenuation efficiency with excellent thermal stability, mechanical reliability, and low density. These multifunctional composites are particularly suited for use in personal protective equipment and modular shielding systems for future human space missions.

Numerical simulations

Numerical simulations were carried out using NASA's on-line tool for the assessment of radiation in space (OLTARIS), considering both the LEO and lunar environments. The computational geometry was modeled as a spherical shell composed of an internal cavity with a radius of 150 cm, surrounded by an external shielding layer made of the investigated material, with areal densities ranging from 0 to 30 g/cm². The shielding effectiveness was determined based on the cross-sectional properties of each configuration, derived from the material's chemical composition and density. Since radiation absorption strongly depends on body morphology and tissue composition, anatomical differences between male and female bodies were taken into account. To represent the biological models accurately, the male adult voxel (MAX) and female adult voxel (FAX) phantoms developed by Kramer et al. were considered as reference anthropomorphic geometries [6,7]. Specifically, both models were applied for LEO simulations, while only the MAX phantom was used for the lunar environment. The simulations yielded the total effective dose equivalent (TEDE) calculated at the phantom's center using three-dimensional radiation transport analyses.

For the LEO analysis, orbital parameters representative of the International Space Station (ISS) were adopted, corresponding to a circular orbit at 400 km altitude and 51.6° inclination. Radiation exposure was evaluated over a one-year mission duration to estimate the cumulative dose from GCRs, SPEs, trapped particles, and albedo neutrons. The AP8 MAX model was used to describe trapped protons [8], while galactic cosmic radiation spectra were represented using the BON2020 model [9]. For the lunar environment, the BON2020 GCR model corresponding to the 2010 solar minimum was applied [9]. Radiation effects were evaluated over a one-year mission duration to assess cumulative exposure from GCRs on the human body [10].

Results and discussion

Fig. 1 shows the total effective dose equivalent (TEDE) obtained for the main reference materials (aluminium, liquid water, and polyethylene) and for the PE/PI-based blends, evaluated using both

Materials Research Proceedings 69 (2026) 620-625 https://doi.org/10.21741/9781644904251-110

MAX and FAX anthropomorphic phantoms under LEO conditions. For all investigated materials and both body models, the analysis demonstrates a consistent decrease in TEDE with increasing areal density. The reduction follows a nonlinear trend, characterized by a steep decline at low areal depths and a gradual attenuation at higher thicknesses, reflecting the progressive moderation of primary and secondary radiation components. Among the materials analyzed, a clear difference in shielding performance is observed, with aluminium showing the lowest effectiveness and polyethylene the best performance, which is consistent with its well-known role as a benchmark hydrogen-rich material for space radiation protection. Liquid water and PE/PI-based materials exhibit intermediate behavior, with water showing slightly lower TEDE values at higher areal densities because of its greater hydrogen content.

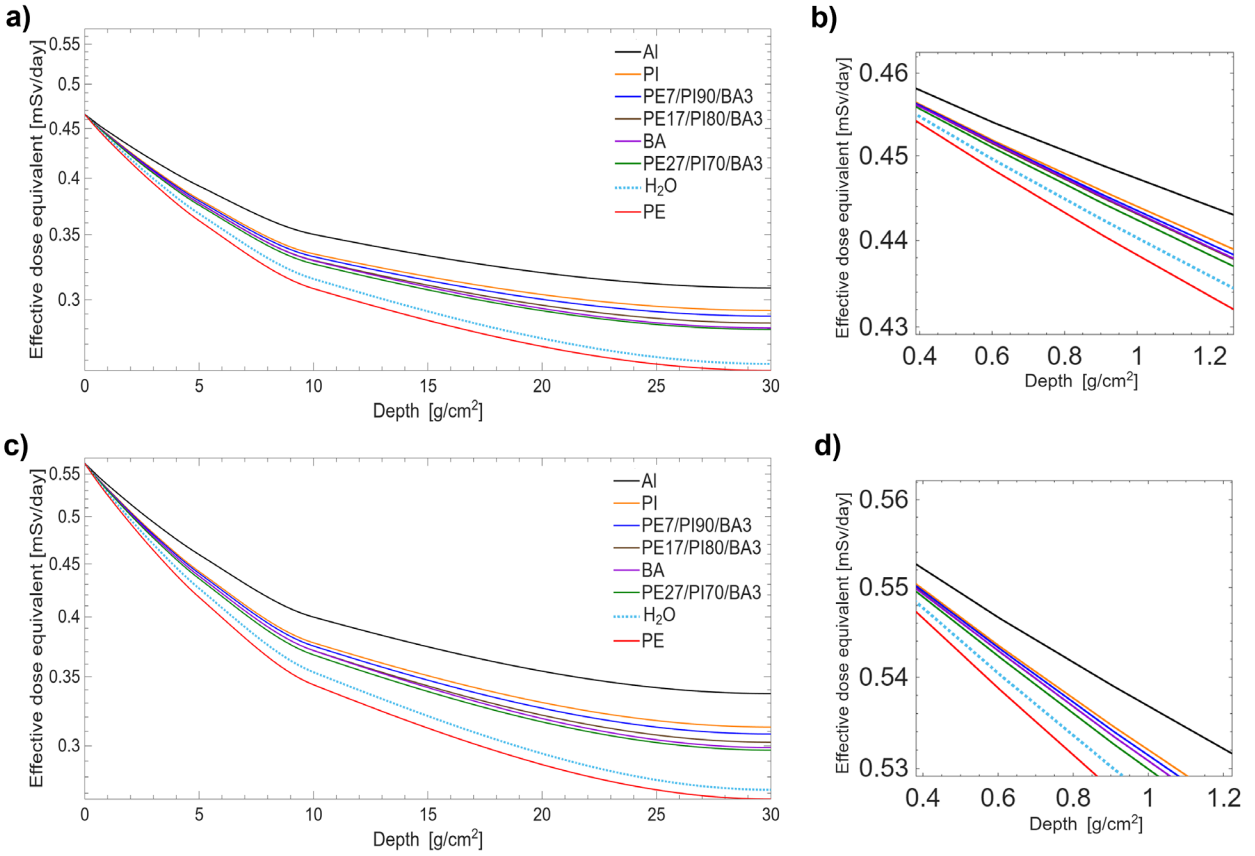

Fig. 1. *TEDE as function of the areal depth in LEO environment for a) MAX and c) FAX human phantom models; b,d) enlarged area of the plots in the depth range 0.4 – 1.2 g/cm².*

The comparison between the MAX and FAX phantoms reveals that the female model consistently receives higher radiation doses than the male model, with an increased exposure risk for women. Consequently, optimized protective strategies, such as localized thickening of spacesuit shielding or habitat walls, may be required to ensure equivalent safety margins for female astronauts.

The stochastic health effects of radiation were evaluated by comparing the TEDE obtained after a one-year exposure at shielding thicknesses of 0.5 and 1.0 g/cm² with the permissible limits defined by the National Council on Radiation Protection and Measurements (NCRP) report No. 167. In this analysis, the PE/PI/BA material with a 27:70:3 ratio was selected for its high hydrogen concentration. The corresponding TEDE values are summarized in Table 1 for both MAX and FAX phantoms. According to the NCRP guidelines for astronauts aged approximately thirty years,

Materials Research Proceedings 69 (2026) 620-625 https://doi.org/10.21741/9781644904251-110

the career dose limits are 620 mSv for males and 470 mSv for females, representing the most restrictive scenario for human space missions.

Table 1. *Total effective dose equivalent after one-year mission in LEO for both MAX and FAX human phantom models considering the PE/PI/BA material with 0.5 and 1.0 g/cm² of areal depth.*

Analysis model	Depth in PE27/PI70/BA3 [g/cm²]	Total effective dose equivalent after one year [mSv]
MAX	0.5 (0.4 cm)	165.4
MAX	1.0 (0.8 cm)	161.5
FAX	0.5 (0.4 cm)	199.1
FAX	1.0 (0.8 cm)	193.4

Results unveiled that the PE/PI/BA material provide substantial radiation attenuation, maintaining TEDE values below the NCRP thresholds even at a minimum thickness of 0.5 g/cm². In the lunar environment, the TEDE values reported in Fig. 2 for the MAX phantom show a progressive decrease in radiation dose with increasing areal depth for all analyzed materials, consistent with the attenuation behavior previously observed under LEO conditions.

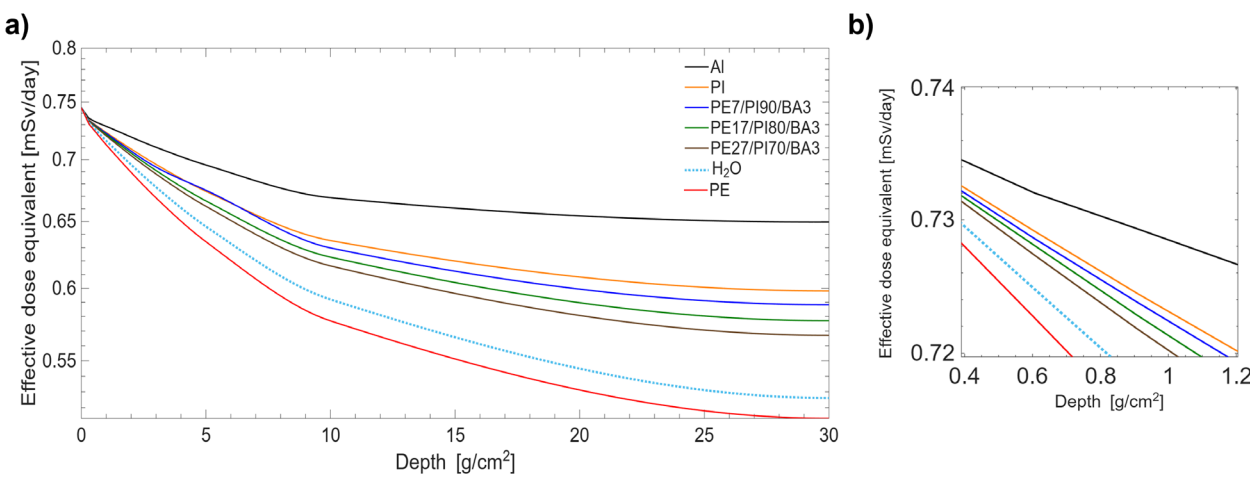

Fig. 2. *a) TEDE as function of the areal depth in lunar environment for MAX human phantom model; b) enlarged area of the plot in the depth range 0.4 – 1.2 g/cm².*

As expected, aluminum exhibits the poorest shielding capability, while PE provides the most effective attenuation owing to its high hydrogen content. The PE/PI/BA materials show intermediate performance between these two reference materials, closely approaching that of PE, and outperforming both pure PI and aluminum. As shown in Table 2, PE/PI/BA materials with ratios of 7:90:3, 17:80:3, and 27:70:3 demonstrated comparable radiation-shielding performance. In particular, TEDE values remain below the career dose limit of 620 mSv, thereby enabling safe exposure durations equivalent to missions of up to two years. Overall, the numerical simulation results underscore the suitability of PE/PI/BA materials as lightweight, efficient, and adaptable candidates for radiation protection in both LEO and lunar environments.

Table 2. *Total effective dose equivalent after one-year mission in the lunar environment for MAX human phantom model considering different PE/PI/BA materials with 0.5 and 1.0 g/cm^2 of areal depth.*

Material	Depth [g/cm^2]	Total effective dose equivalent after one year [mSv]
PE7/PI90/BA3	0.5 (0.4 cm)	266.6
	1.0 (0.7 cm)	263.7
PE17/PI80/BA3	0.5 (0.4 cm)	266.4
	1.0 (0.8 cm)	263.3
PE27/PI70/BA3	0.5 (0.4 cm)	266.2
	1.0 (0.8 cm)	262.9

Conclusions

This study assessed the radiation-shielding performance of hydrogen-rich PE/PI/BA materials through numerical simulations using NASA's OLTARIS tool under both LEO and lunar conditions. The findings show that combining polyethylene with thermally stable and mechanically robust polyimides, together with boric acid as a neutron-absorbing additive, yields hybrid materials that exhibit radiation shielding properties while maintaining low density. The obtained TEDE values remain below NCRP dose limits even at minimal areal densities, allowing safe exposure durations equivalent to up to three years in LEO and two years on the lunar surface. Overall, the PE/PI/BA materials can be considered promising candidates for integration into lightweight and multifunctional shielding components, such as personal protective equipment and modular systems, in future human space missions.

Keywords: Supersonic Inlet, External Compression Inlet, Strong Oblique Shock Wave, Total Pressure Recovery, Ramjet Propulsion, Numerical Simulation (CFD)

Abstract. In this work, we investigate the applicability and performance limitations of a single-ramp, external-compression inlet for ramjet propulsion over a range of supersonic Mach numbers. The current work examines the use of strong oblique shocks instead of terminal normal shocks to enhance inlet performance and reduce the total pressure losses in simplified geometries. A combined analytical and numerical approach is used. Oblique shock theory and the Oswatitsch criterion for optimal multi-shock compression are employed to estimate the performance limitations of the multi-ramp configuration. The analytical predictions are then validated using high-fidelity CFD simulations performed with ANSYS Fluent. The results show that the single-ramp inlets are efficient at lower supersonic speeds (up to approximately Mach 2) due to the use of a strong oblique terminal shock. However, their efficiency deteriorates rapidly at higher Mach numbers, significantly increasing the total pressure losses. Analytical models slightly overpredict pressure recovery by 1.5–2% compared to numerical results. The current work aims to provide insight into the performance envelope of simplified inlet geometries for high-speed air-breathing propulsion systems. The research demonstrates the benefits and trade-offs of various ramp designs and highlights the necessity of more complex geometries, such as multi-ramp designs, for efficient operation at Mach numbers exceeding 2. These findings can support the optimization of a ramjet inlet design and provide guidelines for the development of future propulsion systems.

Introduction

External-compression inlets have been widely studied and successfully employed in high-speed applications, from supersonic aircraft to ramjet-powered cruise missiles. They are attractive due to their relatively simple geometry, predictable starting behavior, and robust operating characteristics. Compared with more advanced inlet configurations, such as divergentless, mixed-compression, or fully internal compression inlets, external compression designs are less efficient in terms of total pressure recovery. Nonetheless, their structural simplicity and reliability make them appealing for practical systems [1-3].

One way to simplify the external-compression inlets is to reduce the number of ramps, which directly affects the inlet's size, drag, and overall performance. Traditional studies focus on multi-ramp designs with carefully tuned ramp angles to balance the total pressure recovery across stages [4]. However, to the best of the author's knowledge, the case of a single ramp inlet utilizing a strong oblique shock as the terminal shock instead of the conventional normal shock has not been explored in the literature. This study focuses on designing a supersonic inlet with a targeted mass flow rate of approximately 1 [kgs^{-1}], which results in a correspondingly small capture area. Inlet geometries with such low mass flow rates present substantial technical challenges that are inadequately documented in the open literature.

Despite their lower efficiency, single ramp external compression inlets offer practical advantages. They are simple to design and can reduce the overall drag due to a smaller capture

Materials Research Proceedings 69 (2026) 626-631 https://doi.org/10.21741/9781644904251-111

ratio. These factors motivate the present feasibility study of single ramp external compression inlets across various Mach numbers, highlighting their potential for cost-effective and compact high-speed propulsion systems, such as ramjets.

Methodology

The analytical formulation in this study is developed under the classical assumptions of steady, adiabatic, inviscid, two-dimensional flow of a perfect gas with a constant specific heat ratio. These assumptions simplify the governing equations and allow for the use of the well-established oblique shock and isentropic flow relations. Within this framework, the inlet geometry can be approximated with reasonable accuracy while preserving physical insight.

In the proposed inlet design, the weak-shock solution is followed by a strong oblique shock to reduce total-pressure losses. Static pressure, temperature, and density ratios are obtained from the standard shock-jump relations. For multi-shock configurations, the *Oswatitsch condition* [4] provides an optimization criterion, i.e. maximum total-pressure recovery is achieved when all shocks are of equal strength, which is equivalent to ensuring that the normal components of the Mach number upstream of each shock are identical. In practice, the design is carried out iteratively by adjusting the initial assumptions on the freestream Mach number until a target condition is satisfied, namely $M > 1.3$ at the diffuser exit. This results in well-balanced shock strengths and improved inlet performance. The inlet geometry was adapted from published work with simplifications introduced for small-scale application purposes [5].

Numerical Model

Simulations were conducted in ANSYS Fluent using the density-based solver. Gas density was calculated from the ideal gas law, while dynamic viscosity was evaluated using Sutherland's law.

A two-dimensional structured mesh was generated with refined near-wall spacing to achieve $y^+ < 1$. The computational domain was extended in all directions, with the additional spacing set equal to the inlet height. Three meshes consisting of approximately 130,000, 200,000 and 300,000 elements were tested. A grid independence study showed that the difference in bleed flow rate between medium- and fine-resolution grids was less than 1%, and total pressure recovery was not sensitive for the mesh study. The medium-density mesh was, therefore, selected as a trade-off between accuracy and efficiency.

A turbulence model sensitivity study was performed using the *RNG k-ε*, *k-ω*, and *SST k-ω* models. The predicted flow characteristics showed no significant differences among the different setups. Based on existing recommendations [6-8], the *SST k-ω* model was selected for the current study.

During the initial 10,000 iterations, the spatial discretization was set to First-Order Upwind to ensure numerical stability. The scheme was then switched to Second-Order Upwind for another 15,000 iterations, where face values were reconstructed using a multidimensional linear approach, thereby increasing spatial accuracy.

For the full multigrid initialization (FMG), the Courant–Friedrichs–Lewy (CFL) number was fixed at 0.05. During the solution process, ANSYS Fluent dynamically adjusted the Courant number, progressively increasing it to a maximum of 2.5 in response to residual stabilization. This adaptive strategy provides a trade-off between numerical stability and computational efficiency.

To model the freestream, a pressure far-field boundary condition was applied. This requires specifying the static pressure, Mach number, and static temperature. The pressure outlet boundary condition was used to represent both the downstream outflow and the bleed outflow; static pressure was prescribed. At the main inlet exit, a pressure boundary condition was imposed to enforce a choked flow condition. For this boundary, static pressure and total temperature were specified, stabilizing the internal shock system and maintaining the goal mass flow rate. The numerical study

Materials Research Proceedings 69 (2026) 626-631 https://doi.org/10.21741/9781644904251-111

was carried out for three freestream Mach numbers: 1.5, 2.0, and 2.5, under the conditions listed in Table 1.

Table 1: Flow conditions of the proposed supersonic inlets. Key parameters besides Mach numbers include freestream pressure, freestream temperature, turbulent kinetic energy, specific dissipation rate, and design mass flow rate, from which inlet and exit pressure and total temperature were prescribed, as well as bleed flow rate.

p_s [kPa]	T_s [K]	k $[m^2s^2]$	ω $[s^{-1}]$	$\dot{m}$ $[kgs^{-1}]$	$\dot{m}_{bleed}$ [%]
101.325	288.15	1735.708	$1.188 * 10^{-7}$	1.0	5

Results

The primary motivation for employing the single compression ramp lies in its geometric and aerodynamic simplicity. In contrast, external compression inlets utilizing multiple ramps typically generate a larger total flow deflection, which, although beneficial for achieving higher pressure recovery, increases the inlet capture area. Since the capture area is directly associated with inlet drag, becomes a critical factor in the inlet design. Figure 1 presents the results obtained using the Oswatitsch condition, which constrains the Mach number to $M = 1.3$ downstream of the final ramp. This condition provides a useful benchmark for evaluating the balance between compression efficiency and drag penalties in different inlet configurations. Therefore, a direct connection between the combined ramp angle and efficiency can be seen. This occurs because a specific Mach number is required to sustain a strong oblique shock wave after the external compression ramps. As the number of shocks increases, the net total pressure loss per shock decreases, resulting in a higher total deflection angle of the external diffuser.

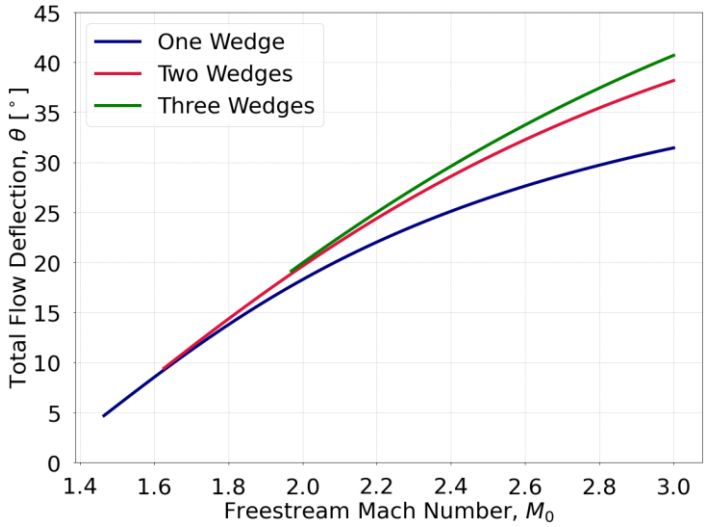

Figure 1: The characteristic of the total flow deflection angle to the Mach number, calculated for different ramp numbers by the Oswatitsch condition.

The MIL-E-5008B standard is employed to estimate the possible operating range for inlets with different numbers of compression ramps. Figure 2 illustrates the results of an analytical calculation based on the assumption of equal pressure-recovery shocks for varying free-stream Mach numbers, with the Mach number constrained after the final shock constrained to $M = 1.3$. The results reveal that a single-ramp inlet can be used effectively up to approximately $M = 1.85$, a double-ramp configuration extends the applicability to approximately $M = 2.5$. A triple-ramp inlet exceeds this standard over the Mach number range of interest. These findings emphasize the role of multi-ramp compression in expanding the operational envelope of supersonic inlets, while maintaining compliance with performance standards.

Materials Research Proceedings 69 (2026) 626-631 https://doi.org/10.21741/9781644904251-111

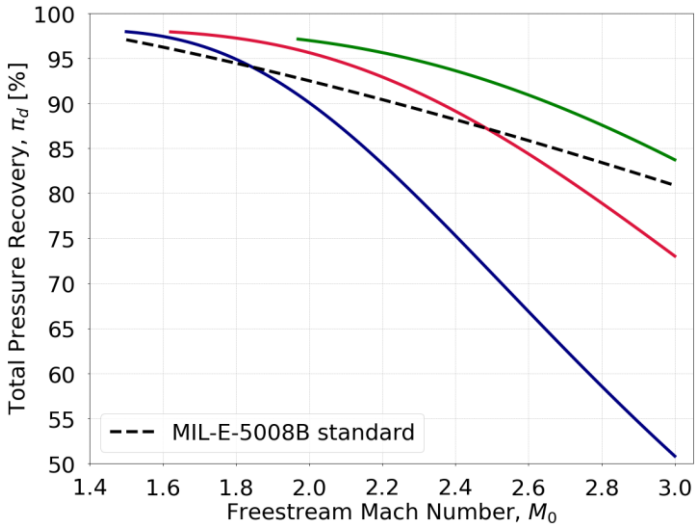

Figure 2: The total pressure recovery characteristic as a function of the Mach number, calculated using the Oswatitsch condition for different ramp numbers. The results are compared to the MIL-E-5008B standard is presented as dashed line.

Table 2 summarizes the results of the present study, which combines the MIL-E-5008B standard with analytical predictions and numerical simulations for three representative Mach numbers and three inlet configurations. For $M = 1.5$, the two- and three-ramp configurations could not be designed according to the Oswatitsch condition for the desired ramp Mach number. The single ramp configuration meets the standard only at that Mach number.

For the remaining Mach number range, the performance drops significantly below the standard. The two ramps configuration falls below the standard for both Mach numbers within the operating range. The three-ramp configuration exceeds the standard at $M = 2.0$, where analytical and numerical calculations are in good agreement. The comparatively high performance of the inlet is primarily due to the use of a strong oblique shock. Furthermore, it is important to emphasize that the analytical model consistently overpredicts the recovery efficiency by approximately 1.5-2%, when compared to numerical simulations. This indicates relatively close agreement between the analytical and numerical estimates. Therefore, the analytical tool can be used with reasonable accuracy, reducing process time by orders of magnitude while preserving an acceptable level of detail for design optimization.

Table 2: The table reports the total pressure recovery ratio for each configuration, expressed as a percentage. Values without markings correspond to the MIL-E-5008B standard. Values with a (′) correspond to analytical calculations, whereas values with a (″) correspond to numerical results. The results demonstrate that the proposed single ramp configuration achieves superior performance at lower Mach numbers. A clear trend of increased performance can be seen with an increased ramp number.

M	π_d	Single ramp		Double ramp		Triple ramp	
		π_d'	π_d''	π_d'	π_d''	π_d'	π_d''
1.5	97.06%	98.50%	97.12%	-	-	-	-
2.0	92.50%	90.25%	88.19%	93.28%	91.59%	93.98%	93.44%
3.0	87.03%	74.27%	73.00%	86.56%	85.02%	90.57%	87.01%

Materials Research Proceedings 69 (2026) 626-631 https://doi.org/10.21741/9781644904251-111

Concluding Remarks

The present study demonstrates that the single-ramp external compression inlet performs sufficiently good over a limited range of supersonic conditions. Specifically, at Mach 1.5 the inlet exceeds the adopted performance standards, indicating robust total pressure recovery. Even at Mach 2.0, the inlet maintains acceptable performance levels. Minor geometric optimizations, such as adjusting the cowl lip angle or throat section parameters, could elevate their efficiency to closely match or surpass established benchmarks. However, performance at Mach 2.5 reveals a critical limitation, that is the inlet experiences a 14% loss in the total pressure. This renders the inlet unsuitable for high-speed applications without a significant redesign.

The performance of the two-ramp configurations falls slightly below the standard, while the three-ramp configurations exceed it. For Mach numbers 2, therefore the use of a double ramp configuration appears to be unjustified. The reason for this is that the two ramp configuration does not meet performance requirements; see Table 2. On the other hand, concerning the performance gain, the three-ramp configuration is preferable; if simplicity of the design is prioritized, then the single-ramp inlet might be considered for application at approximately Mach 2. Nevertheless, the size of the inlet increases with the two- and three-ramp configurations, consistent with the literature on the practical limitations of external compression inlets within the Mach 2.5–3.0 range.

Furthermore, the results corroborate the broader consensus that even strong oblique shock wave, which promise high efficiency, begin to lose their effectiveness at higher Mach numbers for single and double configurations.

In summary, single-ramp inlets show promise for moderate supersonic speeds, offering efficient performance with relatively simple geometry. However, their performance is significantly constrained beyond Mach 2.5 due to the increased total pressure losses as well as reduced inlet efficiency. More advanced inlet configurations, such as multi-ramp designs, provide superior total-pressure recovery and enhanced operational flexibility. This is achieved by distributing compression across multiple weaker shocks and enabling better control over shock position. These geometries mitigate total pressure losses and flow distortion issues, making them better suited for sustained operation in the Mach 2.5–3.0 range.

Keywords: EAD Thruster, Corona Discharge, Pressure, Humidity, Performance

Abstract. A wire-to-grid electroaerodynamic (EAD) thruster is experimentally investigated under varying environmental conditions. Experiments are conducted in a low-pressure chamber to assess the influence of ambient pressure p and relative humidity RH on device performance. The key performance metrics considered are corona current i_c, the thrust density T/A, and the thrust-to-power ratio T/P. Experimental results indicate that decreasing pressure negatively affects all performance indicators while reducing the ignition threshold. Additionally, both current consumption and ignition voltage exhibit a parabolic dependence on relative humidity.

1. Introduction

Electroaerodynamic (EAD) thrusters are emerging as a promising technology for aerospace applications, particularly for lighter-than-air (LTA) vehicles such as airships [1]. These air-breathing devices offer several advantages, including zero emissions, low acoustic noise and the absence of moving parts. Although various EAD thruster concepts exist, they all rely on a common operating principle: two electrodes supplied with a high DC voltage generate a sufficiently asymmetric electric field such that air is ionized at the emitter and drifts toward the collector. The resulting interaction between ions and neutral molecules produces an ionic wind and generates thrust [2]. The performance of EAD thrusters is influenced by environmental conditions such as temperature, pressure and humidity, which can significantly alter their operational characteristics [3,4,5]. In this work, the performance of a gridded EAD thruster developed at Politecnico di Milano within the framework of the EU-funded I-PROP project is experimentally investigated as a function of two environmental variables, namely ambient pressure p and humidity.

2. Experimental Setup

The experimental campaign was conducted in a grounded cylindrical steel chamber capable of sustaining pressures down to a few pascals. The desired pressure level was achieved using a single-stage rotary vane pump connected to a lateral port. The corona voltage was monitored using a voltage divider connected in parallel with the thruster, while the corona current i_c was measured using a contactless probe. Thrust was measured with a load cell and humidity was determined from the output of a dew-point temperature sensor. The water vapor content inside the chamber was reduced using silica gel and increased through controlled water evaporation.

Low-voltage connections (load cell, dew-point sensor, and ground lines) were routed through a feedthrough and EMI-shielded to prevent signal degradation. The voltage supplied by the 0–30 kV DC power supply was delivered to the thruster through a dedicated high-voltage feedthrough. A ballast resistor with resistance $R_b = 1$ MΩ was connected in series for safety purposes.

Materials Research Proceedings 69 (2026) 632-637 https://doi.org/10.21741/9781644904251-112

Analog outputs were acquired using a data acquisition system at a sampling frequency $f_s = 25$ kHz over an observation time $T_{obs} = 2$ s, and subsequently processed in Python. A schematic of the setup is presented in Figure 1. Further details about the instrumentation can be found in [6].

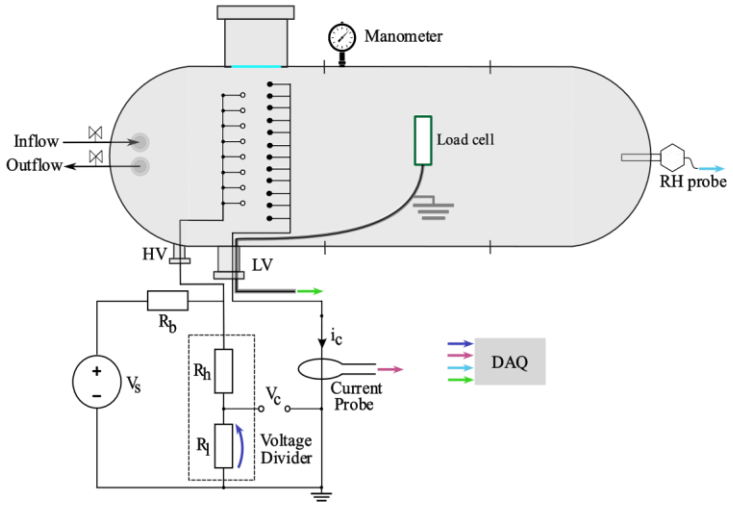

Figure 1 — Schematic diagram of the test facility. Colored arrows indicate acquired signals.

A dedicated test rig was designed to house the wire-to-grid thruster inside the chamber. The adopted thruster configuration replicates the one presented in [6]. The load cell was installed vertically and connected to the test rig through a single-point attachment, while its base was secured to a grounded iron platform. A counterbalancing arm was added to offset the cantilever moment and prevent overload. A schematic view of the complete test rig is shown in Figure 2.

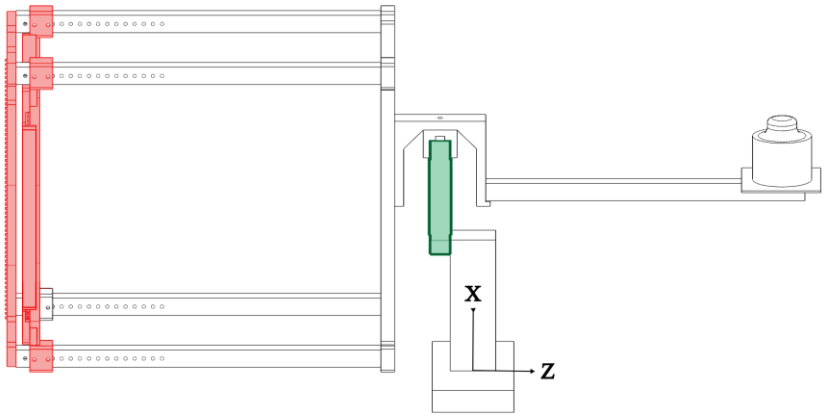

Figure 2 — Complete test rig: the EAD thruster is highlighted in red, while the load cell is depicted in green.

The tested pressure levels ranged from 101 kPa down to 20 kPa. Absolute humidity values between 5 and 20 g/m^3 were achieved, corresponding to relative humidity levels of approximately 20–80%. Temperature could not be actively controlled during the campaign but was continuously monitored and showed no significant variation; it was therefore treated as constant. Thrust, voltage

Materials Research Proceedings 69 (2026) 632-637 https://doi.org/10.21741/9781644904251-112

and current measurements were obtained as the difference between the thruster-on and thruster-off signals. Multiple acquisitions were averaged to obtain the final measurement values. Measurement uncertainty was propagated using the root-sum-square method.

3. Results

The outcomes of the experimental campaign are reported in three parts: the ignition voltage V_{ign}, which sets the lower limit of the thruster's electrical envelope, is addressed first; second, the influence of the tested variables on the corona current i_c is examined; finally, the performance is evaluated through the thrust density T/A, which is an index of thruster compactness, and the thrust-to-power ratio T/P, representative of efficiency.

Ignition Voltage

The ignition voltage is found to be a monotonic function of pressure, as shown in Figure 3. Experimental data are interpolated using a model function resembling Peek's law.

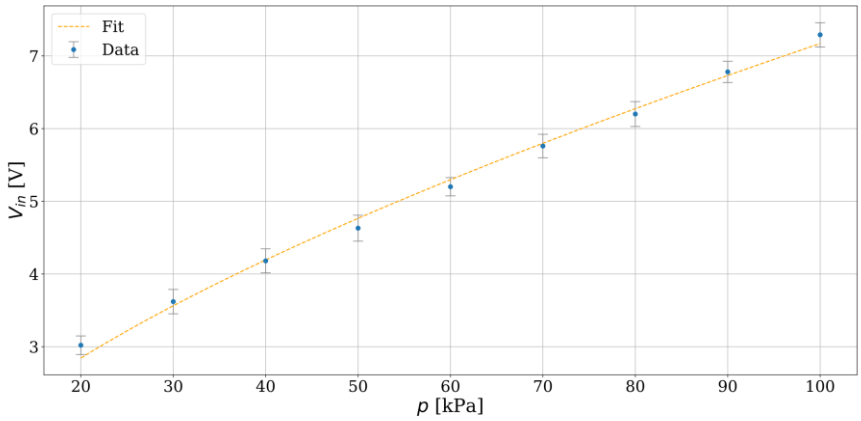

Figure 3 — V_{ign} as a function of pressure p.

The effect of humidity on the ignition voltage is shown in Figure 4. Experimental data are well fitted by a parabolic trend, in agreement with previous findings reported in the literature [7].

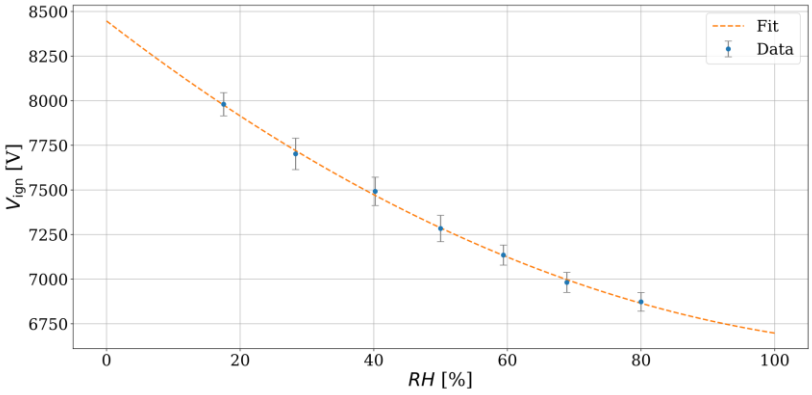

Figure 4 — V_{ign} as a function of humidity.

Corona Current

The corona current increases as pressure decreases, as highlighted in Figure 5, due to the dependence of ion mobility on pressure [8]. The corona current exhibits a parabolic dependence

Materials Research Proceedings 69 (2026) 632-637 https://doi.org/10.21741/9781644904251-112

on humidity, as shown in Figure 6 for three different voltage levels. This behavior is attributed to the combined effects of variations in both ignition voltage and ion mobility.

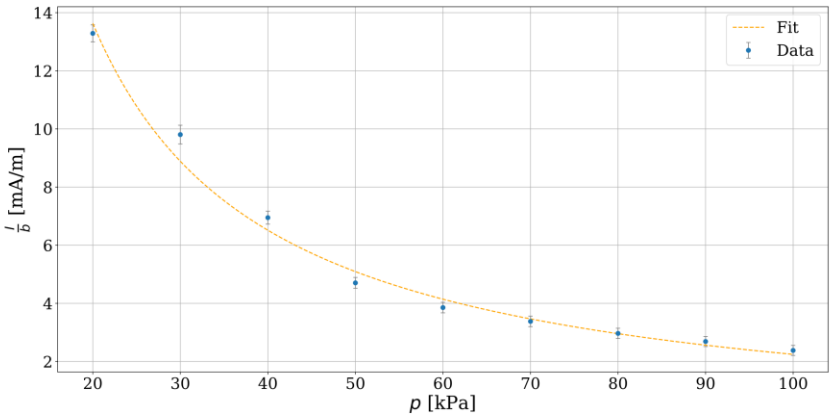

Figure 5 — Corona current i_c as a function of pressure p.

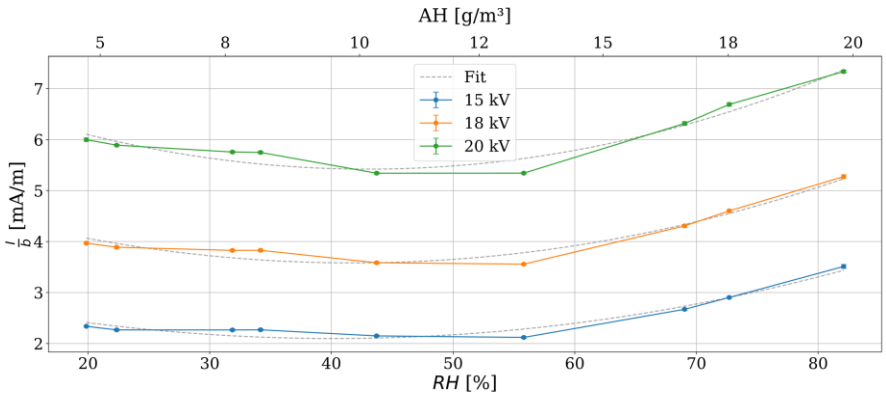

Figure 6 — Corona current i_c as a function of relative humidity RH and absolute humidity AH.

Thrust Density and Thrust-to-Power Ratio

Thrust density exhibits a linear dependence on pressure as shown in Figure 7, resulting from the dependence of the collision frequency νon the gas density ρ. As the gas becomes rarefied, the probability of ionizing collisions decreases, despite the greater ion availability associated with lower ignition voltages, which drives a reduction in space charge density. In other words, although ionization is easier to initiate at lower pressures, the number of effective ionizing collisions decreases, thereby reducing the momentum transfer which is the main mechanism of thrust generation. The corona current, as well as the corona power P, decreases proportionally to $1/p$; the combination of this dependence with the scaling of the generated thrust explains the behavior of T/P, which tends to zero as $p \to 0$, as shown in Figure 8. This is expected, since fewer neutral particles are available at lower pressure levels, resulting in null thrust production regardless of the consumed power. The dependence of thrust density and thrust-to-power ratio on humidity does not exhibit any significant variation, as the measurements acquired at different humidity levels fall within the uncertainty bands.

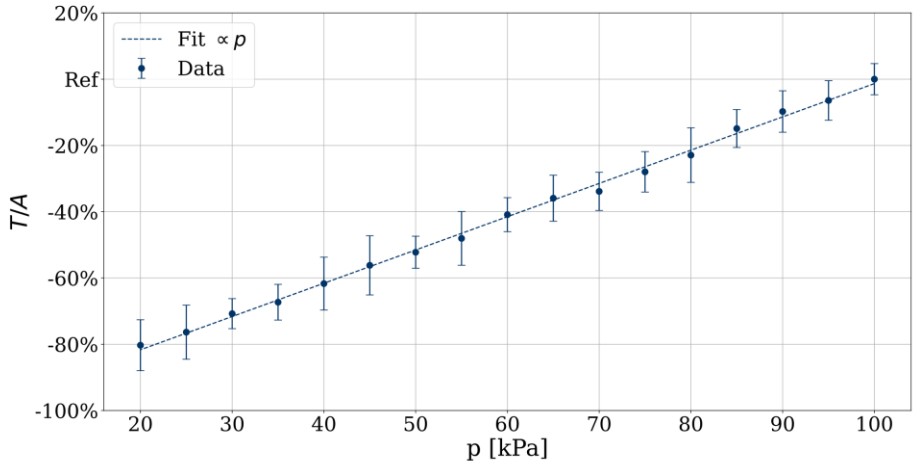

Figure 7 — Thrust density T/A as a function of pressure p.

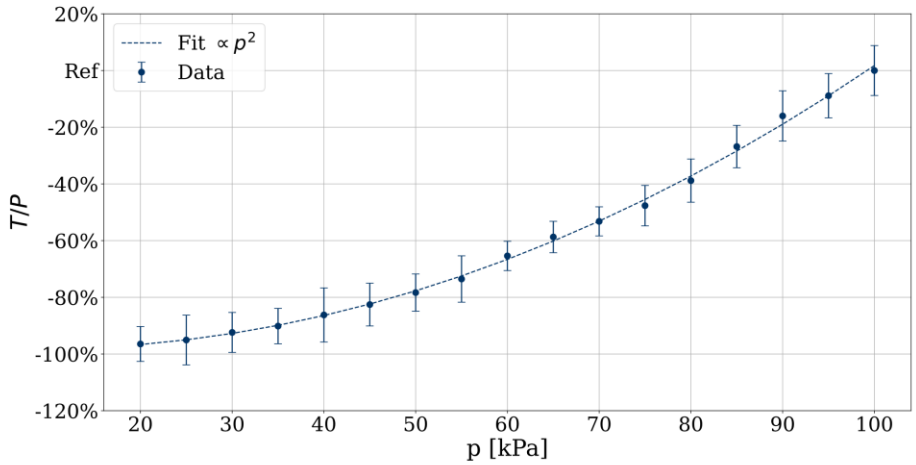

Figure 8 — Thrust-to-power ratio T/P as a function of pressure p.

4. Conclusions

This study experimentally investigates the performance of electroaerodynamic thrusters under varying ambient pressure $p$and relative humidity RH. Experiments are conducted in a low-pressure chamber with controlled environmental conditions. Thrust is measured using a load cell, while corona voltage and current are obtained using a voltage divider and a contactless probe, respectively. Results show that the ignition voltage increases with both pressure and relative humidity, with variations reaching up to 25% between dry and saturated air. A reduction in pressure leads to a decrease in thrust density and thrust-to-power ratio proportional to p and p^2, respectively, while the corona current increases inversely with pressure. These trends are primarily driven by changes in ion mobility and space-charge density. Finally, the corona current is found to scale approximately with RH^2, due to the combined effects of humidity-induced variations in both ignition voltage and ion mobility.

Keywords: EHD Atmospheric Propulsion, Grid Collectors, Double-Level Collectors, Blade Collectors, Green Propulsion

Abstract. This work presents an experimental study of ion thrusters for atmospheric flight, with a focus on the research for an optimal configuration of the collectors. Based on a recent study that demonstrated the advantages of EHD grids as a replacement for classical airfoil shaped ion collectors, test campaigns were carried out with the aim of finding configurations that would further improve their performance in terms of thrust density and thrust-to-power ratio. The main topic of the work is the investigation on the benefits of using a double level of grid collectors, representing the proof of concept for the final examined configuration, which involves the use of metal blade collectors, replacing the classic wires. This latest development could in fact be the ideal solution for practical applications, given the constructional and operational advantages.

Introduction

Ion propulsion is a novel technology for atmospheric applications [1,2], it exploits a high voltage difference between the electrodes to ionize the air and accelerate the ions through the resulting electric field, thus creating thrust through the collision with neutral molecules. The simplest form of EAD thrusters employs the corona effect [3] as the ionization source, enabled thanks to the different geometry of the two electrodes. The emitting electrode must have a high electric field in its surroundings to ionize the air, which is achieved by employing physically small conductive objects as emitters. These should possess regions with a small curvature radius where intense electric field gradients can develop, therefore overcoming the breakdown electric field for air and generating ions. Notable examples include wires with a diameter in the range of tens of micrometers, pins, blades, or sawtooth-shaped electrodes. The collecting electrode should instead inhibit ionization in its surrounding region, which is typically obtained using larger objects as collectors, such as plates [4], large diameter cylinders [5] or metallic airfoils [6]. What is necessary for an efficient ion thruster is the asymmetry of the electric field between the electrodes, which may also be achieved employing the same physical objects for emitters and collectors but in a different spatial density and therefore employing the shielding effect, thus enabling the concept of grid collectors, which may employ the same wires as the emitting electrode. As a result of a recent study that demonstrated the great performance advantages of wire grids as a replacement for classical airfoil-shaped ion collectors, previously established as the canonical geometry for atmospheric ion thrusters, comprehensive test campaigns were carried out with the aim of finding configurations that would further improve their performance in terms of thrust density and thrust-to-power ratio, the two main parameters that characterize the performance of an EAD thruster [7], the first representing an index of compactness and the second one of efficiency. This endeavor has been promoted by the need of minimizing the thruster's drag coefficient, which severely limits the maximum operating velocity of an ion thruster [8], defined as the maximum velocity for which an ion thruster generates positive net thrust, a crucial parameter for any future practical application

of this technology, such as airships [9]. Two possible configurations are here presented to limit the aerodynamic drag generated by a single-level mesh grid collector. A first solution would be using a double level of collectors with the second row in the wake of the first one, therefore reducing the overall drag coefficient. This approach represents the electrical analogue as proof of concept for the final examined configuration, which involves the use of metal blade collectors, replacing the classical wires. This latest development aims to become the ideal solution for practical applications, given the construction and operational advantages paired with the performance improvements of the novel grid collectors, extended to higher velocities. The main geometrical parameter of interest is the grid density, which, for a single-level grid collectors corresponds to the aerodynamic blockage ratio of the grid itself. Previous studies have indicated that a minimum grid density is necessary for the thruster to function efficiently, after which a plateau for all main performance parameters is found, albeit with an increasing drag created by the collectors, which mainly hampers performance in non-zero velocity conditions. The effective grid density of double-level collectors was found to be the sum of its two constitutive levels, thereby allowing a lower blockage ratio and drag for the same grid density and performance, thus becoming promising for practical applications. Blade collectors would be a further aerodynamic improvement, as they substitute the cylindrical wires with ultra-thin metal strips. An overall three-fold thrust increase compared to the baseline configuration found in literature is possible with these types of collectors.

Theoretical aspects

In order to facilitate a direct comparison of the performance of the tested configurations with each other and with other types of thrusters, it is possible to introduce dimensionless coefficients, which remove the dependence of the results on the characteristic dimensions and test voltages. The following three coefficients, obtained in a parallel study currently in its publication process [10], will be utilized:

- Thrust density coefficient (C_{TA}).

$$C_{TA} = \frac{T\chi d}{A\epsilon_0 p V_c \Delta V} \tag{1}$$

- Thrust-to-power ratio coefficient (C_{TP}).

$$C_{TP} = \frac{9T\chi\mu_0 V_c}{8P_c p^2 d^2} \tag{2}$$

- Corona current coefficient (C_c)

$$C_c = \frac{I_c}{\frac{9}{8}\epsilon_0\mu_0\frac{V_c\Delta V}{d^3}} \tag{3}$$

In order to provide a description of the behavior of EAD grid thrusters, it is necessary to introduce parameters that are specific to these systems, related to the geometry of the configurations under consideration. In particular, since both the distance between the wires and their diameter may vary between tests, the grid density parameter ρ_c has been introduced, following the same definition as in [11]. For tests involving double-level collectors, the calculation of ρ_c is derived as the sum of the contributions of the individual grids ρ_{c1} and ρ_{c2}, which are separated by a distance h, regardless of the orientation of the wires at the two levels, such that:

$$\rho_c = \rho_{c1} + \rho_{c2} \tag{4}$$

Materials Research Proceedings 69 (2026) 638-643 https://doi.org/10.21741/9781644904251-113

It has to be pointed out that, in the case of the double-level configuration, the parameter ρ_c defined above has a strictly electrical significance and does not reflect the total blockage ratio of the two collector grids. Previous experimental campaigns have demonstrated that ρ_e and ρ_c are the geometric parameters that most influence the performance of grid ion thrusters. The subsequent results will present the evolution of the dimensionless performance parameters of the thruster as ρ_e and ρ_c vary. For blade collectors the mesh density parameter is again equivalent to the blockage ratio, such that:

$$\rho_c = \frac{t}{s_b} \tag{5}$$

Where t is the blades thickness, here fixed at 0.1 mm and S_b is the spacing between the parallel blades.

Experimental setup

Different custom setups have been designed and built to accommodate the three different configurations (Fig. 1 shows the double-level collectors setup as an example) to be compared in this work, all retaining the same Power Supply Unit (PSU) and nominal geometrical parameters such as frontal area and inter-electrodes gap d (defined as the distance between the emitters plane and the closest point of the collectors, thus being applicable for all configurations). The setup is then mounted on a high precision scale to read the thrust produced T, obtained subtracting the different loads on the balance with the thruster powered on and off. At the same time the corona voltage V_c and corona current I_c are acquired through a voltage divider in parallel with the thruster and a shunt resistor in series with the collector on the ground return path respectively. More details about the setup may be found in [11], which shares the same equipment and measurement techniques.

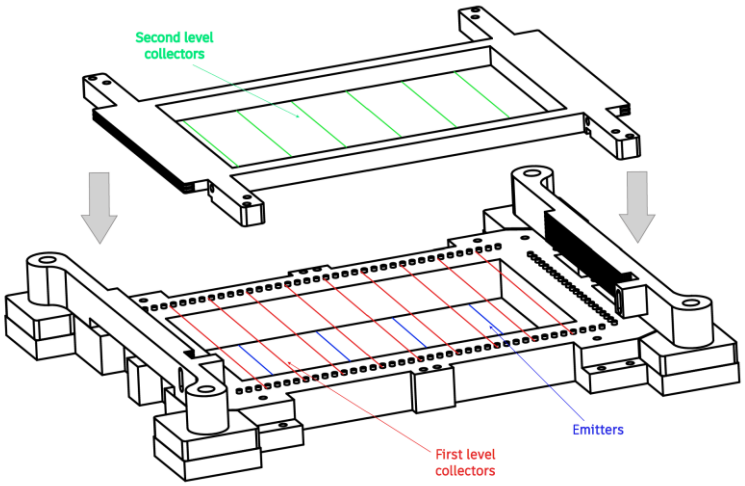

Figure 1: Double-level collectors setup.

Results

In this section the three configurations, namely the original grid collector thruster and the two novel configurations here presented (double-level grid collectors and blade collectors) are compared employing the different performance coefficients at varying grid density levels (ρ_c, defined specifically for each configuration). All the configurations show the typical behavior of mesh grid thrusters, showing a low performance and high power consumption at low grid densities and then improving and finally reaching a plateau at higher grid densities, representing the region where the thruster works as intended with no reverse corona forming, ionization happening

Materials Research Proceedings 69 (2026) 638-643 https://doi.org/10.21741/9781644904251-113

exclusively at the emitters and the collectors functioning as an equipotential plate. The generated thrust actually decreases at very high mesh densities due to the increasing aerodynamic drag generated by the increasingly more numerous collectors. The regression line of all the points inside the plateau of a given configuration are representative of the drag coefficient of that configuration, with the double-level collectors (especially when the second level is exactly in the wake of the first one) and the blade collectors showing a lower drag coefficient compared to the original single-level grid thruster, thus being better suited for high-velocity applications, while retaining the same or even slightly superior static performance. In particular, Fig. 2 shows how the thrust coefficient varies for the different configurations, comparing the novel geometries at different distances h for the double-level collectors setup and different blade chords c for the blade collectors with the classic single-level grid collector design found in [11], displayed at varying emitter densities ρ_e. It has been confirmed that all configurations require a minimum mesh density in order to achieve optimum performance levels, this being confirmed also for the other performance indicators, as in Fig. 3 for the thrust-to-power coefficient and in Fig. 4 for the corona current coefficient, reiterating the presence of adverse reverse corona effects at insufficient grid densities. Outliers in the double-level collectors setup are relative to configurations with increasing drag, i.e. when the second level does not lie in the wake of the first one.

Keywords: Hybrid-Electric Aircraft, Sustainable Propulsion Systems, Energy Management, Mission Simulation

Abstract. In response to the aviation sector's decarbonization goals, particularly the European Union's 2050 net-zero target, this study proposes an advanced hybrid-electric propulsion system for regional aircraft integrating four energy sources to enhance energy efficiency and environmental sustainability. Building upon a prior three-source model comprising a gas turbine, a hydrogen fuel cell, and one lithium-ion battery, this work introduces a second battery to create a four-source Serial-Parallel-Partial Hybrid (SPPH) architecture. The powertrain includes two 2,550 kW gas turbines (specific fuel consumption: 0.213 kg/kWh during cruise), two 1,500 kW hydrogen fuel cells (55% peak efficiency), and two lithium-ion batteries: a power-oriented 100 kWh unit (C-rate: 2 h^{-1}, 96% efficiency) designed for transient power demands, and a 300 kWh energy-optimized unit (C-rate: 0.33 h^{-1}, 96% efficiency) intended for steady operating phases such as cruise. A throttle-based control algorithm dynamically allocates power among the different energy sources according to mission requirements, ensuring optimal energy management and thermal balance. Simulations of regional aircraft missions demonstrate the advantages of the proposed configuration compared with its three-source predecessor. The dual-battery system enables targeted energy deployment: the high-power battery supports takeoff and climb phases, while the energy-oriented battery sustains cruise operations, reducing gas turbine and fuel cell loads during transient conditions. This results in lower fuel consumption, reduced thermal peaks, and extended component lifetime. Furthermore, the architecture improves redundancy, fault tolerance, and overall system resilience. Environmental benefits include reduced CO_2 and NO_x emissions enabled by the integration of hydrogen fuel cells and the strategic reduction of gas turbine utilization. Compatibility with renewable energy sources for battery charging and hydrogen production further strengthens the sustainability potential of the proposed system. The four-source hybrid-electric architecture therefore represents a promising pathway toward cleaner regional aviation, offering enhanced efficiency, operational flexibility, and improved integration with future green energy infrastructures.

Introduction

The aviation industry is under increasing pressure to reduce its environmental impact, especially with the European Union's aim of achieving net-zero CO_2 emissions by 2050 [1, 2]. Achieving this aim will necessitate the innovation and implementation of new propulsion technologies. An hybrid-electric aircraft architecture integrates conventional gas turbine engines with one or more electrical power sources, such as batteries, fuel cells, allowing for flexible distribution of energy according to De Vries et al. [3]. Such architectures aim to reduce emissions, and enable the use of renewable energy vectors. Recent studies have explored hybrid-electric configurations ranging from various topologies, demonstrating the potential for energy savings and emission reductions across regional and short-haul aircraft missions, as highlighted by Yuanyuan Li et al. and Nasoulis et al. [4, 5]. However, most state-of-the-art systems focus on single battery packs, which limits possible mission strategies. The present work extends the tri-source architecture proposed by

Materials Research Proceedings 69 (2026) 644-649 https://doi.org/10.21741/9781644904251-114

Grazioso et al. [6], which couples fuel cells and batteries with conventional thermal engines, by adding an additional battery element as a fourth energy source. Among the various possible architectural combinations, one was chosen that allows for independent management of individual battery packs, ensuring more efficient energy distribution during all phases of flight and supporting sustainable regional aviati on missions.

Generalizing hybrid-electric powerplant system

The tri-source architecture discussed in [6], which includes only one battery element, has inherent limitations. When batteries of different types are used, this configuration cannot manage them effectively, making it necessary to adopt the four-source architecture. The powertrain model is characterized by gas turbine engines, fuel cell systems and two separate battery elements [7]. One objective of such a system could be to ensure independent control of two different battery packs, such as a power-sized battery and an energy-sized battery. The hybrid electric architecture in

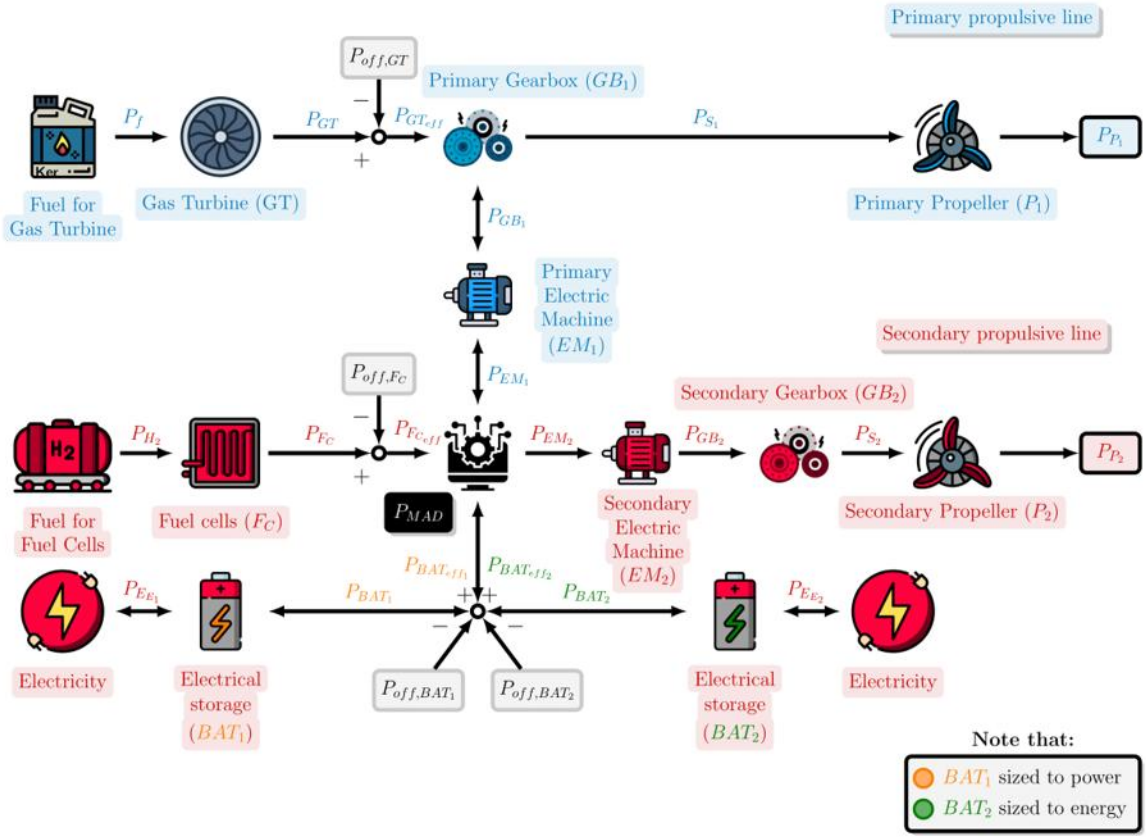

Figure 1 supports multiple operating modes, shown by double arrowheads indicating electric machines that can act as generators or motors, and batteries that can charge or discharge.

Case study: regional transport aircraft

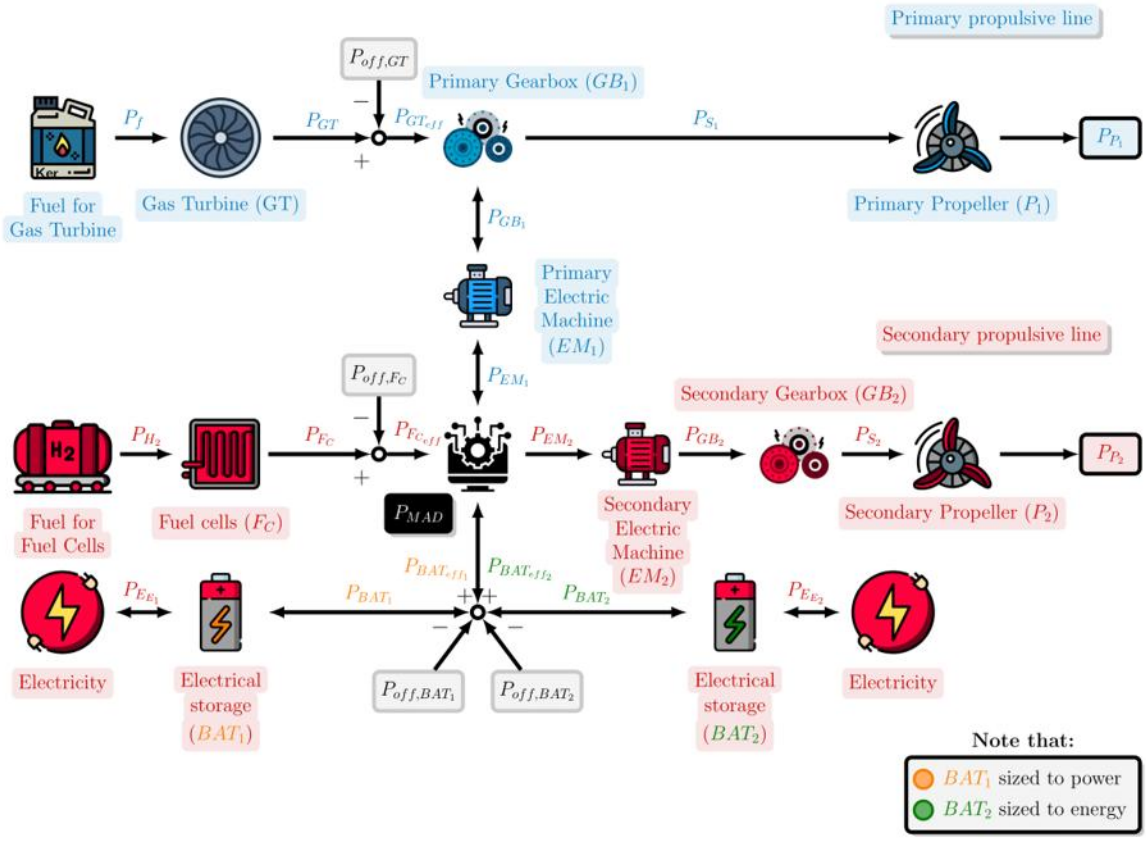

Figure 1: Logic diagram of the four source hybrid-electric architecture (SPPH configuration).

The proposed regional transport aircraft is designed to carry 80 passengers (at an average weight of 110 kg each) over a range of 600 nmi. Both takeoff and landing field lengths are approximately

Materials Research Proceedings 69 (2026) 644-649 https://doi.org/10.21741/9781644904251-114

1,400 m. The aircraft is expected to cruise at 300 KTAS at FL250 and achieve a climb from FL150 to FL250 in 20 minutes at maximum takeoff mass. Fuel reserves are sized to cover a 100 nmi diversion, 30 minutes of holding, and 5 % additional trip fuel. The minimum and maximum state of the charge are set respectively to 20% and 80% for both battery packs in order to preserve the element life cycle.

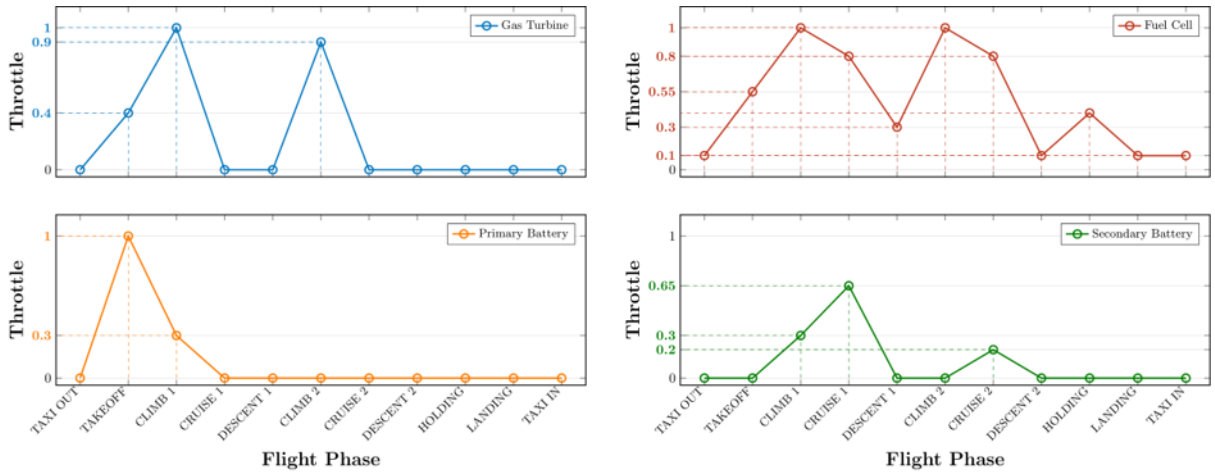

Figure 2: Powerplant throttles settings for the selected mission profile.

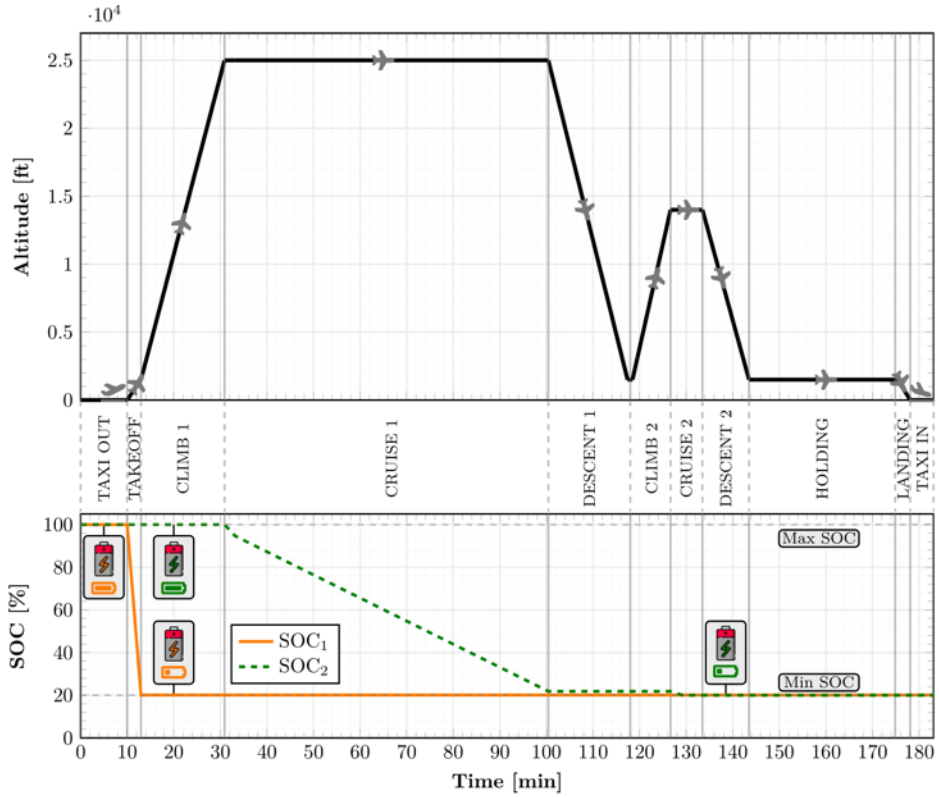

Figure 3: Mission profile and state of charge. Phases number 1 indicates block, instead number 2 stands for diversion.

The four-sources model uses an architecture inspired by the more general serial parallel partial hybrid (SPPH), regulated by energy flow equations and a throttle-based power management algorithm to dynamically respond to mission power requirements. The high- power battery (primary battery), characterized by a high discharge rate (c-rate) and lower capacity, is mainly

Materials Research Proceedings 69 (2026) 644-649 https://doi.org/10.21741/9781644904251-114

depleted during the takeoff phase, when the peak power demand is at its highest. In contrast, the energy-optimized battery (secondary battery), with higher capacity and lower discharge rate, supports power delivery throughout the cruise phase of the mission, when a constant and continuous power supply is essential. The targeted use of each battery based on its functional strength improves the overall energy handling of the powertrain.

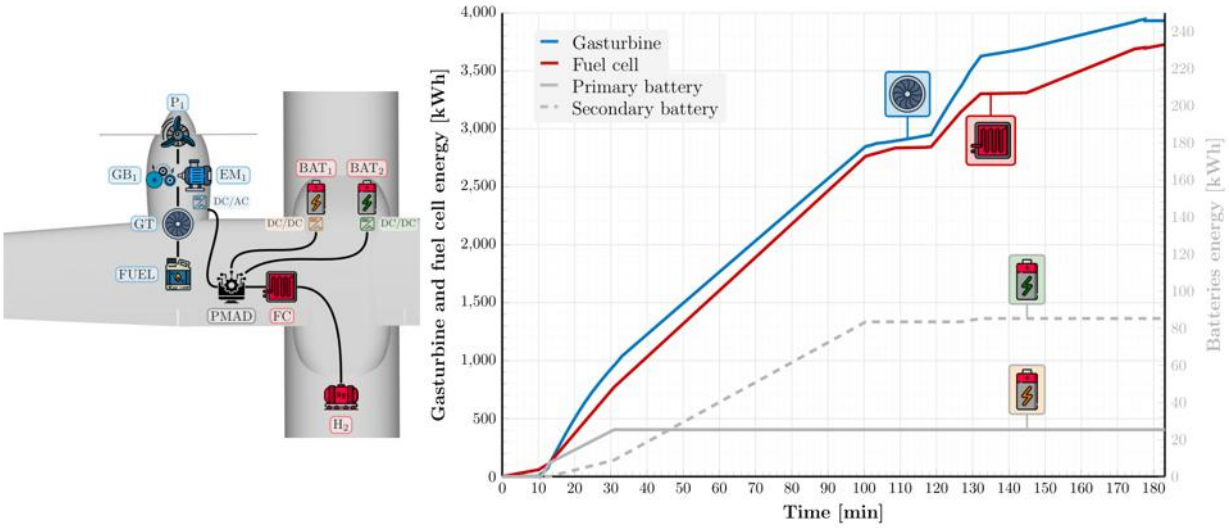

Figure 4: Actual hybrid aircraft configuration integrating four power sources (left), and the corresponding energy profile for each source throughout the mission (right).

Table 2: Mission range 600 nmi.

	Mission analysis results	Units
Block Kerosene fuel	637.36	[kg]
Block H_2 fuel	188.59	[kg]
Final primary battery SOC	20	[%]
Final secondary battery SOC	20	[%]
Block time	125.15	[min]

Table 3: Advantages and shortcomings of chosen hybrid powerplant architecture.

	Description
Advantages	Greater operational flexibility
	Reduced dependence on turbine and fuel cell during transient phases, leading to lower fuel consumption and smoother power delivery.
	Use of smaller, specific batteries minimizes energy waste compared to a single oversized pack.
Shortcomings	Increased system weight.
	More complex architecture in terms of control, maintenance, integration, and cooling.
	Hydrogen production and storage may still be associated with certain emissions.

Abstract. This work presents the development and implementation of a fully automated flight testing methodology for the SwitchMaster, a Distributed Electric Propulsion (DEP) demonstrator designed to investigate aero-propulsive coupling effects. Previous manual flight campaigns were limited by variability in trim conditions and inconsistent excitation inputs, constraining both data quality and the range of blowing conditions achievable in flight. The proposed framework integrates mission design, nonlinear Simulink simulation, Software-in-the-Loop validation and autonomous flight through the onboard PX4 autopilot, forming a coherent and reusable flight test suite. A total of 38 autonomous missions and 141 maneuvers were conducted across an expanded envelope of airspeeds and climb angles, enabling exploration of blowing regimes previously inaccessible. Automated trim acquisition and maneuver execution significantly improved repeatability and reduced variability in key stability and control derivatives, yielding clearer trends with the propeller advance ratio J and enhancing subsequent model-identification fidelity. The methodology provides a robust foundation for future DEP research, control-law development and aero-propulsive modelling.

Introduction

Distributed Electric Propulsion (DEP) represents one of the most promising technological pathways for future sustainable aviation. By distributing multiple propellers along the wing, DEP enables aero-propulsive coupling effects that can enhance lift, modify stability characteristics and introduce new opportunities for vehicle control. The SwitchMaster demonstrator (Fig. 1), a scaled aircraft equipped with six wing-mounted electric motors, was developed within this broader research effort to experimentally investigate these phenomena. Previous work focused on establishing the AeroSwitch [1] concept and on developing modeling strategies capable of capturing the influence of the propeller advance ratio J on aerodynamic derivatives [2]. These studies demonstrated the potential of DEP architectures but also highlighted the need for more refined flight data to support accurate model identification.

In this context, the present contribution describes the transition from manual to automated flight testing, providing the methodological foundations required to acquire consistent, repeatable and high-quality flight data, widening the spectrum of the conditions to be tested with respect to previous campaigns. The development of an autopilot, based on a Total Energy Control System [3], and the associated control logic is addressed in a complementary article [4], while another contribution focuses on advanced modeling and identification techniques [5]. Here, attention is devoted to the experimental framework that supports those efforts, with particular emphasis on trim stabilization, maneuver execution and the resulting improvements in data fidelity.

Figure 1: The SwitchMaster before a test flight.

Limitations of manual Flight Testing

Initial test campaigns relied on a remote pilot to perform trim and excitation maneuvers [6]. Although adequate for preliminary qualitative analyses, manual piloting introduced intrinsic variability that limited the reliability of the collected data. Achieving a stable trim condition requires finely balancing airspeed, climb angle and control surface deflections, a task that proved difficult to perform consistently across multiple repetitions. Even small deviations in the steady-state flight condition resulted in significantly different levels of propeller blowing and, consequently, different values of the aerodynamic coefficients at the start of each maneuver.

Similarly, manual execution of elevator, aileron or rudder doublets and 3-2-1-1 inputs leads to variations in amplitude, timing and input shape, reducing the effectiveness of the excitation and making it challenging to isolate specific dynamic modes such as the short-period and Dutch-roll.

Moreover, high-blowing conditions typically require trimming the aircraft in steep climbs, a regime that was difficult to maintain manually with sufficient precision. These limitations motivated the development of a fully automated testing system, capable of reproducible trim settings and consistent maneuver execution across the entire test matrix.

Automated Flight Test Framework

To address these challenges, a complete automated testing framework was developed, integrating mission planning, autonomous flight control and maneuver execution into a unified methodology. A nonlinear simulator built in MATLAB/Simulink, incorporating flight dynamics, aerodynamics and autopilot logic, served as the foundational tool for mission design. This simulator allowed the prediction of trim points across a wide range of airspeeds and climb angles, ensuring that each combination corresponded to a feasible steady-state flight condition.

Onboard, the aircraft relied on a customized autopilot system capable of reaching and maintaining precise trim values of airspeed and climb angle. Once stabilized, the controller executed predefined excitation maneuvers while following programmed flight paths. Only the essential aspects of this control architecture are recalled here, as the detailed implementation is discussed separately; the focus of this article remains on its role within the experimental process. Importantly, automation allowed not only superior data quality but also access to flight regimes previously unreachable.

Flight Test Planning and Mission Design

Mission profiles were designed to span the entire range of propeller advance ratio J relevant for the aero-propulsive characterization of the SwitchMaster. For each airspeed setpoint, several climb

Materials Research Proceedings 69 (2026) 650-655 https://doi.org/10.21741/9781644904251-115

and descent angles were selected to vary blowing intensity while remaining within the limits of the aircraft performance and battery endurance. The simulator was used to calculate the expected mission duration, the time required to reach trim conditions and the geometry of the flight path, including straight segments and turns. Fig. 2 illustrates a representative mission profile generated during simulation.

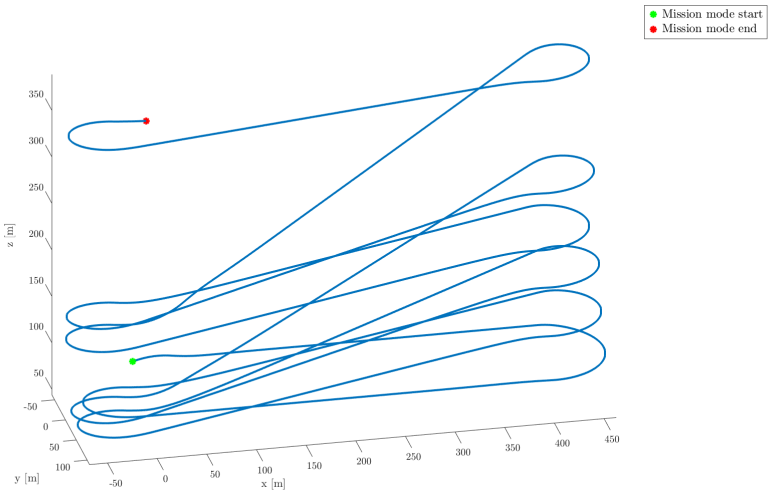

Figure 2: Example of a simulated mission.

This approach ensured that each mission could be completed safely, with sufficient energy margins for contingencies. The resulting mission plans were translated into MAVLink-compatible files and uploaded directly to the aircraft, enabling fully autonomous execution without the need for manual intervention (except for takeoff and landing).

Automated maneuver execution and environment

Once the aircraft reached the prescribed trim state, the system evaluated the tolerances on airspeed and climb angle before triggering the selected maneuver. The maneuvers included elevator doublets, ailerons and rudder doublets, 3-2-1-1 sequences and combined inputs. Each excitation was parameterized to deliver consistent spectral content close to the natural frequencies of the relevant dynamic modes.

The execution took place at the Mach Aurora airfield, east of Milan, where the flight path was designed to account for nearby obstacles and geometric constraints. During each maneuver, the autopilot temporarily suspended TECS and other modules regulation, applied the commanded input and then allowed the aircraft to settle, ensuring clear observation of both forced and free responses. Fig. 3 shows a typical elevator doublet executed during a stabilized descent.

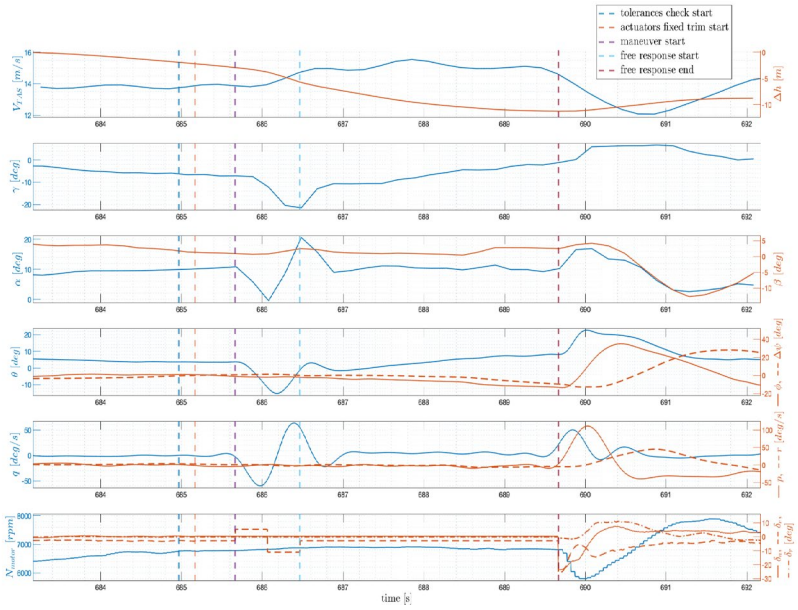

Figure 3: Elevator doublet time histories during stabilized descent.

The improvement in input precision achieved through automation is evident when comparing automated and manual doublets. Fig. 4 illustrates this contrast, highlighting the superior repeatability and stability obtained through autonomous maneuver execution.

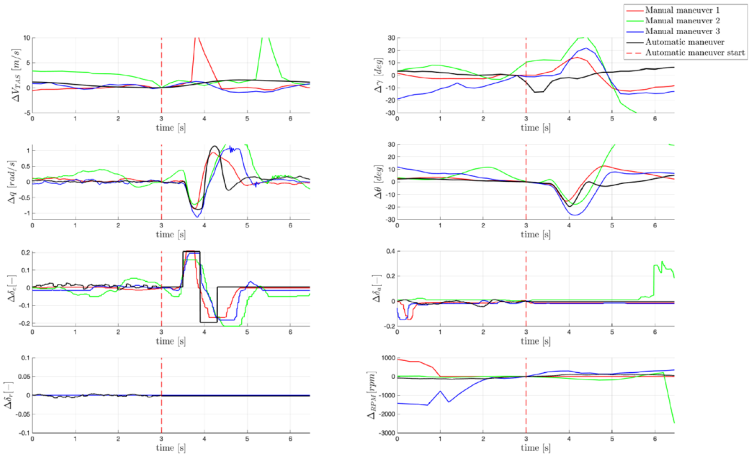

Figure 4: Comparison between manual and automated elevator doublets.

Beyond enabling automated trim acquisition and maneuver execution, the methodology developed in this work effectively constitutes a coherent and reusable flight testing suite specifically tailored for DEP aerodynamic and aero-propulsive investigations. The suite integrates all stages of the experimental workflow into a unified process, ensuring continuity between mission design, simulation and real-flight execution. Mission profiles are first generated and analyzed within a nonlinear MATLAB/Simulink environment, where the complete aeromechanical model of the SwitchMaster and the high-level autopilot logic are used to predict trim feasibility, expected values of the advance ratio J, maneuver windows and total mission duration. The same missions are then replicated in a Software-in-the-Loop environment based on Gazebo, enabling verification of the flight path, software testing and safety protections within a physics-based simulation prior to deployment.

Once validated, the mission and software build is transferred unchanged to the real aircraft and executed by the onboard PX4 autopilot, ensuring full traceability between predicted and observed

aircraft behavior. This integrated workflow provides a robust methodological backbone for conducting systematic DEP flight test campaigns and ensures that variations observed in aerodynamic coefficients derive from physical effects rather than inconsistencies in piloting or test execution.

Safety Checks

Following an accident during a test flight [7], the safety architecture of the system was substantially reinforced. Prior to each maneuver, the autopilot verified that the computed control surface offsets required to maintain trim remained within acceptable bounds. If the aileron or rudder offsets exceeded these thresholds, the maneuver was not initiated, even if all other conditions were satisfied.

During maneuvers, additional protections monitored attitude limits, aborting the excitation if excessive roll or pitch angles were reached. In addition, there were checks on altitude, airspeed, vertical speed and horizontal limits, plus a manual switch for the pilot to interrupt a maneuver and possibly regain manual control. These safeguards contributed to the integrity of the test campaign, ensuring both the safety of the vehicle and the consistency of the logged dataset.

Flight test campaign and data acquisition strategy

The final campaign included the setpoints listed in Table 1, covering airspeeds between approximately 12 m/s and 20 m/s and climb angles from about −15° to +40°. This structure enabled the acquisition of data in conditions of descent, level flight, moderate climb and steep climb, the latter being particularly valuable for exploring strong blowing conditions.

Table 1: Tested flight conditions.

Airspeed setpoint [m/s]	Angle of Climb setpoint [deg]
20, 18	40, 30, 20
16, 14	10, 0, -5
13, 12	-10, -15, glide

Between February and June 2025, a total of 38 autonomous missions were executed, yielding 141 valid maneuvers. These included elevator doublets, 3-2-1-1 sequences and combined ailerons and rudder doublets, each initiated from a stable trim condition. The avionics suite, comprising PX4 inertial sensors, GPS, Pitot probe, telemetry and RC link, provided comprehensive logging of all variables required for model identification.

All logs were stored in *.ulg* files for offline processing. The consistency of the trim states and the precision of the maneuver execution rapidly became evident when comparing automated data with that obtained during earlier manual tests.

Results and impact on model identification

The transition to automated testing produced a clear and quantifiable improvement in the quality of the recorded data. Time histories of doublets and 3-2-1-1 inputs exhibited sharply defined input profiles with uniform amplitude and timing. The stabilization preceding each maneuver was markedly more precise, resulting in consistent initial conditions even across different days and environmental conditions.

These enhancements translated directly into improvements in system identification. The reduced variability in the experimental data led to tighter clustering of aerodynamic derivatives, clearer trends with the propeller advance ratio J and more reliable application of both Equation-Error and Output-Error methods. Particularly, coefficients such as C_{m0} and selected lateral-directional derivatives displayed smoother and more physically interpretable behaviors, reinforcing the validity of the underlying modelling assumptions. The automated framework thus

proved essential for obtaining the fidelity required to advance the aero-propulsive modelling of DEP configurations.

Conclusions

The automated flight testing methodology presented in this work represents a significant advancement in the experimental analysis of DEP aircrafts. By eliminating the variability inherent in manual piloting and enabling consistent execution of trim and excitation maneuvers, the framework provides a robust foundation for accurate model identification.

Together with ongoing developments in modelling and control, the results obtained from this campaign contribute to a broader effort aimed at understanding and exploiting the unique characteristics of Distributed Electric Propulsion. Future work will extend this methodology to expanded flight envelopes, advanced control strategies and more refined modelling approaches, further strengthening the experimental basis for DEP technologies.

Keywords: Distributed Electric Propulsion, Flight Control System, Automated Flight Testing, Model Identification

Abstract. The scope of this work is the realization of a fully automated testing campaign, through the development of an autonomous Flight Control System (FCS), in order to support the model identification of a Distributed Electric Propulsion (DEP) scaled demonstrator. The autopilot has been used to follow a GPS trajectory, reach trim conditions, execute the required maneuvers, define and tune specific control actions and carry out automatic safety checks. The chosen software environment is PX4, an open-source professional autopilot, which has been extended and customized to carry out the flight operations needed for parametric identification, while fulfilling functional and safety-related requirements. In addition, a simulation environment has been set up for software testing and pre-flight configuration. The result is a fully automated platform for flight testing and advanced research within DEP models.

Introduction

In earlier works [1], a parametric model identification of a DEP flying model, the SwitchMaster, was carried out, leading to a numerical definition of its stability and control derivatives. Besides, it was observed how the blowing effect on the wings impacts several derivatives, which in particular can have an exponential growth as the blowing intensifies, due to the aero-propulsive coupling generated by the faster air flow on the wings with respect to that along the fuselage. The blowing can be quantified in terms of propellers advance ratio $J = \frac{V}{nD}$, where V is the true airspeed, n is the propellers rotational speed and D the propellers diameter. In fact low J values, that can be achieved at low airspeed and high propellers rotational speed, correspond to high blowing, and vice versa. The unblown case, defined as $J \to +\infty$, can be obtained by gliding. However, the main limitation of this work was the difficulty to have good trim conditions and a precise execution of the maneuvers, especially at high climb angles which are required to experiment high blowing, mainly due to the manual remote piloting. Hence, it was necessary to develop an autopilot to support the realization of a fully automated testing campaign and then improve the quality of the data collected to feed the model identification process, leading to a more realistic estimated DEP model.

System Requirements Analysis

Following a standard software engineering procedure, it was started defining the Goals of the System and the Domain Assumptions, which are hypotheses assumed to hold about the environment and the user's behavior. With this procedure, the System Requirements can be defined, being essentially conditions that the System must satisfy to reach the Goals, assuming true the Domain Assumptions. The main Goal can be expressed as follows:

Content from this work may be used under the terms of the Creative Commons Attribution 3.0 license. Any further distribution of this work must maintain attribution to the author(s) and the title of the work, journal citation and DOI. Published under license by Materials Research Forum LLC.

Materials Research Proceedings 69 (2026) 656-661 https://doi.org/10.21741/9781644904251-116

The System must be able to reach trim conditions at any feasible combination of J and α, holding V_{TAS} and γ setpoints while following a GPS flight plan, then executing safely and autonomously all the needed maneuvers for parametric identification.

Hence, here are provided some examples of the Requirements that had to be satisfied, which led to significant changes and extensions of PX4:

1. The System must be able to execute climb and descent, following a climb angle γ setpoint defined by the User. The level flight should be treated as a particular case with $\gamma = 0$ deg.
2. Multiple circuits could be executed in automatic flight, following a GPS flight plan, and along each straight leg of the circuit one climb angle has to be scheduled.
3. After each climb or descent, the aircraft smoothly stabilizes at a given altitude, defined in the loaded flight plan. If that altitude cannot be reached within the given leg length, then it proceeds following the next waypoint, loitering to the final altitude if needed.
4. A Glide Mode has to be available, as a special case of descent, in which the aircraft keeps the motors at zero power and follows only a V_{TAS} setpoint, thus ignoring γ.
5. During each leg of the circuit, the System must be able to check whether trim conditions have been reached and maintained for a minimum time, then executes the scheduled maneuver automatically. During the whole maneuver duration, the autopilot must remain disengaged, as the control system should operate in open-loop. In addition, the control surfaces not involved in the excitation input at a certain time, must remain locked at a fixed computed trim value. However, the correction of the bank angle by the autopilot during longitudinal maneuvers could be tolerated in certain cases. When it is done, including the required free response time, the autopilot regains control and continues with the flight plan.
6. The System must provide a wide list of maneuvers, basically doublets and 3-2-1-1 involving all the control surfaces (elevator, ailerons and rudder), selectable from the ground station parameters menu. Each maneuver must be configurable at runtime, to comply with the parametric identification process and follow the flight campaign planning.
7. There must be automatic controls to abort an ongoing maneuver, or to prevent its beginning, whenever anomalous conditions are sensed in flight, like low airspeed and altitude, critical attitude and others. The maneuvers must also be interrupted when the aircraft is near to the altitude setpoint or to the next GPS waypoint. In addition, at any time the Test Pilot must be able to interrupt a maneuver and possibly regain manual control. The Glide Mode should be subjected to similar safety checks.

As a result of the requirements analysis, many functionalities have been progressively developed: Gamma Mode, Glide Mode, Trim conditions evaluation, Maneuver launch and execution, Maneuver aborting, Safety features, Control surfaces trim computation, Maneuver testing on the ground, TECS Stand-by Mode and Failure injection.

Control System Development

PX4 Autopilot consists of two main layers: the Flight Stack is an estimation and flight control system layer, while the Middleware is a general robotics layer that can support any type of autonomous robot, providing internal/external communication and hardware integration [2]. The Flight Stack is composed of many modules. The most important ones are Commander, Navigator, Position Control, Attitude Controller and Control Allocator, which are also shared by almost any airframe. For the fixed-wing configuration, there is also a Total Energy Control System (TECS), that is the core library of the PX4 Flight Stack.

Materials Research Proceedings 69 (2026) 656-661 https://doi.org/10.21741/9781644904251-116

In order to implement the above functionalities, three major PX4 modules were modified: Position Control, TECS and Control Allocator. The newly introduced Position Control sends to the TECS the altitude, climb rate and true airspeed setpoints, plus a message for Glide Mode triggering, along with many other flight data and information. The climb rate setpoint, when present, is derived from the scheduled γ_{sp}, by the simple relation: $\dot{h}_{sp} = V_{TAS}^{sp}\, sin(\gamma_{sp})$.

The Position Control can also start and abort the maneuvers, when needed, using a dedicated message. The main output of the TECS is the couple thrust setpoint T_{sp} in percentage and pitch angle setpoint θ_{sp}, in radians. Then, the Attitude Controller, which has not been modified, transforms the Euler Angles setpoint into an angular acceleration setpoint vector, in body frame, while leaving the thrust setpoint as it is. A standard geometrical turn coordination algorithm is also exploited, to compute the optimal yaw rate setpoint from the roll and pitch angles. Finally, the Control Allocator takes in input the angular acceleration vector and thrust setpoints and applies the Allocation Algorithm, to compute the actuator input values normalized between -1 and 1 (0 and 1 for the motors). These, are then converted by a driver into PWM signals for the servos and UAVCAN values to be sent to the Electronic Speed Controllers.

For the development of the control system to be used in the testing campaign, it was decided not to completely replace the existing TECS [2], but to extend it and make it able to support the requirements and the introduced functionalities. This, mainly due to compatibility and integration with the existing software reasons, which lead to several advantages in terms of reliability and effectiveness of the new system. The general functioning of the Total Energy Control System is described in various other works [3], among which an earlier implementation in Simulink used for the definition of an automated testing campaign within the SwitchMaster project [4, 5]. The specific original PX4 implementation can be found in the related documentation [6]. In this work, it is described the development of an Extended TECS, realized by adding to the original multiple new inner states.

As described by the finite state automaton in Fig. 1, from Normal Mode the TECS can go to Glide Mode by reading a specific message, coming from the Position Control, as long as the climb rate setpoint does not exist. In this mode, the throttle setpoint is zero and the energy weights are set to give maximum priority to the Kinetic Energy Rate, while the Potential Energy Rate is ignored. This, because during a glide only the V_{TAS} setpoint should be followed, acting on the pitch output, whereas the vertical speed at trim conditions is dependent on the speed.

Climb and Sink Modes are activated when exists an altitude rate setpoint positive or negative, respectively, coming from Position Control. They are the two states supporting the Gamma Mode, with the level flight, namely $\gamma = 0°$, included into the climb case. An altitude margin h_m is derived from the climb rate setpoint and a fixed time margin t_m, and corresponds to the Δh where the TECS starts reducing the climb rate to stabilize at the final altitude setpoint.

To achieve this, a gain k_h is computed as altitude error divided by altitude margin, then constrained between 0 and 1. Hence, when the distance in altitude to the setpoint goes below the margin (in climb coming from below the setpoint and vice versa), the gain starts decreasing from 1 to 0. Then, the nominal climb rate is reduced gradually, multiplying it by k_h, effectively stabilizing the aircraft near the altitude setpoint. The Stand-by Mode is an extra condition that can be activated in all the cases where a maneuver can be triggered, so in each of the previous modes but the Normal one, and allows to keep the TECS integrator states steady during the maneuvers, thus preventing saturation due to error increase caused by the disengaged control action.

Materials Research Proceedings 69 (2026) 656-661 https://doi.org/10.21741/9781644904251-116

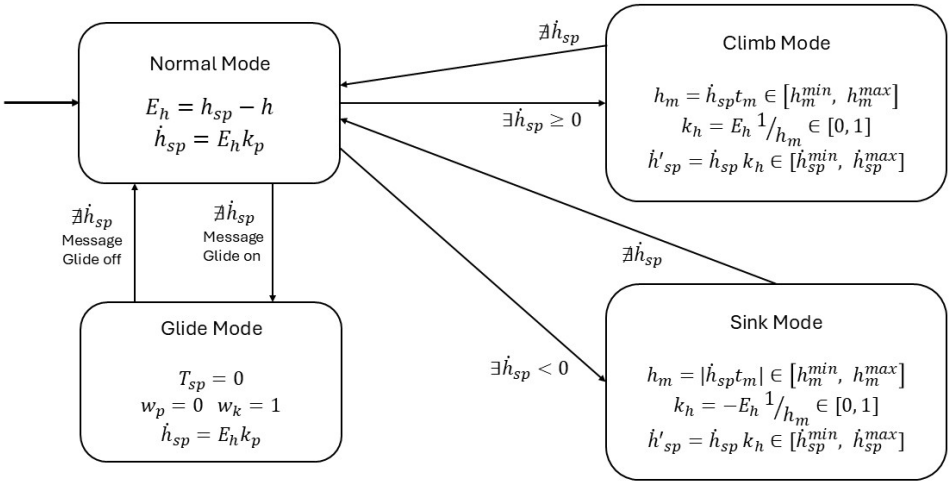

Figure 1: Simplified finite state automaton of the Extended TECS.

At each call of the main Position Control procedure, the system checks whether the distance between previous and next waypoint is greater or equal than a fixed minimum distance, defined as a parameter. Along with the distance, also the difference in altitude is evaluated: if the difference is positive, meaning that there is a climbing path between the waypoints, then it activates the Climb Mode, otherwise it goes towards the glide/sink branch, while the level path is included into the climb case. The Position Control scheduler then evaluates the current γ angle and computes the climb rate setpoint to be sent to the TECS. The case of $\gamma < 0$ (usually set to -1) is reserved for the triggering of the Glide Mode, whereas in each other case a positive angle is inserted as parameter in the system. In Normal Mode, the original PX4 algorithm is used, with altitude setpoints forming a linear trajectory between the aircraft and the next waypoint and the climb rate setpoint is computed by the TECS from the altitude error.

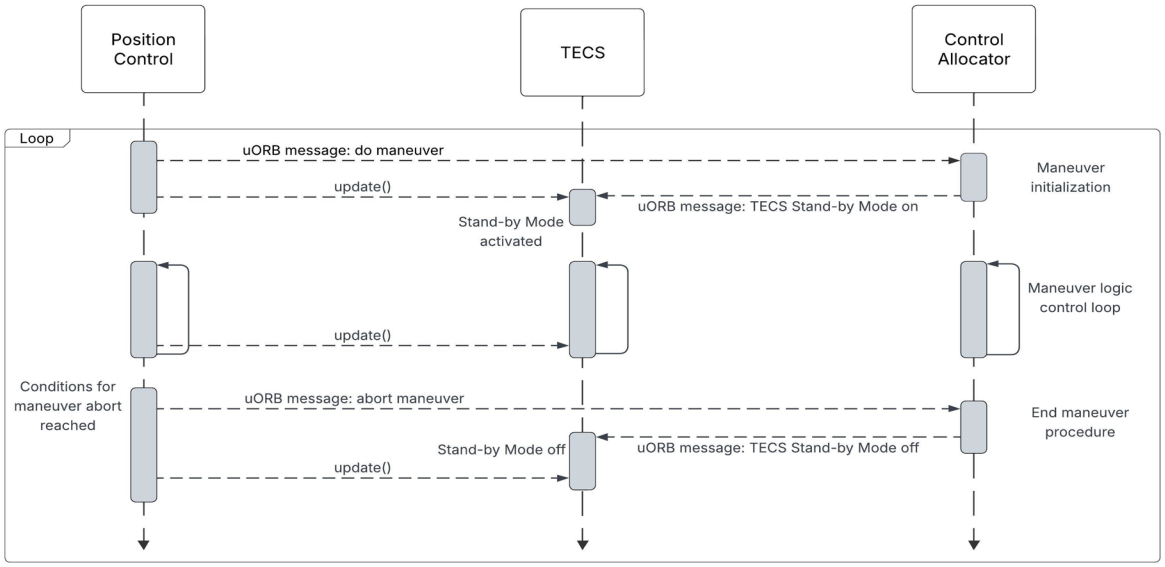

Figure 2: Sequence diagram describing the communication during a maneuver.

The other fundamental operations performed by the Position Control are trim conditions evaluation and safety checks. Regarding the trim evaluation, errors on γ and true airspeed with respect to the setpoint are continuously evaluated during the Climb and Sink modes, usually activated on the straight leg of the circuit [7], whereas in glide the only error considered is that on airspeed. Subsequently, as soon as the errors have been staying inside fixed thresholds for a

Materials Research Proceedings 69 (2026) 656-661 https://doi.org/10.21741/9781644904251-116

minimum user-defined time, the selected maneuver (such as an elevator doublet) is launched, by sending a specific message to the Control Allocator, as shown in Fig. 2. For what concerns the safety checks, they are similarly scheduled at each call of the Position Control procedure, as detailed in the next paragraph.

Finally, the modified procedures of the Control Allocator module are in charge of selecting and executing the commanded maneuver, configured by specific system parameters, through the manipulation of the actuator input values. In addition, a trim control value is computed for all the control surfaces and motors as a mean value of the sampled inputs immediately prior to the maneuver beginning and is used as a fixed offset to be maintained for the whole duration, including the final free response time. Hence, within this period of time the Control Allocator ignores all the inputs coming from the autopilot, realizing an open-loop behavior, plus initiates and ends the TECS Stand-by Mode, by sending a proper message. In this way, the maneuver execution is managed independently of the higher layer autopilot modules, which enables a responsibility decoupling and a safer logic. The sequence diagram in Fig. 2 describes the communication scheme among these modules throughout the maneuver execution.

Safety Features

Numerous automatic safety checks have been implemented and extended throughout the testing campaign, which in general do not require the pilot intervention and give control back to the autopilot, in case critical or upset conditions are sensed during the maneuvers or glide. The Position Control schedules these control procedures periodically, through the analysis of altitude, airspeed, sink rate, GPS position and attitude in real time. If a maneuver has to be aborted, the Position Control sends a message to the Control Allocator, which interrupts it in case it is still ongoing. The Control Allocator can also prevent the maneuver initiation in the case of out-of-bound ailerons or rudder trim computation. Lastly, the pilot can use two manual switches mapped on the remote control, one safety switch to override the maneuver logic and go back to automatic flight and a standard mode switch to activate the manual flight and immediately regain control, in which case the maneuvers and glide are always aborted.

Figure 3: The SwitchMaster demonstrator.

Conclusions and Future Developments

This work represents a remarkable advancement in the field of DEP advanced research and parametric model identification, since it has produced a complete platform for autonomous and safe flight testing of DEP demonstrators. The better quality of the trim conditions and executed maneuvers, made possible by the features implemented, allows an improved system identification process with respect to that performed with manual piloting [8]. The simulation and software testing subject, part of this project and as much important as the FCS development, will be dealt with in future publications, as it deserves a separate and exhaustive discussion.

In future developments, the whole FCS could be further extended with new functionalities and a more effective control action, starting from a better tuning of the TECS gains and the refinement of the control logic in glide, which in some cases showed poor performance.

In addition, a Total Heading Control System [9] is being evaluated to integrate the sideslip angle estimation into the yaw rate control logic of the Attitude Controller, in order to achieve a better turn coordination. Finally, the FCS should be generalized and adapted to models different from the DEP one, to obtain a portable platform which could support the automatic flight testing of other airframes, possibly also in general aviation. This could involve a change of the underlying software and hardware environment to become feasible.

Keywords: Hydrogen-Powered Aircraft, Airport Infrastructure

Abstract. This paper illustrates a general methodology aimed at coping with the need to preliminarily assess the feasibility, cost and performance of a future commercial aviation system based on hydrogen as the in-flight energy source. The methodology is devoted to the preliminary sizing of the complex airport infrastructure needed to service hydrogen-powered airliners, namely on-site generator and liquefier, storage tank, and dispensing units, providing an optimal solution in terms of acquisition and operating costs, and eventually hydrogen cost "at the pump". A sensitivity analysis shows how the system performs in off-design conditions, with the price of the various components needing to be shared by a smaller hydrogen production.

Introduction

A revolution in future civil aviation is currently being envisaged through the switching of the current jetliner fleet to hydrogen-powered aircraft, seeking a significant reduction of the environmental impact of commercial air transport. While the technology of hydrogen propulsive systems is currently undergoing research and initial development, making the implementation of suitable airframes reasonably likely in the next decades, another significant hurdle for the entry-into-service of such a fleet is posed by the need to provide the required quantity of hydrogen at airports. Therefore, a methodology to estimate the infrastructural needs is essential to support feasibility analysis and scenario studies towards the fleet switching from kerosene- to hydrogen-powered airliners. Similarly to what was accomplished for the preliminary sizing of a battery-recharging airport equipment[1], this paper introduces a methodology to preliminarily size an infrastructure devoted to the on-site production, storage and delivery of liquid hydrogen.

The sizing is based on an optimal procedure that, based on the flight scheduling at a given airport, computes the need for hydrogen generation, liquefaction, storage and just-in-time distribution to each aircraft, by minimizing the total cost of acquisition and operation of the hydrogen plant and thus of the fuel. Grid electricity cost day variations are considered, as well as other factors impacting costs and operations. The hydrogen needs for each aircraft model are computed by using a dedicated preliminary sizing methodology that allows substituting current aircraft models with performance-equivalent hydrogen-powered ones [2].The process not only delivers the overall sizing of the hydrogen generator, liquefier, cryogenic tank and of the set of dispensing units, but also provides the optimal time scheduling of hydrogen mass flows across the various components of the infrastructure.

A similar approach is shown in [3], which identifies that hydrogen can be delivered as a liquid or a gas to the airport, or produced on-site, with the last two instances requiring on-site liquefaction. After being stored as a liquid at the airports, the cryogenic fuel can be delivered via LH2 tank trucks or an airport pipeline infrastructure, with aircraft serviced by dispensing trucks.

The former is more flexible and economical for airports with annual demands below 125 kt of LH2. In contrast, the latter is economically viable for airports with higher demands, offering faster and safer refueling. The expected hydrogen price will be between 2.6 and 3.9 $/kgH2 for a 2050 time horizon, depending on the airport size and refueling layout. For a large airport, 69 % of the hydrogen cost at refueling is represented by the GH2 supply, followed by 25 % for the liquefaction. The remainder is represented by storage, dispenser and pipeline costs.

Besides the methodology description, presented in ch. 2, an example application and sensitivity studies referred to existing international airports with actual aircraft movements are discussed in ch. 3.

Methodology

The objective of the work presented here is to size the main elements of an airport hydrogen refueling facility in support to hydrogen-powered airliners. This allows to quantify the required electricity supply, with a view to the foreseen adoption of this fuel in place of jet-fuel for commercial aircraft operations. The developed methodology is called Airport Hydrogen Refueling Equipment Sizing (AHRES). The airport refueling station includes three main elements:

- The generator, consisting of an electrolyzer, a buffer tank, and a liquefier, where, starting from liquid water, hydrogen is obtained through an electrolysis process powered by electric energy from the grid or from a local renewable electricity plant; the gas is then cooled to cryogenic temperatures for storage in liquid form;
- The storage tank which accumulates the hydrogen produced earlier than it is required, e.g., during a time slot when electricity is cheaper, so that there is enough of it stored to refuel departing aircraft;
- Dispensing units that pump liquid hydrogen from the storage tank to the aircraft tank.

Details on the cost of the components implemented within AHRES can be found in *[4] [5]*.
The preliminary sizing of an airport's hydrogen refueling infrastructure, characterized by a large number of variables and parameters, is approached as an optimization problem. Thus, a cost function, representing the daily cost of the system as the sum of the costs of its components and cost of electricity and power, is defined. The cost function is minimized while all relevant constraints are satisfied. The constraints of the optimizer aim to ensure that the problem properly reflect real-world operations: maximum capacity of the ground and aircraft tanks is respected, there is enough availability of hydrogen and dispensing units for each departure, the electrolyzer is always running at least at its minimum production rate.

The solution of the problem, based on the daily schedule of the busiest day of operations at the selected airport, details the nominal production rate of the hydrogen generator and liquefier, the size of the cryogenic ground tank, the number of required dispensing units and the detailed refueling time history over the considered time frame. The selection of the busiest day ensures that the refueling system is properly sized for the traffic received at the airport. The ultimate output is the cost of 1 kg of hydrogen.

Results

Here results considering the Milan Malpensa short-haul flights are presented, as both the airport operator [6] and one of the main airlines [7] have shown particular interest in developing climate-neutral flight technologies. In particular, the busiest day of operations (Most Demanding Day – MDD) in 2022 showed 239 short-haul flights, all considered in the following analysis. Namely, two pricing models for electricity have been introduced, enabling the comparison of the sizing with a fixed electricity rate or with cheaper prices at night. Table 1 details the results. The main differences between the mono- and dual-rate electricity cost simulations are the operation and sizing of the hydrogen generator and the size of the tank. The overall daily costs to support the hydrogen production plant, including the cost of the components, the peak power, and the

Materials Research Proceedings 69 (2026) 662-665 https://doi.org/10.21741/9781644904251-117

electricity, increase by 7.7% going from a mono- to a dual-rate electricity cost. The lower electricity costs permitted by the dual-rate scenario (-4.9%) are outbalanced by an increased maximum power (+81.4%), generator (+85.3%), and tank (+125.6%) costs. The hydrogen cost increases by 7.3%, going from 4.104 €/kg to 4.405 €/kg.

Table 1: Comparison of the results for Milan Malpensa considering mono- and dual-rate

Indicator	Mono-rate	Dual-Rate	Change[%]
Cost function [€/day]	$1.70 \cdot 10^{+6}$	$1.83 \cdot 10^{+6}$	7.7
Consumed energy [kWh/day]	$2.57 \cdot 10^{+7}$	$2.58 \cdot 10^{+7}$	0.3
Electricity cost [€/day]	$1.45 \cdot 10^{+6}$	$1.38 \cdot 10^{+6}$	-4.9
Max. power [kW]	$1.07 \cdot 10^{+6}$	$1.94 \cdot 10^{+6}$	81.4
Power cost [€/day]	$8.94 \cdot 10^{+4}$	$1.62 \cdot 10^{+5}$	81.4
H2 production [kg/day]	$4.14 \cdot 10^{+5}$	$4.16 \cdot 10^{+5}$	0.3
GNR cost [€/day]	$1.42 \cdot 10^{+5}$	$2.63 \cdot 10^{+5}$	85.3
Max mass in ST [kg]	$1.14 \cdot 10^{+5}$	$2.58 \cdot 10^{+5}$	125.6
Boil-off mass [kg]	$1.14 \cdot 10^{+3}$	$2.58 \cdot 10^{+3}$	125.6
ST cost [€/day]	$6.26 \cdot 10^{+3}$	$1.41 \cdot 10^{+4}$	125.6
Number of DU [-]	9	9	–
DU cost [€/day]	$9.47 \cdot 10^{+3}$	$9.47 \cdot 10^{+3}$	0.0
Cost of 1 kg of LH2 [€/kg]	4.104	4.405	7.3

The lowest obtained hydrogen pricing (4.10 €/kg for the Malpensa mono-rate scenario) is in line with the information presented by McKinsey in their 2021 Hydrogen Insight Report [8], which shows the price of 1 kg of green hydrogen in the range of 3.5-4.8 $/kg (3.2-4.3 €/kg) for 2023. The cost of energy is also coherent across the two models, with ours considering 0.0565 €/kWh and [8] a range of 25-73 $/MWh (0.023-0.067 €/kWh).

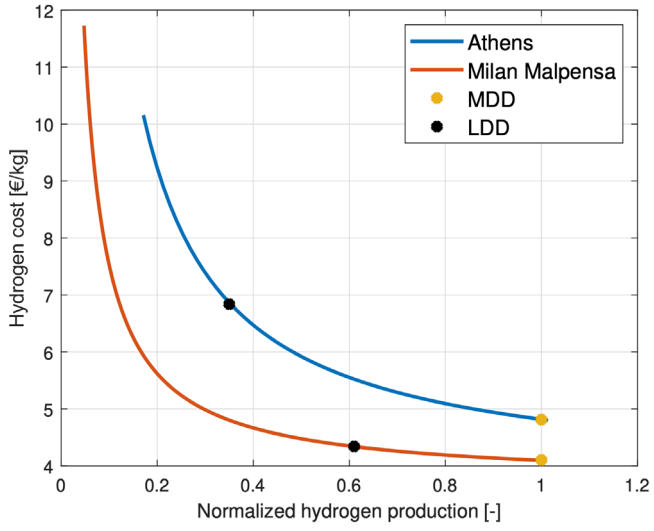

Figure 1: Variation of the cost of 1 kg of hydrogen as a function of the normalized production level.

Since the refueling system has been sized considering the busiest day, it is relevant to assess the impact on the hydrogen price on off-design conditions, with a lower required production. Figure 1 shows how the price of 1 kg of hydrogen for the considered scenario and for a smaller

airport sized for regional hydrogen-powered operations only. The Least Demanding Day (LDD) is also shown, indicating the day with the least operations. It is acceptable that larger plants work at 30% of their nominal capacity, with the cost of 1 kg of hydrogen rising to 5 €/kg. For smaller plants, the price is already high at the nominal production level, therefore an oversizing will make innovative aircraft not competitive with conventional ones in terms of fuel cost.

conclusion

This paper presents the AHRES methodology, whose objective is to optimize the sizing of a hydrogen production plant at airports, developed with the objective of supporting hydrogen-powered aircraft. A proper assessment of the impact on supporting infrastructures for hydrogen flights is important, in order to facilitate a smooth entry into service of novel aircraft. In fact, all the aviation stakeholders have the common objective of reducing the environmental impact of air transport: to achieve this, parallel development of hydrogen aircraft and of the refuelling infrastructures at airports is necessary, as the introduction of hydrogen as the main energy carrier onboard aircraft will represent a complete revolution for the aeronautical sector. The presented methodology is capable of sizing the generator, tank and amount of dispensing units necessary to support a given schedule while optimizing the overall cost. Particularly, the explication of the mathematical modeling and constraints and the application to selected scenarios are introduced. The results, with the cost of 1 kg of hydrogen being the ultimate indicator, are comparable with scenarios presented in the literature.

Abstract. This work proposes a modified Breguet-type range formulation for liquid hydrogen-powered aircraft during cruise. While hydrogen enables CO_2-free propulsion and significantly reduces NO_x emissions, its low volumetric energy density requires cryogenic storage, introducing thermomechanical challenges and boil-off losses. Current simulation frameworks can accurately model coupled heat and mass transfer inside the tank but are computationally expensive. The proposed formulation is derived from a surrogate model trained on a structured design of experiments using high-fidelity tank simulations that account for venting pressure, fill level, insulation configuration, and tank geometry. The resulting model, expressed as a modification of the well known Breguet equation taking venting losses into account, achieves a prediction error below 8% for short tanks, demonstrating both accuracy and generalization capability. The final analytical formulation preserves physical interpretability while reducing computational effort, making it suitable for early-stage sizing and trade-off studies of hydrogen-powered aircraft.

Introduction

The aviation sector is facing increasing pressure to reduce its environmental impact and contribute to climate-neutral mobility. Recent studies highlight that future commercial aviation will require disruptive solutions rather than incremental improvements to achieve meaningful emission reductions [1-3]. Among emerging propulsion technologies, hydrogen has gained strong interest due to its ability to eliminate CO_2 emissions during flight and significantly reduce NO_x formation when properly integrated into propulsion architectures [4]. Despite its high gravimetric energy density, liquid hydrogen (LH_2) presents a major challenge due to its low volumetric energy density, which necessitates cryogenic storage in insulated tanks [4,5]. Cryogenic conditions introduce complex thermodynamic phenomena such as boil-off and venting, which affect the quantity of usable fuel and, consequently, the achievable cruise range. Detailed simulation frameworks can model these coupled heat- and mass-transfer processes [6,7], but their computational cost may limit their applicability in conceptual aircraft design. Therefore, simplified yet physically consistent range formulations are required to enable rapid early-stage trade-off studies.

Material and Methods

The study adopts a workflow consisting of three main blocks, depicted in Fig. 1:

- Reference aircraft selection: the aircraft main parameters, such as aerodynamics, propulsion settings, mission profile, and weight breakdown, are defined;
- Tank geometry and main parameters: tank geometry and position can be arbitrarily defined; in the illustrative example proposed in this work, a cylindrical tank with hemispherical end-caps and located in the aft fuselage, is selected; its cross section is coincident with the fuselage cross-section;
- Mission performance analysis: the aircraft flight profile and tank internal thermodynamics are co-simulated over the cruise phase of the mission to assess usable LH_2, boil-off losses, weight evolution, and fuel flow. The remaining liquid hydrogen is checked against a minimum reserve threshold. Once the threshold is satisfied, achievable range is computed.

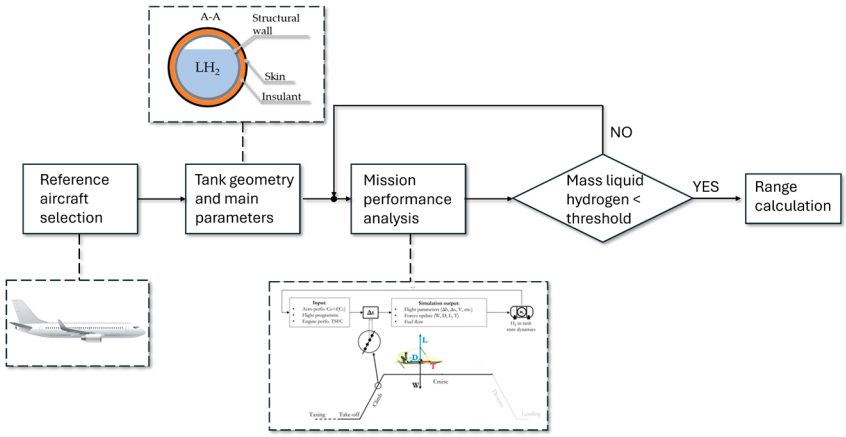

Figure 1. Workflow to assess LH_2 aircraft range.

Reference aircraft selection. The reference aircraft is defined as a short/medium-range twin-engine transport aircraft. Aerodynamic, propulsion and mass characteristics are known at the beginning of the workflow; in the considered study case, the aircraft characteristics are fixed, allowing the tank behaviour to be isolated as the only design variable during the mission simulations. The aerodynamic model adopts a classical parabolic drag polar, where drag is expressed as a combination of zero-lift drag and induced drag. Wing geometry and aerodynamic efficiency parameters (such as wing aspect ratio and Oswald factor) are selected to be representative of a tube-and-wing single-aisle commercial aircraft. The propulsion system assumes a hydrogen-fuelled turbofan with thermodynamic efficiency comparable to that of a conventional kerosene engine, consistently with the assumptions in ref. [7]. As a consequence, the thrust specific fuel consumption of the hydrogen engine is scaled based on the relative energy densities of the fuels, according to Eq. (1); all reference parameters are reported in Table 1.

$$c_{LH2} = c_{ker} E_{ker} / E_{LH2} \quad (1)$$

Tank geometry and main parameters. The liquid-hydrogen storage system is modelled as a cylindrical cryogenic tank with hemispherical end-caps, installed in the aft fuselage. The tank is composed of three concentric layers: a load-bearing structural shell that determines the internal volume to host hydrogen, a foam-based insulation layer surrounding the structural shell to limit heat transfer from the aircraft environment, and a thin outer skin enclosing and protecting the insulation, and providing mechanical integration with the surrounding fuselage structure. The

Materials Research Proceedings 69 (2026) 666-671 https://doi.org/10.21741/9781644904251-118

internal volume contains two regions, the lower liquid hydrogen portion and an upper vapour ullage, whose height varies during cruise according to boil-off rate and venting. A representative cross-section of the tank is shown in Fig. 2.

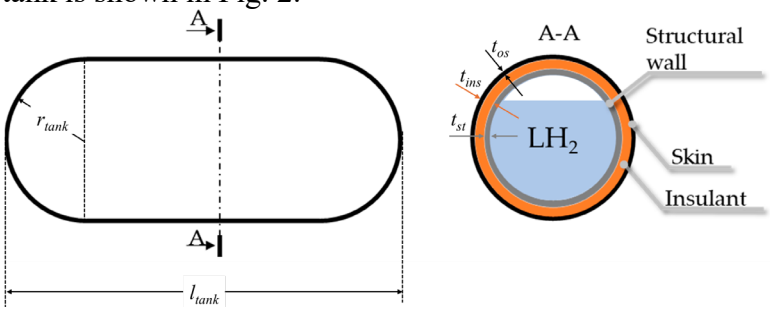

Figure 2. Simplified schema of the liquid hydrogen tank.

All parameters related to tank geometry are summarized in Table 2, and, by using well known geometric relationships of solids, it is possible to derive additional geometrical parameters such as internal volume.

Table 2. Main data of LH2 tank.

CATEGORY	PARAMETER	SYMBOL	MATERIAL	VALUE	UNIT

	Tank radius	r_{tank}	–	2	m
	Structural layer thickness	t_{st}	Aluminium Alloy 2219	10	mm
	Insulation thickness	t_{ins}	Polystyrene foam	[20, 240]	mm
	Outer skin thickness	t_{os}	Aluminium Alloy 2219	2	mm
THERMODYNAMICS	Venting pressure	P_v	–	1.59	bar

Mission performance analysis. The mission module computes the evolution of aircraft mass, fuel consumption, and tank thermodynamic state during the cruise phase. The analysis is performed through a time-marching integration, where the aircraft equations of motion and the cryogenic tank thermal model are solved simultaneously at each time step Δt. The procedure is detailed in refs. [7,10]. The time evolution of the system is computed using the forward Euler method. Three hypotheses are assumed to model aircraft mission: *(i)* aircraft is modelled as a point mass, *(ii)* quasi-steady flight conditions, meaning that accelerations are negligible over each integration step, *(iii)* the motion is confined to the vertical plane, as a direct consequence, lateral dynamics is not considered. According to the above hypotheses, Eq. (2) describes the equilibrium equation during cruise phase where L, D, and W are aircraft lift, drag and weight respectively, and T is engine thrust. Eq. (3) assesses the distance x travelled by the aircraft, V is the aircraft speed, and t is time.

$$\begin{cases} L = W \\ T = D \end{cases} \tag{2}$$

$$x(t+\Delta t) = x(t) + V\Delta t \tag{3}$$

The tank internal simulation module is based on the coupled heat- and mass-transfer framework described in ref. [7]. At each time step of the mission analysis, the model computes the heat entering the tank through external convection and thermal radiation at the outer protective skin, and conduction through the insulation layer. As heat is transferred to the liquid hydrogen, a portion

Materials Research Proceedings 69 (2026) 666-671 https://doi.org/10.21741/9781644904251-118

of the liquid evaporates, increasing the vapour mass in the ullage region. The evaporation process causes a rise in the internal pressure. Whenever the internal pressure exceeds the venting threshold, the simulation procedure computes the mass of gaseous hydrogen that must be vented to restore the pressure to its allowable value. At each time step the following sequence is executed: *(i)* the aircraft lift and engine thrust are computed by Eq. (2), *(ii)* the fuel consumption $\dot{W}_{LH2}$ requested by the engine is computed by Eq. (4), *(iii)* the tank thermal model computes boil-off and possible venting mass flow rate $\dot{W}_{vent}$, *(iv)* the aircraft weight is updated based on Eq. (5).

$$\dot{W}_{LH2}=c_{LH2}T \tag{4}$$

$$\dot{W} = \dot{W}_{LH2} + \dot{W}_{vent} \tag{5}$$

Table 3 details the initial condition of the simulation, specifically the parameter f_f indicates the amount of internal volume of the tank occupied by the liquid hydrogen, and it is assumed that the tank internal pressure is close to the venting pressure.

Table 3. Initial conditions of the simulation.

CATEGORY	PARAMETER	SYMBOL	VALUE	UNIT
AIRCRAFT	Initial weight	W_i	70000	kg
TANK	Initial LH_2 volume percentage	f_f	0.95	-
	Initial tank internal pressure	P_i	$0.99P_v$	bar

Surrogate modelling and range formulation. To derive a preliminary mathematical formulation (i.e. a modified Breguet range equation) several simulations were carried out by varying two parameters, tank length and insulation thickness, according to the boundaries defined in Table 1. This is an initial simplified illustrative example of the procedure, that can be extended to a broader set of sampling variables. For each couple (t_{ins}, l_{tank}), the workflow depicted in Fig. 1 computes the aircraft range, the amount of hydrogen burned in the engine and vented in each time step of the cruise phase. The total hydrogen mass flow lost by the aircraft is computed by Eq. (5), so it is possible to define an equivalent thrust specific fuel consumption c_{eq} which can be computed by Eq. (6).

$$c_{eq}=\frac{\dot{W}_{LH2} + \dot{W}_{vent}}{T}=c_{LH2}+c_{vent} \tag{6}$$

c_{eq} varies over time because venting events depend on the tank thermodynamics, which changes during cruise phase. Its time-average over the cruise phase, denoted by $\bar{c}_{eq}$, is used in a Breguet-type formulation for range calculation (X), as detailed in Eq. (7).

$$X=\frac{V}{\bar{c}_{eq}}\frac{L}{D}\ \log\left(W_i/W_f\right) \tag{7}$$

where W_i and W_f are the aircraft weight at the beginning and at the end of cruise. A subset of simulated configurations is used to estimate $\bar{c}_{eq}$ and identify a compact analytical expression relating tank length and insulation thickness according to Eq. (8).

$$\bar{c}_{eq} = c_{LH2}+\bar{c}_{vent} = c_{LH2}+k\left(\frac{t_{ins}}{t_0}\right)^{\alpha}\left(\frac{l}{l_0}\right)^{\beta} \tag{8}$$

The coefficients k, α, and β are identified by applying a non-linear least square method and minimizing the squared difference between the range calculated by Eq. (7) and the range computed by Eq. (3) over a calibration subset of configurations. Reference scales t_0 and l_0 (medians of Table 2) are used for normalization. The remaining simulations are used to validate Eq. (7).

Materials Research Proceedings 69 (2026) 666-671 https://doi.org/10.21741/9781644904251-118

Results

This section presents a selection of the most representative results. Fig. 3-left illustrates the effect of tank geometry and insulation on hydrogen venting losses. The contour map shows the total mass of liquid hydrogen expelled during the mission as a function of tank length and insulation thickness. Configurations characterized by long tanks with limited insulation experience the highest venting. In these cases, the increase in external surface area relative to the stored volume results in greater heat entry, which accelerates liquid-vapor state change and triggers venting. Increasing the insulation thickness markedly reduces heat transfer and venting, while shorter tanks tend to be less sensitive to insulation because of their lower exposed area. Fig. 3-right introduces a new performance indicator, named the Propulsive Energy Utilization Factor Ψ, and defined according to Eq. (9).

$$\Psi = E_m / E_{LH2,0} \tag{9}$$

E_m is the energy spent to fly, and $E_{LH2,0}$ is the chemical energy stored in liquid hydrogen at departure. This factor measures the fraction of the initial energy load that is ultimately exploited for propulsion, inherently accounting for both boil-off and venting losses. The contour map shows that Ψ increases as venting decreases: configurations with thicker insulation and optimized tank geometry retain a larger portion of the stored energy, yielding higher propulsive utilization. Conversely, thermal-inefficient configurations waste energy through venting, resulting in lower Ψ.

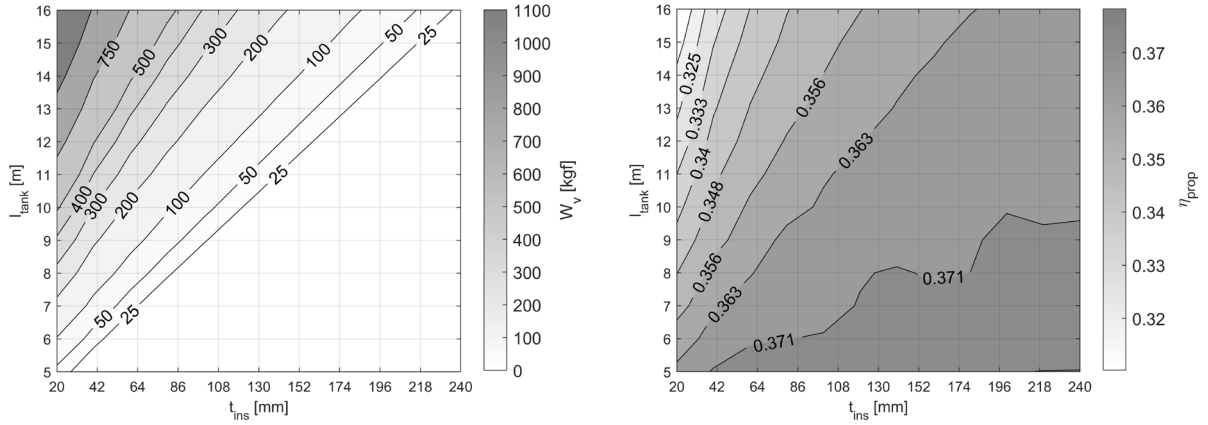

Figure 3. Vented mass (left) and efficiency (right) varying tank length and insulant thickness.

Based on the grid-search procedure, the optimal parameters for the modified Breguet formulation are $k = 0.0126$, $\alpha = -0.62$, $\beta = 1$. Table 4 reports the comparison between some cases of the mission-simulated range and the range predicted by the modified Breguet equation on the validation set. The validation results show that the modified Breguet formulation provides accurate predictions and the maximum error is below 7%. The current formulation captures geometric and thermal effects but additional physical parameters are necessary for a complete formulation. The refinement of the model is ongoing.

Table 4. Comparison between some cases of the mission-simulated range and the range predicted by the modified Breguet equation.

l_{tank} [m]	t_{ins} [mm]	x (simulation) [km]	X (Breguet) [km]	X-x [km]	X-x [%]
5	40	2998	2910	-87	-2.92
7	100	4367	4287	-80	-1.84
9	80	6043	5910	-133	-2.20
11	80	7625	7436	-189	-2.47
13	80	9182	8949	-233	-2.54
15	20	10410	9688	-722	-6.93
15	140	10292	10045	-247	-2.40

Summary

This work presented the initial foundation for the extrapolation of a modified Breguet-type formulation able to predict the cruise range of liquid hydrogen-powered aircraft while accounting for boil-off and venting losses. A coupled mission-tank simulation framework was used to generate high-fidelity data, from which an equivalent fuel consumption term was derived and expressed as a function of tank geometry and insulation. Validation against full mission simulations shows that the formulation provides accurate range predictions with a maximum error below 7%. Future developments will expand the surrogate formulation to include additional design variables and mission phases.

Defining Control Loops for a Fuel Cell Powered Aeronautic Propulsion System

Rudy CEPEDA-GOMEZ[1,a *]

[1]DLR Institute of Electrified Aero-Engines, Leiberoser Straße 13a, 03046 Cottbus, Germany

[a]rudy.cepedagomez@dlr.de

Keywords: FADEC, Electric Propulsion, Control Loops

Abstract. The main function of the Full-Authority Digital Engine Controller in turbofan engines is to ensure that the thrust required by the aircraft is provided while avoiding exceedances on engine parameters. Limits on maximum and minimum values of shaft speeds, temperatures, and pressures are defined to protect the engine from damage and to ensure its correct operation. The maximum available thrust becomes a function of environmental variables like altitude, ambient pressure and temperature, and of some operational parameters such as airspeed and auxiliary power demands (air conditioning, anti-ice, etc). This work explores the definition of similar control loops for an electric power train. It is assumed that the main source of energy is a hydrogen fuel cell and that it is supported by a battery to shave power demand peaks at certain phases of flight. A top-down methodology is used, in which the different operational scenarios (both steady-state and transient) are considered and the management problem for each one is discussed.

Introduction

The main function of the propulsion system of an aircraft is to provide thrust. Since this variable cannot be normally measured directly, Full-Authority Digital Engine Control (FADEC) systems are designed to regulate a variable that can be correlated with thrust. In turbofan engines, the Engine Pressure Ratio (EPR) or the fan rotational speed (equivalent to the speed of the low pressure shaft, NLP) are commonly used to this end, with the fuel mass flow rate being used as manipulated variable. Other engine actuators such as the compressor stator vanes and bleed valves, are usually scheduled in open-loop to maintain the operational margins of the engine.

The EPR or NLP demand is set by the FADEC based on the Power Lever Angle (PLA), which is the main interface between pilot and the engine control system, and depending on the difference between demand and current value, a fuel flow command is issued. This command, however, may be limited by a set of protection rules which, due to safety and operability restrictions, regulate excessive transients and other engine limits which could lead to compressor stalls and surges or other failures in the engine. Upper limits are commonly in place for shaft speeds (NHP, NLP), for the compressor discharge pressure (P30), for turbine temperature, and for the acceleration and deceleration during transient maneuvers. Minimum limiters on P30 and NHP are used to ensure that the engine does not flame out, and usually correspond to certain pre-determined idle schedules. The selection process follows a min/max approach, and is schematically shown in Fig. 1, which has been adapted from [1].

In an (Hybrid)-Electric Aircraft Propulsion ((H)-EAP) system, the propeller rotational speed and its pitch angle, if it is variable, are the parameters to be regulated to set the thrust. Controlling these two parameters based on pilot's input is a relatively straightforward task, considering that an electric motor is a very simple machine for which a high level of understanding has been already achieved. However, depending on the specific architecture of a H-EAP system, the control task can be way more complex than in a turbofan engine, since a larger number of subsystems need to be controlled. Furthermore, a generic architecture for such a controller is not possible, given the fact that there are many different ways of arranging an (H)-EAP: pure electric with batteries, turbo-

Materials Research Proceedings 69 (2026) 672-676 https://doi.org/10.21741/9781644904251-119

electric with or without batteries, parallel-hybrid, series-hybrid, etc. The control challenges posed by H-EAP systems are the main topic in [2]. The authors of that work, however, focus mainly on hybrid electric systems, in which a turbomachine still provides a certain amount of the power required.

The present work considers the particularities of controlling a very specific architecture: a pure EAP in which the energy comes from a hydrogen fuel cell and a battery is used for power shaving. The problem of energy and power management for such a propulsion system has already been treated in the literature. An implementation point of view is considered for example in [3], where a module to essentially control the flow of energy between fuel cell, motor and battery is described. A methodology for energy management based on heuristic rules is shown in [4], whereas [5] treats the problem using dynamic programming.

The following section of the paper describes the EAP system that is addressed in this work. After that, the control loops that are considered necessary for normal operation of this plant are described. The paper is closed with a conclusion section in which the main points of the work a re-stated and brief discussion of the future work to be developed is performed.

The System under Consideration

This paper considers an EAP composed by an electric machine actuating a propeller. The energy for the motor is provided by an electrical power distribution system, whose main task is to manage the flow of energy between the machine and the main two sources of power: a battery and a hydrogen fuel cell. It is assumed that only the battery can have a bi-directional flow of energy, i.e., it can be charged or discharged during the operation, acting either as a sink or source of energy. The fuel cell only provides energy, and the electrical machine is limited to operate as a motor, so no energy recovery from windmilling is considered.

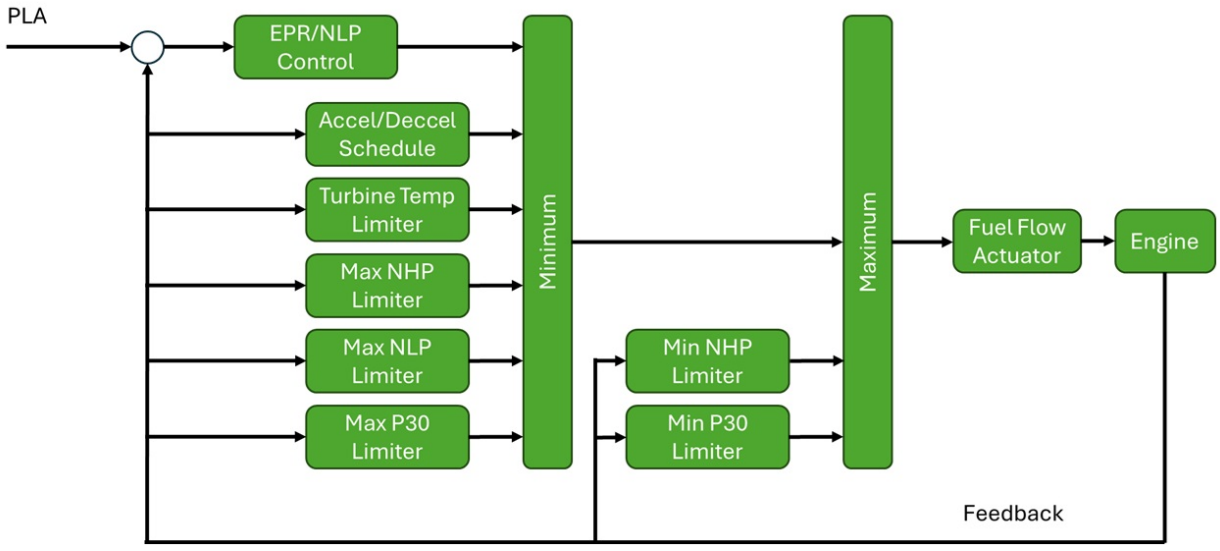

Figure 1: Standard Control Laws for a Turbofan Engine

Materials Research Proceedings 69 (2026) 672-676 https://doi.org/10.21741/9781644904251-119

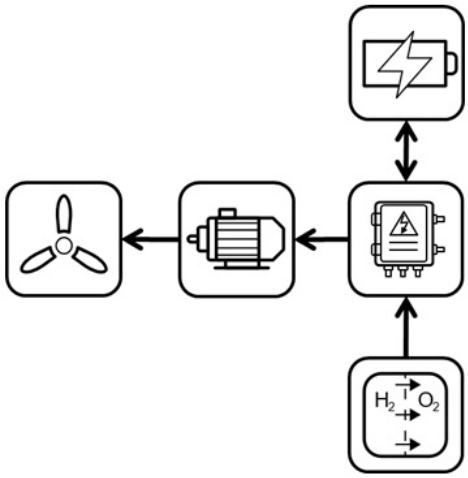

Figure 2: Generic Structure of a Battery/Fuel Cell Electric Power Train

A generic diagram of the architecture of such a system is shown in Fig. 2, from which the multivariable nature of the control problem becomes evident. While the PLA command defining the demanded thrust directly translates into a set point for the speed/torque of the electric motor, it is not immediately clear how the power required for this should flow from the two sources. The definition of the appropriate set points for the other main components, namely the battery management, the fuel cell, and the power distribution systems, is not a straightforward task and requires a careful design.

The different components of the system are sized during the EAP design process to achieve a certain performance during most critical static operating points. For example, the fuel cell could be sized to achieve its highest efficiency at the standard power level needed by the aircraft during cruise, whereas the battery would have enough storage capacity to provide the extra energy needed to maintain take-off power for the required time [6]. While very important for the tuning of the control loops, this sizing is not that crucial for the architectural definition presented in the next section.

Control Loops for the EAP System

A max/min approach, similar to that of used in turbofan engines and shown in Fig. 1, is also proposed for the EAP. The proposed control logic is presented in Fig. 3. The way the limiters act and interact is however different, due to the increased complexity of the system and its individual subsystems.

Steady State Loops. An example schedule for power split between the battery and the fuel cell depending on the demanded propulsive power can be seen in Fig. 4, which has been adapted from [2]. In this case, the fuel cell is sized such that it can provide alone up to 67% of the maximum rated power. This point would probably be the Maximum Continuous power (MCT) rating of the EAP. To reach the full power, the Battery is needed, but this level of thrust could only be maintained for as long as the battery still has sufficient charge. This would be the case during take-off or a go-around maneuver. For power demands below MCT, the fuel cell has extra power capacity, which can be used to charge the battery in phases of flight that not require extreme power.

The power that can be delivered by the fuel cell or the battery at a given instant, however, is not constant. It will be limited by factors such as the Outside Air Temperature (OAT), which affects the effectiveness of the thermal management systems of the power sources. The states of charge (SoC) and health (SoH) of the battery will also act as limiters for the power available. The thermal challenges are usually addressed by the control system of turbofan engines by means of de-rating the maximum available thrust. When the OAT is below the value for which the turbine would reach its thermal limit, the maximum thrust is available. For OAT values beyond this, the

Materials Research Proceedings 69 (2026) 672-676 https://doi.org/10.21741/9781644904251-119

maximum available thrust is reduced proportionally. In the case of an EAP, these limitations are more dynamic, since they depend on more factors and affect several different components.

Transient Loops. One of the advantages of electric motors over turbomachines are their faster dynamics. An electric machine can change its speed almost instantaneously. These fast dynamics, however, cannot be followed up by a fuel cell, whose electrochemical processes have a large inertia and very long time constants. To have time to adjust the power delivered by the fuel cell, the transients have to be absorbed by the battery. The transient control loops will ensure that the battery provides the extra power needed during acceleration maneuvers, and absorbs the surplus power during deceleration.

Idle Limiter. Contrary to internal combustion engines, electric motors do not need to remain on when not needed, wasting energy while idling. Fuel Cells, however, need to provide at least a minimum amount of power required by its auxiliary systems and the aircraft. This minimum fuel cell power requirement plays a role similar to the idle limiters in turbofan controls. Any excess in power can be used to charge the battery when the conditions allow it.

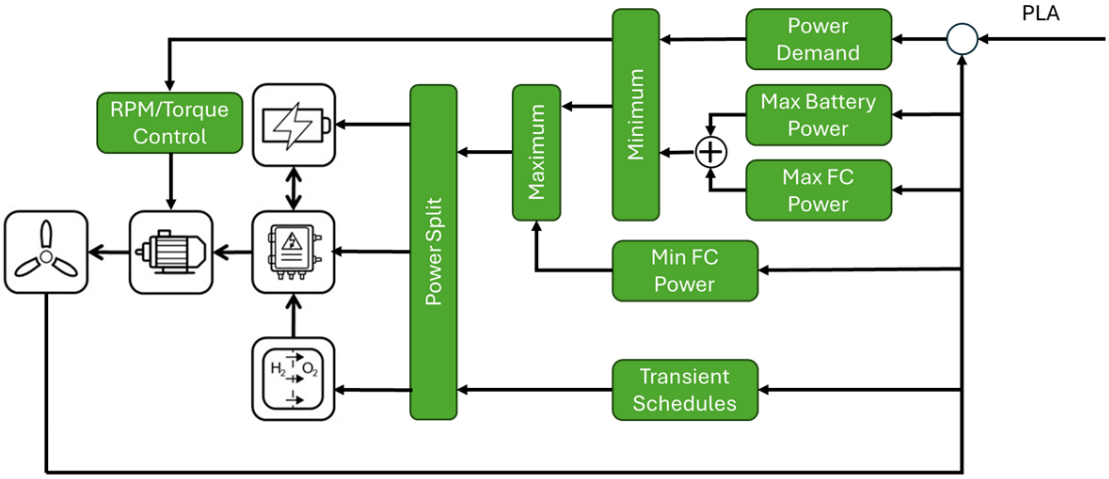

Figure 3: Proposed Set of Control Laws for an Electric Aircraft Propulsion System

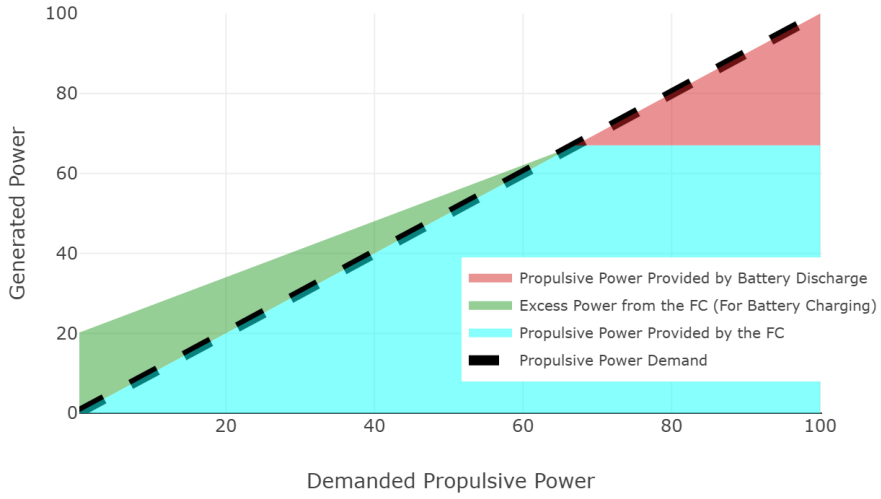

Figure 4: Example of a Schedule for Power Split According to Demanded Propulsive Power

Closing Remarks and Future Work

This work discussed some of the control challenges presented by an Electric Aircraft Propulsion system powered by a combination of fuel cell and battery. An architectural design of such a system

is proposed, discussing which control laws are considered necessary for the correct operation of the system. The factors which would limit the available thrust are mentioned and their effect in the design of the control loops are also considered.

The next steps are the detailed design of such control loops for an exemplary system. This includes the definition of numerical values for parameters such as the different required power levels and the minimum and maximum limiters, but also numerical targets regarding required acceleration times, contingency ratings, and other needs imposed, for example, by certification requirements. The specific control algorithms to be used for the definition of the loops, and the hardware and software architectures needed to implement the logic in an actual system, are also topics of extreme interest, which will be addressed in future works.

It must be stated again, that the generalization of such a control architecture is an almost impossible task, since each electrified topology would require specific considerations. A *one-size-fits-all* solution cannot be achieved.

Keywords: Eco-Design, Sustainable Space Propulsion Systems, Water Electrolysis

Abstract. In the context of the New Space Economy, sustainability has become a key driver for the development of next-generation space systems. The growing intensity of orbital activity is pushing space stakeholders to align future missions with global environmental goals, guided by space agencies and inspired by best practices from other industrial sectors. This paper proposes an eco-design workflow to support the design of in-space propulsion systems, focusing on an innovative patented water-electrolysis concept. The objective is to ensure high technical performance while integrating environmental sustainability considerations from the earliest design phases. Preliminary benchmark results on propellant production impacts offer a first perspective on how sustainability assessments can guide the design of advanced propulsion technologies.

Introduction

Sustainability is increasingly recognized as a strategic priority in the space sector, which historically has lacked alignment with ecological and long-term impact considerations. Although no specific environmental regulations currently exist for space activities, growing efforts are being made to raise awareness and reduce the environmental footprint of space systems design [1].

Major research efforts currently focus on satellite constellations in Low Earth Orbit (LEO), due to the already high number of operational satellites and the expected increase driven by the wide range of services offered at these altitudes [2]. This scenario has significant implications for both the orbital environment, where space debris and end-of-life management are critical issues, and the terrestrial environment, affected by development, production, launch, ground operations, and re-entry activities; both dimensions must be preserved for a truly sustainable space sector.

Recent studies on rocket launchers highlight the complexity of applying eco-design principles to space systems, due to the significant uncertainties in modeling emissions across different atmospheric layers and in characterizing the environmental behavior of the unique manufacturing processes and materials [3]. These challenges are also relevant for in-space propulsion systems. These are directly affected by the ongoing shift toward sustainable space development, particularly through the transition toward "green" propellants as alternatives to conventional options such as toxic hydrazine or expensive, resource-intensive xenon [4].

Frameworks to account for sustainability in space system design, with a specific focus on space propulsion, have already been proposed: Canepari *et al.* [5] developed a tool to select the most suitable propulsion system for different in-space mission scenarios, based on four figures of merit namely performance, cost, reliability, and environmental performance; Wilson *et al.* [6] proposed replacing hydrazine-based propulsion with a "green" chemical propellant, namely LMP-103S, for their case-study mission. Although this change reduced operational hazards, it resulted in a burden

Materials Research Proceedings 69 (2026) 677-682 https://doi.org/10.21741/9781644904251-120

shift at the propellant production stage rather than a net improvement in overall environmental performance. Across these studies, Life Cycle Assessment (LCA) is commonly employed as a methodological tool to quantify environmental burdens and identify key hotspots for improvement. Most recent analyses implement the European Space Agency (ESA) LCA guidelines and database, the first eco-instruments developed explicitly for space applications [7].

It is important to highlight that the propulsion architectures analyzed in recent studies are based on existing technologies (i.e., *as-is* systems) and their environmental performance is evaluated *ex post*. To date, there are few studies addressing the sustainability-oriented design of novel in-space propulsion technology concepts. The goal of this work is therefore to introduce an engineering eco-design workflow that supports the early development of a novel water electrolysis propulsion concept from both technical and environmental perspectives.

The following section outlines the proposed workflow and describes the case study, followed by results and discussions. The paper ends with conclusions and a description of future work directions.

Methodology and Materials

Product design is inherently an interdisciplinary iterative process that evolves from a conceptual stage toward detailed specification. In eco-design, this evolution entails that, alongside technical requirements, early decisions on materials and processes are made and progressively refined through manufacturing routes, geometries, masses, and interfaces. Design for Environment (DFE) is an established industrial eco-design practice aimed at reducing environmental impact while improving cost and quality [8]. Its principles provide a reference for integrating environmental considerations into the engineering design of space systems.

When designing novel and innovative products, the product structure and complete material list are not yet defined in the early design phase. Consequently, conducting a rigorous LCA study as required by ISO 14040 and ISO 14044 is challenging due to the lack of comprehensive and well-defined information. However, environmental criteria can still be integrated from the very beginning using complementary approaches such as streamlined and Fast-Track LCA, supported by benchmarking, literature analysis, lookup tables (e.g., eco-cost indicators), and material selection software such as Cambridge Engineering Selector [9]. These methods enable parallel progress in data collection and design exploration, following an iterative cycle that continues until the detailed design stage. Moreover, they can provide sufficiently accurate results to support design decisions and accelerate the transition toward prototyping.

Workflow. Fig. 1 illustrates the proposed workflow integrating life-cycle environmental considerations into the engineering design process of innovative in-space propulsion systems. As in any design process, technical requirements are first derived from external and internal inputs, including stakeholder needs, applicable standards and regulations, and the technological concept itself (e.g., from patents). Establishing a Design Reference Mission (DRM) provides the common basis for both the system sizing and the LCA framework, including the definition of the functional unit, system boundaries, and goal and scope. These elements are expected to evolve iteratively at each design loop, depending on the specific design inputs; however, the system-level definition and its design objective should remain consistent to ensure traceability and comparability of results. From the DRM, mission goals determine sizing parameters such as propellant mass, system architecture, and mission duration. Additionally, including the emerging New Space design drivers as input ensures compliance with current development scenarios [10]. The following engineering design stages include iterations for requirement analysis and system modeling through functional allocation and product tree definition [11]. The subsequent stage integrates the typical steps of LCA, adapting them at each iteration to the current level of detail and accuracy. In the first analysis, openLCA 2.5.0 and the Ecoinvent v3.10 database (APOS) are used.

Materials Research Proceedings 69 (2026) 677-682 https://doi.org/10.21741/9781644904251-120

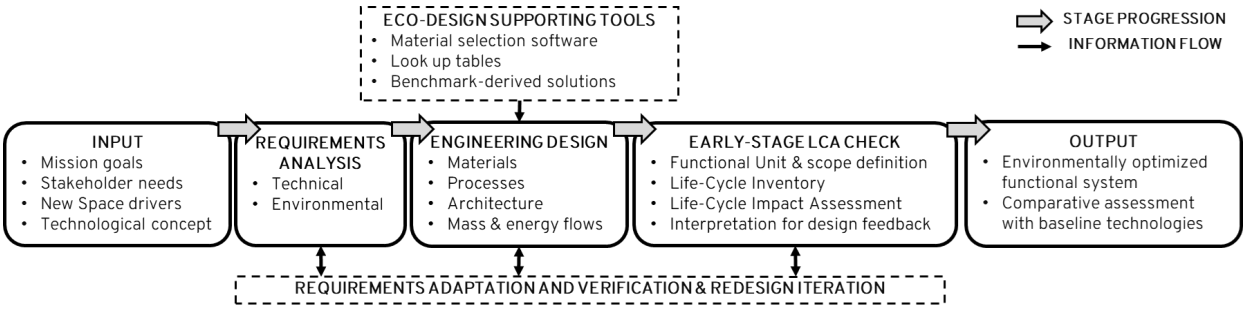

Figure 1: Proposed eco-design workflow for the early-stage development of innovative in-space propulsion systems.

Within the information flow, the iteration loop includes both technical and eco-design refinement, ensuring that environmental feedback informs engineering choices. The design phase is over when both performance and environmental requirements are satisfied in accordance with the defined goals, verified through analysis, demonstration, or testing within a rapid prototyping approach. The findings are finally benchmarked against publicly available data from existing propulsion solutions to investigate the potential of the proposed case study.

Case study. This study focuses on an industrial in-space propulsion concept that uses water as propellant, protected by patent WO 2019/0212347A1 [12]; Fig. 2 illustrates the minimal functional architecture: it consists of a modular unit capable of delivering high thrust by splitting water into hydrogen and oxygen on demand via electrolysis directly in orbit and subsequently combusting the resulting gas mixture. The system is designed to maximize propulsion efficiency and combustion performance within a compact size, making it particularly suitable for small satellite applications. Water is an environmentally benign monopropellant option: it is non-toxic, inert, widely available, inexpensive, storable, and has a favorable density. While the concept of water electrolysis propulsion dates to the 1970s, technological progress, together with the evolving needs of the New Space sector, now make this solution both technically and economically viable.

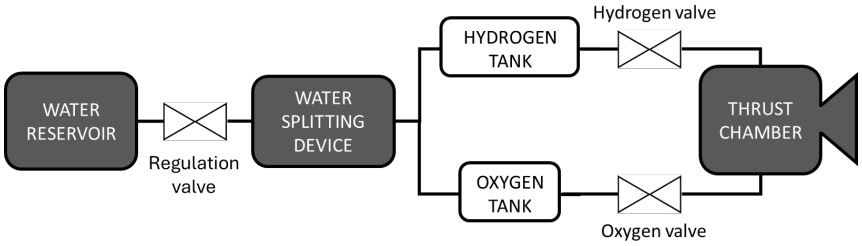

Figure 2: Scheme of the minimal functional architecture of the water-electrolysis high thrust propulsion system based on the patent WO 2019/021234 [12].

Motivation of the work. The patented water-electrolysis propulsion concept is a promising candidate for high-performance and environmentally aware in-space propulsion. Nevertheless, its potential can only be fully realized through an eco-design approach that integrates technical performance and environmental criteria from the outset. This case study applies the workflow in Fig. 1, supported by preliminary LCA, to guide the development of the system in Fig. 2 and provide an early quantitative basis for sustainability-driven design decisions.

Results and Discussion

As LEO missions are among the most critical from a sustainability perspective, the DRM has been defined with reference to such a scenario. Furthermore, the selected mission parameters are representative of an actual mission under investigation for this case study. Table 1 summarizes the main DRM parameters.

Materials Research Proceedings 69 (2026) 677-682 https://doi.org/10.21741/9781644904251-120

Table 1: Design Reference Mission (DRM) main parameters.

Mission parameter	Value
Mission type	Orbit maintenance and collision avoidance
Orbit	Low Earth Orbit (LEO)
Δv budget [m/s]	100
Satellite dry mass [kg]	150
Nominal lifetime [years]	7

The main functional unit is defined as *one propulsion system able to perform the DRM reported in Table 1*. Full system boundaries and full scope will be defined as the design matures and the conceptual architecture, transport scenarios, and life-cycle stages become better defined, following the iterative approach suggested in [9]. In this first design iteration, the study adopts a system boundary limited to the initial life-cycle stage, namely the *production of propellant quantities for the selected DRM (cradle-to-gate)*. The system boundary does not include space-grade conditioning (final purification, tank filling, etc.), which may be modelled in a separate analysis. Focusing on the production phase isolates the upstream contribution of the propellant, the key element characterizing a space propulsion system. Production impacts are expected to reveal the potential environmental advantages of a water electrolysis-based solution, subject to the assumptions on energy supply and process modelling.

The early LCA scope is defined as a *comparison between water-electrolysis, xenon-based Hall Effect, and hydrazine monopropellant propulsion alternatives*, offering a preliminary benchmark against conventional systems. Propellant masses required to achieve the mission are computed using Tsiolkovsky's rocket equation, assuming an appropriate specific impulse for each technology; see Eq. 1, where m_p is the propellant mass, m_f the satellite dry mass, Δv the mission velocity budget, I_{sp} the specific impulse, and g_0 the standard gravity. The resulting propellant masses are reported in Table 2 together with the specific impulse.

$$m_p = m_f(e^{\frac{\Delta v}{I_{sp} g_0}} - 1). \quad (1)$$

Table 2: Propellant masses required to meet the DRM for each propulsion system.

Propulsion system type	Specific impulse [s]	Propellant mass [kg]
Hydrazine monopropellant thruster	220	7.1
Xenon-based Hall Effect Thruster	1300	1.2
Water-electrolysis propulsion system	300	5.2

The preliminary results for propellant production are shown in Fig. 3 and refer to five impact categories and corresponding LCIA (Life-Cycle Impact Assessment) methods recommended by ESA [6,7]. The results are scaled with respect to xenon production. Each production process was modelled in openLCA for the propellant masses in Table 2: hydrazine (Raschig process), xenon (cryogenic air separation), and deionized water (ion exchange) as proxies, representing large-scale European production (Switzerland excluded only for water for dataset availability).

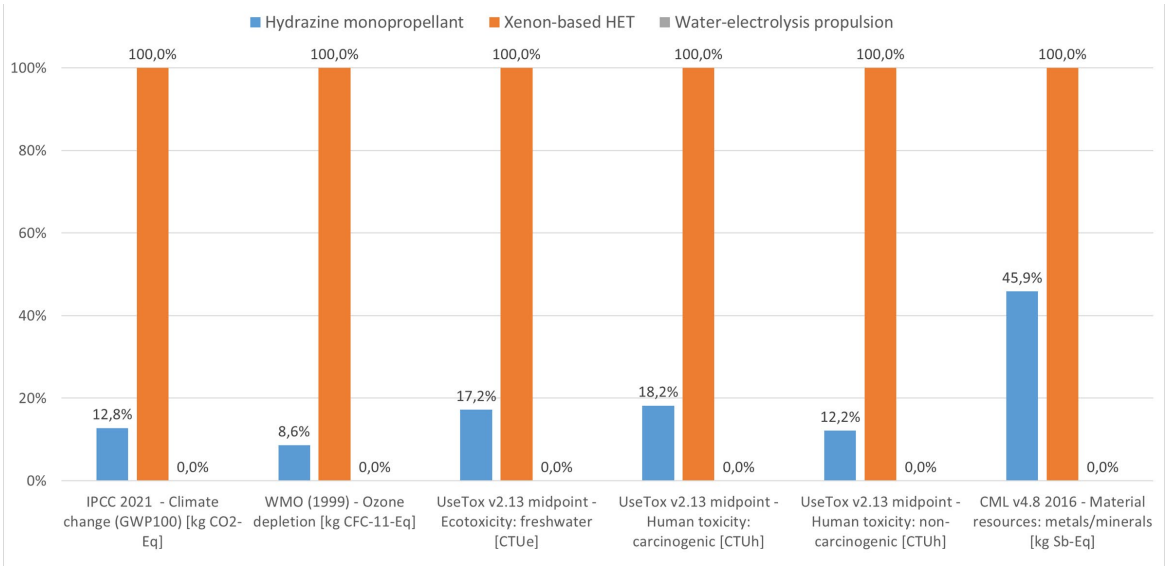

Figure 3: Preliminary LCIA comparison for the production of propellant masses required by the DRM. Modelling in openLCA 2.5.0 using Ecoinvent v3.10 (APOS, Europe).

These results confirm that the environmental burden associated with the production of deionized water in large-scale European processes is negligible, corresponding to a relative impact close to 0% compared to xenon within the scope of this analysis (Fig. 3). In contrast, xenon production exhibits the highest environmental impact among the three investigated propulsion systems. This aspect becomes particularly relevant when designing large-scale LEO constellations, as the advantages of carrying smaller propellant quantities using HETs may be offset by the xenon's high manufacturing footprint. Hydrazine, on the other hand, despite being more hazardous than xenon and less mass-efficient, shows comparatively lower impacts (ranging from 9% to 46%). However, this apparent advantage is expected to diminish once downstream life-cycle stages (handling, transport, and refueling) are included. This is due to the toxic nature of the propellant, which entails specific safety procedures and equipment for storage and operations, increasing both mission costs and lead times. In light of these preliminary findings, the environmental impact of water during the production phase is negligible, confirming its potential to enhance the mission's overall sustainability.

Conclusions

This study introduces a workflow for the early sustainable design of a water-electrolysis propulsion system. The preliminary LCA analysis focused on comparing the production process of three space propellants: water, hydrazine, and xenon. The initial results indicate that conventional propellants are increasingly misaligned with the perspective of a sustainable space sector, supporting the rationale for continued investment in water-propulsion as an effective alternative. Future work will extend the analysis to the main components and life-cycle phases of the innovative water-electrolysis propulsion solution to verify whether it maintains the environmental advantages highlighted in this study and to integrate economic and social considerations.

Keywords: UAV Propulsion, Wankel Engine, Modelling and Simulation, Testing, Sustainable Propulsion, Helicopters

Abstract. This work deals with the development of a reduced-order dynamic model of a Wankel rotary engine for the propulsion of a lightweight helicopter UAV, to be used for in-flight health-monitoring. The model, which is real-time executable by the on-board electronics of the UAV, includes the simulation of mechanical power generation, intake manifold pressure dynamics, fuel flow consumption, and thermal transfer in the combustion chamber. Aiming to develop a simulator based on physical principles, a correlation analysis among the experimental measurements obtained by endurance tests has been carried out, up to select the states and the inputs of the model sections and to identify their parameters via ordinary least square method. Simulation demonstrates to satisfactorily reproduce the experimental behaviour (maxima errors are lower than 5%), when the engine works near its nominal operating conditions, i.e. at constant rotor speed, while the model errors increase (up to 30%) during the transients from/to warm-up phases.

Introduction

The interest in the development of hybrid-electric powertrain for efficiency enhancement, noise abatement and reduction of pollutants emission of UAV propulsion systems is continuously increasing in the aeronautical sector [1]. The hybridization of UAV propulsion has found fertile ground due to the promises of extended endurance and lower fuel consumption combined with emissions abatement and thermal signature minimization, resulting in a solution that is attractive for both civil and military applications [2, 3, 4]. Wankel rotary engines [5] have emerged as a viable solution for the internal combustion power source in hybrid-electric configurations [6], given their high-power density, extreme compactness, and lower noise emission with respect to conventional reciprocating engines [7]. The application background of rotary engines is undoubtedly poorer than that of four-pistons engines and extended dissertations are not available in literature. Mean Value Engine Models (MVEMs) have been developed for Wankel engines [8], but their effectiveness strongly depends on detailed knowledge of geometry, size, and operating conditions [9, 10], so that they are not suitable for control design or digital twin development, which requires real-time execution capabilities. Within this context, this paper deals with the development and experimental validation of a reduced-order model of a Wankel engine, using as a case study the one employed in the propulsion system of a lightweight helicopter UAV by Leonardo Elicotteri. In the initial architecture layout, the propulsion system integrates a Wankel engine mechanically coupled to a mixing unit whose output shaft rotates synchronously with the engine shaft. This shaft is connected to the drive system, enabling power distribution to the helicopter rotors and it is then connected to the driving system allowing distribution of power to the helicopter rotors. The engine shaft can be decoupled from the mixing unit during idling or

warm-up phases. An innovative version is under evaluation, in which an electric motor will be integrated with a downsized version of the Wankel engine to achieve a hybrid-electric configuration.

Materials and methods

Experimental set-up

The modelling and simulation activities have been supported by the availability of an experimental database related to endurance tests, in which the propulsion system is required to operate under three different loads scenarios, referred to take-off at maximum weight, cruise at maximum speed and cruise at nominal speed, respectively.

During the tests, the propulsion system was equipped with sensors providing:

- throttle valve opening
- fuel flow
- air-to-fuel ratio
- angular speed of the engine
- manifold air pressure
- temperatures of external air, exhaust gas and coolant
- external load applied to the mixing unit output shaft
- angular speed of the mixing unit output shaft

Model sections and identification technique

The Wankel engine model has been developed including the following sections:

- mechanical power generation
- fuel flow consumption
- intake manifold pressure dynamics
- thermal transfer in the combustion chamber

For each section of the model, a correlation analysis among the available measurements from tests was conducted, identifying physically-based relationships between inputs (e.g. throttle valve opening) and dynamic states (e.g. shaft speed, manifold air pressure, etc.). The parameters of model sections were then identified via Ordinary Least Squares (OLS) technique [11]. According to OLS, if the linearly dependence of a quantity Y on data x and z through unknown parameters $\beta_0, \beta_1, \beta_2$

$$Y = \beta_0 + \beta_1 x + \beta_2 z \tag{1}$$
